We describe the application of ultrafast atomic-scale coherent imaging techniques based on single-shot x-ray photon correlation spectroscopy (XPCS) to resolve the nucleation and growth of a new phase during a prototypical light-induced solid-solid phase transition. We show that a two-time correlation approach provides enhanced sensitivity to the diffuse x-ray scattering which encodes the heterogeneous mesoscopic response of the material, in contrast to a standard crystallographic measurement which probes only the ensemble-averaged structure. Through this approach, we demonstrate a new way of visualizing the nucleation and growth of domains and probe selectively the dynamics occurring at domain wall boundaries and the annihilation of these defect states. We find unexpectedly that this non-equilibrium response spans approximately ten orders of magnitude in time scales (from 100 femtoseconds to 1 millisecond), extending a thousand times longer than expected from crystallographic studies. This work defines new possibilities for visualizing the non-equilibrium dynamics of disordered and heterogeneous materials and the atomic-scale dynamic processes underlying the synthesis of new phases of matter.

Ultrafast Nano-Imaging of Dark Excitons MarcelReutzel[1], DavidSchmitt[1], Jan PhilippBange[1], WiebkeBennecke[1], GiuseppeMeneghini[2], AbdulazizAlmutairi[3], MarcoMerboldt[1], JonasPöhls[1], SabineSteil[1], DanielSteil[1], ThomasWeitz[1], StephanHofmann[3], SamuelBrem[2], G. S. MatthijsJansen[1], ErminMalic[2] and StefanMathias[1]; [1]Georg-August-Universität Göttingen, Germany; [2]Philipps-Universität Marburg, Germany; [3]University of Cambridge, United Kingdom

Dynamical processes in the condensed matter occur on the femtosecond time- and the nanometer length-scale. This very general statement holds true for fundamental processes such as the dissipation of energy after an optical excitation or the creation of light-matter coupled phases. At the same time, it showcases that any nanoscale inhomogeneity that affects the quasiparticle dynamics can, in the end, limit the performance of a real-world device. In consequence, there are a multitude of research efforts that work towards the development of new experimental techniques that can provide a holistic picture of dynamical processes on ultrashort time- and length-scales.

In this contribution, we discuss our recent efforts to extend the full capabilities of time- and angle-resolved photoemission spectroscopy (trARPES) to the nanoscale. In short, we will show how we can monitor the femtosecond evolution of spectral weight at a specific in-plane momentum k and kinetic energy E with 50 fs time- and 500 nm spatial-resolution [1]. Experimentally, this is achieved by the development of ultrafast dark-field photoelectron microscopy: We employ our table-top high-repetition rate high-harmonic generation beamline and time-of-flight momentum microscope [2] and combine it with the full capabilities of dark-field imaging techniques [1].

In the presentation, we then present the capabilities of ultrafast dark-field photoelectron microscopy in three steps: First, in a spatially integrated mode of the experiment, we will discuss momentum-resolved photoemission signatures of intralayer, interlayer and hybrid excitons and identify distinct hallmarks of the moiré superlattice [3]. Second, we will show that interlayer excitons are effectively formed via exciton-phonon scattering, and subsequent interlayer tunneling at the interlayer hybridized Σ_W valleys on the sub-100 fs timescale [3,4]. And third, we will report on the spatio-temporal and spatio-spectral dynamics of bright and dark excitons in a laterally inhomogeneous TMD heterostructure. Most interestingly, we find that the rate of charge transfer across the type-II band aligned WSe2/MoS2 interface can vary by more than a factor 2. We explain this discrepancy with a locally varying energy landscape of excitons, as directly accessible with ultrafast dark-field photoelectron microscopy [1].

Ultrafast Optical Probing of Temperature-Induced Antiferrodistortive Phase Transition in $SrTiO_3$SaqeebAdnan[1], AmeyKhanolkar[2], DavidHurley[2] and MaratKhafizov[1]; [1]The Ohio State University, United States; [2]Idaho National Laboratory, United States

$SrTiO_3$ (STO) is a highly versatile perovskite renowned for its wide array of ionic transport, dielectric and ferroelectric properties, making it a subject of great technological interest, particularly in energy, information processing, and data storage. In this study, we monitor the ultrafast dynamics of the antiferrodistortive (AFD) phase transition in STO via time-domain Brillouin scattering (TDBS). Monitoring the depth-resolved Brillouin oscillation (BO) frequency (associated with longitudinal coherent acoustic phonons), we demonstrate the presence of fingerprint frequencies of cubic and tetragonal phases across the high and low temperature regions of the sample, respectively. Coupled with a time-resolved heat diffusion model, the BO frequency profiles provide evidence of a ultrafast transformation of the low temperature tetragonal phase into cubic phase driven by thermal energy deposition[1]. The initial rapid phase change is followed by a slower reverse cubic-to-tetragonal phase transformation occurring on a time scale of hundreds of picoseconds. The observed phase transformation can be attributed to a structural resemblance between atomic displacements of the R-point soft optic mode of the cubic phase and the tetragonal phase of the perovskites, both exhibiting an anti-phase rotation of oxygen octahedra. The evidence of such a fast structural transition in STO offers opportunities for developing novel ultrafast switching and phase-changing devices.

Battery Cathode Electrochemistry via X-Ray Spectroscopy ThomasDevereaux; Stanford University, United States

In this talk I will present some thoughts on the mechanisms for cathode electrochemistry from the viewpoint of x-ray spectroscopy. A focus is placed on charge transfer energetics and how they can be connected to high battery capacity and cyclability. Efforts towards understanding high valent redox using time-domain x-ray spectroscopy will be reviewed.

4:30 PM *EL02.04/QT02.06.07
Time-Resolved Resonant Inelastic X-Ray Scattering Studies at the SCS Instrument of EuXFEL AndreasScherz; European XFEL, Germany

Femtosecond lasers are important tools to modify and control the properties of quantum materials on ultrashort time scales. Resonant inelastic X-ray scattering (RIXS) spectroscopy has emerged over the last decades as a powerful method to explore low-energy orbital, spin, lattice and charge excitations in quantum materials. The main limiting factor to attain RIXS at high energy- and time-resolution is the low repetition rate and photon flux of the first-generation X-ray free-electron lasers (XFEL). Taking advantage of the Megahertz repetition rate of the European X-ray free electron laser (EuXFEL), the high-resolution spectrometer of the Heisenberg User consortium (hRIXS) enables users to perform RIXS spectroscopy of material dynamics in nonequilibrium with unprecedented time- and energy-resolution.

We report from the user-assisted commissioning program in 2022 addressing charge transfer (CT) excitations in NiO and La2CuO4 transition metal oxides. The paradigmatic charge transfer insulator and antiferromagnet NiO was excited across the CT gap by a 50 fs laser pulse at 266 nm. Using time-resolved RIXS at the Ni L3 edge with an energy resolution of 80 meV and a time-resolution of ~120 fs, we observe prominent localized CT excitons that decay and delocalize in a few picoseconds. The CT excitation is accompanied by a broadening and shift of the dd excitations indicative of ligand field effects in the excited state, seen over tens of picoseconds. The first results demonstrate the potential of time-resolved RIXS at MHz-repetition rate XFELs to explore nonequilibrium dynamics of quantum materials.

Using Time-Resolved Microscopy to Probe Exciton Diffusion in $CsPbBr_3$ Superlattices ThomasSheehan[1], WenbiShcherbakov-Wu[1], TarasSekh[2,3], IhorCherniukh[2,3], MaksymV. Kovalenko[2,3] and WilliamTisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]ETH Zürich, Switzerland; [3]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Exciton transport is critical to the performance of semiconductor nanocrystals in optoelectronic devices. Within most nanocrystal assemblies, exciton transport is a diffusive process mediated by Förster resonant energy transfer (FRET). Both structural and dynamic disorder can affect FRET-mediated exciton diffusion through their impact on factors such as nanocrystal spacing, transition dipole alignment, exciton radiative lifetimes, and excitonic coherence. The combined impact of these factors on exciton transport is complex and not well-understood in emerging semiconductor materials like lead halide perovskites. Here, we use time-resolved photoluminescence microscopy to investigate the effects of different types of disorder on exciton transport in $CsPbBr_3$ nanocube assemblies. This technique allows us to directly visualize the movement of excitons within the nanocrystal assembly. We determine the effect of structural disorder across different nanocrystal sizes by comparing exciton transport in highly ordered superlattices and in disordered assemblies, and we determine the effect of dynamic disorder by varying the temperature from 5K to room temperature. These investigations shed light on exciton transport mechanisms and could inform future design strategies for nanocrystals in optoelectronic devices.

8:00 PM EL02.05.02
Electroluminescence and Photoluminescence Characterization of LEDs / OLEDs using a Single Micro-Photoluminescence Spectroscopy Setup ChristianOelsner; PicoQuant GmbH, Germany

Opto-electrical characterization of LEDs/OLEDs is of essential importance for thorough understanding of light generation and emission properties of light emitting materials as a response to an applied electric current. The combination of photoluminescence (PL) and electroluminescence spectroscopy techniques can reveal the relationship of structure-lighting properties of novel LED/OLED materials and whole devices. Without doubts, this can help to optimize the composition and as a result the performance (brightness, lifetime, color) of these devices.

Herein we demonstrate a cost-effective way to get the electroluminescence properties, namely steady-state emission spectra and luminescence decays of different species within LED devices by applying an electric current without requiring an additional external bias source and/or external arbitrary function generator. Our solution allows a unique control over pulse rate, intensity, and pattern. It enables steady-state as well as time-resolved electroluminescence together with PL characterization of LEDs/OLEDs utilizing a single setup consisting of a microscope coupled to a PL spectrometer. All the measurements can be performed with high spatial, spectral, and timing resolution for better device optimization.

8:00 PM EL02.05.03
Ultrafast Transient Absorption Anisotropy to Monitor Relaxation in Carbon Dots SukanyaSaha; Western Michigan University, United States

In recent years, carbon dots (CDs) have emerged as a new class of carbonaceous materials that are easy to synthesize and characterize and show promising optical properties. One of the interesting aspects is their excitation wavelength dependent photoluminescence (PL). Although several CDs with different precursors are synthesized and characterized. Corresponding excited state optical properties on these materials are sparse. In this study, ultrafast excited state relaxation dynamics of CDs based on Pyrene are presented. Steady state, femtosecond transient absorption, and anisotropy data measurements are carried out to understand the relaxation pathways in these CDs. Pyrene-based aminated CDs are synthesized by hydrothermal method. The CDs were transferred to organic solvents (e.g., toluene, THF, and ACN) using surfactants via the phase transfer method. It is interesting that the CDs in different solvents exhibit both solvent dependent and excitation wavelength dependent PL. Excited state absorption decay of these CDs has shown ultrafast excited state decay that can be assigned to inter chromophore or chromophore solvent bath interactions. Transient absorption anisotropy measurements have shown faster picosecond time scale relaxation that cannot be assigned to the rotational reorientation of the CDs as the volume is greater. Transient absorption measurements have also shown differences in relaxation for bare CDs in water and CDs passivated with surfactants as in the case of CDs in non-aqueous solvents. The decay of anisotropy was assigned to energy transfer between the chromophores of different conjugation lengths in the CD. This is ascribed to HOMO fluorescence resonance energy transfer (HOMO-FRET) with time constants ranging from 50 to 90 ps. In THF, long-lived anisotropy decay is observed which is assigned to the rotational relaxation of the entire CD. Interesting ultrafast growth of anisotropy was observed in non-aqueous solvents, which is assigned to faster localization of the excitation from the core to a chromophore.

Quantum Enhanced Nonlinear Spectroscopy of Strongly Coupled Microcavities EvanJ. Kumar[1], LorenzoUboldi[2,1], EstebanRojas-Gatjens[3,1], LucaMoretti[2,1], CristianManzoni[2], GiulioCerullo[2] and Ajay RamSrimath Kandada[1]; [1]Wake Forest University, United States; [2]Politecnico di Milano, Italy; [3]Georgia Institute of Technology, United States

The use of quantum entangled photons is suggested as a way to improve upon limitations in measurement sensitivity in conventional nonlinear optical spectroscopy. In addition, time-frequency entangled photon probes can potentially enable isolation of specific many-body interactions in condensed matter. Here, we discuss an experimental implementation of a nonlinear spectroscopy system based on spectrally entangled biphoton states. Using modified Mach-Zehnder interferometry, we present a methodology to estimate spectral correlations between entangled photons, which are generated through spontaneous parametric down-conversion of ultrashort optical pulses. We observe that the correlations in the biphoton state, characterized by the two-dimensional joint spectral amplitude (JSA), are transformed due to matter interactions. Specifically, we explore estimation of many-body interactions of polaritons in a strongly coupled semiconductor microcavity through an in-depth analysis of the experimentally obtained JSA of the biphoton state transmitted through the microcavity.

Excited State Dynamics of Metal Halide Perovskite Nanocrystals - Role of Surface States and Inter-Particle Interactions KatherineA. Koch[1], DavidO. Tiede[2] and EstebanRojas-Gatjens[3]; [1]Wake Forest, United States; [2]Institute of Materials Science of Seville, Spain; [3]Georgia Institute of Technology, United States

Ultrafast spectroscopy has been successfully employed in the investigation of carrier dynamics in metal halide perovskite nanocrystals (NCs). While most of these studies have been performed primarily on perovskite NCs that are mostly fabricated as colloidal suspensions, recently a new synthesis route has emerged in which the NCs are grown within silica scaffolds. This method enables fabrication of formamidinium lead bromide (FAPbBr3) NCs directly in a device compatible solid-state architecture, while keeping the effects of quantum confinement intact. Here we provide a comprehensive photo-physical characterization of these material architectures of FAPbBr3 ranging from a bulk system to strongly quantum confined dot like structures. We employ two-photon excitation spectroscopy and temperature dependent ultrafast transient absorption spectroscopy to probe the effect of quantum confinement and surface states on the excited-state energy landscape, carrier thermalization and recombination. We also probe the nature of coherent nonlinear interactions, inter-particle and electron-phonon coupling through two-dimensional coherent electronic spectroscopy. We demonstrate that the NCs grown within the scaffold are subject to a large size distribution with substantial contribution from optically dark surface states in the carrier dynamics. However, we provide evidence for greater inter-particle coupling and optimal interconnectivity between the NCs, thus offering an effective strategy to control energy and charge transport.

Light-Driven Ultrafast Phenomena in Ferroelectric Complex Oxides Heterostructure Hyeon JunLee[1], YoungjunAhn[2], HaidanWen[3], Ji YoungJo[4] and PaulEvans[2]; [1]Kangwon National University, Korea (the Republic of); [2]University of Wisconsin–Madison, United States; [3]Argonne National Laboratory, United States; [4]Gwangju Institute of Science and Technology, Korea (the Republic of)

Above bandgap excitation in ferroelectric oxides can lead to a series of changes in the energy landscape of polarization and domain configuration, ultimately resulting in lattice distortion. A key consequent result is the photoinduced lattice distortion on the picosecond timescale set by the acoustic wave propagation. Probing the time-dependent dynamics is crucial to understanding mechanisms of the transitions and discovering new physical phenomena that can exist at an ultrafast time scale.
The picosecond dynamics of structural distortion following photoexcitation were probed at the Pohang Accelerator Laboratory X-ray Free-electron Laser (PAL-XFEL). Acoustic pulses resulting from the above bandgap absorption leads to changes in the x-ray diffraction pattern over the picosecond time scales. The detailed analysis reveals that ultrafast changes in polarization and nanodomain configuration involve complex mechanisms. The mechanisms discussed in this presentation include enhanced polarization by depolarization field screening, polarization rotation, externally imposed mechanical strain, and sub-picosecond-timescale polarization change.

We report that complex strain pulses produced by the photoexcitation drive a time-dependent distortion of nanodomains in $PbTiO_3/SrTiO_3$ superlattice film on $SrRuO_3/SrTiO_3$ substrate. Acoustic pulses resulting from the absorption of the incident optical beam lead to changes in the x-ray diffraction pattern of the SL over the picosecond time scales. The picosecond scale variation of the nanodomain diffuse scattering intensity is consistent with a larger polarization change than would be expected due to the polarization-tetragonality coupling of uniformly polarized ferroelectrics. The strong coupling is consistent with polarization rotation facilitated by the reorientation of the in-plane component of the polarization at the domain boundaries of the striped polarization structure.

The fundamental timescale of the optically induced stress genteration has been studied by comparing the measurement and simulation. Optical excitation leads to ultrafast stress generation in the multierroic BiFeO3 thin film. High-dynamic range femtosecond time-resolved x-ray diffraction to probe the initial stages of the impulsive stress generated by an optical pulse and find that fast components of the stress generation extend to characteristic 1/e times at least as short as 300 fs. The experiments reported here reveal that there are contributions to the stress generated by the absorption of a femtosecond-duration above-bandgap optical pulse that extend over a range of timescales spanning an immediate stress at a scale of far less than 1 ps to timescale of on the order of a few ps.

8:00 PM EL02.05.07
Impact of Different Ligands on Nanocrystal Structural Disorder and Quantum Yield LandonRice[1], ElizaWieman[1], BurakGuzelturk[2] and BenjaminCotts[1]; [1]Middlebury College, United States; [2]Argonne National Laboratory, United States

The goal of our lab is to understand the influence of surface states and transient disorder on the photoluminescence efficiency of semiconductor nanocrystals for use in device applications. A few NC systems (e.g. CdSe:CdS and PbS) have been optimized to reach near-unity quantum yield under weak excitation, but have been shown to achieve lower quantum yield under intense excitation required for certain applications such as lasers or LEDs. We use correlative measurements to understand the role of structural disorder in increased nonradiative decay under high intensity excitation.
We first quantify the power-dependent photoluminescence quantum yield of semiconductor nanocrystals (NCs) as a function of surface ligand chemistry, using a homebuilt quantum yield spectrometer, calibrated by primary standards. Nanocrystals with differing ligand passivation are measured with time-resolved photoluminescence and photoluminescence quantum yield to understand their radiative and nonradiative decay pathways. Finally, time-resolved X-ray diffraction (XRD) is used to measure the influence of differing ligands on electron-photon coupling and transient disorder in NC systems.

8:00 PM EL02.05.08
Electron dynamics of modified p-InP surfaces JonathanDiederich[1], JenniferVelasquez-Rojas[1], AminZare Pour Mohammed[2], AgnieszkaPaszuk[2,3], AzahelRuiz[4], ChristianHöhn[1], DavidOstheimer[2], KlausSchwarzburg[1], RainerEichberger[1,2], GeroSchmidt[4], ThomasHannappel[2], Roelvan de Krol[1] and DennisFriedrich[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]TU Ilmenau, Germany; [3]Helmholtz Centre for Energy and Materials Berlin, Germany; [4]Universität Paderborn, Germany

Within the transition towards renewable energies, green hydrogen is expected to play a prominent role due to its high gravimetric energy density and the complete absence of CO_2 emissions . A promising way of producing green hydrogen is photo-assisted electrochemical water splitting, using semiconductor absorbers with band gaps near the optimum for solar energy conversion. The highest solar-to-hydrogen efficiencies to date of up to 19% have been achieved using InP based absorbers protected by a TiO_2 layer through atomic layer deposition (ALD), both for voltage bias-assisted (p-InP) [1] and unassisted water splitting (AlInP window layer, GaInP top cell) [2].

However, understanding of electron dynamics both at the pure p-InP surface as well as at the p-InP / TiO_2 interface remains limited, in part due to the difficulty in experimentally probing surface conduction band states. We chose to study the (2×1/2×2)-reconstructed P-rich, p-type InP (100) surface prepared through metalorganic chemical vapor deposition (MOCVD), which is commonly utilized in record-breaking cells. Measurements using XPS, UPS, LEED, AFM and time-resolved two-photon photoemission spectroscopy (tr-2PPE) were performed, the latter accessing unoccupied states with a time resolution of 30fs.

We for the first time report detailed dynamics in sub-surface and surface conduction band states up to 2 eV above the p-InP conduction band minimum (CBM), tracking electron lifetimes and average decay paths. Moreover, we explore the impact of TiO_2 layers with varying thickness deposited via ALD on the formation of TiO_2 features, unveiling distinct TiO_2 conduction band states in thin layers, deviating from the conventional TiO_2 density of states reported in the literature. Dynamics and lifetimes of electrons photoexcited in the p-InP bulk are again for the first time tracked across the interface and through the observed TiO_2 states.

A surface treatment protocol using water- and heat exposure in ALD is described, which allows for TiO_2 conduction band states with favourable band alignment to be observed at considerably reduced layer thicknesses. Our measurements indicate enhanced interfacial charge transfer as well as a thinner interlayer region. These improvements are linked to changes in P-dimer surface domains of the p-InP surface during water- and heat exposure, leading to more homogenous P-oxide layer formation and TiO_2 nucleation. Such pre-treatment of the p-InP surface holds the potential to substantially enhance interfacial quality, allowing for thinner TiO_2 layers and reduced defect-mediated recombination, opening exciting opportunities for optimizing cell performance.

Many-Body Exciton-Polariton Quantum Dynamics in Ruddlesden-Popper Metal-Halide Optical Microcavities EstebanRojas-Gatjens[1,1], VictoriaQuiros Cordero[1], MartinGomez-Dominguez[1], CarloPerini[1], ArturoCamacho Guardian[2], GiuseppePirruccio[2], Hugo A.Lara-Garcia[2], HaoLi[3], EricBittner[3], Juan-PabloCorrea-Baena[1] and CarlosSilva[1,1,1]; [1]Georgia Institute of Technology, United States; [2]Universidad Nacional Autónoma de México, Mexico; [3]University of Houston, United States

We probe the quantum dynamics of exciton-polaritons in the prototypical Ruddlesden-Popper metal halide $(PEA)_2PbI_4$ (PEA = phenylethylammine) by means of two-dimensional coherent electronic spectroscopy (2DES), over the temperature range 5–300 K, and as a function of excitation density. We analyze the coherent optical lineshape to extract the homogeneous linewidth, which is governed by optical dephasing of the third-order mesoscopic polarization generated by a time-ordered, phase-matched femtosecond pulse sequence. We quantify excitation-induced

dephasing (EID), which is the contribution to the dephasing due to multi-particle correlations that lead to elastic Coulomb scattering, by analysis of the homogeneous linewidth as a function of polariton density, and by the density dependence of the real and imaginary parts of the complex lineshape. Excitons in $(PEA)_2PbI_4$ films exhibit clear signatures of EID, with a homogeneous linewidth that increases linearly with excitation density, and by evidence of phase shifts of the real and imaginary spectra with respect to the low-density pure dephasing limit [1]. However, comparison of EID parameters with respect to covalent 2D semiconductors such as single-layer transition-metal dichalchogenides reveals that polaronic effects due to the ionic nature of the lattice screen the multi-particle correlations by orders of magnitude with respect to non-ionic semiconductors. In the optical microcavity, such signatures of polariton EID are amplified with respect to the bare excitons, and the spectral structure becomes more intricate, with cross-peak structure that differs with respect to that of the bare exciton. We model the optical lineshapes via quantum-dynamical simulations [2], and find that while the polariton dispersion relation reflects the exciton spectral fine structure, which we ascribe to polaronic effects that lead to distinct exciton polarons with binding energies that differ by ~35 meV [3] due to specific lattice dressing [4], which modulates the permittivity, the strength of multi-particle interactions is substantially higher in the microcavity. We hypothesize that this arises from diminished polaronic screening of polaritons with respect to excitons due to long-range interactions mediated by the photon component. We discuss these findings in the context of mechanisms for polariton condensation in this class of materials.

Alternative Referencing Scheme Suppresses Large Noise Contributions for Pump-Probe Spectroscopy with Visible to Near Infrared Detection KailaM. Yallum, NatalieBanerji and JulienRéhault; Universität Bern, Switzerland

Femtosecond transient absorption (TA) allows us to observe photophysical processes on the pico-, nano-, and micro-second timescales with femtosecond time resolution. Broadband white-light generation and detection determine the scope and limits of a TA setup. With the goals of 1) extending the white light into the NIR, and 2) removing the gap in the 750-850 nm range, a different white light generation scheme was employed consisting of a 800 nm-pumped optical parametric amplifier (OPA) to generate an idler around 2000 nm. The 2000 nm idler is used as the driving beam in a Yttrium Aluminum Garnet (YAG) crystal to generate a white light supercontinuum that spans a range starting at 600 nm up to 1700 nm. Because the white light generation relies on the OPA, additional shot-to-shot noise is introduced yielding shot to shot noise of up to 15%. Such significant noise contributions prevent this generation mechanism from being useful for TA experiments with a classic ratiometric referencing scheme. Therefore, an improved referencing scheme was employed in the signal processing to recover the signal to noise ratio[1].

In short, the proposed B-matrix referencing scheme relies on a cross covariance matrix, **B**, to predict the change in intensity between two pumped shots, $\Delta\Delta I_r^*$, for each wavelength. The difference between the measured change in intensity, $\Delta\Delta I_m^*$, and the reconstructed $\Delta\Delta I_r^*$, is taken to isolate the sample response, $S = \Delta\Delta I_m^* - \Delta\Delta I_r^*$. Calculations to determine **B** can be carried out by a series of unpumped shots measured before the experiment, therefore removing the need for a chopper, or it can be simply calculated by the unpumped shots measured when the chopper is in the closed position. In practice, the B-matrix referencing method reduced the root mean square error in detection by a factor of 40 when compared to the ratiometric referencing scheme.

The case study presented herein focuses on the benefits of the white-light generation and noise reduction methods employed on a spectroscopic study of the organic photovoltaic (OPV) blend PM6:Y6. Newer generation organic semiconducting materials for photovoltaic applications have been chemically modified to absorb closer to the red edge of the visible light spectrum[2]. Because of this, the spectra of triplet and charged states of these materials are often observable in the NIR. Furthermore, the ground-state bleach (GSB) associated with these materials falls into the detection gap brought about by the optical filters needed to remove the 800 light. Furthermore, the overlapping GSB and excited-state absorption result in a differential absorption of the exciton in the linear regime of often less than 1 mOD, sometimes as low as 50 $\Delta\Delta$OD. The referencing scheme employed in this unique TA setup successfully represses the noise in order to recover such small signals.

9:15 AM EL02.06.03
Hot Multiexciton Dynamics in CdTe Nanocrystals: Effect of Spin Blockade ApurbaDe[1], JayantaDana[1], AdarLevy[1], EfratLifshitz[2], UriBanin[1] and SandyRuhman[1]; [1]The Hebrew University of Jerusalem, Israel; [2]Technion Israel Institute of Technology, Israel

The relaxation dynamics of hot multiexcitons can be influenced by the presence of another charge carrier in the band edge level (cold carrier). This phenomenon can be understood by considering Pauli spin blockade where the same spin orientation of both the hot and the cold carrier can inhibit the relaxation of the former. This we first demonstrated in CdSe/CdS nanocrystals (NCs) in one of our earlier studies (*J. Phys. Chem. Lett*. **2019**, 10, 2341-2348). The idea of 'spin blockade' of the hot multiexciton in semiconductor materials is of great interest since it can open up multiple opportunities like in hot-carrier solar cells, photo catalysis etc. To test the generality of such behavior in II-VI quantum dots family members, we extend our study to CdTe. Experimentally this is performed by adopting a unique approach, 'spectator exciton' approach where the multiexciton relaxation dynamics is compared with and without a singly deposited cold exciton (we call it 'spectator exciton'). This spectator exciton actually impose the spin conflict for the cooling of hot multiexcitons. A major observation is that the bleach associated to the state filling of $1s^e$-$1h^e$ level becomes half in amplitude in presence of spectator exciton. The comparison of carrier cooling time in the absence and presence of spectator reveal a prolonged time scale in case of later which is indicative of effective spin blockade. While in case of CdSe/CdS, there is clear separation between the cooling (~ 2 ps) and spin flip time (~25 ps), which made it easy for the determination of spin flipping time, for CdTe situation become a little complex. Mixed-up situation of the time scales in CdTe further influence the Auger process afterward. In this situation, the Auger process appeared to be slower than expected. We thus suggest that hot multiexciton dynamics should be investigated with extra caution since spin blockade can influence the decay dynamics of such. Further we validate this generality with varying sizes of CdS shell thickness for CdSe/CdS NCs. Overall, our findings prove the generic behavior of spin blockade and provides a unique visualization to the multiexciton dynamics of this II-VI family.

Determining Structural Response of CdSe:CdS Nanocrystals to High Energy Excitation ElizaWieman[1], NejcNagelj[2], LandonRice[1], MiaTarantola[1], JacobOlshansky[2], BurakGuzelturk[3] and BenjaminCotts[1]; [1]Middlebury College, United States; [2]Amherst College, United States; [3]Advanced Photon Source, Argonne National Laboratory, United States

Colloidal semiconductor nanocrystals (NCs) are used in optoelectronic applications due to their tunable size, shape, composition, and surface chemistry. NCs reach near-unity radiative efficiencies when excited under weak conditions. However, less is known about nonradiative events under high excitation conditions. In applications such as lasers, photodetectors, and electrically pumped LEDs, NCs are exposed to much higher excitation conditions, causing a rapid increase in nonradiative relaxations. Elucidating the structural origins of thermalization pathways is essential for engineering NCs that can suppress nonradiative processes to improve device efficiency.

Our past work examined the effect of different energy excitation levels on localized lattice disordering in CdSe:CdS core/shell particles using femtosecond electron diffraction. At lower excitation energy (510 nm), the lattice response was dominated by the Debye-Waller effect. However, at higher excitation energy (340 nm), which is significantly higher than the band gap, a deviation from the expected Debye-Waller response was observed, suggesting additional short-range localized disordering. Transient differential atomic pair distribution function analysis corroborated that the localized disorder was likely associated with hot hole trapping on the NC surface.

This work implies that the observed localized structural disorder may be associated with certain lattice planes. However, lower Q-resolution and lack of long delay time capabilities at the facilities used in earlier experiments prevented clear distinguishing of peaks, for determination of the structural geometry of the small polarons, and to measure their recovery dynamics. Additional time-resolved X-ray diffraction (TR-XRD) experiments were conducted on CdSe:CdS core-shell particles in order to resolve the observed structural disorder to specific lattice planes. Both liquid jet and solid-state experimental setups were used, and current work involves analyzing this TR-XRD data in order to both determine the relationship between localized disorder and non-radiative cooling and compare the efficacy of these two methods for resolving the structural response of NCs to photoexcitation.

Molecular dynamics (MD) simulations and X-ray pair distribution function (PDF) experiments were performed to examine the response of CdSe:CdS NCs to heating. Combining these three methods will help to decouple the purely thermal response in the MD simulations and X-ray PDF experiments from the additional photoinduced structural disorder observed in the TR-XRD data. Results of this work will allow for a more thorough understanding of the localized disorder caused by hot hole trapping processes and improve NC engineering methods to create more efficient optoelectronic devices.

Decoupling Two-Photon Absorption and Photoluminescence in Nanomaterials with Heterostructure Engineering ArthurAlo[1], LeonardoW. Barros[1], GabrielNagamine[1], JonathanC. Lemus[1], JosepPlanelles[2], JoséL. Movilla[2], JuanI. Climente[2], Hak JuneLee[3,4], Wan KiBae[4] and LazaroPadilha[1]; [1]Universidade Estadual de Campinas (UNICAMP), Brazil; [2]Universitat Jaume I, Spain; [3]Seoul National University, Korea (the Republic of); [4]Sungkyunkwan University (SKKU), Korea (the Republic of)

Quantum dots (QDs) were expected to offer enhanced nonlinear optical properties due to quantum confinement. However, it has been observed that QDs exhibit two-photon absorption (2PA) cross-sections that scale linearly with their volume. Consequently, the only way to increase the 2PA in QDs is by increasing their volume. Considering that the emission spectra of QDs are also coupled to their size, this can become a limiting factor if one wishes for QDs with large 2PA cross-sections that emit light in a specific wavelength range. Successful strategies to decouple emission wavelength and nanocrystal (NC) size involve doping, to create red-shifted trap-mediated emission, and heterostructuring, by growing core/shell NCs. On the other hand, little is known about how these heterostructures affect the nonlinear response.
Thus, in this work, we explore how heterostructures affect the 2PA volume scaling and how efficiently they can decouple 2PA cross-section and emission spectra. For this, we measured the 2PA cross-section of three types of samples: CdSe core-only QDs, CdSe/ZnCdS type-I, and CdSe/CdS quasi-type-II core/shell NCs. Type-I and quasi-type-II core/shells are differentiated by their band alignment and how their electron and hole are spatially confined, with type-I having electron and hole confined to the core of the heterostructure, while quasi-type-II have the electronic wavefunction spread through the entire heterostructure while the hole is confined to the core. These core/shell samples have fixed core sizes, and their total volume is increased by thickening their shells. This way, we found that type-I and quasi-type-II heterostructures present sublinear 2PA volume scaling, in contrast to the linear scaling observed in core-only QDs. Furthermore, type-I NCs exhibit a lower 2PA volume scaling than quasi-type-II.
To understand this difference in 2PA cross-section volume scaling, we performed theoretical calculations using the k.p method. As it has been previously reported in the literature, we verify that the linear volume scaling of the 2PA in core-only QDs is due to the reduced density of states for smaller QDs, which counteracts the increase in the oscillator strength for individual two-photon transitions. Similarly, the 2PA volume scaling in core/shell NCs is also dictated by their reduced density of states. Type-I NCs were seen to have the lowest volume scaling for their density of states, while quasi-type-II present an intermediate volume scaling for the density of states.
Furthermore, these calculations along with experimental data suggest that, for the quasi-type-II NCs, the higher the shell-to-core volume ratio, the higher the density of states for the two-photon transitions. We verified this with another series of quasi-type-II samples with smaller core volumes, which we observed to have a 2PA volume scaling similar to the core-only samples. This way, as these core/shell samples offer minimum shift in their emission spectra with increasing shell thickness, they offer the possibility of obtaining NCs with larger 2PA cross-sections at a specific emission wavelength.

Transient Microscopy of Mobile Excitons in 2D Semiconductors AlexeyChernikov; TU Dresden, Germany

Transport of optical excitations in semiconducting solids plays a central role from both fundamental and technological perspectives. In systems with strong Coulomb interaction the propagation of optically injected carriers is dominated by excitons instead of free electrons or holes. These correlations can affect both the overall energy landscape and the interactions with vibrational modes, with a strong impact on the mobility of the excitations.
In this talk I will discuss recent studies employing the technique of transient microscopy to monitor propagation of mobile exciton quasiparticles in two-dimensional van der Waals semiconductors. In these systems, the electron-hole correlations present a particularly interesting case combining the properties of Wannier-Mott excitations in inorganic quantum well systems with high exciton binding energies that are more characteristic for Frenkel-like states in molecular crystals. I will discuss linear and non-linear phenomena, influence of environmental screening and disorder, and present strategies to externally manipulate exciton propagation. I will outline the limits of semi-classical and hopping transport in monolayer semiconductors and illustrate the impact of free charge carriers on the exciton diffusion.

Dynamics of Photoexcitations in SnS_2 Single Crystals KaterynaKushnir, SepidehKhanmohammadi, ErinMorissette, ErikaColin-Ulloa, CurtisDorian, JuliaMartin, RonaldL. Grimm and LyubovV. Titova; Worcester Polytechnic Institute, United States

Tin disulfide (SnS_2) is a layered material that is environmentally stable, composed of earth-abundant materials, has a moderate bandgap of ~2.3 eV and high absorption in the blue-green spectral range, making it attractive for optoelectronic and solar energy applications. We have previously shown that photoexcited carriers in single crystalline SnS_2 and in vertical nanoflakes have a high mobility of ~ 300 cm^2/Vs and lifetimes in excess of 1 ns [1,2]. Additionally, above band gap excitation of single crystalline SnS_2 at normal incidence results in emission of THz radiation, a hallmark of a second order nonlinearity. This observation is surprising due to inversion symmetry being present in unexcited SnS_2 even in a monolayer limit, and we hypothesize that photoexcitation dynamically breaks the inversion symmetry by excitation of an in-plane phonon mode. Here, we use time-resolved THz spectroscopy, THz emission spectroscopy and transient optical absorption to uncover the complete picture of the ultrafast electronic responses following photexcitation. Our experimental results provide important checkpoints for theory of nonlinear effects in SnS_2 and other 2D dichalcogenide materials.

Probing The Carrier Dynamics around The Band Gap of Amorphous Silicon Telluride Md. RafiqulIslam[1], KiumarsAryana[1], DerekStewart[2], MichaelGrobis[2], JoyeetaNag[2] and PatrickE. Hopkins[1]; [1]University of Virginia, United States; [2]Western Digital Corporation, United States

Amorphous chalcogenide alloys are key materials for data storage and energy scavenging applications due to their large non-linearities in optical and electrical properties. Silicon telluride (SiTe) is an example of these amorphous alloys because it undergoes a solid-state phase transformation upon the application of a sufficiently large electric field, commonly referred to as threshold switching. Here, we investigate the impact of this phase transformation on electrical properties by monitoring carrier lifetimes at and around the transformation. We implement an ultrafast near-infrared pump-probe spectroscopy technique that allows for direct monitoring of electronic and vibrational energy carrier lifetimes in amorphous silicon telluride. We confirm the ultrafast findings with the help of density functional theory calculations and ellipsometry. From the DFT calculation we find the optical bandgap of the film is 0.695+/- 0.15 eV and the mobility gap is 1.12 +/- 0.05 eV. We probe the reflectivity response of this alloy after pump heating in the energy range of 0.5 to 2.07 eV. From ultrafast technique we find that SiTe demonstrates the direct valence mobility edge to conduction mobility edge transition at 1.24 eV. It is slightly larger than the reported optical band gaps. Besides, we identify a hole trap state at 1.08eV which is near the valence band edge, indicating that the flow of electrons in SiTe is possible under the threshold voltage. The electrons of the low energies relaxes faster than the free electrons of bandgap energy, confirming the presence of trap states in SiTe and its conductive nature under its threshold voltage. The presence of localized states at the band edge is expected in the electronic structure of amorphous materials and is consistent with previous studies of Si−Te materials. These findings open the way of tuning the property of this chalcogenide alloy, which will lead to building new electronic devices with higher efficiency and better performance.

11:30 AM *EL02.06.09
The High-Frequency Limit of Schottky Rectification MariaT. Schlecht[1], TobiasWeitz[1], ChristianHeide[2], SebastianLotter[1,2], StefanMalzer[1], PeterHommelhoff[1] and HeikoB. Weber[1]; [1]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [2]Stanford University, United States

A Schottky diode, i.e. a metal-semiconductor junction, is among the simplest yet fastest electronic components. The underlying general theory has been developed by Schottky for the stationary, i.e. DC case. When operating it at high frequency, the RC timescale sets an extrinsic limit.
Using graphene as a metal and Silicon carbide (SiC) as semiconductor, epitaxial graphene on SiC provides a monolithic and extremely robust Schottky diode. Its current-voltage characteristics can accurately be described by Schottky's model. When driving the diode at high frequency, an RC damping at around 400 GHz could be determined [1]. We recently studied this diode replacing the voltage drop by the electric field of ultrashort light pulses in the mid-infrared regime. It turns out that the Schottky physics remains predictive up to 82 THz, even with the parameters determined at DC. One only has to make a correction that describes an incoherent and easily understood recapture mechanism [2].
We have now adapted the same experimental strategy to visible pulses, with a center frequency of 300 THz. Simultaneously, we have chosen a slightly lower Schottky barrier. The result is again a field driven current, as identified by a carrier-envelope phase dependent contribution. It increases with an effective power law. In order to understand this behavior, the Schottky model is inappropriate. Rather, a time-dependent Schrödinger equation is the correct description. This crossover of the physical description can be understood by a Keldysh-Parameter close to unity. We conclude that the Schottky description, being accurately predictive over many magnitudes from 1Hz-82 THz, fails at only slightly higher frequencies.

2:00 PM EL02.07.01
Predicting Dielectric Function from Scattering-Type Scanning-Near-Field Optical Microscopy (s-SNOM) TomVincent[1], XinyunLiu[1], DanielJohnson[1,2], LarsMester[3], NathanielHuang[2], OlgaKazakova[2] and JessicaL. Boland[1,2]; [1]Photon Science Institute, University of Manchester, United Kingdom; [2]National Physical Laboratory, United Kingdom; [3]Attocube Systems AG, Germany

Scattering-type scanning near-field optical microscopy (s-SNOM) is a powerful tool that enables optical microscopy and spectroscopy with extreme sub-wavelength spatial resolution [1]. It is used heavily to characterise optical metamaterials, low-dimensional materials, and surface states in topological insulators, which may have nanoscale dimensions that can't be detected by traditional optical microscopy. But relating material dielectric function to the observed optical contrast requires modelling the interaction between a SNOM tip and the sample, which can be both conceptually and computationally challenging.

The finite dipole model (FDM) has shown excellent agreement between experimental and modelled data based on known dielectric functions [2]–[4]. However to date there are only a few works that fit the FDM to experimental SNOM data to retrieve *unknown* dielectric functions [5]–[7].

In this work, we investigate in-detail how the FDM relates the dielectric function to the observed optical contrast. We demonstrate its application on real SNOM spectra from topological insulator thin films and InN nanoparticles, with reference to measurements simulated by our soon-to-be-released modelling package, *pysnom*. We identify the key challenges involved in fitting to the FDM, including non-unique solutions and finite size effects, and we present the strategies we've developed to overcome them. By following the steps outlined in this presentation, and taking advantage of our optimised code library, we hope that extracting quantitative measurements of dielectric function from SNOM experiments will become more achievable for the wider scientific community.

2:15 PM EL02.07.02
Terahertz Radiation of Hot Carriers: A Far-Field Probe for Near-Field Spatiotemporal Dynamics MohammadTaghinejad[1], ChenyiXia[1], MartinHrton[1], KyutaeLee[2], AndrewKim[2], QitongLi[1], BurakGuzelturk[1], FenghaoXu[1], WenshanCai[2], AaronLindenberg[1] and MarkL. Brongersma[1]; [1]Stanford University, United States; [2]Georgia Institute of Technology, United States

From the birth of plasmonics, the hot-carrier generation in nanostructured metals was considered as an innate roadblock towards the efficient usage of the light energy stored in sub-diffraction plasmon modes. The observation of the hot-carrier transport at metal/dielectric Schottky junctions, however, transformed this limitation into a unique opportunity for enabling a light-field control over photochemical and photophysical processes in a spectrally selective and spatially fashionable manner. Despite successful prototype device demonstrations, the scarcity of experimental knowledge about the spatiotemporal dynamics of the transport has impeded the expansion of hot-carrier applications, particularly in activating photocarrier-driven coherent processes. Here, we employ the electric-field of terahertz bursts radiated by transport-induced current pulses as a coherent electromagnetic probe to monitor the photoemission dynamics of hot carriers at a plasmonic Schottky junction. The time-domain analysis of the terahertz field indicates that the charge ejection process is dominated by nonthermal hot carriers and occurs within an ultrashort timeframe (~10 fs) controlled by the plasmon lifetime, electron-electron scattering rate, and the charge transport with a narrow interfacial boundary layer. By employing the polarization and phase attributes of the radiated THz field we are able to probe the in-plane ballistic transport trajectory of electron via in a far-field detection scheme.

Ultrafast and Nanoscale Raman Approaches for Materials Science ReneeFrontiera; University of Minnesota, United States

Our lab focuses on the development and application of Raman spectroscopies with high temporal and spatial resolution, with the goal of understanding local environmental impacts on chemical reaction dynamics. This talk will focus on the use of these spectroscopic and microscopic approaches in order to understand two coupled light-matter systems: plasmon-molecule interactions and excitonic polariton dynamics. In the quest to understand how plasmonic nanomaterials can serve as photocatalysts, we have developed ultrafast surface-enhanced Raman approaches to understand molecule responses following photoexcitation. This talk will focus on our quantitation of plasmon-to-molecule charge transfer, which enables us to determine the yield and energy of hot carriers relevant for driving chemical reactions. Secondly, we have used femtosecond stimulated Raman spectroscopy and resonance Raman intensity analyses in order to understand the similarly strong coupled light-matter system of excitonic polaritons. Here we map out multiple dimensions of the coupled potential energy landscape to determine how coupling to a photonic cavity can change molecular reaction coordinates. Taken together, these works demonstrate how probing multiple molecular degrees of freedom can lead to new insights into the rational design of coupled systems.

4:00 PM EL02.07.04
Imaging Nanosecond Charge Recombination Dynamics via Scanning Probe Microscopy RachaelCohn, ChristopherPetroff, VirginiaE. McGhee and JohnA. Marohn; Cornell University, United States

Bulk heterojunction organic photovoltaics (OPVs) exhibit charge recombination times that are 10s to 1000s of times longer than predicted by Langevin theory. Understanding the mechanism of charge generation and recombination is critical to furthering the development of photoactive materials used in OPVs. We use electric force microscopy (EFM) to better understand the temporal dynamics and spatial distribution of charge generation and recombination in OPVs. Achieving nanosecond time resolution is required to observe photogenerated charges before they recombine.

We find that charge recombination in the OPV films that we study is too fast to observe in a real-time time resolved EFM (tr-EFM) experiment. We measure temporal changes in the film's photo-induced capacitance and resistance on the nanosecond timescale using an electrical scanned-probe microscope experiment. Time resolved microwave conductivity is typically used to measure photoinduced changes in the film charge density on the nanosecond time scale, but the technique lacks spatial resolution and devices with contacts pose difficulties. Scanning probe microscopy has nanometer spatial resolution, but has previously lacked nanosecond time resolution. A time resolution of 10 ns is claimed for the fast-free tr-EFM experiment [1], but this time is shorter than one cantilever oscillation cycle and is, therefore, unphysical [2,3].

The phase-kick EFM (pk-EFM) experiment, introduced by Dwyer *et al.* [2], measures the photocapacitance and photoresistance charging time, τ_R, by measuring the change in cantilever frequency and phase as a function of the delay times, t_p, between light and voltage pulses. After performing the experiment at various delay times, we plot the total phase shift $\Delta\varphi$ *vs.* t_p to obtain the sample's charge recombination transient and the recombination time, τ_R. The pk-EFM method has a well-defined theory for both the signal [4] and the signal to noise ratio (SNR) [2] and is capable of achieving sub-cycle, nanosecond time resolution [2]. We describe our efforts to push pk-EFM's temporal resolution from microseconds to nanoseconds in an OPV film.

3D Ultrafast Optical Microscopy of Semiconductors and Quantum Materials AkshayRao; University of Cambridge, United Kingdom

Elucidating the three-dimensional transport of excitations in condensed matter systems is key to advancing in our understanding and utilisation of functional materials ranging from novel quantum systems to next-generation optoelectronic materials. Of particular interest are quantum coherent processes in heterogeneous, disordered systems which require both ultrafast time resolution and local measurements to study and understand their transport characteristics. In this talk, I will discuss our recent work using interferometrically enhanced femtosecond pump-probe microscopy, that now enable us to track carrier and quasi-particle motion in three dimensions with sub-10 nm spatial precision and sub-10 fs temporal resolution. I will highlight recent results looking at charge carrier and spin motion in hybrid perovskites [1-2], excitons and polaritons in organic semiconductors [3-4], quantum dot films [5] and exciton condensates [6]. This new methodology [7] unlocks new regimes of spatially resolved ultrafast dynamics for investigation across a range of solid-state systems.

9:00 AM EL02.08.02
THz Bandwidth Activation of Anharmonic Coupling in $CdWO_4$MeganNielson, BrittanyKnighton, LaurenDavis, AldairAlejandro, ClaireRader and JeremyA. Johnson; Brigham Young University, United States

Terahertz (THz) frequency light is uniquely suited to resonantly probe collective electronic, phonon, magnon, and electromagnon modes, and we are showing that intense THz pulses enable coherent control and the direct measurements of coupling between these excitations.

When intense electromagnetic pulses are used in any kind of pump-probe spectroscopy, several nonlinear excitation pathways can result, leading to scenarios that required the development of multi-dimensional spectroscopies to illuminate the observed dynamics. New developments in 2D THz spectroscopy in our lab and others are enabling the direct measurement of nonlinear excitation of phonon, magnon, and electronic modes, and preliminary measurements are directly showing couplings between them. We have demonstrated clear examples where two-dimensional (2D) THz vibrational spectroscopy is needed to distinguish between nonlinear-excitation pathways, and it enables the selection of one pathway over another.

With intense THz pulses, Raman-active vibrational modes can be nonlinearly excited in centrosymmetric crystalline $CdWO_4$. However, in single-pulse measurements, it's unclear whether the nonlinear pathway is a photonic process (THz Raman excitation) or a phononic process (anharmonic coupling). In previous work, we showed that Raman excitation is the dominant nonlinear pathway at moderate THz field strengths. With an improved 2D THz experimental setup, we can minimize the Raman excitation and clearly isolate the anharmonic coupling signals.

Interestingly, our analysis shows that coupling between IR-active modes at 2.94 THz and 3.65 THz and the Raman-active mode at 2.33 THz clearly occurs. At first glance, the coupling between three modes should only be efficient when the frequencies of the IR-active modes add up to or subtract down to the frequency of the Raman-active mode, which is not the case here. But when we consider the IR-active mode motion after resonant excitation with a broadband THz pulse, we recognize that the spectrum of the initial motion contains the resonant frequency of the mode itself, as well as a broad range of frequencies that essentially matches the spectrum of the driving THz pulse. Therefore, although the anharmonic coupling between these modes is predicted to be inefficient based on the resonant frequencies of the IR-active modes, we show that the initial THz pulse itself drives motion with more than just the resonant frequency, activating efficient coupling between vibrational modes in $CdWO_4$.

Insights into Explicit Anharmonic Effects in Crystals via Intensity Analysis of THz-Range Raman Spectra NoamPinsk, AdiCohen and OmerYaffe; Weizmann Institute of Science, Israel

In optical spectroscopy, the harmonic approximation is commonly used to assign peaks and lineshapes to eigenstates, providing valuable information about the system's internal structure. However, understanding explicit anharmonic effects, such as eigenstate coupling and phase transformations, typically necessitates advanced techniques like 2D spectroscopy or calorimetric measurements, which may not provide detailed mechanistic insights.
Nevertheless, the intensity of peaks in THz-range Raman spectroscopy measures the population of vibrational states and contains valuable information about anharmonic interactions. In this talk, I will illustrate how analyzing the temperature dependence of Raman peak intensities can provide valuable mechanistic insights into the coupling between eigenstates and phase transformations.
The first example is in Bismuth Vanadate, where the soft mode loses intensity and depopulates towards its first-order phase transition, evident in the discontinuity of integrated intensity for all lattice modes. The second example is in alpha-glycine, where we discover a local phase transformation manifested by a change in the hydrogen bond free energy surface and accompanied by highly anharmonic lattice behavior. These findings represent an important initial step towards utilizing THz-range Raman spectroscopy as a direct probe for studying equilibrium and non-equilibrium dynamics.

Charge Transport Mechanism in Photoconductive Metal Organic Frameworks JierHuang[1], JamesNyakuchena[2], DenanWang[1], DanielStreater[2], JensNeu[3] and GaryBrudvig[4]; [1]Boston College, United States; [2]Marquette University, United States; [3]University of North Texas, United States; [4]Yale University, United States

Metal organic frameworks (MOFs), built from inorganic and organic linkers, represent an emerging class of porous crystalline materials that have demonstrated many potential applications encompassing energy conversion and storage, gas separation and storage, chemical sensor, and drug delivery. Recent reports of electrical conduction in MOFs expand their applications in devices such as supercapacitors, electrocatalysts, chemiresistive sensors, and batteries. However, the charge transport mechanism that guides the rational design of highly conductive MOFs remains underexplored; yet it is essential to further promote these materials for the above-mentioned applications.
In this talk, I will present our recent progress in fundamental understanding of charge transport mechanism in a series of MOFs and the correlation of the metal nodes and organic linkers with their photophysical property and photoconductivity. We found that structural preference in M-THQ MOFs (M = Fe, Ni, Cu and Zn; THQ = tetra-hydroxybenzoquinone) is controlled by metal node identity where Cu prefers a square planar coordination which leads to a 2D Kagome type structure. Fe, Ni and Zn prefer an octahedral sphere which leads to a 3D structure. Fe-THQ has the smallest band gap and highest photoconduction as well as a long-lived ligand to metal charge transfer state due to the mixed valence state revealed by time resolved optical and X-ray absorption and terahertz spectroscopy. On the other hand, charge transport mechanism is controlled by the size of the organic linker, where some MOFs prefer through space transport while others undergo through bond charge transport mechanism. These results demonstrate the importance of the building blocks in tuning the photophysical and photoconductive properties of MOFs.

High Pressure Tuning of the Excited State Dynamics in Fe Complexes Toward Solar Energy Conversion YingqiWang[1], WengeYang[1], CunmingLiu[2] and XiaoyiZhang[2]; [1]Center for High Pressure Science & Technology Advanced Research, China; [2]Argonne National Laboratory, United States

Earth-abundant-metal-based photosensitizers as substitutes for their noble metal analogues have attracted increasing interests in recent years owing to their environmental and economic benefits. However, the rapid deactivation of their charge transfer (CT) excited state hinders their practical applications in solar cells and photocatalysis. Here we demonstrate a novel approach to stabilize the metal to ligand CT (MLCT) state in iron polypyridyl complexes by tuning the potential surface of its main deactivation channel: the metal core spin state, using high pressure. The MLCT state lifetime increased by 5 orders of magnitude from sub-50 femtosecond at ambient condition, to 9 nanoseconds under high pressure. Applying ultra-fast optical transient absorption spectroscopy (OTA) technique, we witness the ligand field splitting increases significantly with applied pressure, which moves the energy of the metal centered T_{2g} state up while leaves the MLCT state relatively unchanged. From 0 to 5 GPa, the ground state bleaching lifetime decreases due to the increased energy gap between high spin (HS) and low spin (LS) transition. Beyond 5 GPa, the energy of T_{2g} state surpasses that of the MLCT state, resulting in prolonged photoactive MLCT state, which is further confirmed by the appearance of solvated electron peak in OTA spectra. Our results show that the excited state energy and lifetime of iron complexes can be tuned by reducing bond length and increasing ligand field strength, enabling the harvesting of photoexcited electrons and photoenergy with 3*d* metal complexes.

Artificial Neural Network-Aided Fast Determination of Electrical Conductivity From Contact-Free Terahertz Time-Domain Spectroscopy PatrickKung, M.ZekiGüngördü and SeongsinM. Kim; University of Alabama, United States

Terahertz time-domain spectroscopy (THz-TDS) is a contact-free characterization method that is commonly used to yield conductivity, carrier density, and mobility in semiconductor materials. However, when doing so, these material characteristics are not immediately accessible. Instead, many extensive steps are involved in the analysis of the acquired terahertz signal data prior to being able to extract relevant material information. These typically include first carrying out a Fast Fourier Transform of the measured time-domain data, followed by fitting the resulting spectra to determine the conductivity spectra.
In this work, we demonstrate an effective, swift, and stable method for obtaining the conductivity of nanowire-based films by leveraging the power of artificial intelligence to streamline the process. Specifically, we show that both shallow neural networks (SNN) and deep neural networks (DNN) are capable of yielding the THz frequency-dependent conductivity directly from THz time-domain waveform data as input without data processing steps. As experimental validation, we used THz-TDS data measured from four independent datasets: Al-doped and undoped ZnO nanowires on sapphire substrates, and silver nanowires on polyethylene terephthalate and polyimide substrates. After training and testing the SSN and DNN to obtain the optimum model, the frequency-dependent conductivity predicted by our models successfully matched the conductivity calculated using the conventional multi-step method. Mean Squared Error and R-values are used as the main performance criteria of our systems analysis. This study revealed that one can determine a sample's conductivity within seconds without having to carry out Fast Fourier Transform and the conventional conductivity calculation steps from experimental THz-TDS waveform. This AI-based method of training and predicting conductivity will significantly facilitate the subsequent process of fitting the conductivity data to the Drude model in order to extract other physical parameters underlying ultrafast carrier dynamics.

11:15 AM EL02.08.07
Resonant Self-Diffraction of Femtosecond Extreme Ultraviolet Pulses at the M-Edge of Cobalt AlexeiMaznev[1], FilippoBencivenga[2], RiccardoMincigrucci[2], EttorePaltanin[2], WonseokLee[3], ScottK. Cushing[3], NicolasJaouen[4], FabianKammerbauer[5], VincentPolewczyk[6], CyrilLéveillé[4], LauraFoglia[2], DannyFainozzi[2], NupurN. Khatu[2,7], DarioDe Angelis[2], ChristianGutt[8] and DmitriyKsenzov[8]; [1]Massachusetts Institute of Technology, United States; [2]Elettra Sincrotrone Trieste, Italy; [3]California Institute of Technology, United States; [4]Synchrotron SOLEIL, France; [5]University of Mainz, Germany; [6]Istituto Officina dei Materiali, Italy; [7]University of Venice, Italy; [8]University of Siegen, Germany

The advent of free electron lasers (FELs) enabled the expansion of nonlinear optical spectroscopy methods into extreme ultraviolet (EUV) and x-ray ranges. In particular, four-wave mixing techniques with EUV and EUV/optical fields are being actively developed [1-4]. Self-diffraction is the simplest non-collinear four-wave mixing process, in which the interference of two beams crossed in the sample results in a spatially periodic excitation acting as a diffraction grating for the same beams. Self-diffraction is being widely used in optics but has not hitherto been observed in the EUV or x-ray ranges. Generally, the self-diffraction signal from femtosecond EUV FEL pulses is expected to be low, as the polarizability in the EUV range is mainly determined by the average electron density, which does not have time to change significantly within the femtosecond pulse duration. In this report, we show that the EUV self-diffraction efficiency is greatly enhanced and very bright signals are observed when the EUV photon energy is tuned to an absorption edge of the sample. In an experiment conducted at the TIMER beamline at the FERMI FEL, we crossed two 70 fs EUV pulses in a 20 nm –thick cobalt film and scanned the photon energy between 52 – 74 eV. At the $M_{2,3}$-edge of Co (59 eV) we observed a sharp peak in the self-diffraction efficiency, with the signal level reaching ~4000 photons/shot. DFT/Bethe-Salpeter equation based simulations involving a model assumption that the excitation is equivalent to an increase of the electronic temperature are found to reproduce the peak at the M-edge but not the fine structure observed above the edge. We believe that the results open the prospect for a new element-specific nonlinear EUV spectroscopy technique.

An Experimental Technique for Directly Measuring Ultrafast Ion Hopping and Its Inherent Many-Body Correlations ScottK. Cushing and KimPham; Caltech, United States

In superionic conductors, ion hopping involves a complex interplay of ion-phonon, ion-electron, and ion-ion correlations that is challenging to measure experimentally. In this presentation, we present a new experimental technique that can directly measure ultrafast ion hopping on its inherent picosecond and longer timescale. The technique works by measuring the time-resolved

perturbation to a GHz impedance signal when potential ion-coupling interactions are driven with UV to THz irradiation. The use of high-bandwidth, real-time electronics allows synchronization of the impedance measurement to the ultrafast laser pulses for varying carrier frequencies. The result of the measurement is the relative strength of different correlations in the many-body ion hopping Hamiltonian. We demonstrate the technique on $Li_{0.5}La_{0.5}TiO_3$ (LLTO), a solid-state Li^+ conductor. The ultrafast laser-driven impedance measurements reveals that the dominant ion hopping mechanism in LLTO is through a coupled phonon-ion THz rocking mode. Although this higher frequency mode is less than one quarter of the overall phonon density of states, it leads to the majority of ion hops as compared to other optical and acoustic phonon modes. Metastable states lasting tens of minutes were also measured for ion-electron perturbations. Further work on extending the technique to measure ion-ion correlations is currently underway, but the technique is already generally applicable to any complex ion conducting system such as polymers, fuel cells, and membranes.

Despite extensive studies on size effects in ferroelectrics, how structures and properties evolve in antiferroelectrics with reduced dimensions still remains elusive. Given the enormous potential of utilizing antiferroelectrics for high energy-density storage applications, understanding their size effects would provide key information for optimizing device performances at small scales. In this presentation, I will introduce our recent study about the fundamental intrinsic size dependence of antiferroelectricity in lead-free NaNbO3 freestanding membranes [1]. Via a wide range of experimental and theoretical approaches, we probe an intriguing antiferroelectric-to-ferroelectric transition upon reducing membrane thickness. This size effect leads to a ferroelectric single-phase below 40 nm as well as a mixed-phase state with ferroelectric and antiferroelectric orders coexisting above this critical thickness. Furthermore, we show that the antiferroelectric and ferroelectric orders are electrically switchable. Such a structural evolution also drives a non-monotonic thickness dependence of Young's modulus. We further reveal the observed transition is driven by the structural distortion arising from the membrane surface. Our work provides direct experimental evidence for intrinsic size-driven scaling in antiferroelectrics and demonstrates enormous potential of utilizing size effects to drive emergent properties in environmentally benign lead-free oxides with the membrane platform.

Ultrahigh Electromechanical Response in Antiferroelectric Thin Films: Unconventional Coupling of Phase Transitions and Mechanical Clamping HaoPan[1], MenglinZhu[2], EllaBanyas[3], LouisAlaerts[4], MeghaAcharya[1], JiyeobKim[1], HongruiZhang[1], IsaacHarris[1], JamesM. LeBeau[2], JefferyNeaton[3] and LaneW. Martin[1,5,5]; [1]Universisty of California, Berkeley, United States; [2]Massachusetts Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Dartmouth College, United States; [5]Rice University, United States

Electromechanical transduction has been a fundamental enabler for various modern technologies such as actuation, ultrasound imaging, and resonators. Electrostrain (*i.e.*, the strain induced by an electric field) is one of the key parameters for electromechanical applications. Currently mainstream electromechanical materials are ferroelectric ceramics/crystals, in which the best cases have realized electrostrain values of ~1.0% due to their high piezoelectricity. When ferroelectrics are scaled down sub-micrometer thick films, however, the electrostrain performance is generally degraded significantly because of size effects and the mechanical constraint from the substrate (so-called clamping). Needless to say, such observations have been a critical obstacle to developing high-performance, micro-/nano-electromechanical systems. On the other hand, antiferroelectrics, which exhibit antipolar order and a reversible field-induced transition to polar (ferroelectric) order, also exhibit large electrostrains (0.4-1.0%) and have been considered as potential candidates for electromechanical devices since the 1960s. More intriguingly, in antiferroelectric films at the micrometer scale, electrostrain values comparable to those in bulk materials have been observed; this is distinctly different to the scaling behaviors of ferroelectrics. A clear understanding of the mechanism of electrostrain and the "absence" of size effects in antiferroelectrics is absent but would be of significance for their further optimization and application.
Combining macroscopic epitaxial thin-film growth, electromechanical measurements, first-principles calculations, and *in situ* transmission electron microscopy, we have systematically studied the antiferroelectric-to-ferroelectric phase transition and demonstrated an unconventional interaction of the phase transition and mechanical clamping that leads to high electrostrain properties in antiferroelectric films. Focusing on model systems such as $PbZrO_3$, we find that detilting of oxygen octahedra happens along with a field-induced phase transition from antiferroelectric (orthorhombic, *Pbam*) to ferroelectric (rhombohedral, *R3m*), which causes an abrupt lattice-volume expansion and thus large electrostrain. We note that the lattice expands in all dimensions, that is, not only along the direction of the applied electric field. In this case, the substrate constraint actually enhances, instead of degrades, the electrostrain in the

antiferroelectric films (contrary to that in ferroelectric films) since the in-plane lattice expansion is hindered by the substrate constraint during the antiferroelectric-to-ferroelectric transition thus adding to the out-of-plane expansion. By thoughtfully designing antiferroelectric thin films to take best advantage of the phase transition and substrate constraint, we realize ultrahigh electrostrain as large as ~1.7% in the canonical antiferroelectric $PbZrO_3$ films in films just 100 nm thick. Such responses also exhibit robust frequency stability and fatigue resistance. The high performance and new understanding of the mechanism for response in antiferroelectric thin films provide a promising pathway to overcome general scaling obstacles for electromechanical materials for high-performance micro-/nano-electromechanical systems.

11:15 AM EL03.01.03
High-Throughput Screening Search for Antiferroelectricity and Experimental Validations TomokiMurata[1], HirofumiAkamatsu[2], DaisukeHirai[1], AkiraTakahashi[3], FumiyasuOba[3] and SakyoHirose[1]; [1]Murata Manufacturing Co., Ltd., Japan; [2]Kyushu University, Japan; [3]Tokyo Institute of Technology, Japan

Ferroelectric materials have been widely used for many applications such as multilayer ceramic capacitors (MLCC), piezoelectric actuator, and random-access memory, and much effort has been made to explore new ferroelectric materials and improve their properties. Recently, antiferroelectric materials have attracted much attention due to their unique and useful responses to an electric field. An antiferroelectric material has a phase transition from an antipolar state to a polar state in an external electric field. This phase transition accompanies a drastic change in dielectric polarization. Consequently, the large dielectric responses (e. g. large permittivity and discharge capacity) are observed around the critical field. However, the known antiferroelectric materials are almost limited to the perovskite materials containing Pb^{2+} or Bi^{3+} ions on A-site, which strongly limits the designer's perspective.
Unlike ferroelectric materials, which can be identified from a space group symmetry, searching for antiferroelectric materials is not so simple because an antipolar structure could not be distinguished only by looking at the space group. Antipolar structures have no net polarization and are classified into nonpolar space groups. The symmetrical definition of antipolar structure is not apparent and had lacked for decades. In 2016, Toledano *et al*. proposed a new symmetrical definition of antipolar structure based on a local symmetry on crystallographic sites [1]. When a crystallographic site undergoes a symmetry lowering and acquires a polar site symmetry on the phase transition, the low-symmetry structure can be antipolar.
In this study, we performed high-throughput screening of ICSD database in search for antiferroelectric materials. We adopted the symmetry criteria for antipolar structures in the initial screening, and the formula-based screening of chemical compositions to narrow down the candidates. Then, we picked up some candidate materials and performed a stable structure search via first-principles phonon calculations. In some materials, we successfully find polar and antipolar structures which are energetically comparable, possibly indicating antiferroelectricity. Finally, we experimentally synthesized the obtained candidate materials and fabricated MLCCs to characterize their dielectric and antiferroelectric properties. Though most of them are paraelectric, $Bi_2Ti_4O_{11}$ and $Na_2Nb_4O_{11}$ showed clear antiferroelectricity, evidenced by double-hysteresis polarization-field loops and positive DC-field dependences in dielectric permittivity. These experimental results clearly demonstrates that our screening search is effective. Our work provides an effective computational design strategy to explore antiferroelectricity, and moreover, this strategy could be applicable to other functionalities originating from structural phase transitions.

1:30 PM *EL03.02.01
Understanding, Controlling and using Antiferroelectric Thin Films LaneW. Martin[1,2,3]; [1]Rice University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States

Antiferroelectrics are experiencing a renaissance of interest. These materials possess antipolar order (*i.e.*, antiparallel alignment of polarization at zero field) that can be switched to polar (parallel) order by an external electric field thus producing a reversible antiferroelectric-to-ferroelectric phase transition and a characteristic double polarization-electric-field hysteresis loop. Such a unique field-induced antipolar-to-polar transition endows antiferroelectrics with properties that are of great interest for a range of applications including nonlinear dielectrics, capacitive-energy storage, electrothermal-energy conversion, and electromechanical actuation. While these materials have been known for many decades, they remain relatively less studied and well understood as compared to their ferroelectric brethren. To better understand the nature of such phase transitions in antiferroelectrics and to finely engineer the polarization properties for targeted applications requires that one can fabricate high-quality versions of antiferroelectric materials. In this spirit, recent years have seen a growth in efforts to study these materials, particularly as thin films. Epitaxial films offer researchers the opportunity to finely control and manipulate the structure, orientation, strain, and much more. In turn, we are offered unprecedented insights into the nature and evolution of these complex and, at times, poorly understood physical phenomena.

Here, we apply the lessons of thin-film epitaxy to the study of antiferroelectrics. This talk will provide an overview of our recent efforts to synthesize, control, and study antiferroelectric perovskite oxides. Our attention will focus on classic, prototypical antiferroelectric materials such as $PbZrO_3$ and $PbHfO_3$ and solid solutions derived from these parent materials. In turn, we will demonstrate how epitaxy, strain, and buffer layers can allow us to finely control the orientation of the resulting orthorhombic films and, in turn, how this orientation control affects the manifestation of properties. Furthermore, we will explore how the growth process – and namely the introduction of defects during growth – can dramatically impact the properties of these materials. For example, it is possible to induce ferroelectric-like response in $PbZrO_3$ despite the material remaining in the antiferroelectric phase. How defects can pin the antiferroelectric-to-ferroelectric phase boundary thus producing such effects will be developed and the effective pinning energies extracted (0.11-0.2 eV). This also allows us to reversibly adjust the nature of dielectric tunability from "positive" to "negative" tunability near zero field. From here, we will explore interesting applications of antiferroelectrics, including looking at their microwave dielectric response, potential for use in capacitive-energy storage, and for electromechanical actuation. For example, we will explore the use of materials such as $Pb_{1-x}Sr_xHfO_3$ and designer relaxor-antiferroelectrics to improve breakdown strengths, reduce loss, and extend energy-storage density. Finally, we will explore the large electromechanical responses reported in antiferroelectric thin films including developing a mechanistic understanding of the effects and showing routes to improve those responses (*e.g.*, through orientation control and multilayer structuring). Ultimately, antiferroelectrics represent a relatively understudied realm of ferroic materials, ripe for the application of thin-film epitaxy to accelerate our understanding and use of these interesting materials.

2:00 PM EL03.02.02
High-Throughput Combinatorial Approach to the Synthesis of a Lead-Free Ferroelectric Relaxor System DiZhang[1], KatherineHarmon[2], MichaelZachman[3], PingLu[4], DoyunKim[5], Ken WilliamSsennyimba[1], ZhanZhang[2], ReidMarkland[1], YogeshSharma[1], BinodPaudel[1], ZachHughes[1], YueCao[2], HaoZheng[2], ChaseSomodi[1], BenFreiman[1], MattSchneider[1], AlessandroMazz[1], NickCucciniello[1], SundarKunwar[1], PinkuRoy[1], QingTu[5], RodneyMcCabe[1] and AipingChen[1]; [1]Los Alamos National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]Oak Ridge National Laboratory, United States; [4]Sandia National Laboratories, United States; [5]Texas A&M University, United States

Materials discovery and optimization have usually been a frastrating slow process due to the limited materials combination options in traditional sysnthesis methods. Here, a high-throughput combinatorial approach which can fabricate nanocomposite materials with compositional gradients at nanoscale has been demonstrated. In this work, the lead-free (BCT-BZT) nanocomposite system was chosen owing to their large piezoelectric coefficient, high dielectric permittivity and robust thermal stability, making it a promising candidate to replace Pb-based energy storage devices. A series on BCT-BZT superlattice structures with continuous compositional gradient were fabricated through a combinatorial pulsed laser technique (cPLD). Ferroelectric property measurements demonstrate the tunable ferroelectricity and relaxor behaviors at different locations on the specimens by changing the BCT: BZT composition ratio as well as the alternating layersnumber and thicknesses. Detailed microstructural characterization including high resolution X-ray, transmission electron microscopy, and spectroscopy analyses were conducted to clarify the superlattaice epitaxy quality, interface structural coupling, and the structure-property correlation of the {xBCT/(1-x)BZT} superlattice films. The high-throughput synthesis approach demonstrate in this work can be applied to various materials systems to expedite the synthesis and property optimization processes of novel materials systems.

2:15 PM EL03.02.03
Designing "Artificial Relaxor" Behavior in $[BaTiO_3]_m/[BaZrO_3]_n$ Superlattices ZishenTian[1,2], MichaelXu[3], JieunKim[1], HaoPan[1], DjamilaLou[1], XiaoxiHuang[1], JamesM. LeBeau[3] and LaneW. Martin[1,2,4]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Massachusetts Institute of Technology, United States; [4]Rice University, United States

Relaxor ferroelectrics, the disordered cousins of long-range ordered ferroelectrics, have sparked interest among both physicists and materials scientists, due to their exotic physics and immense potential for applications. Relaxor-like behavior is observed in complex solid solutions such as $(1-x)PbMg_{1/3}Nb_{2/3}O_3$-$(x)PbTiO_3$ and $BaZr_xTi_{1-x}O_3$ where the chemical disorder generates random fields in the lattice and breaks the long-range polar order into characteristic nanoscale polar order. Manipulation of the chemical order opens a pathway to control the

nanoscale polar order, which is useful tool for exploring the physics and tailoring material properties. In these *natural* relaxors based on solid solutions, however, deterministic control of the chemical order is challenging due to the inherent randomness, which calls for a new platform for manipulation of the chemical and polar order.
We will discuss the design and synthesis of *artificial* relaxors based on superlattices. Such an approach has been proposed as a novel pathway to control the chemical-order with unit-cell precision [1]. In this regard, $[BaTiO_3]_m/[BaZrO_3]_n$ superlattices were proposed and tested as a model system to explore the effect of chemical-order control, wherein the nanoscale-polar structures are confined to the ferroelectric $BaTiO_3$ layers, and the spacing between neighboring layers of nanoscale-polar structures is controlled by the dielectric $BaZrO_3$ layers. Superlattices with m, n = 4-12 unit cells were fabricated via reflection, high-energy electron diffraction-assisted pulsed-laser deposition and then characterized by X-ray diffraction and atomic-resolution microscopy. These studies confirm the production of high-quality heterostructures, wherein the $BaTiO_3$ and $BaZrO_3$ layers are coherently strained to each other with relatively sharp interfaces in between. Measurement of dielectric permittivity along the in-plane [100] revealed significantly enhanced dielectric-maximum temperature T_m in superlattices compared with the corresponding solid solution (from 173 K to ≥ 433 K), and further enhanced T_m in superlattices as the polar-layer thickness increases from m = 4 to 12 (from 433 K to ≥ 573 K). Subsequent measurements of polarization-electric field hysteresis and third-harmonic nonlinearity along the in-plane [100] revealed relaxor-like behavior in the superlattices with the thinnest polar layers m = 4 and ferroelectric-like behavior in the superlattices with thicker polar layers m = 8-12. Finally, the third-harmonic nonlinearity was fitted to the spherical-random-bond-random-field model. It was observed that the random-field strength sharply increased as the polar-layer thickness reduced from m = 8 to 4, which hints at the importance of random fields in the formation of the relaxor state.
Altogether, the chemical order in the $[BaTiO_3]_m/[BaZrO_3]_n$ superlattices can be deterministically controlled, and the polar order can be tuned between that with ferroelectric-like, long-range order and that with relaxor-like, nanoscale order. This allows the fabrication of an artificial relaxor, and provides a novel platform for exploring the complex physics and tailoring the useful properties of relaxor ferroelectrics.

Sodium niobate ($NaNbO_3$) and other alkali metal niobates are seen as promising alternatives to replace the commonly used lead-based ferroic materials. $NaNbO_3$ has a rich phase diagram with multiple competing ground states and temperature-driven phase transitions, primarily governed by oxygen octahedral rotations[1]. The characterization of $NaNbO_3$ phases is challenging due to the weak scattering cross-section of the light oxygen atoms. Here we study epitaxial thin films of $NaNbO_3$ grown using pulsed laser deposition on dysprosium scandate ($DyScO_3$) substrate using recent advances in electron ptychography that have enabled both robust imaging of the lighter atoms and provided depth-sectioning capabilities[2].

The epitaxial tensile strain transmutes $NaNbO_3$ from being a room-temperature antiferroelectric to a ferroelectric with a predominantly in-plane polarization along the (110) pseudo-cubic axis and a small out-of-plane polarization. Measurement of the atomic positions from ptychographic images reveal large displacements of the oxygen atoms, in contrast with the prototypical ferroelectric perovskites where cation displacements drive the polarization. The distorted octahedra also show an in-phase tilt pattern along both in-plane pseudo-cubic axes, a tilt pattern which has not been reported before for $NaNbO_3$ in literature. Using density functional theory (DFT) calculations, we confirm the existence of monoclinic phases of $NaNbO_3$ that match our observations from ptychographic images. Further, we also obtain direct visual evidence of the theoretically predicted nanotwin phase[3,4] with an incommensurate tilt pattern of the oxygen octahedra along the growth direction.

Epitaxial Si-Integrated Defective BaTiO3 as Giant Electrostrictors at >1kHz PavanNukala; Indian Institute of Science, India

Defect-engineering to induce giant electrostriction has been gaining popularity in CeO2 and Bi2O3 based systems [1]. However, the enhancement is well pronounced only below 100 Hz. Here we show that 10% A-site deficient BTO, grown epitaxially on Si with TiN as a buffer layer, shows record electrostrictive strain coefficients ($M31=10^{-14}$ m^2/V^2) even upto 5 kHz frequencies. Our samples are replete with PNRs and twin boundaries. I'll show how Joule heating and ferroelectricity don't play any significant role in the observed electrostrain values, and it is indeed defect-induced electrostriction that contributes to it. Our impedence spectroscopy data clearly shows that the dielectric relaxation behavior of BTO layer correlates very closely with the observed electromechanical data (in both amplitude and phase). I'll end by suggesting guidelines to design Pb-free materials with large M at higher frequencies for MEMS based applications [2].

Transient and Remanent Optical Control of the Domain Configuration in Ferroelectric Epitaxial Oxide Thin Films MartinF. Sarott[1], MarvinJ. Müller[1], JannisLehmann[2], BenjaminJ. Jacot[1], ManfredFiebig[1] and MorganTrassin[1]; [1]ETH Zürich, Switzerland; [2]RIKEN, Japan

Light-matter interaction in ferroelectric materials forms the basis for light to be used as a non-invasive probe for the spontaneous polarization. In recent years, a shift in perspective has given rise to the question whether light could also be used to actively manipulate domain configurations or even switch the ferroelectric polarization. Realizing such an electric-field-less remote handle of the polarization holds the potential to drastically simplify state-of-the-art ferroelectric device architectures and coin entirely new ferroelectrics-based optoelectronic applications.

In this work, we demonstrate optical control of the ferroelectric polarization in epitaxial PZT-based heterostructures. In this prototypical ferroelectric model system, we track the dynamic response of the polarization under above-bandgap excitation by UV light in real time using optical second harmonic generation. In films with a single-domain configuration, we find that UV-light exposure induces a transient change of the spontaneous polarization that depends on its out-of-plane direction. We attribute this behavior to a modification of the charge-screening environment driven by the separation of photoexcited charge carriers in the built-in electric field of the Schottky junction formed with the bottom electrode. Taking advantage of this phenomenon in films with a pristine depolarized multi-domain configuration, we accomplish remanent optical poling into a single-domain configuration at room temperature. We further demonstrate the reversibility of this optical poling by subsequent thermal annealing. Hence, our work paves the way for the all-optical control of the spontaneous polarization in ferroelectric thin films.

Ferroelectric Domain Observations with Helium Ion Microscopy Dong-JikKim[1], ValentinV. Hevelke[1,2], JürgenAlbert[1], AdnanHammud[3], SebastianSchmitt[1], Young JaiChoi[4], VeereshDeshpande[1] and CatherineDubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin fuer Materialien und Energie, Germany; [2]Freie Universitaet Berlin, Germany; [3]Fritz-Haber Institute of the Max-Planck Society, Germany; [4]Yonsei University, Korea (the Republic of)

We present a systematic demonstration of the capability of helium ion microscopy (HIM) to visualize the polar and nonpolar domains in ferroelectric $LiNbO_3$ and $ErMnO_3$ single crystals. Through a wide range of acceleration voltages and beam currents of He^+ ions, HIM reproduces domain and domain wall maps with significant spatial resolution, consistent with the observations by piezoresponse force microscopy and conductive atomic force microscopy at the same locations. In the HIM domain images, the contrast of the polar domains with out-of-plane polarization can be attributed to the differences in the surface potential or the work function between oppositely poled domains. Intriguingly, HIM also exhibits contrast for nonpolar domains with in-plane polarization. During initial HIM scanning on the nonpolar surface of an $ErMnO_3$ single crystal, only dmain walls are visible, but consecutive scanning leads to the growth of domain contrast along its polar axis, implying a complex interaction between He+ ion implantation and the bulk photovoltaic effect of the ferroelectric materials. Our observations make HIM included in the list of the characterization tools for ferroelectric domains.

4:15 PM EL03.03.05

Polar Instability in Ferroelastic Bismuth Vanadate $BiVO_4$MaelGuennou[1], ChristinaHill[2,1], DavidVincent[3], XavierRocquefelte[3], CosmeMilesi-Brault[4], ElenaBuixaderas[4] and TorstenGranzow[2]; [1]University of Luxembourg, Luxembourg; [2]Luxembourg Institute of Science and Technology, Luxembourg; [3]Université de Rennes, France; [4]The Czech Academy of Sciences, Czechia

Bismuth vanadate $BiVO_4$ is known as a model ferroelastic crystal displaying a second-order transition where shear strain is the primary order parameter. More recently, it has attracted attention for its optical properties, but also for its potential antiferroelectric character, a property that might in fact be common to all proper or pseudo-proper ferroelastics. In this work, we report a combined theoretical and experimental study of the low frequency polar modes in $BiVO_4$. Infrared spectroscopy and inelastic neutron scattering are used to measure the polar mode at the Brillouin zone center and follow its dispersion as a function of temperature. We demonstrate the existence of a strong coupling between the polar mode and the primary order parameter that causes the crystal to display a dielectric anomaly typical of antiferroelectric systems. We also discuss how the polar instability is reflected from first-principles calculations, and how polar displacements of Bismuth produce unsual phonon-phonon coupling in the inelastic neutron spectra.

Evidence of High Remanent Polarization in Epitaxial Thin Film Ferroelectric $BaTiO_3$ Integrated onto Silicon ArnabSen Gupta, RachelSteinhardt, PratyushBuragohain, JohnPlombon, I-ChengTung, PunyashlokaDebashish, RaseongKim, KevinP. O'Brien, CarlyRogan, MarkoRadosavljevic, UygarE. Avci, ErnisseS. Putna, ShaneM. Harlson, IanYoung, TristanTronic and MatthewV. Metz; Intel Corporation, United States

The computing world is approaching a global energy crisis due to the exponential growth of energy requirement as CMOS transistors scale to smaller dimensions. One path forward is to lower the device supply voltages. In this regard, low power beyond-CMOS technologies such as devices based on ferroelectric materials are receiving renewed interest from both the scientific and technological communities. Perovskite BaTiO3 (BTO) ferroelectric thin films are highly promising due to their low coercivity, large remanent polarization and environmental friendliness. Copious progress has been made towards optimizing ferroelectric BTO on oxide substrates including recent reports on BTO-based devices for ultra-low-voltage operation.[1] However, to be compatible with high volume manufacturing, integration of high quality BTO onto Silicon is key. Thus far, quantitative reports on the ferroelectric properties of BTO on Si substrates have been sparse. Properties tend to be degraded including higher leakage and low remanent polarization (Pr) of 5-12 $\mu C/cm^2$.[1-5] Additionally, films tend to be in the range of 50-200nm thick.[1-5] Ideally for scaled devices, films of BTO on Si would be as thin as possible, with low coercivity, low leakage, high endurance, and Pr close to the bulk value of 30 $\mu C/cm^2$. In this work, we report remanent polarization up to ~ 20 $\mu C/cm^2$ in Pulse laser deposition (PLD) grown ultrathin 30-nm-thick BTO films grown on Molecular Beam Epitaxial SrTiO3 (STO)-buffered Si (Si:STO) substrates, with leakage in the order of ~ $1A/cm^2$. The Si:STO/SRO/BTO/Ti/Pd devices did not undergo dielectric breakdown up to 10^9 cycles, with only a 5% reduction in Pr observed after cycling. Structural characterizations revealed epitaxial growth of BTO films with relaxed lattice parameters. The quality of the STO buffer on Si was found to be critical for optimizing the ferroelectricity in BTO. This improved remanent polarization in ultrathin BTO with low leakage paves the way towards integrating a semiconducting channel with this device to create the next generation transistor. Nevertheless, a pursuit towards a 300 mm compatible perovskite process entails a concerted effort among academia, semiconductor manufacturers and tool manufacturers.

Photo-Induced Transport Properties in Ferroelectric Domains and Domain Walls in Lithium Niobate Single Crystals LiliDing[1,2], BeyreutherElke[1], KonradKempf[1], MichaelRüsing[1] and LukasEng[1]; [1]Technische Universität Dresden, Germany; [2]School of Physics, Sun Yat-sen University, China

Ferroelectric materials exhibit a spontaneous and stable dielectric polarization, resulting in a rich and variable assembly of domain and domain wall structures that is receiving continued attention [1, 2]. Furthermore, the multifield-controlled (electrical, mechanical, optical) electrical transport across these crystals offers many prospects for the vivid application of ferroelectrics into electronic devices, such as ferroelectric sensors, memories, and even ferroelectric synaptic circuits [3-5]. Notably, (external) control of the electronic transport by means of photons is very desirable since being non-invasive and ultrafast, but has been studied only sparsely so far. In particular, polarization switching of domains and domain walls, band gap modulation, or domain wall dynamics, all are susceptible to the photon-electron interaction, and thus need fundamental and profound investigations as basis for further application.
In this work, we combine local-scale scanning probe techniques with analyzing the impact of light irradiation onto lithium niobate domains and domain walls, and vary both intensity and wavelength to probe the (local) electronic conductivity. On this basis, we can also realize the configuration of high density domain pattern array and modulate the domain wall conductivity through scanning probe microscopy and the assistance of UV light. Then, we demonstrate that the enhancement of transport properties and the switching behavior of lithium niobate domain walls can be regulated by illumination adjacent to the band gap. This multi-method approach thus will improve our in-depth knowledge on the local band structure and energy level distribution within domain walls, and will lay the foundation to design integrated electro-optical components thereof.

Pushing the Limits of Retention, Endurance and Leakage in Ultra-Thin $BaTiO_3$ Films HarishKumarasubramanian[1], PrasannaV. Ravindran[2], MythiliSurendran[1], AsifI. Khan[2] and JayakanthRavichandran[1,1]; [1]University of Southern California, United States; [2]Georgia Institute of Technology, United States

Over the last fifty years, miniaturization has been the primary driver in improving efficiency, facilitating higher speed and reduced cost in MOSFETs while enabling an exponential increase in computational and storage capabilities. Progress in ferroelectric based memory and logic systems with the conventional perovskite systems have stagnated since the early 2000s on account of their high critical thickness and are therefore challenging to scale down. The thinner versions of these perovskite films have also been plagued by high leakage currents and depolarizing fields. Simultaneously, the discovery of ferroelectricity in CMOS-compatible gate dielectrics such as Hafnia and Zirconia at a few unit cells of thickness has facilitated their usage as high K dielectrics. This has provided an additional impetus in lowering the threshold voltage and the power dissipation in FETs [1]. However, despite the scaling down in physical dimensions of the gate oxide, the power supply voltage or the physical voltage has been stuck around 1 V or above for the last 15 years [2]. The extremely high coercive fields (>1 MV/cm) of fluorite oxides has

impeded the reduction in switching voltage. It has thus become imperative to develop and investigate leakage free, low voltage technological platforms especially for low power applications. The more conventional ferroelectric systems like perovskite oxides have recently shown much lower switching voltages (<0.1 V) [3].
In this work, we have achieved robust retention (>10^4 s) and stable endurance (> 10^9 cycles) with low ultra-low switching voltages (<50mV) [4] in sub 20 nm ferroelectric thin films based on epitaxial oxide perovskites in the Metal-Insulator-Metal geometry. More specifically we have deposited epitaxial $BaTiO_3$ (BTO) thin films on $GdScO_3$ (110) substrates using Pulsed Laser Deposition (PLD). We have minimised depolarization effects in our thin films by sandwiching the BTO with an epitaxial conductive oxide perovskite ($SrRuO_3$) on either side. Our BTO films have also shown leakage currents at least 3 orders of magnitude lower than HfO_2 and SiO_2 at sub 1 nm equivalent oxide thicknesses. Strategies to achieve low defect density and subsequently, robust ferroelectricity in ultra-thin BTO films would be discussed.
To satisfy a broader set of applications, it is essential to achieve a similar or better set of ferroelectric/leakage properties on Metal-Insulator-Semiconductor (MOS) structures. Even though Si has been the workhorse of the semiconductor industry for at least half a century, the scaling requirements have increasingly eaten into its primary advantages, namely its thermally grown dielectric native oxide. There is an urgent need to replace SiO_2 with other other high K oxides and hence there is an impetus towards replacing Si with other commercially viable semiconductors. Ge, in particular, has many advantages as the replacement channel material. Additionally, Ge provides an excellent epitaxial template for BTO (<0.5 % strain). Integration and performance of epitaxial BTO thin films on Ge would be elaborated upon. The effect of thin blocking layers of high band gap, epitaxially compatible perovskite dielectric oxides with large enough valence and conduction band offsets with Ge will also be discussed.

Exchange-Interaction-Like Behavior in Ferroelectric Bilayers PravinKavle[1,2], AidenM. Ross[3], JacobA. Zorn[3], PiushBehera[1,2], EricParsonnet[1], XiaoxiHuang[1,2], Ching-CheLin[1,2], LucasCaretta[1,2,4], Long-QingChen[3] and LaneW. Martin[1,2,5]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The Pennsylvania State University, United States; [4]Brown University, United States; [5]Rice University, United States

Coupling across interfaces is vital for many fields from composite materials with different mechanical properties, to magnetoelectric coupling across magnetic and piezoelectric materials, to exchange interactions between ferromagnets and antiferromagnets. Among these, the exchange bias (or exchange anisotropy) between a ferromagnet and an adjacent ferromagnetic or antiferromagnetic layer has been widely studied and utilized in magnetic read-write heads and random-access memory. In exchange bias, the magnetic response of a ferromagnet is shifted away from zero magnetic field. Other related phenomena include exchange-spring magnets which are achieved by coupling hard and soft ferromagnets such that the hard magnet provides high anisotropy and coercive fields, while the soft magnet enhances the magnetic moment. The soft magnet rotates back into alignment with the hard magnet when the applied field is removed, hence the analogy to a spring. Likewise, analogous coupling across the interface between different ferroelectric materials via dipolar (electrostatic and potentially elastic) interactions could possibly lead to anisotropic dipole interactions. Effects akin to exchange bias have been observed in ferroelectrics as shifted hysteresis loops due to the internal bias field arising from aligned defect dipoles and compositional (or strain) gradients. Such observations, however, fall short of effects that are truly analogous to exchange interactions.
In-plane polarized ferroelectric films, where polarization lies parallel to the substrate surface, could provide an opportunity to tune interface-controlled effects. Here, we demonstrate the formation of such in-plane domains in $Pb_{1-x}Sr_xTiO_3$ ($0.4 \leq x \leq 0.8$) films grown on $DyScO_3$ (110) substrates. Strontium content in the $Pb_{1-x}Sr_xTiO_3$ impacts the domain size and coercivity to form “hard” and “soft” coercivity versions. Next, the switching mechanisms of these domains have been analyzed via piezoresponse force microscopy after applying an electric field at 0° and 45° with in-plane devices. Phase-field studies revealed low-energy, stepwise-90° switching steps as the most effective switching pathway instead of single 180° switching. To analyze the interface-controlled switching properties, bilayers of 50-nm-thick x = 0.6 layers on top of x = 0.4 layers were explored where two-step switching was observed. Phase-field studies provide details about the equilibrium domain structure where the difference in domain periodicity of two layers leads to the formation of needle-shaped domain-dislocations in the x = 0.4 layer along with continuous domains across the interface. The minor switching loop indicating the switching of the x = 0.6 layer showed a horizontal shift of 14 kV cm^{-1} due to the formation of 90° domain walls at the interface, leading to the exchange-bias-like behavior. Further increase in the electric field led to domain reshuffling in the bottom x = 0.4 layer to realign domains across the interface in an elastically compatible way before switching, resulting in coercivity hardening. This two-step switching is then analyzed for multistate functions, where robust retention and fatigue performance was recorded. Inserting $SrTiO_3$ dielectric layers between the two layers led to a decoupling of layers and the disappearance of observed shifts, further strengthening the interlayer coupling claim. Switching of a bilayer of 50-nm-thick x = 0.8 top layer on a x = 0.4 bottom layer was analyzed where strong back switching minor loops for the x = 0.8 layer were observed, indicating exchange-spring-like behavior. Bilayers with 40-nm-thick x = 0.6 top layers on x = 0.4 bottom layers reveal single switching with reduced coercivity due to the absence of any domain dislocations and continuous propagation of switched domains observed via phase-field studies, like the exchange-spring. Such phenomena extend the parallels between ferromagnets and ferroelectrics beyond the structural analogs like skyrmions.

Enhanced Hard and Soft Piezoelectric Properties of $(Pb_{0.94}Sr_{0.06})[(Zr_{1-x}Ti_x)-(Zn_{1/3}Nb_{2/3})]$ Multilayer Ceramics Sintered at Low-Temperature GeunsooLee, Jung-SooKim, SanKwak and SahnNahm; Korea University, Korea (the Republic of)

High-power piezoceramics have been utilized in different piezoelectric devices, such as piezoelectric transformers, motors, and ultrasonic transducers. As a large amount of heat is usually generated from high-power devices, the piezoceramics used in these devices need to have a Q_m. Moreover, these high-power piezoceramics should have a large d_{33} value and a high T_C. In this study, the $(Pb_{0.94}Sr_{0.06})[(Zr_{1-x}Ti_x)_{0.75}(Zn_{1/3}Nb_{2/3})_{0.25}]O_3$ (PS-ZT-ZN) piezoceramics were produced at a low temperature of 950ºC and their structural and piezoelectric properties were investigated. In particular, the piezoceramic (x = 0.50) exhibited the excellent hard and soft piezoelectric properties (d_{33} = 357, k_p = 0.53, and Q_m = 1511) along with a high T_C of approximately 250ºC. Hence, this piezoceramic is a promising material for the high-power devices. Moreover, the PS-ZT-ZN multilayers were fabricated using piezoceramic (x = 0.5) at 950ºC with the 80Ag/20Pd inner electrodes and their structural and piezoelectric properties were also investigated to assess their suitability for use in high-power multilayer devices.

10:30 AM EL03.04.06
Preparation of {100}-Oriented Epitaxial (1-*x*)(Bi,K)TiO_3-*x*$CaTiO_3$ Solid Solution Films by Hydrothermal Method and Their Ferroelectric PropertyTaichiMurashita, HuYuxian, YumaTakahashi, ReikaOta, KazukiOkamoto: and HiroshiFunakubo; Tokyo Institute of Technology, Japan

(Bi,K)TiO_3 is a well-known traditional tetragonal ferroelectric material discovered in the 1950s by Smolenskii *et. al.* [1] However, the preparation of high-quality (Bi,K)TiO_3 is still challenging due to the preparation difficulty. The fundamental ferroelectric properties have not been well understood so far. In 2022, our group succeeded to grow the polar-axis-oriented epitaxial (Bi,K)TiO_3 films at the low deposition temperature of 240 ºC by hydrothermal method.[2] Their tetragonality (*c*/*a* ratio) and remnant polarization (P_r) values are 1.046, and 84 μC/cm^2, respectively. These values are larger than previously reported ones for (Bi,K)TiO_3 ceramics. [3] The enhanced tetragonality of the (Bi,K)TiO_3 films is possibly attributed to the unique displacement of the Bi and K in A-site cations ascertained by TEM observation. These (Bi,K)TiO_3 films showed high Curie temperature, T_c, above 800 ºC. Based on this research, solid solution epitaxial films of (Bi,K)TiO_3 with ferroelectric rhombohedral (Bi,Na)TiO_3 were successfully obtained by hydrothermal method.[4] X-ray diffraction analysis showed a continuous decrease of the *c*/*a* ratio with increasing K/(K+Na) ratio and the *c*/*a* ratio become unity near the K/(K+Na) ratio = 0.15. This suggests the existence of tetragonal-rhombohedral morphotropic phase boundary near *c*/*a* = 1. This research demonstrated the preparation of solid solution film by hydrothermal method. As the next challenge, we should decrease the extremely high T_c above 800 ºC of (Bi,K)TiO_3 films for the application of pyroelectric devices.
In this study, we tried to hydrothermally grow epitaxial solid solution films of (Bi,K)TiO_3 with paraelectric $CaTiO_3$, (1-*x*)(Bi,K)TiO_3-*x*$CaTiO_3$ films to increase the pyroelectric coefficient by decreasing T_c. The film composition region can be divided into three from the viewpoint of the crystal structure. Films in the range of *x* = 0 - 0.12 (Region 1) and 0.60 - 1.0 (Region 3) consisted of single phases and their lattice parameters continuously changed with the *x* value. The phases are tetragonal and pseudo-cubic symmetry in Region 1 and Region 3, respectively. This suggests a formation of a solid solution in these two regions. On the other hand, these two phases (tetragonal and pseudo-cubic symmetry) coexisted in the intermediated range of *x* = 0.18 - 0.43 (Region 2). In this coexistence composition region, the volume fraction of these two phases changed with the *x* value, while their lattice parameters were almost independent of the *x* value. This suggests the solubility limit of this system. In Region 1 and Region 2, *P*-*E* hysteresis loops originating from the ferroelectricity were clearly observed. The P_r values continuously decreased with increasing *x* in Region 1, mainly due to the decrease in the *c*/*a* ratio of the ferroelectric phase. This decrease of P_r with *x* was also observed in Region 2 mainly due to the decrease in the volume fraction of the ferroelectric phase. In the next step, these films were annealed at 950 ºC by face-to-face annealing to decrease T_c. After annealing the film with *x* = 0.12, the film showed lowered T_c of 450 ºC and a higher pyroelectric coefficient than that of the film with *x* = 0 ((Bi,K)TiO_3). These data show that the properties of (Bi,K)TiO_3 films can be controlled by the synthesis of a solid solution.

Dielectric and Electro-Mechanical Properties Controlled by Polarization Switching in $PbZr_{0.2}Ti_{0.8}O_3$-ZnO Thin-Film Heterostructure AlexeiGrigoriev, RuohanyangLeng and JuanWang; University of Tulsa, United States

Development and characterization of new heterostructure materials and interfaces is critical for a sustained progress of the performance and functionality of electronic, electro-mechanical, and electro-optical devices. We report experimental studies of ferroelectric-semiconductor $PbZr_{0.2}Ti_{0.8}O_3$-ZnO heterostructure that enables ferroelectric polarization control of ZnO electronic and dielectric properties. The time-resolved x-ray microdiffraction measurements have revealed the piezoelectric coefficient d_{33} of about 2.8 pm/V for pure high-quality epitaxial ZnO thin films. This linear piezoelectric response becomes more complex in the ferroelectric-ZnO heterostructure revealing different regimes of the electro-mechanical response. Polarization switching of $PbZr_{0.2}Ti_{0.8}O_3$ controls the interface electronic properties leading to switchable capacitance of at least 35% and over an order of magnitude difference in the interface charge carrier densities for two different polarization states of the ferroelectric layer. These results are important for understanding ferroelectric-semiconductor interactions and engineering new ZnO-based ferroelectric-semiconductor heterostructures such as $BiFeO_3$-ZnO or HfO_2-ZnO with new switchable electronic and dielectric properties.

11:00 AM EL03.04.08
Determination of Nonlinear Dielectric and Electrostrictive Constants of Lithium Tantalate Single Crystal YasuoCho[1], RyoNakagawa[2], ToshimaroYoneda[2], TakeshiNakao[2] and MamoruIkeura[2]; [1]Tohoku University, Japan; [2]Murata Manufacturing Co., Ltd., Japan

To increase telecommunications capacity, surface acoustic wave (SAW) devices have become smaller and have more channels and higher power. However, the intermodulation caused by material nonlinearity has become increasingly apparent. To effectively utilize SAW devices in sixth-generation communication systems, it is necessary to mitigate this nonlinearity. However, a full set of nonlinear constants (nonlinear elastic, piezoelectric, electrostrictive, and dielectric constants) for piezoelectric single crystals has been measured for only lithium niobate ($LiNbO_3$) single crystals[1]. The nonlinearity of a single crystal of lithium tantalate ($LiTaO_3$), the most widely used ferroelectric crystal in SAW devices for communications, has not been quantitatively evaluated.
Against this background, we started research on the measurement of all nonlinear constants of $LiTaO_3$ single crystals as part of basic research for the realization of next-generation ultra-low-nonlinearity SAW devices.
This paper describes a measurement methods and reports the obtained nonlinear dielectric constants and electrostrictive constants for $LiTaO_3$. In the experiment, a dynamic measurement method based on capacitance variation with an alternating electric field was employed for the nonlinear dielectric constants [2] and capacitance variation under applied stress was also measured for electrostrictive constants.
We show the measured relative capacitance variation in $LiTaO_3$ single crystal plate as a functions of an applied electric field and stress, respectively. Using measured five data (for nonlinear dielectric constants) and twenty data (for electrostrictive constants) with different crystal orientation, we have determined three independent nonlinear dielectric constants and eight electrostrictive constants in the stress-free state (d-form) ε^T_{ijk} and $^2d_{(ij)k}$. The corresponding nonlinear constants in the strain-free state (e-form) ε^S_{ijk} and $^2e_{(ij)k}$ were also calculated using the d-from constants and will be presented at the meeting.

Strain Fluctuations Unlock Ferroelectricity in ZnO:MgO StevenM. Baksa[1], SimonGelin[1], RuiZu[1], SedaOturak[1], SusanE. Trolier-McKinstry[1], VenkatramanGopalan[1], Jon-PaulMaria[1], AndrewRappe[2] and IsmailaDabo[1]; [1]The Pennsylvania State University, United States; [2]University of Pennsylvania, United States

Abstract
The palette of ferroelectric materials for thin-film microelectronics is currently restricted to select families of non-centrosymmetric structures, including perovskite oxides (*e.g.*, $PbZr_xTi_{1-x}O_3$) and fluorite oxides (*e.g.*, $Hf_{1-x}Zr_xO_2$). While some of these ferroelectrics have been successfully integrated into electronic devices such as random-access memories, the fabrication of ultrathin microelectronics is challenging due to film-thickness scaling limitations, which impede ferroelectric switching. Non-centrosymmetric wurtzite materials, including $Al_{1-x}B_xN$ [1] and $Zn_{1-x}Mg_xO$ [2], have recently been found to exhibit ferroelectricity. Although applied epitaxial strains above 5% may induce a ferroelectric response in wurtzites [3,4], $Zn_{1-x}Mg_xO$ shows strain magnitudes of less than 1%. Here, we demonstrate that atomic-scale strain fluctuations of up to 5% can emerge near Zn and Mg cations leading to a reduction of more than 40% in the local switching barriers. This observation strongly suggests that strain fluctuations from dopant cations can promote polarization reversal in wurtzite materials, opening up a general design strategy to discover and optimize ferroelectrics for use in thin-film devices.

SESSION EL03.05: Ferroelectrics III
Session Chairs: John Heron and Morgan Trassin
Tuesday Afternoon, November28, 2023
Hynes, Level 1, Room 107

1:30 PM EL03.05.01
Emerging Materials and Design Principles for Wurtzite-type Ferroelectrics Cheng-WeiLee[1], NaseemUd Din[1], KeisukeYazawa[1,2], GeoffL. Brennecka[1], AndriyZakutayev[2,1] and PrashunGorai[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

The semiconductor industry has been enabled by tetrahedral semiconductors such as Si, GaN etc. Historically, complex oxides with octahedral bonding have been the focus of ferroelectrics research. Unfortunately, such oxides are prone to oxygen-related defects, which along with a mismatch to tetrahedral symmetry, makes integration with conventional semiconductors challenging. Discovery of tetrahedral ferroelectrics will enable device integration and alleviate the need for aggressive defect engineering. At present, there are only a handful of modified wurtzite structures that exhibit robust polarization switching. These include wurtzite-type (Al,Sc)N, (Al,B)N, and (Zn,Mg)O alloys, but none are single-phase compounds. Furthermore, the coercive fields needed to switch these wurtzite-type alloys are on the order of few MV/cm, which is 1-2 orders of magnitude larger compared to oxide perovskites (<100 kV/cm). Instead of further engineering AlN-based alloys, we explore the possibility of identifying new ternary and multinary compounds with switching energy densities lower than AlN and ZnO while still possessing high enough dielectric breakdown fields. In this work, we use DFT calculations to search for new ternary and multinary wurtzite-type tetrahedral ferroelectric materials. We identify several promising nitrides and oxides as candidates for future experimental verification and engineering. Our results also show that small wurtzite c/a lattice parameter ratio is not a good descriptor of lower coercive fields, in agreement with recent studies [1]. We also derive design principles based on metal-anion bond ionicity and lattice softness for lower switching barriers. Finally, we offer new insights into the polarization switching mechanism in ternary compounds and wurtzite-type alloys.

Switching Kinetics and Wakeup Behavior of Wurtzite Ferroelectrics KeisukeYazawa[1,2], DanielDrury[2], JohnHayden[3], Jon-PaulMaria[3], SusanE. Trolier-McKinstry[3], AndriyZakutayev[1] and GeoffL. Brennecka[2]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States; [3]The Pennsylvania State University, United States

Ferroelectricity enables key integrated technologies from non-volatile memory to precision ultrasound. Wurtzite nitride ferroelectric materials such as (Al,Sc)N and (Al,B)N have recently received significant attention because of robust ferroelectricity [1,2] and the compatibility of the existing Si and III-V semiconductor processes. The mechanism and origin of the wurtzite ferroelectrics have been rigorously investigated [1,3] to control the ferroelectric properties and discover novel ferroelectric materials, but many questions remain, including in switching dynamics and the origin of wakeup behavior. Those questions are directly relevant to ferroelectric applications such as FeRAM.

In this presentation, we demonstrate and interpret anomalous switching dynamics in the wurtzite nitride thin film ferroelectrics $Al_{0.7}Sc_{0.3}N$ and $Al_{0.94}B_{0.06}N$, which is explained with neither the conventional KAI nor NLS models [4]. When substantial growth and impingement occur while nucleation rate is increasing, such as in these wurtzite ferroelectrics under high electric fields, abrupt polarization reversal leads to very large Avrami coefficients (n = 11), inspiring an extension of the KAI model that distinctly describes the nucleation rate and domain growth. This extended model explains the abrupt transition arising from significant growth prior to peak nucleation rate.

We also demonstrate that polarization switching to the polarity opposite of the growth polarity is critical to the observed wakeup behavior of thin film $Al_{0.94}B_{0.06}N$ [5]. The polarization switching curve, is orders of magnitude slower for the transition from the growth polarity to the antiparallel polarization state than going from antiparallel state back to the growth polarity. The domain wall density and/or domain wall mobility for switching from the antiparallel state to the growth polarity gradually increases with the number of cycles, causing the measured remanent polarization to increase for electric fields just above the coercive field, resulting in the observed wakeup behavior. Reversible and irreversible Rayleigh coefficients, piezoelectric coefficients, and chemical etching results reveal the domain structure and its evolution with the number of electric field cycles. These are consistent with the domain states predicted by the nucleation time and domain wall velocity from switching kinetics studies on the same films.

Ferroelectric Property Improvement of $(Al_{1-x-y}Ga_xSc_y)N$ Ternary Thin Films ReikaOta[1], ShinnosukeYasuoka[1], KazukiOkamoto:[1], YoshihiroUeoka[2], YoshiroKususe[2], MasamiMesuda[2] and HiroshiFunakubo[1]; [1]Tokyo Institute of Technology, Japan; [2]Tosoh Corporation, Japan

After the first demonstration of ferroelectricity of $(Al_{1-x}Sc_x)N$ films by Fichtner *et al*[1], wurtzite-based ferroelectric films have been one of an important family due to their large remanent polarization and high Curie temperature. However, a large coercive field (E_c) is one of the drawbacks to the real applications of ferroelectric memories with low-voltage operation even if the large ferroelectricity over 100 μC/cm^2 is ascertained to be observed down to 9 nm in thickness.
Our research teams demonstrate the ferroelectricity of not only Sc-doped AlN films but also Sc-doped GaN [2-8]. Especially, Sc-doped GaN films show a lower coercive field than that of Sc-doped AlN films. However, Sc-doped GaN films show a relatively large leakage current density. In the present study, we investigate the Sc-(Al,Ga)N films to satisfy low coercive field with keeping large remanent polarization.
By adding Ga into Sc-doped AlN, $(Al_{1-x-y}Ga_xSc_y)N$, Sc content to keep wurtzite structure increased compared with widely investigated Sc-AlN films. Coercive field of the films monotonously decreased with increasing Sc content of the films. Resultantly E_c decreased down to 2 MV/cm comparable to HfO_2-based ferroelectrics. Present results show that E_c of wurtzite ferroelectrics can decrease by designing the film composition and the possibility to use $(Al_{1-x-y}Ga_xSc_y)N$ films for ferroelectric memories with the low-voltage operation.

2:15 PM EL03.05.04

A Novel, High Temperature, Ferroelectric Non-Volatile Memory Device DhirenK. Pradhan[1], DavidMoore[2], GwangwooKim[1], YunfeiHe[1], NicholasGlavin[2], JoshuaKennedy[2], RoyH. Olsson III[1] and DeepM. Jariwala[1]; [1]University of Pennsylvania, United States; [2]Air Force Research Laboratory, United States

Non-volatile memory (NVM) technology that reliably operates at temperatures above 300 ºC is not available commercially. There are numerous emerging harsh environment applications such aerospace/defense, space exploration, and oil and gas exploration, that require complex computing and sensing capabilities in-situ. Such a vision is impossible without a NVM device which can reliably operate at temperatures exceeding 500 °C. Ferroelectric $Al_xSc_{1-x}N$ has strong potential to be utilized in NVM devices as it exhibits stable and high remanent polarization (P_r) above 100 μC/cm^2 when operated at very high temperature (> 500 ºC) and has a ferroelectric transition temperature (T_c) > 1000 °C. In the present study, we demonstrate a $Al_{0.68}Sc_{0.32}N$ ferroelectric diode based NVM memory that can operate up to 600 ºC. Our devices are metal insulator metal (MIM) capacitors with a structure of the Ni/$Al_{0.68}Sc_{0.32}N$/Pt (111). $Al_{0.68}Sc_{0.32}N$ thin film of thickness of ~45 nm were grown on a 4" Pt (111)/Ti/SiO_2/Si substrate by pulsed- DC co-sputtering from separate Al (1000W) and Sc (655W) targets. The deposition was carried out at 350 ºC, with a flow of N_2 gas (20 sccm) under a vacuum of 8 x 10^{-4} torr. Photolithographically defined 100-nm thick top Ni circular electrodes were sputtered to form MIM structures. The coercive field (E_c) from the I-V curves acquired by the dynamic hysteresis measurements is found to be -5.48 (E_c^-) and +6.26 (E_c^+) (+/- 0.2) MV/cm at room temperature. PUND current densities at RT show ferroelectric switching in both positive and negative voltage pulses. The temperature dependent DC I-V curves exhibit ferroelectric diode behavior with clear ferroelectric switching up to 600°C with distinguishable ON and OFF states. The coercive field (E_c) and ON/OFF ratio decreases with increasing temperature. At 500 °C, these devices show ~1 million read cycles with a stable ON/OFF ratio above 1 for > 6 hours. The operating voltages of our devices are < 15 V even at 600 ºC which is well matched and compatible with Silicon Carbide (SiC) based high temperature logic technology. Detailed temperature dependence studies and other memory device characterizations of these NVM devices will be presented in the meeting.

Combinatorial Synthesis of Highly-Oriented Ferroelectric AlScN Thin Films using Metal-Ion Synchronized High-Power Impulse Magnetron Sputtering. JyotishPatidar[1], SiarheiZhuk[1], AmitSharma[2], MonalisaGhosh[1], AlexanderWieczorek[1], KerstinThorwarth[1] and SebastianSiol[1]; [1]Empa - Swiss Federal Institute of Materials Science and Technology, Switzerland; [2]Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Piezoelectric micro-electro-mechanical systems (MEMS) are one of the building blocks of modern electronics and are used in many applications such as RF filters, resonators, and sensors. AlScN in wurtzite structure is one of the most promising materials for such applications due to its high-temperature stability and linear frequency response compatibility with CMOS processing.[1] Since the demonstration of ferroelectric switching in AlScN the material has gained a renewed interest for a number of alternative applications.[2]
The functional properties of AlScN, such as the piezoelectric response or the switching behavior are generally improved by high Sc contents. However, under those conditions the heterostructural nature of the alloy system and low Sc miscibility lead to a high degree of structural frustration. Hence, the synthesis of Sc-rich AlScN with high crystallinity and uniform texture remains an important challenge, especially at moderate substrate temperatures.
In this work, we present the utilization of metal-ion synchronized high-power impulse magnetron sputtering (MIS-HiPIMS) along with a combinatorial screening approach to deposit highly oriented AlScN films. A substrate bias potential is used to accelerate the ions onto the growing film. By synchronizing this potential to the metal-rich part of each HiPIMS-pulse we can tailor the ion kinetic energy of the film-forming species, while simultaneously avoiding process-gas incorporation and point-defect formation.[3]
Combinatorial libraries of AlScN are deposited with different biasing conditions as well as substrate temperatures leading to a set of roughly 300 distinct synthesis conditions. The

combinatorial libraries are then fully characterized with respect to their phase constitution, structure and composition using state-of-the-art techniques. Residual stress, piezoelectric coefficients and ferroelectric switching behavior are studied for selected samples.
We find, that applying synchronized substrate-bias potentials significantly improves the crystallinity as well as the texture of the AlScN thin films, especially at low deposition temperatures. Depending on the kinetic energy of the constituent metal-ions (i.e. Al and Sc) the residual stress in the films can be varied over a large range from 1.5 GPa (tensile) to -3.0 GPa (compressive). This is strongly correlated with a change in Sc solubility from 42 at.% to 22 at.%, respectively. In addition, we demonstrate that accelerating the ions with potentials as low as -30 V promotes growth along the substrate normal and virtually eliminates misoriented grains.
The synthesis approach demonstrated here can be transferred to many different piezoelectric and ferroelectric thin film materials. Furthermore, the ability to precisely tailor the residual stress and the potential to deposit highly-textured thin films on structured as well as temperature-sensitive substrates might open up exciting applications, *e.g.* for flexible electronics, in the future.

Single Crystal Epitaxial Ferroelectric Aluminum Scandium Nitride Nanowires XiaomanZhang[1], WangwangXu[1], WenJ. Meng[1] and AndrewC. Meng[2]; [1]Louisiana State University, United States; [2]University of Missouri–Columbia, United States

Wurtzitic aluminum nitride based ferroelectrics such as aluminum scandium nitride hold significant promise for wide memory window, high on/off ratio, non-volatile memory devices for neuromorphic computing applications. However, both polycrystalline and single crystal wurtzitic aluminum nitride-based alloy thin films on a variety of substrates commonly exhibit crystallographic defects arising from mosaic disorder related to Volmer-Weber growth. We demonstrate that ultra-high vacuum reactive sputtering in a high substrate bias, low atomic flux regime results in a combination of growth and etching to achieve vertical nanowire arrays. Characterization of the nanowire arrays using X-ray diffraction and transmission electron microscopy show that the wires are epitaxial single crystals with significantly reduced mosaic spread. Using differential phase contrast scanning transmission electron microscope images, we observe nanowires consisting of single ferroelectric domains. Ferroelectric properties of the nanowires were characterized using piezoresponse force microscopy.

3:30 PM EL03.05.07
Novel Ferroelectric CMOS Compatible Binary Oxide ZhuotongSun[1], NivesStrkalj[1], MingXiao[2], ZiyiYuan[1], AtifJan[1], SunilTaper[1], W.ChuckWitt[1], GiulianaDi Martino[1] and JudithL. Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]Sun Yat-sen University, China

Interest in ferroelectric materials for processing, memory and sensing devices has been spurred by the discovery of nanoscale ferroelectricity in insulating binary oxides based on HfO*2* and ZrO*2*. However, stabilizing the ferroelectric phase and achieving good ferroelectric performance in these materials is challenging because several non-ferroelectric phases have similar formation energy to the ferroelectric phase. The search for other binary oxide ferroelectrics which can be achieved by industry-friendly processes is therefore still ongoing. Here, we report the stabilization of epitaxial films of a binary oxide at temperatures below 400°C using atmospheric pressure chemical vapor deposition. In these films, strain imposed by the substrate gives rise to the spontaneous polarization evidenced by piezo-response force microscopy. Furthermore, conductive AFM shows different conductance in up and down polarized domains with a ratio over 500. Exploring ferroelectricity in binary oxide films could provide a new platform for polarization-controlled memory applications and allow combining ferroelectric and photosensitive properties for photoferroelectrics applications.

Experimental Observation of Polarization Screening via Free-Oxygen in Ultrathin Epitaxial Doped-Hafnia MeganO. Hill[1], NivesStrkalj[1], MoritzMuller[1], Ji SooKim[1], MaximilianT. Becker[1], DibyaPhuyal[2,1] and JudithL. Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]KTH Royal Institute of Technology, Sweden

Ferroelectric (FE) HfO_2 is posed to overcome many of the scaling challenges that have limited the use of perovskites in ferroelectric random access memory, FE tunnel junctions, and FE field effect transistors. HfO_2 is CMOS-compatible, highly scalable, and over the past decade significant research has contributed to an improved understanding of the ferroelectric nature of this material. However, many open questions remain, particularly around the interfacial electrochemistry and effect of oxygen on ferroelectric polarization and screening. For instance, oxygen vacancies are predicted to stabilize multiple metastable ferroelectric phases in HfO_2 [1] and there is experimental evidence of field-driven oxygen migration between metal contact layers sandwiching FE HfO_2 films [2]. Despite recent advancements, understanding of the interfacial chemistry in such HfO_2-based metal-FE-metal devices is still largely unexplored. This is particularly true for ultrathin epitaxially grown HfO_2 films which offer advantages over more established amorphous/polycrystalline HfO_2 structures (ex: minimal wake up effects and better control of microstructure) [3].

In this work, hard X-ray photoelectron spectroscopy (HAXPES) studies of polarization-defined epitaxial Y-doped HfO_2 ultrathin films were conducted in order to investigate the relationship between interfacial chemistry and polarization in real device stacks. YHO devices were set to down and up polarized states and HAXPES was used to access the band position shifts and oxidation state changes in buried layers. A comparison was done on films poled using piezo-response force microscopy (PFM) and poled using sandwiched metal contact layers (LSMO and Ti/Au). By combining HAXPES analysis on sandwiched and bare films, we observe both polarization-driven oxidation occurring in the Ti/Au contact and changes in the electronic energy-level alignment at the interface. Further, X-ray energies of 1, 5.9, and 9.2 keV were utilized to probe multiple depths within the device stack, decoupling the performance at the YHO/metal and the YHO/LSMO interfaces.

HAXPES reveals a significant increase in non-lattice oxygen at the metal-ferroelectric interface in the polarization upwards condition. This reorganization of oxygen moving counter to the direction of the applied field suggests a polarization screening via free oxygen at the metal interface. Such screening effects using free oxygen species have not been experimentally reported. These results represent an important step towards understanding the role of oxygen motion and redox processes on the polarization and transport mechanisms in junctions based on ultrathin ferroelectric films.

Free-Standing Epitaxial Oxide Nanomembranes—Opportunities and Challenges BharatJalan; University of Minnesota, United States

With a rapidly growing family of vdW materials, the role of dielectric and metals have become more important than ever. In this talk, I will present challenges associated with the synthesis of atomically-precise three-dimensional (3D) perovskite nanomembranes followed by our group’s effort to address them. Using hybrid molecular beam epitaxy that employs a metal-organic precursor, titanium isopropoxide (TTIP), to supply both Ti and oxygen (without the need for additional oxygen), epitaxial $SrTiO_3$ (STO) films were grown directly on a graphene layer transferred on to bulk STO substrate. Films were then successfully exfoliated and transferred onto other substrates. Using Raman spectroscopy and high-resolution X-ray diffraction, we show that the transferred STO membrane is single-crystalline and can be integrated with other vdW materials. I will also present sacrificial layer route to create oxide membranes resulting in room temperature dielectric constant of ~ 300. Finally, I will present several opportunities for materials physics and devices engineering using 3D nanomembranes.

9:00 AM EL03.06.02

High-Mobility Ferroelectric Two-Dimensional Electron Gases Based on Strain-Engineered $SrTiO_3$ Thin Films RuchiTomar[1], TatianaKuznetsova[2], SrijaniMallik[1], LuisM. Vicente-Arche[1], MaximilienCazayous[3], RomanEngel-Herbert[2,4] and ManuelBibes[1]; [1]Unité Mixte de Physique, CNRS, Thales, Université Paris-Saclay, 91767 Palaiseau, France, France; [2]Pennsyvlania State University, University Park, PA 16802, USA, United States; [3]Laboratoire Matériaux et Phénomènes Quantiques (UMR 7162 CNRS), Université de Paris, 75205 Paris Cedex 13, France, France; [4]Paul Drude Institute, Berlin, Germany, Germany

Two-dimensional electron gases (2DEGs) based on the quantum paraelectric $SrTiO_3$ display fascinating properties such as large electron mobilities, superconductivity and efficient spin-charge interconversion owing to their Rashba spin-orbit coupling.[1-3] However, such 2DEGs have almost exclusively been generated in $SrTiO_3$ single crystals, with the few attempts to replace crystals by heteroepitaxial $SrTiO_3$ thin films leading to low carrier mobilities. This is limiting the potential to integrate $SrTiO_3$ 2DEGs in future devices as well as the possibility to introduce additional functionalities specific to $SrTiO_3$ thin films, such as strain-induced ferroelectricity. Here, we use oxide molecular beam epitaxy to grow high quality strain-engineered $SrTiO_3$ films that are ferroelectric up to 170 K. We then generate a 2DEG by sputtering a thin Al layer and demonstrate an increase in both the low and room temperature mobilities by up to factor of four compared to earlier literature. Furthermore, through Raman spectroscopy and magneto-transport measurements, we show that the ferroelectric character is retained after 2DEG formation. These results thus qualify our samples as ferroelectric 2DEGs up to temperatures well above previous results based on Ca-$SrTiO_3$ substrates (~30 K)[4], opening the way towards ferroelectric 2DEGs operating at room temperature.

Buffer-Free Production of Single-Crystalline Complex-Oxide Membranes and Their Applications XinyuanZhang, Min-KyuSong, CelestaS. Chang, SanghoLee and JeehwanKim; Massachusetts Institute of Technology, United States

There have been serious efforts to develop a universal method for producing freestanding epitaxial membranes, which would allow for the creation of artificial heterostructures with interfacing structurally and chemically incompatible materials. In particular, a combination and match of complex-oxide membranes that exhibit unique electronic, photonic, and magnetic properties is expected to enable a wide range of innovative applications. Recent developments in graphene-based remote epitaxy and mechanical lift-off techniques have allowed for the generation of a variety of freestanding complex-oxide membranes, including perovskite $SrTiO_3$, spinel $CoFe_2O_4$, and garnet $Y_3Fe_5O_{12}$. However, it is particularly difficult to form an atomically clean graphene surface on growth substrates of complex-oxides in a scalable and controlled manner, which significantly limits the manufacturing of large-area oxide membranes of high quality. In addition, typical 2D materials, including graphene, are easily damaged during plasma processing in an oxygen environment, which is commonly required for complex-oxide film growth.

Here, alternative lift-off methods are introduced to expand the material spectrum of complex-oxide thin films that can be released from substrates and integrated onto platforms of interest. Firstly, chemical lift-off is used to obtain a single-crystalline $BaTiO_3$ (BTO) membrane by dissolving the water-soluble interlayer of $Sr_3Al_2O_6$, which is otherwise hard to be produced by remote epitaxy due to requirement of high growth temperature. It is then transferred onto a complementary metal–oxide–semiconductor (CMOS) platform. This provides an efficient route to fabricate capacitive memory devices with superior device performance, such as a noticeably large memory window and low energy consumption due to outstanding properties of single-crystalline BTO. Also, such BTO-based memory components integrated onto a silicon wafer ensure their great CMOS compatibility. Next, buffer-free mechanical lift-off is demonstrated to exfoliate a $Pb(Mg_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ membrane with atomic precision and to develop pyroelectric devices with ultra-broad band response and significantly improved detectivity compared to the clamped counterparts.

Domain Walls in Multiferroics and Multiferroic Domain Walls ManfredFiebig; ETH Zurich, Switzerland

A reason for the interest in multiferroics is that magnetic and electric orders do not simply exist side by side, but exhibit "added value" in the form of magnetoelectric interactions and functionalities between the ordered states. Likewise, in a ferroic material, regions with different orientation of the order parameter, the domains, do not simply exist side by side, but they exhibit new phases and properties in the domain walls. Because of their discontinuous, confined, and topological nature, domain walls exhibit functional states that are not possible in the bulk. Continuing this line of thought, one should expect domain walls in multiferroics to be a particularly rich source of novel phenomena. Here one must distinguish between (i) "domain walls in multiferroics", where only the ferroelectric (or magnetic) order is considered so that little is learned about the multiferroic state, and (ii) "multiferroic domain walls" where the ferroic phase coexistence of the wall itself is of interest. The latter are rarely studied, and I will discuss some of their intriguing features in my talk. Specifically, I will report on the continuous transfer of a multiferroic order between a bulk and a wall state, novel types of domain walls in multiferroic thin films, and various examples of multiferroic domain walls in a non-multiferroic environment.

10:30 AM EL03.07.02

Vertically Aligned Nanocomposites and Interfacial Coupling of Multiferroic $LuFeO_3$ and Magnetic $Co_xFe_{3-x}O_4$ Thin Films EunsooCho and CarolineA. Ross; Massachusetts Institute of Technology, United States

Nanocomposite thin films composed of two or more ferroic materials are particularly attractive for the development of energy-efficient, high-speed memory and logic devices. This is because such heterostructures provide a platform to incorporate multiple functionalities and utilize the interaction at the interface between different phases to enable magnetoelectric switching. For example, we showed voltage-controlled magnetic properties of a $Sr(Co,Fe)O_{3-\delta}$-Co_3O_4 nanocomposite by ionic liquid gating [1].
Here, we investigated vertically aligned nanocomposite thin films grown using pulsed laser deposition, consisting of pillars of spinel $Co_xFe_{3-x}O_4$ and/or rocksalt CoO phases embedded in a matrix phase of perovskite $LuFeO_3$. $LuFeO_3$ is a rare earth orthoferrite with an orthorhombically distorted perovskite structure, and is a canted antiferromagnet with concurrent ferroelectricity (thus multiferroicity) depending on cation stoichiometry [2]. Spinel $Co_xFe_{3-x}O_4$ has a strong antiferromagnetic superexchange interaction between cations on the tetrahedral and octahedral sites, with Fe-rich compositions showing high temperature ferrimagnetic behavior and notable magnetoelastic properties. Lastly, rocksalt CoO is a G-type antiferromagnet.
Pulsed laser deposition yielded two-phase (perovskite and spinel) or three-phase (perovskite, spinel, and rocksalt) epitaxial nanocomposites on $SrTiO_3$ substrates, depending on which combination of targets was used and on the deposition temperature and oxygen pressure. For example, alternating ablation from $Lu_{0.6}FeO_{3-\delta}$ and Co_3O_4 targets produced CoO and Fe_3O_4 pillars embedded in Fe-rich $LuFeO_3$, whereas alternating ablation from $Lu_{1.4}FeO_{3+\delta}$ and $CoFe_2O_4$ targets resulted in pillars of $Co_{1.3}Fe_{1.7}O_4$ in a matrix of Fe-rich $LuFeO_3$. The structure and chemistry of the films are characterized in detail via x-ray diffraction and atomically resolved scanning transmission electron microscopy techniques. The perovskite phase preferentially contains Fe whereas the Co segregates to the spinel or rocksalt phase, especially when a Co_3O_4 target is used.
Magnetization-magnetic field hysteresis measurements revealed the correlation between magnetic properties and growth conditions. For instance, $Lu_{0.8}FeO_{3-\delta}$-$Co_{1.3}Fe_{1.7}O_4$ films with about 37% $Co_{1.3}Fe_{1.7}O_4$ pillars with ~15 nm diameter had a saturation magnetization of 100 kA/m and coercivity of 450 Oe. By cooling the composites from 360 °C in a field of 10 kOe, an exchange coupling between antiferromagnetic $Lu_{0.8}FeO_{3-\delta}$ and ferrimagnetic $Co_{1.3}Fe_{1.7}O_4$ was established with an exchange bias of 110 Oe at room temperature. The magnetoelectric coupling in these two- and three-phase epitaxial nanocomposite thin films of $LuFeO_3$, $Co_xFe_{3-x}O_4$ and CoO will be described.

10:45 AM EL03.07.03

Low-Temperature Epitaxial $BiFeO_3$ Thin Films on Bismuth Substituted Metal Perovskite SajidHusain[1], IsaacHarris[2], PeterMeisenheimer[2], PiushBehera[1,2], TaeY. Kim[2], DidierPerrodin[1], LaneW. Martin[1,2], Zhi(. Yao[1] and RamamoorthyRamesh[1,2,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Bismuth Ferrite ($BiFeO_3$, BFO) has attracted considerable attention as a promising candidate for magnetoelectric spin-orbit coupled logic-in-memory compute elements. As a model system, epitaxial BFO thin films have been deposited typically at relatively high temperatures, (~650-800°C); somewhat higher than the maximum temperatures desired for direct integration of materials with silicon-CMOS platforms. Here, we circumvent this problem by growing La-substituted $BiFeO_3$ ($La_{1-x}BiFeO_3$, LBFO) thin films at 450°C (which is compatible with silicon-CMOS integration) on epitaxial bismuth-substituted a metallic perovskite $BaPbO_3$ ($BaPb_{1-x}Bi_xO_3$, BPBO) electrode. BPBO is recently reported to exhibit large spin Hall effect for spintronic applications. Using symmetric and asymmetric X-ray diffraction, LBFO is found to be fully relaxed on the BPBO electrode. Notwithstanding the large lattice mismatch between the LBFO, BPBO, and $SrTiO_3$ substrates, all the deposited layers in the heterostructure are well ordered. Piezoresponse force microscopy reveals a 180° phase reversal and suggests robust piezoelectric behavior for the LBFO. The ferroelectric nature of the LBFO is further evident from polarization-electric field hysteresis loops measurements. Current-voltage, pulsed switching, fatigue, and retention measurements follow the characteristic behavior of high-temperature grown LBFO, where $SrRuO_3$ typically serves as the metallic electrode. These results provide a possible route for realizing epitaxial multiferroics on complex oxides buffer layers at low temperatures and open the door for potential silicon-CMOS integration.

Spin-Induced Multiferroicity in 2d Transition-Metal-Halides SilviaPicozzi; Consiglio Nazionale delle Ricerche, Italy

Two-dimensional multiferroics with large magnetoelectric coupling may open interesting avenues in the context of multifunctional systems. Here, we study a class of spin-chirality-driven van der Waals multiferroic monolayers, such as transition metal halides, by combining first-principles calculations with the generalized spin-current model. The recent reports of multiferroicity in NiI2 layers [Q.Song et al, Nature **602**, 601 (2022)], obtained via a joint theory-experiments approach down to the single-layer limit, show the potentiality of cross-coupling phenomena in van der Waals magnets. Another example is represented by vanadium dihalide-monolayers, featuring 120-degree frustrated magnetic structures which develop on the underlying triangular lattice and show competing spin-spiral planes spanning the (001) and (100) crystalline planes. The non-collinear spin configurations induce a ferroelectric polarization which is perpendicular to the spin-spiral plane, switched by the spin-chirality change and whose magnitude is not only determined by the strength of the atomic spin-orbit coupling of the halogen anion, but also affected by structural properties.

11:30 AM EL03.07.05
Subnanosecond Reconfiguration of Ferroelectric Domains in Bismuth Ferrite BurakGuzelturk; Argonne National Laboratory, United States

Domain switching is crucial for achieving desired functions in ferroic materials that are used in various applications. Fast control of domains at subnanosecond timescales remains a challenge despite its potential for high-speed operation in random access memories, photonic, and nanoelectronic devices. In our recent work [1], we show that ultrafast laser excitation can transiently melt and reconfigure ferroelectric stripe domains in multiferroic bismuth ferrite on a timescale faster than 100 ps. This dynamic behavior is visualized by a novel approach of picosecond and nanometer-resolved X-ray diffraction. In addition, we developed and used time-resolved X-ray diffuse scattering to track the transient response of the domain walls. The disordering of stripe domains arises from the screening of depolarization fields by photogenerated carriers resulting in the formation of charged domain walls which is further supported by phase field simulations. Furthermore, the recovery of disordered domains exhibits subdiffusive growth on nanosecond timescales, with a nonequilibrium domain velocity reaching up to 10 m/s. These findings present a new approach to image and manipulate ferroelectric domains on subnanosecond timescales, which can be further extended into other photoferroic systems to modulate their electronic, optical, and magnetic properties beyond GHz frequencies. This approach could pave the way for high-speed ferroelectric data storage, computing and photonic applications in a range of photoferroics, and, more broadly, defines new approaches for visualizing the non-equilibrium dynamics of heterogeneous and disordered materials.

Ultra-Low-Voltage, Beyond CMOS Microelectronics RamamoorthyRamesh; Rice University, United States

Despite ever-improving computing efficiency, information technology (IT) represents the fastest growing energy consumer and will have significant implications for U.S. energy consumption. This impending cliff threatens the nation's ability to solve important problems across science, technology, national security, and energy. Without improvements in computing efficiency, the explosion of the Internet of Things (IoT) and artificial intelligence (AI) applications will exponentially increase energy consumption. A complete rethinking of how computing is performed today is needed to develop the next-generation of beyond-CMOS microelectronics. Our scientific mission is built on a core guiding principle that a significant opportunity exists for use-inspired basic science to enable highly energy efficient computing by exploiting correlated phenomena and consequently lowering the operating voltage. Orders of magnitude improvement in energy efficiency are possible by exploiting correlations (electronic charge/spin and dipolar). We aim to design and manipulate this energy barrier to specifically reduce the operating voltage substantially below what is achievable by today's CMOS technology. This fundamental physics approach to solving systems-level techno-economic problems can lead to dramatically lower energy consumption, in addition to a completely new hierarchy of logic-in-memory information technology building blocks.

2:00 PM EL03.08.02
Understanding and Optimizing Magnetoelectric Switching in BiFeO3 NatalyaFedorova[1], DmitriNikonov[2], JohnMangeri[1], HaiLi[2], IanYoung[2] and JorgeIniguez[1,3]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]Intel Corporation, United States; [3]University of Luxembourg, Luxembourg

Magnetoelectric multiferroics are materials that simultaneously show magnetic and electric orders. Interest in them largely originates from the possibility of affecting one order using the stimulus that usually controls the other, offering great potential for development of multifunctional devices. BiFeO3 is among the most exciting representatives of this family because it displays both orders at room temperature. Moreover, a deterministic reversal of magnetization by an electric field was experimentally observed in BiFeO3 films by J. T. Heron et al. [1]. It has been proposed that this magnetoelectric switching is the result of a peculiar polarization switching process that occurs in two steps: a 109o out-of-plane polarization rotation followed by a 71o in-plane rotation. However, the origin of such two-step polarization reversal is still not well understood, which hampers its optimization (faster switching at a smaller coercive field).

In this work we combine density functional theory (DFT), a phenomenological Landau model and the Landau-Khalatnikov time-evolution equation (LKE) [2] to elucidate the origin of the two-step polarization switching process in BiFeO3. First, we introduce the simplest Landau-like potential for BiFeO3 and ensure that it accurately reproduces the DFT energies and distortion amplitudes for a set of relevant structural polymorphs of BiFeO3 [3]. Then, we extend our model by introducing additional constraints which account for the presence of the substrate and multidomain configuration observed experimentally in BiFeO3 films. We then solve this model using the LKE to investigate the role of the introduced constraints on ferroelectric switching. We are able to reproduce the two-step polarization switching in multidomain system, reveal its physical underpinnings, and identify potential strategies to optimize the switching characteristics.

Work funded by the the Semiconductor Research Corporation and Intel via Contract No. 2018-IN-2865. We also acknowledge the support of the Luxembourg National Research Fund through Grant No. C21/MS/15799044/FERRODYNAMICS and the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement SCALES-897614.

Nanoscale Multiferroic Properties for Neuromorphic Computing Applications DaniloG. Barrionuevo Diestra, PatriciaGierbolini-Santos, EdwardHickey-Figueroa, EricSanchez-Ayala and CynthiaRodriguez-Cruz; University of Puerto Rico at Cayey, United States

Significant advancements in intelligent tasks, such as artificial intelligence, big data analytics, autonomous vehicles, and voice recognition, have presented increasingly demanding requirements for computing speed and power consumption. Addressing these demands, a neuromorphic computing system emerges as a viable solution. Moreover, a neuromorphic computing system possesses the ability to autonomously learn and execute tasks by engaging in its environment. Harnessing the potential applications of tunneling in the assembly of neuromorphic computation, the integration of multiferroic tunnel junctions offers a promising opportunity to combine the respective advantages of swift, low-power electrical write operations and non-destructive magnetic read operations. This amalgamation leads to the realization of four-state logic, thereby propelling the field forward. A single-phase multiferroic material, $Pb(Zr_{0.53}Ti_{0.47})_{0.60}(Fe_{0.5}Ta_{0.5})_{0.40}O_3$ (PTZFT), shows promise as a tunnel barrier in multiferroic tunnel junctions. To investigate the impact of thickness on electrical and magnetic properties across a spectrum ranging from thicker to ultrathin films, we conducted film growth experiments employing pulsed laser deposition (PLD) techniques, depositing PZTFT films with thicknesses ranging from 7 to 80 nm on (001) LSMO/$(LaAlO_3)_{0.3}(Sr_2AlTaO_6)_{0.7}$ (LSMO/LSAT) substrates. Remarkably, we observed well-saturated ferroelectric loops in PZTFT films, exhibiting a remanent polarization of 32, 25, and 10 mC/cm^2 for films with thicknesses of 80, 50, and 20 nm, respectively. Additionally, an enhanced saturated magnetization (Ms) was observed with increasing PZTFT layer thickness in PZTFT/LSMO structures. At 300 K, the average Ms values for PZTFT/LSMO heterostructures were 33, 25, and 15 emu/cm3 for thicknesses of 80, 50, and 20 nm, respectively. This increase in magnetization can be attributed to the interface effect between the PZTFT and LSMO layers. Piezo force microscopy measurements conducted on ultrathin 7 nm PZTFT films displayed clear and reversible out-of-plane phase contrast above ± 3 V, indicating the ferroelectric nature of these ultra-thin films. Furthermore, magnetic force microscopy revealed magnetic stripe domains in the 7 nm ultrathin PZTFT films. The impact of PZTFT film thickness on temperature-dependent dielectric and transport properties will be addressed. Notably, our most significant finding is the retention of multiferroic properties in 7 nm ultrathin PZTFT films at room temperature, highlighting their potential as single-phase barriers in multiferroic tunnel junction devices. These devices demonstrate four resistance states: two electroresistance states and two magnetoresistance states, enabling the achievement of multilevel resistance states. This discovery underscores the possibility of fine-tuning their properties at the nanometer scale, thereby opening new avenues for technological applications in nanoelectronics, particularly in the realm of multiferroic tunnel junctions for next-generation nonvolatile memory devices.

$KTaO_3$ Two-Dimensional Electron Gases: Spin-Orbit Coupling, Superconductivity and the Introduction of Ferroic Orders ManuelBibes; CNRS/Thales, France

Two-dimensional electron gases based on $KTaO_3$ (KTO) have recently emerged as an exciting new platform for oxide electronics and spintronics since they possess a large low-temperature mobility, a large Rashba spin-orbit coupling and are superconducting with a critical temperature of about 2 K for (111) oriented samples. The 2DEGs can be defined from KTO single crystals substrates by growing on top a perovskite film or a reactive metal such as Eu or Al (which oxidizes and creates oxygen vacancies in the KTO, doping it with electrons). We will shed light on the physics of this system through a combination of advanced measurements including ARPES, resonant microwave transport, harmonic transport and electron tunneling. We will finally discuss the role of the magnetic vs nonmagnetic overlayer materials and how to introduce ferroelectricity in the system.

4:00 PM EL03.09.02
Disentangling the Roles and Length Scales of the Crystal Lattice, Electronic and Magnetic Degrees of Freedom in Correlated Electron Materials AlexandruGeorgescu; Indiana University Bloomington, United States

We present new phenomenological descriptions of electronic phase transitions in correlated electron materials, with a focus on metal-insulator transition (MIT) materials.
First, we show how to build and understand a computational energy landscape, disentangling the role of electronic and crystal lattice symmetry breaking in the MIT of rare earth nickelates RNiO$_3$, with R a rare-earth metal, using dynamical mean field theory [1]. We find that the electron-lattice coupling is key to stabilizing the insulating state.
This theory is general, and may be applied to other materials displaying a simultaneous electronic and crystal lattice phase transition.
Then, by studying multiple superlattices including rare-earth nickelates ($NdNiO_3$/$NdAlO_3$ [1], $NdNiO_3$/$SmNiO_3$ [2,3] and NdNiO3/LaAlO3/SmNiO3 [4]) we clarify the interplay of the crystal lattice, electronic symmetry breaking, and magnetic degrees of freedom and the length scales of the order parameter propagation throughout the transition. We find that the electronic order parameter characterizing the transition has a dominant role in its propagation. While the magnetic order parameter is subsidiary to the electronic order parameter in the bulk, the second order nature of the magnetic transition leads to longer length scales for the magnetic degrees of freedom than that of the MIT.

Structure-Property Relations at Charged Interfaces in Ferroic Oxides DennisMeier; Norwegian University of Science and Technology (NTNU), Norway

Oxide materials exhibit a broad range of tunable phenomena, including magnetism, multiferroicity, and superconductivity. Oxide interfaces are particularly intriguing, giving a new dimension to property engineering of functional materials[1]. The low local symmetry at the interfaces, combined with their sensitivity to electrostatics and strain, leads to unusual physical effects, offering amazing opportunities for fundamental and applied research.

In my talk, I will discuss the unique electronic properties that arise at natural and artificially designed charged interfaces in ferroelectric and multiferroic oxides. To give an overview and demonstrate how structural, electric, and compositional degrees of freedom at such interfaces control the material's behavior, I will present three examples: (i) ferroelectric domain walls in hexagonal manganite single crystals[2], (ii) grain boundaries in ferroelectric $ErMnO_3$ polycrystals[3,4], and (iii) epitaxial heterointerfaces in multiferroic $(LuFeO_3)_9/(LuFe_2O_4)_1$ superlattices. To characterize the different types of interfaces, we perform correlated microscopy measurements, combining scanning probe microscopy, electron microscopy, and atom probe tomography. The imaging experiments provide new insight into the atomic-scale structure and chemical composition at charged oxide interfaces, clarifying the key role polar discontinuities and point defects play for their emergent physical properties.

High-Pressure Synthesis of Ferroelectric Y-Doped HfO_2TakanoriMimura, AyakaShimazu, NaokiNoda and YoshiyukiInaguma; Gakushuin University, Japan

The discovery of ferroelectric HfO_2-based films by Böscke et al. was a great surprise since these materials were used as high-k gate dielectrics in Si-based complementary metal-oxide-semiconductor (CMOS) devices. Only the paraelectric monoclinic ($P2_1/c$), tetragonal ($P4_2/nmc$), cubic (Fm-$3m$), orthorhombic I ($Pbca$), and orthorhombic II ($Pnma$) phases exist in the equilibrium pressure-temperature phase diagram of HfO_2. On the other hand, the origin of the ferroelectric phase is the metastable orthorhombic $Pca2_1$ phase which is usually stabilized by the film thickness effect due to surface energy. Therefore, the ferroelectricity was observed in thin HfO_2 films with a thickness below ~30 nm. This implies that the material properties include thin film-specific effects such as surface energy and strain effects, and the fundamental characteristics are unknown. To understand essential properties, the synthesis of ferroelectric bulk HfO_2 is indispensable. Recently, Mimura *et al*., fabricated 1 μm-thick ferroelectric 7%$YO_{1.5}$-93%HfO_2 films, which suggests that ferroelectric bulk HfO_2 could be synthesized using Y doping. After that, *Xu* et al., synthesized a 12%$YO_{1.5}$-HfO_2 single crystal with a $Pca2_1$ structure using a laser-diode-heated floating zone technique. In this study, we demonstrate the high-pressure synthesis of ferroelectric bulk $YO_{1.5}$-HfO_2 using high-pressure synthesis.
Starting materials, Y_2O_3 and HfO_2 powders with compositions of x%$YO_{1.5}$-(1-x)%HfO_2 (x = 0, 3, 5, 7, 12) were mixed using an agate mortar. High-pressure synthesis was carried out by the following two routes. 1.) The mixed powders were pressed into pellets and calcined at 1500°C for 10 h in air. Then, the calcined pellets were ground into powder. The powders were allowed to treat in a TRY cubic multi-anvil-type high-pressure apparatus (NAMO 2001) and then quenched to room temperature. 2.) The mixed powders from starting materials were directly allowed to treat in a high-pressure apparatus. The pressure, temperature, and holding time were at 3-7.7 GPa, 800-1400°C, and for 30 min, respectively for each route. To identify the crystal phases, XRD 2θ-θ scanning (X'Pert^3 Powder, PANalytical, λ = 0.154 nm) was performed.
For route 1, the calcined samples before high-pressure synthesis showed the monoclinic and cubic phases in x = 3-12, suggesting consistency with the phase diagram of the Y_2O_3:HfO_2 system. After high-pressure synthesis, the orthorhombic phase $Pca2_1$ or $Pbca$ was obtained. With an increase in the pressure and temperature, the yield of the phase increased, but the maximum was 28.9 wt% in 5% $YO_{1.5}$-95%HfO_2 treated at 7.7 GPa, 1300°C. The yield of the cubic phase did not change much before and after the high-pressure synthesis, suggesting that only the lower-density monoclinic phase transforms into the higher-density phase while the highest-density cubic phase does not at high pressure. For route 2, the orthorhombic phase was obtained with > 70 wt%. These results suggest that the high-pressure synthesis method is one of the methods to stabilize bulk HfO_2-based ferroelectrics. The results of second harmonic generation (SHG) measurements to confirm the non-centrosymmetric ferroelectric phase will be discussed at the conference.

8:00 PM EL03.10.02
Correlation Between Reduced Dielectric Loss and Charge Migration Kinetics in $NdFeO_3$- Modified $Ba_{0.7}Sr_{0.3}TiO_3$ Ceramics LakhwantSingh, SurinderSingh and AnumeetKaur; Guru Nanak Dev University, India

We report here a significant reduction in the dielectric loss at room temperature from 0.149 to 0.027 in the composite of $(NdFeO_3)_{0.1}$-$(Ba_{0.7}Sr_{0.3}TiO_3)_{0.9}$ as compared to the undoped $Ba_{0.7}Sr_{0.3}TiO_3$ and correlates with the charge compensation due to the ionic substitutions for both A site (Nd_{Ba}) and B (Fe_{Ti}) site generated excess electrons, localized hole states and robust oxygen vacancies (V_O) along with different cationic oxidation states. The V_O mediated F center charge transfer mechanism i.e., bound magnetic polaronic behaviour and defect complex generated between acceptors and ionized V_O reduce electrical conductivity and loss factor. The presence of weak ferromagnetism in the M-H loop reconfirms the F center exchange mechanism in mixed phase symmetry. The activation energy calculated from impedance spectroscopy, electrical modulus and electrical conductivity analysis supports the presence of doubly ionized V O . Further, density functional theory based first principle calculation manifests that the impurity induced depopulation of valence band edge electrons into a single spin up channel which distorts TiO_6 octahedra with fluctuating bond length and Ti 3de_g orbital splitting observed in decomposed density of states for accommodating excess electrons. These trapped and accommodated electrons reduce the effective electron concentration which in turn decreases the electrical conductivity and loss factor.<quillbot-extension-portal></quillbot-extension-portal><quillbot-extension-portal></quillbot-extension-portal>

8:00 PM EL03.10.03
Characterization of Ferroelectric Switching Properties for (Al,Sc)N Films with Various Composition ShinnosukeYasuoka[1], KazukiOkamoto:[1], TakaoShimizu[2,3] and HiroshiFunakubo[1]; [1]Tokyo Institute of Technology, Japan; [2]National Institute for Materials Science, Japan; [3]Precursory Research for Embryonic Science and Technology, Japan

Ferroelectric wurtzite-(Al,Sc)N is promising for future ferroelectric devices because of its superior properties, including large remanent polarization that is almost 5 times larger than that of HfO_2-based ferroelectrics. Therefore, (Al,Sc)N film has been investigated by many researchers after the experimental demonstration of its ferroelectricity in 2019 [1-3]. Nevertheless, the investigation of switching kinetics of ferroelectric to elucidate the physical properties of this material has been still limited, although it is essential not only to understand the fundamental properties, but also to promote the development of next-generation ferroelectric devices.
In this study, we investigated the polarization switching kinetics of (Al,Sc)N thin films with different Sc/(Al+Sc)N. The pulse-width dependent polarization switching was conducted and analyzed in term of a phenomenological and macroscopic approach for the $(Al_{0.9}Sc_{0.1})N$, $(Al_{0.8}Sc_{0.2})N$, and $(Al_{0.7}Sc_{0.3})N$ films. The switching characteristics obtained by switching test with various pulse width were in good agreement with t the KAI model [4]. The fitting parameter, the Avrami index n, were approximately 2, indicating the bidimensional in-plane propagation of the switched domains as reported for typical oriented ferroelectric thin films [5,6]. The activation field, E_a, which is evaluated from the time dependent current (I-t) curve through the switching time, t_{sw} based on Merz's law, which is obtained from the current-depended on the film composition. That of $(Al_{0.8}Sc_{0.2})N$ was slightly smaller than those of the films with other composition[7]. This may be due to differences in fundamental switching characteristics, which is significantly affected by composition and/or crystal quality.

This work was partly supported by the project of MEXT Initiative to Establish Next-generation Novel Integrated Circuits Centers (X-NICS)(JPJ011438) and MEXT Program: Data Creation and Utilization Type Material Research and Development Project (JPMXP1122683430). Temperature-Composition Phase Diagram and Strain-Driven Domain Decomposition in the $Ba_{1-x}Ca_xTiO_3$ Thin Film System AidenM. Ross, JacobA. Zorn, BoWang and Long-QingChen; The Pennsylvania State University, United States

The macroscale properties of a ferroelectric crystal can be manipulated by controlling its mesoscale domain structure. Here, we performed a systematic theoretical analysis of $Ba_{1-x}Ca_xTiO_3$ ($0 \leq x \leq 0.25$) ferroelectric thin films on $SmScO_3$ substrates using thermodynamics and phase-field simulations to computationally establish the multi-phase/multi-domain composition-temperature phase diagrams. We identified a strain-driven decomposition of the $a_1/a_2 - c/a$ ferroelectric domains at room temperature similar to those reported recently in $Pb_xSr_{1-x}TiO_3$ thin films. The strain-driven domain decomposition is shown to extend into the low temperature regime, wherein a distinct decomposition phenomenon between orthorhombic and rhombohedral phases is observed. Our results provide the theoretical guideline for experimentalists to compositionally and mechanically manipulate phase transitions and domain formation and optimize electromechanical responses in ferroelectric thin films of perovskite oxide solid solutions.

Exploring the Impact of Sr(Zr,Ti)O_3 Buffer Layers for Controlling Domain Structure of Ferroelectric Thin Films. KeisukeIshihama[1], KazukiOkamoto:[1], MasanoriKodera[1,2], TomohideMorikawa[1], TakaoShimizu[1,3,4] and HiroshiFunakubo[1]; [1]Tokyo Institute of Technology, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]National Institute for Materials Science, Japan; [4]Precursory Research for Embryonic Science and Technology, Japan

In recent years, ferroelectrics have been used as important components in many devices such as nonvolatile memory, sensors, and energy harvesters. This study focuses on ferroelectric thin films with domain structures affected by the strain induced from the substrate. It is known that the misfit strain caused by the difference in lattice constants between the substrate and ferroelectric thin film is important in controlling the stress in epitaxial thin films. However, there are limits to the range of lattice constants that can be achieved with single-crystal substrates. In this study, Sr(Zr,Ti)O_3 solid solution (SZTO), which has cubic-like structure and a wide lattice parameter selection range of 0.39~0.41 nm, was employed as a new buffer layer to overcome this problem.[1] It can be expected to change the lattice constant continuously and control the amount of strain precisely by using SZTO with various compositions as a buffer layer. We prepared SZTO buffer layers on (100) LSAT substrates and Pb(Zr,Ti)O_3 (PZT) films on them by pulsed laser deposition (PLD).
XRD 2θ-θ measurement results indicated that buffer layer lattice parameters could be effectively manipulated by altering Zr content of SZTO. This study reveals a strong dependence of crystal structure and thickness in SZTO films with different composition, and the domain structure of PZT films is found to be significantly influenced by the lattice constant of the buffer layer. These findings underline the potential of SZTO in controlling lattice constants and strain in ferroelectric thin films.

Electric Control of Spin Supercurrents in Hybrid Rashba Structures QiaodongSun[1], AdrianIonescu[1], NadiaStelmashenko[1], LeylaC. Arslan[1,2] and JasonW. Robinson[1]; [1]University of Cambridge, United Kingdom; [2]Gebze Technical University, Turkey

The digital economy ever-increasingly requires denser, faster and more energy-efficient data processing, but heat-dissipating ohmic losses limit further performance improvements. Superconducting electronics offers the potential to enhance magnetic memory and logic performance because readout can be achieved with record-low heat dissipation. Furthermore, intrinsic or interfacial spin-orbit coupling (SOC) can enable a thin-film superconductor to exceed the paramagnetic limit. For Rashba-type SOC, theory indicates that the superconducting thermodynamic properties of a finite-size thin film are strongly sample-size dependent due to the creation of edge states: for example, for a geometrically anisotropic thin film superconductor, the critical field can be tunable through the direction of an externally applied in-plane magnetic field. These findings open perspectives for the development of superconducting spin-orbitronic devices as well as superconducting structures in which the superconducting state can be controlled with an electric field. In this poster, we discuss our experimental results towards the development of a hybrid superconducting device in which Rashba-SOC and charge accumulation within a thin-film heavy metal (HM) can be tuned via an electric field and so control the superconducting transition of a proximity-coupled thin film superconductor. The electric field is applied to the HM via a ferroelectric lead magnesium niobate-lead titanate (PMN-PT) substrate.

Impact of Phase Composition on Bipolar Resistive Switching Performance in Polycrystalline $ErMnO_3$ Based Devices RongWu[1,2], FlorianMaudet[1], Thanh LuanPhan[1], SebastianSchmitt[1], VeereshDeshpande[1] and CatherineDubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Freie Universität Berlin, Germany

Rare-earth hexagonal manganites, h-*R*MnO_3 (*R*=Y, Er, Ho to Lu) have been widely studied for their multiferroic properties. Polycrystalline hexagonal $YMnO_3$ thin films with promising resistive switching performance were reported recently [1], which gained interest for neuromorphic applications owing to the peculiar ferroelectric domain pattern and vortex lines in hexagonal *R*MnO_3 [2].
In this work, we report the demonstration of bipolar resistive switching behavior in polycrystalline $ErMnO_3$-based capacitors. The $ErMnO_3$ films (~ 60 nm) were prepared by room temperature RF sputtering on Pt/Ti/SiO_2/Si substrates, followed by post-deposition annealing. The Al/Ti top electrodes were patterned by photolithography. The post-deposition annealing resulted in the formation of polycrystalline $ErMnO_3$ thin films with orthorhombic and hexagonal phases as shown by X-ray diffraction. We investigated the influence of these different crystalline phases on the switching performance and, for this purpose, developed a way to quantify the relative amount of both phases by scanning electron microscopy, Raman spectroscopy and conductive atomic force microscopy. Through a detailed structural evaluation combined with electrical characterization we developed an understanding of the physical origin of resistive switching in polycrystalline $ErMnO_3$ and the role of the different phases. The Au/Ti/$ErMnO_3$/Pt devices exhibit a bipolar resistive switching with a R_{OFF}/R_{ON} ratio larger than 10^4 and an ultra-low resistance of only 10 Ω in the low resistance state, which can be of interest for CMOS circuitry with low power consumption [3] and for RF power switches [4]. We attribute the switching performance to the formation and rupture of conductive oxygen vacancy-based filaments. We find that a higher fraction of orthorhombic phase reduces the operation voltage but leads to a decrease of the memory window, which can be ascribed to higher Mn^{4+} concentration and more oxygen vacancies in the orthorhombic phase. These findings emphasize the potential of polycrystalline $ErMnO_3$ films as promising candidates for neuromorphic applications and provide valuable insights for enhancing the device performances by engineering the $ErMnO_3$ switching layer.

Improving the Activity and Selectivity of the CO_2 Reduction Reaction with 2D Ferroelectric Materials MoLi and JoshuaYoung; New Jersey Institute of Technology, United States

With the great concern of global warming, removing CO_2 from the atmosphere and converting it into useful commercial chemical products through the electrochemical CO_2 reduction reaction has attracted intense interest. Two-dimensional (2D) materials such as Ti_2CO_2 and transition metal (TM)-doped graphene have been shown to be effective catalysts for the CO_2 reduction reaction (CO2RR). However, due to the complexity of the CO2RR, various species can be produced as products, indicating a poor selectivity of the reaction. Furthermore, ways to overcome limiting scaling relationships and break the Sabatier principle are also desired. To solve these problems, we investigated using 2D ferroelectric (FE) materials, which show a spontaneous electric polarization that is switchable by an electric field, as substrates for CO2RR active catalysts. By switching the polarization, the activity of the surface can be changed, leading to a way to alter the adsorption strength or stability dynamically and overcoming the limiting Sabatier principle. Using density functional theory calculations, we first studied the 2D MXene Y_2CO_2 and found that switching the polarization results in different pathways for the reduction of CO_2 to methanol. Second, we studied heterostructures of the 2D ferroelectric In_2Se_3 and TM-doped graphene, with the TM coordinated in different ways. We found that (1) having the In_2Se_3 enhances the CO2RR activity of the TM-doped graphene and (2) switching the polarization of the In_2Se_3 layer alters the adsorption properties of the intermediates. The beneficial nature of the switchability of the ferroelectric materials provides us with a promising way to control the surface properties, which leads to further control of the desired products in this challenging reaction.

Behaviour of Ferroelastic and Ferroelectric Domains in $AgNbO_3$ Under Temperature and Stress Influence XiShi[1], NeamulKhansur[1] and HanaUršič[2]; [1]University of Erlangen Nuremberg, Germany; [2]Jozef Stefan Institute, Slovenia

By deploying different modes of atomic force microscopy, both ferroelectric and ferroelastic domains with distinct morphology and orientations are observed in the well-known antiferroelectric $AgNbO_3$, consistent with the theoretical studies. With temperature, ferroelectric domains disappear across its M_1 -M_2 phase boundary when it becomes antiferroelectric. In contrast, ferroelastic domains remain stable at 100 °C, consistent with the fact that the ferroelasticity persists till high-temperature antiferroelectric phase regions. In addition, it is found that the number of ferroelectric domains inside the sample is related to the level of Ag deficiency. With applying compressive stress, the ferroelectric surface domains would gradually respond to the stress, which either grows, shrinks or changes shape. In comparison, the ferroelastic surface domains seem to show better mechanical resistance and did not respond as much as the ferroelectric domains.

8:00 PM EL03.10.10
Increase of Faraday Rotation Angle of Cerium-Substituted Yttrium Iron Garnet Film using Vacuum Annealing HibikiMiyashita[1], YukiYoshihara[1,2], TakumiKoguchi[1,2], KantaMori[1], MitsuteruInoue[1], KazushiIshiyama[1] and TaichiGoto[1]; [1]Tohoku University, Japan; [2]Toyohashi University of Technology, Japan

Magnetooptical materials have been applied in various devices, such as optical isolators, spatial light modulators, and Q-switches. A magnetic garnet was used in these devices because of its large Faraday rotation angle and low optical loss. In particular, cerium-substituted yttrium iron garnet (Ce:YIG) shows good magnetooptical characteristics in the near-infrared region, used in optical isolators [1]. In Ref [2], the polycrystalline Ce:YIG was deposited onto silica substrates, showing the Faraday rotation (FR) angle of 1.64 degree/micron at a wavelength of 532 nm and

the optical absorption α of 4.17 dB/micron. The figure of merit (FOM) defined as FR/α was 0.39 degree/dB. This study changed the annealing condition to increase this FOM, and magnetooptical properties were characterized.
A 338 nm thick $Ce_1Y_2Fe_5O_{12}$ film was deposited on a 1-inch synthetic fused silica substrate using a radio-frequency ion beam sputtering (RF-IBS). The substrate temperature was held at 200°C during deposition. The sample was cut into 5×5 mm^2 and annealed using a heater in a vacuum glass chamber. The pressure was less than 2 Pa during the annealing.
The annealing procedure comprised three parts: heating up, keeping, and cooling down. We changed the heating-up speed, the temperature of the keeping step, and the cooling-down speed. The heating-up speed was varied from 0.11 to 16 °C/s, and the temperature of the keeping step was varied from 600 to 900°C. The temperature was kept for 10 minutes. The FR loops and absorption of all samples prepared by the various annealing conditions were measured at the wavelength of 532 nm. The largest FR of 1.55 degree/micron, the smallest absorption of 3.24 dB/micron, and the largest FOM of 0.48 degree/dB were obtained with a heating-up speed of 1.33°C/s and a temperature of 800°C. The cooling-down rate varied from –0.097 to –0.39 °C/s, unaffecting the FR and absorption. Thus the fastest speed was used.
The obtained FOM of 0.48 degree/dB was 1.23 times larger than the prior study's. The microscopic image of the sample surface became uniform as the heating-up speed decreased. Such a behavior may indicate the consistent growth of nanocrystalline grains. In the symposium, crystalline, electronic structures, and magnetic and optical properties will also be discussed.

8:00 PM EL03.10.11
Influence of Thickness and Composition Dependence on Dielectric Tunability in $Ba(Zr_xTi_{1-x})O_3$ Films Grown on MgO Substrate RyoTakahashi[1], YoshitakaEhara[1], YosukeHamasaki[1], ShinyaSawai[1], ShintaroYasui[2], ShinnosukeYasuoka[2], HiroshiFunakubo[2] and KenNishida[1]; [1]National Defense Academy, Japan; [2]Tokyo Institute of Technology, Japan

Microwave tunable devices are necessary components for next-generation communication applications. Semiconductors, ferrite and ferroelectrics are typical tunable materials. Ferroelectric films have been studied because of their high dielectric tunability and low power consumption. Moreover, for microwave dielectric materials, they show advantages in terms of simple device structure, low loss, good temperature stability and low cost in producing communication devices. To date, $(Ba_{1-x}, Sr_x)\ TiO_3$ [BST] is one of the most popular ferroelectric materials for tunable microwave devices. However, its dielectric loss is large and the temperature dependence of the dielectric constant is also insufficient for applications. $Ba(Zr_xTi_{1-x})O_3$ [BZT] solid solutions are tunable materials with potential use in elements of phased array antenna, just above their Curie temperature in a paraelectric state. BZT is a possible alternative to BST in tunable microwave applications Zr^{4+} is chemically more stable than Ti^{4+} and maintains a low dielectric loss. BZT in the paraelectric phase also has higher temperature stability than BST. Therefore, we focused on BZT films as a tunable ferroelectric material.
To evaluate electric properties with microwave region, BZT films are deposited on MgO substrate, which has low dielectric constant compare to films. The lattice mismatch strain between substrate and film, induces remarkable change in crystal structure. This is important parameter to use BZT film into microwave application but not to be reported about influence of thickness and composition dependence of BZT film grown on MgO substrate. Thus, we will discuss these dependence and their impact on microwave applications.
(100)-oriented BZT (x = 0 ~ 1.0) thin films with various thickness by pulse laser deposition [PLD] technique on MgO substrates. The structural properties of the films were characterized by x-ray diffraction [XRD] (MRD, PANalytical). Wavelength-dispersive x-ray fluorescence spectrometry [WDX] (ZSX Primus4, Rigaku) was carried out to investigate the composition and thickness of BZT thin films. All the XRD patterns showed only (001)/(100) diffraction peaks and no secondary phase. Reciprocal space mappings (RSMs) of BZT thin films showed that BZT thin films epitaxially grew on MgO(100) substrates. The composition dependence of tetragonality, remanent polarization, and dielectric constant suggested that there may be a phase boundary between x = 0.2 and 0.3, and this tendency is similar to BZT ceramics. Therefore, our results suggest that BZT (x = 0 ~ 0.5) can be one of the significant candidates for microwave application which requires high tunability and low loss.

Free-Standing Functional Oxide Membrane Through CVD Graphene and MoS_2AsrafulHaque, Sumank. Mandal, RaviK. Mishra, ShubhamK. Parate, ShankarK. Selvaraja, PavanNukala and SrinivasanRaghavan; Indian Institute of Science, India

The integration of complex oxides with myriad functionalities onto Si and flexible substrates is in high demand. One way to integrate functional oxides onto Si is to scavenge the inherent native oxide using TiN, MgO, and STO buffer layers on Si. Alternatively, it can be done by growing them on an oxide substrate and then transferring it onto Si. To enable the transfer process the interfacial bond between the film and substrate is weakened by incorporating 2D materials like graphene. Here, we have demonstrated the growth of BTO via remote/pin-hole epitaxy and then transferred it onto Si using a combination of Ni stressor layer and thermal release tape. We have employed pulsed laser deposition which is an easier and cheaper way to grow these functional oxides, unlike molecular beam epitaxy. Finally, we have shown PFM results to demonstrate the ferroelectricity of our free-standing membrane.
Integrating complex oxides with various functionalities onto Si and flexible substrates is in high demand. The traditional way includes growing TiN, MgO, $SrTiO_3$ (STO), etc. buffer templates for complex oxides integration[1]. Alternatively, the complex oxides can be grown on a single crystalline substrate via a two-dimensional material at the interface, then transferred onto Si[2]. Here, we have demonstrated the growth of $BaTiO_3$ (BTO) via remote/pin-hole epitaxy on a graphene-coated STO substrate. We have employed pulsed laser deposition (PLD), a more accessible and cheaper way to grow these functional oxides, unlike molecular beam epitaxy. After that, the BTO layer has been successfully transferred from its parent STO substrate. Our piezo-force microscopy (PFM) results confirm the ferroelectricity of the BTO membrane. In this conference, I will discuss the underlying strategy to optimize the growth of functional oxide without damaging the graphene layer, followed by its transfer.

8:00 PM EL03.10.13
Effect of Epitaxial Strain and Strain-Mediated Defects on Crystal Structure and Ferroelectricity in Epitaxial $SrMnO_3$ Film Grown on Piezoelectric PMN-PT Substrate SeongMinPark[1], JaegyuKim[2], GopinathanAnoop[1], WooJunSeol[1], Su YongLee[3], HyunjinJoh[1], Tae YeonKim[1], Je OhChoi[1], SeungbumHong[2], Chan-HoYang[2], Hyeon JunLee[4] and Ji YoungJo[1]; [1]GIST, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Pohang Accelerator Laboratory, Korea (the Republic of); [4]Kangwon National University, Korea (the Republic of)

Strain-engineering of perovskite $SrMnO_3$ (SMO) film has attracted research interest due to the theoretical prediction that the application of epitaxial strain (ε, < -1.4% and > 1%) can induce phase transition from paraelectric phase to ferroelectric phase [1]. The strain-induced ferroelectricity so far has been observed in SMO films grown on $(La_{0.3}Sr_{0.7})(Al_{0.65}Ta_{0.35})O_3$ (ε = 1.79%) and $DsScO_3$ (ε = 3.68%) substrates [2,3]; however, the film grown on $SrTiO_3$ (ε = 2.76%) substrate does not exhibit ferroelectric phase transition. This discontinuity in strain-induced ferroelectricity of SMO film can be attributed to distinct morphology and composition of the surface of the perovskite substrate [4]. Furthermore, the tensile strain promotes the formation of oxygen vacancy, which contributes to structural deformation, resulting in the modification of polar orders [5]. Research on deposition and characterization of SMO film using previously unused substrates provides a pathway to understand the effect of misfit strain with crystallographic orientation, crystal structure, and defects chemistry on ferroelectric properties.
Piezoelectric materials have been utilized as functional substrates that can change the biaxial strain of thin film in the real time through the piezoelectric distortion under the electric field [6]. $(1-x)Pb(Mg_{1/3}Nb_{2/3})O_3$-$x$PbTiO$_3$ (PMN-PT), which exhibits the outstanding piezoelectricity, is widely used for the growth of epitaxial oxide film [7]. However, the growth of single crystal SMO film on the PMN-PT substrate has not been studied yet. The significant lattice mismatch against SMO (larger than 5.79%) makes the growth of epitaxial film on PMN-PT substrate challenging. Growth of single crystal SMO film on PMN-PT substrate requires the buffer layer to reduce elastic energy of the SMO film and optimization of growth condition for maintaining the perovskite structure.
In this study, we demonstrate the structural and ferroelectric properties that arise from the interplay of strain and oxygen vacancy in the single crystal SMO film epitaxially grown on (110)-oriented $(La_{0.7},Sr_{0.3})MnO_3$ buffered PMN-PT substrate. We found that the 85 nm thick SMO film exhibits tetragonal structure simultaneously showing expansion in unit cell lattice than bulk structure derived by the strain-mediated oxygen vacancy. Unlike the previously reported tensile strained SMO film, piezoelectric response in both lateral and vertical direction with out-of-plane 180° phase reversal is observed, indicating the existence of ferroelectric polarization rotated toward the out-of-plane direction. Moreover, the use of piezoelectric PMN-PT substrate allows to control the epitaxial strain of SMO film through the converse piezoelectric effect exhibiting 90% of strain transferring efficiency.

Tunable Electronic Structure by *In-Situ* Ferroelectric Domain Writing in Graphene/BiFeO3 HeterostructuresMonikaL. Eggenberger and YoshinoriOkada; Okinawa Institute of Science and Technology, Japan

Integration of functional ferroic domain structures in 2D systems with existing layered electronic architectures represents a major opportunity for advancement of tunable nanoelectronics. Here, we demonstrate nanoscale writable electronic structure of graphene by in-situ ferroelectric domain manipulation in high-quality graphene/BiFeO3 heterostructures. Crystalline BiFeO3 thin films are grown by pulsed laser deposition, and the ferroelectric domain structure and domain wall properties are characterized by piezoresponse force microscopy (PFM). Few- and monolayer graphene flakes are transferred in ultrahigh vacuum by direct bonding for a pristine interface. The ferroelectric polarization domains in BiFeO3 determine the local charge landscape at the heterointerface, which modulates the band structure of the adjacent graphene layer and results in large switchable resistivity. We characterize the effect of the domain polarization on the electronic structure of the graphene layer by STM, with particular focus given to the domain wall region. Additionally, we show that the electronic structure of graphene can be locally patterned by in-situ manipulation of the ferroelectric domains by external field. Finally, we discuss the stability of written domains and suitability for device application.

8:00 PM EL03.10.15
Direct Probing of Dielectric Property of BaTiO3 Nanoparticle on Conducting Substrate WonhyungKim[1,2], EunjinKoh[1], ChoongseopJeon[2], SeungyongLee[2], JunghyunAn[2], DongchanSeo[2], JeongryeolKim[2], JungwonLee[2] and YunseokKim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Samsung Electro-Mechanics Co. Ltd, Korea (the Republic of)

With the development of technology, the performance of electronic devices is improving, increasing the number of components need to be used, so the size of the passive components, including multi-layer ceramic capacitors (MLCCs), should be downsized. Therefore, the size of BaTiO3, the raw dielectric material of MLCC, needs to be reduced. It is known that the dielectric properties of BaTiO3 nanoparticles are dependent on size and synthesis method. In previous studies, the dielectric properties of BaTiO3 nanoparticles were mainly studied using the slurry method, which is dielectric measurement of slurry consisted of solvent and nanoparticles. But this method has limitations in that the dielectric properties of the nanoparticles and solvent are measured together, so the information about the nanoparticles cannot be directly obtained. On the other hand, many researchers study dielectric properties in thin films or particles using scanning dielectric microscopy (SDM) measurement, which is an atomic force microscope (AFM)-based measurement method. In this study, the dielectric properties of BaTiO3 according to size and the synthesis method were measured using SDM to directly observe BaTiO3 nanoparticles. The capacitance gradient (dC/dz) was obtained using SDM measurement and the dielectric constant was studied. Through this study, we learned about the dielectric characteristics of BaTiO3 at the particle level, and it is expected that this will help select the appropriate type of dielectric powder in the development of next-generation MLCCs.

Crystallization of Amorphous $Hf_{1-x}Zr_xO_2$ Thin Films by Electric Field Cycling AhyoungJeong, DeokjoonEom, HyoungsubKim and YunseokKim; Sungkyunkwan University, Korea (the Republic of)

Hafnium oxide (HfO_2)-based ferroelectrics exhibit robust ferroelectricity even at extremely thin thicknesses, in contrast to conventional perovskite-based ferroelectrics. Numerous research efforts are underway to enhance the ferroelectric properties of HfO_2 and, recently, the crystallization of amorphous hafnium zirconium oxide (HZO) through electric field cycling has been reported. Electric-field-induced crystallization might enable the crystallization process to occur at lower temperatures compared to traditional methods. To investigate the mechanism of electric-field-induced crystallization, it is necessary to study nanoscale ferroelectricity analysis. However, the conventional approach of studying ferroelectricity using polarization-electric field hysteresis loop measurement is limited in its ability to discern the underlying nanoscale mechanisms due to the presence of leakage currents. In this study, we investigated the electric-field-induced crystallization of HZO thin film at the nanoscale level using piezoresponse force microscopy. This research can provide opportunities for understanding the electric-field-induced crystallization and origin of ferroelectricity of HfO_2-based thin films.

Growth Orientation Dependence on the Stabilization of the Polar Orthorhombic Phase of $Hf_{1/2}Zr_{1/2}O_2$ Thin Films ArnabDe[1], Seung GyoJeong[1], JinyoungOh[1], Seong BinBae[2], Young HoonKim[1], Young MinKim[1], Sang MoYang[2] and Woo SeokChoi[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sogang University, Korea (the Republic of)

Ultrathin ferroelectrics possess enormous potential for the implementation of next-generation nonvolatile memories, actuators, sensors, and opto-electronic devices [1]. Since the discovery of the unexpected ferroelectricity in HfO_2 (hafnium-dioxide) thin films in 2011 [2], intensive research has been conducted for the realization of the silicon-compatible nanoscale devices. However, to fully exploit the potential of ferroelectric HfO_2-based thin films, we must address fundamental questions regarding the origin of ferroelectricity and develop strategies for controlled implementation at the nanoscale. The stability of the polar orthorhombic phase responsible for the robust polarization is believed to be influenced by various extrinsic factors, including finite-size effects, surface/interface effects of small grains, compressive stress, dopants, and oxygen vacancies[3,4]. However, a deeper understanding of the extrinsic and intrinsic parameters that control the phase transitions among different polymorphs (i.e., orthorhombic, tetragonal, and monoclinic) of HfO_2 is still needed. In this study, we investigate the influence of substrate orientations on the relative stability of different phases of $Hf_{0.5}Zr_{0.5}O_2$ grown epitaxially on (001) and (011) oriented $La_{0.7}Sr_{0.3}MnO_3/SrTiO_3$ using pulsed laser epitaxy (PLE). Ferroelectric measurement reveals remanent polarization as high as 40 μC/cm^2 with negligible wake-up effect. A systematic variation on the growth conditions show that the fraction of polar orthorhombic and non-polar monoclinic phases can be controlled by manipulating the epitaxial strain arising from the different substrate orientations. This study provides a promising direction for enhancing the stability of the ferroelectric phase in HfO_2 based thin films through substrate orientation engineering.

Giant Voltage Amplification Under Scrutiny ArkadyP. Levanyuk[1], IbrahimB. Misirlioglu[2], MahmutB. Okatan[3] and AndresCano[4]; [1]University of Washington, United States; [2]Sabanci University, Turkey; [3]Izmir Institue of Technology, Turkey; [4]University Grenoble Alpes, France

If a capacitor contains both ferroelectric and dielectric layers then, under certain conditions, the drop in the electrical potential across the dielectric can be higher than the external voltage applied to the capacitor. This is recently of practical interest in relation to field-effect-transistors (FET) for example. Such a “voltage amplification”, which can be seen as arising due to a “negative-capacitance effect” associated with the ferroelectric, has been mostly discussed in relation to multidomain ferroelectricity (A. M. Bratkovsky and A. P. Levanyuk, Appl. Phys. Lett. 89, 253108 (2006)). However, it can also be realized when the ferroelectric is in its paraelectric phase but such that it would be in the ferroelectric state had it been in a short-circuited capacitor without a dielectric and with ideal electrodes (A. Cano and D. Jimenez, Appl. Phys. Lett. 97, 133509 (2010)). In a recent paper by Graf et al. (Nature Materials 21, 1252 (2022), a “giant voltage amplification” with a factor ~12 is reported for a special case of an infinite $PbTiO_3/SrTiO_3$ multilayer in the paraelectric state. In this presentation, drawing from the results of our earlier work (A. P. Levanyuk and I. B. Misirlioglu, J. Appl. Phys. 110, 114109 (2011)), we report on our theoretical investigation so as to how this result transforms when applied to finite systems that are closer to those of interest for applications. Using the Landau-Ginzburg-Devonshire (LGD) theory we consider a uniaxial ferroelectric with different dielectric surroundings.

We find that the voltage amplification depends strongly on the configuration of the system and the characteristics of the electrodes of the capacitor. In a special case of symmetrical configuration of the dielectric layers and ideal electrodes our results reproduce the giant voltage amplification reported by Graf et. al. In asymmetric configurations, however, we find that the voltage amplification decreases substantially.

Local Investigations of the Electrocaloric Effect using Scanning Thermal Microscopy OliviaBaxter, AmitKumar, J. MartyGregg and RaymondMcQuaid; Queen's University Belfast, United Kingdom

The electrocaloric effect is a well-known phenomenon where adiabatic application of an external electric field to a material results in a reversible temperature change. Interest in using these materials for environmentally friendly solid-state refrigeration applications has been rejuvenated by the discovery of giant electrocaloric effects in thin films. While the electrocaloric effect can be well described macroscopically through a thermodynamic approach and is understood to arise from changes in dipolar configurational entropy, the effect at the microscopic scale is not as well characterised. To date, infrared cameras represent the best spatial resolution available for in-situ imaging of temperature fields associated with electrocaloric effects, but features are limited in detail to the level of a few microns.

Scanning Thermal Microscopy is emerging as a powerful Atomic Force Microscope based platform for mapping dynamic temperature distributions on the nanoscale. To date, however, spatial imaging of temperature changes in electrocaloric materials using this technique has been very limited. We build on the work of previous studies to show that Scanning Thermal Microscopy can be used to spatially map electrocaloric temperature changes on microscopic length scales, here demonstrated in a commercially obtained multilayer ceramic capacitor. In our approach, the electrocaloric response is measured at discrete locations with point-to-point separation as small as 150nm, allowing for reconstruction of spatial maps of heating and cooling as well as their temporal evolution. This technique offers a means to investigate electrocaloric responses at sub-micron length scales, which cannot easily be accessed by the more commonly used infra-red thermal imaging approaches. We intend to use this technique to elucidate the behaviour of other electrocaloric materials and to examine the influence of microstructural inhomogeneity on electrocaloric response.

Heat Assisted Ferroelectric Reading for High Speed Ferroelectric Probe Data Storage YasuoCho; Tohoku University, Japan

We previously proposed ferroelectric data storage that uses scanning nonlinear dielectric microscopy (SNDM), called SNDM probe memory, as a next-generation ultrahigh-density information recording method. We confirmed an extremely high recording density and high-speed writing using $LiTaO_3$ single crystal media [1][2].
However, since reading is based on the detection of very small nonlinear dielectric constants of ferroelectric materials using SNDM technique, slow playback speed (actually 2Mbps) hinders the practical use of SNDM probe memory [3].
To solve this problem, a material with a large nonlinear dielectric constant is required. Our basic experiments revealed that a nonlinear dielectric constant has an extremely large temperature dependence and is proportional to $(T_0\text{-}T)^{-3.5}$, where T is the medium temperature and T_0 is the Curie temperature[4]. This means that an increase in the nonlinear dielectric constant, which would enable ultrahigh-speed reading (Gbps or faster), can be easily obtained even in $LiTaO_3$ crystal by making T close to T_0. However, simply increasing the medium temperature closer to the Curie temperature under thermal equilibrium degrades the polarization retention characteristics.
Therefore, we propose a heat-assisted ferroelectric reading (HAFeR) method that increases the reading speed while maintaining the polarization retention characteristics. This is achieved by locally heating the medium for a very short time at the data reading position using laser pulse irradiation. We conducted a basic experiment and confirmed that laser pulse irradiation increased the SNDM signal strength much more.
We also discuss the relationship between the maximum number of laser irradiation pulses and the optical pulse width for a medium heated to 550 °C (equivalent to a reading speed of 5 Gbps). The proposed method overcomes the fundamental problems of next-generation ultrahigh-density ferroelectric data storage.

***In Situ* Characterisation of Ephemeral p-n Junctions inside Ferroelectric Domain Walls**KristinaHolsgrove, JesiMaguire, ConorJ. McCluskey, AhmetSuna, RaymondMcQuaid, AmitKumar and J. MartyGregg; Queen's University, United Kingdom

Ferroelectric materials are renowned for their distinctive microstructure, characterised by a patchwork of domains where local electrical dipoles align, separated by domain walls that act as interfaces between these domains. When subjected to applied fields, certain domain orientations become stabilised and tend to grow, while unstable ones diminish. Consequently, the movement of domain walls becomes an inherent necessity. The creation of new domains necessitates the formation of domain walls, while the disappearance of domains leads to the disappearance of walls. Therefore, domain walls exhibit both mobility and transience in response to varying field conditions. What's particularly noteworthy is that while most ferroelectrics possess inherent electrical insulation properties, domain walls can exhibit conductivity [1]. In such cases, domain walls serve as quasi-2D electrical pathways within an otherwise insulating ferroelectric matrix. This intriguing characteristic paves the way for envisioning dynamically reconfigurable domain walls capable of creating, erasing, and rewriting entire nanoscale circuits in different configurations.
Our team has devoted several years to the study of conducting domain walls in thin film heterostructures of lithium niobate (LNO) [2-4]. It is now recognised that when a modest positive bias is applied, the domain walls exhibit a remarkable behaviour, tilting away from the polar axis and forming what are known as charged head-to-head (n-type) domain walls, which exhibit strong conductivity. In this study, we perform *in situ* cross-sectional transmission electron microscopy (TEM) imaging of bias-induced domain wall dynamics, allowing us to "live" image the domain wall tilting under applied electric fields.
This investigation has yielded a remarkable finding: certain sections of conducting domain walls transition from n-type to p-type as the direction of the applied bias changes - a result that has never been observed before and is incredibly exciting. It seems that we are creating a new kind of dynamically formed domain wall p-n junction. Although p-n junctions are commonly found in improper ferroelectric systems like boracites and rare-earth manganites, what we have observed in focused ion beam (FIB) slices of LNO represents a unique phenomenon. The in-wall p-n junctions (which could be described as 'zero-dimensional' entities due to the one-dimensional nature of the domain walls) only exist within a finite bias range, and hence are truly ephemeral in nature.
Through monitoring the current-voltage response, we observe striking diode-like characteristics. Moreover, thanks to the dynamic nature of these *in situ* TEM studies, we have been able to evaluate the switching mechanisms involved in the formation of these conductive pathways and transient p-n junctions. This work is expected to provide valuable insights into in-wall p-n junctions and contribute significantly to the advancement of domain wall nanoelectronics.

Ultrashort Electric Pulse-Driven Polar State in Paraelectric $SrTiO_3$ Thin Film at Room Temperature Hyeon JunLee; Kangwon National University, Korea (the Republic of)

Access to hidden metastable phases of matter is a crucial early stage to explore exotic properties. Strontium titanate ($SrTiO_3$) is a quantum paraelectric in which quantum fluctuations of ionic positions prevent the long-range polar order even at zero kelvin. Application of external bias overcoming the fluctuations has dynamically induced metastable polar states at the cryogenic temperature. However, the existence of these polar states above room temperature has not been proved and explored yet because the magnitude of the electric field required to drive the polar state in $SrTiO_3$ can be larger than the low-frequency dielectric breakdown field in principle. Using nanosecond electric pulse for which the high field can be applied without the breakdown, we found an ultrafast phase transition into the polar state.

We measured the electromechanical response of a 50 nm-thick paraelectric $SrTiO_3$ epitaxial film grown on the (001) oriented $SrRuO_3$ electrode and $SrTiO_3$ substrate as a function of the

magnitude of electric field up to 1.5 MV/cm using advanced time-resolved x-ray microdiffraction. At a low field regime, the out-of-plane lattice constant of the film increased quadratically due to the electrostrictive response of the dielectric component. At above 1 MV/cm, $SrTiO_3$ film exhibited the linear lattice expansion with increasing the electric field, which is consistent with piezoelectric distortion, indicating that the high field induced the transition into polar states. We found that the electrostrictive coefficient (g_{11}) linking the applied electric field to the measured piezoelectric strain is 3 times larger than previously reported value for $SrTiO_3$ at 1985. Due to this large electrostrictive coefficient, ferroelectric phase of $SrTiO_3$ thin film can be stable even under -1 % compressive strain at room temperature. We will discuss the new phase diagram based on the electrostrictive coefficient measured in this study.

Simultaneous Growth of Lateral Heterostructures of Epitaxial Garnet and Polycrystalline Perovskite Phases PeteE. Lauer, KensukeHayashi, YuichiroKunai and CarolineA. Ross; Massachusetts Institute of Technology, United States

Iron garnets based on Y3Fe5O12 (YIG) are ferrimagnetic insulators and form essential components of optical communications and microwave devices. To enhance their functionality and allow device scaling, it is of great interest to interface them with other functional oxides such as ferroelectric perovskites, which could enable electrical control of the magnetic properties. Here we describe a fabrication pathway capable of creating a lateral heterostructure that includes both a garnet and a perovskite phase with feature sizes as low as 50 nm during a single deposition step. The methodology first uses electron beam lithography to create a resist pattern on a Gd3Ga5O12 (GGG) substrate. Pulsed laser deposition (PLD) is used to grow a 25 nm thick layer of amorphous SrTiO3 (STO) at room temperature over the resist. After liftoff, the patterned STO is crystallized by a rapid thermal anneal at 700 °C. A 200 nm thick layer of YIG is then grown on the STO-patterned GGG substrate at elevated temperature (650 °C) to form the lateral heterostructure: in regions with exposed GGG, epitaxial growth of YIG occurs, but in regions seeded with STO, a polycrystalline Fe-rich YFeO3 (YFO) perovskite forms. Electron-beam backscatter diffraction reveals the phase distribution of both YFO and YIG, the single-crystal growth of the YIG and the polycrystallinity of the YFO. This phase formation is consistent with prior work in which epitaxy stabilizes YIG or YFO phases even when the composition differs from the ideal bulk composition [1,2]. Furthermore, off-stoichiometric YFO can exhibit a ferroelectric response [2]. The YIG/YFO interfaces are vertical leading to YIG features separated by YFO walls or fins. We demonstrate the process conditions that yield vertical phase separation by changing the Y:Fe ratio of the deposited material and the deposition temperature and oxygen pressure. The thermodynamic and kinetic considerations of the competition between the two-phase growth will also be discussed. Extension to other materials systems will be described, in particular the growth of a ferroelectric/magnetooptical BiFeO3/ Bi3Fe5O12 heterostructure.

10:45 AM EL03.12.02
Magnetic Proximity Effect in Oxide Heterostructures BhagwatiPrasad, SuryakantaMondal and NaveenNegi; Indian Institute of Science, India

The fabrication of spintronics devices, encompassing spin transistors and spin valves, requires complex multi-layer structures composed of varying magnetic materials. This complexity opens the possibility of myriad interface effects, one of which is the proximity effect. This fascinating effect is the phenomenon where one layer's physical characteristics influence the properties of another layer within the same structure. Manganite thin film heterostructures could be a suitable candidate for the in-depth investigation of these proximity effects as manganites are known to display emergent phenomena stemming from the dynamic interplay between charge, spin, orbital, and lattice degrees of freedom [1]. Its intriguing properties include colossal magnetoresistance and metal-insulator transitions, among others. These unique features result from the complicated interplay between charge carriers, spin ordering, and lattice distortions, with modulating influences from external stimuli, such as magnetic fields or electric fields.
The physical properties of manganites, such as $Sm_{1-x}Sr_xMnO_3$ (SSMO), can be significantly changed by varying the percentage of Sr doping. Depending on the doping ratio, SSMO can manifest as a ferromagnetic or antiferromagnetic magnetic phase or even a mixture of both magnetic phases [2]. The vast range of tunable phenomena owing to Sr concentration in SSMO underscores its scientific significance and makes it an interesting candidate for the study of various properties [3, 4]. In this study, we explored the magnetic proximity effect in SSMO bilayer and tri-layer heterostructures. First, we deposited a single layer of ferromagnetic metal (FMM) and an anti-ferromagnetic insulator (AFI) using the pulsed laser deposition (PLD) method on a $SrTiO_3$ (STO) substrate. Their magnetic properties were analyzed using a SQUID magnetometer, with the results aligning well with the previously reported data. Next, we deposited a bi-layer stack of FMM/AFI and a corresponding tri-layer structure of AFI/FMM/AFI on the STO substrate. We discovered a significant increase in magnetic moment across these structures, suggesting the magnetic proximity effect in the heterostructures as the primary cause. In a nutshell, the manganite heterostructures provide a promising platform for delving deeper into new electronic and magnetic phenomena at the interfaces.

11:00 AM *EL03.12.03
Ferrimagnetic Garnets: Nanocomposites, Superlattices and Defect Engineering CarolineA. Ross; Massachusetts Institute of Technology, United States

Iron garnets (IGs) are exciting materials for spintronics, with TmIG and TbIG/Pt bilayers exhibiting interfacial DMI and field-free spin orbit torque switching, [1] and BiYIG exhibiting relativistic domain wall velocities of 4.3 km/s [2] and spin wave-driven domain wall motion [3]. In this presentation we will focus on the synthesis and behavior of garnet superlattices and garnet/perovskite nanocomposites and the effect of cation site-occupancy on the magnetic properties of garnet films.

Manipulating site-occupancy, for example by epitaxial growth of off-stoichiometric garnets, yields properties not seen in bulk. For example, in Tb-rich TbIG, excess Tb occupies octahedral sites making the compensation temperature 90K higher and the Curie temperature 40K lower than bulk [4]. Mixed REIGs such as EuTmIG exhibit ordering of the RE cations on non-equivalent dodecahedral sites during film deposition, leading to a strong growth-induced anisotropy that yields an out-of-plane easy axis even in unstrained films. Layered garnets provide another avenue for properties engineering. IG superlattices are unexplored, despite the emergent phenomena seen in other oxide superlattices such as interfacial conductivity, magnetism and anisotropy in perovskites. We show using transmission electron microscopy and atom probe measurements that pulsed laser deposition can produce epitaxial coherent TbIG/TmIG and BiYIG/LuIG superlattices with well defined nm layers. TbIG/TmIG superlattices exhibit perpendicular magnetic anisotropy in contrast to the in-plane easy axis of intermixed TbTmIG films, and BiYIG/LuIG superlattices exhibit lower damping than intermixed BiYLuIG films. Finally, garnet-perovskite nanocomposite thin films offer the possibility of magnetoelectric control of the garnet via coupling to a ferroelectric perovskite. We demonstrate a process to produce patterned YIG/YFeO3 and BiIG/BiFeO3 two-phase thin films on garnet substrates in which the perovskite orthoferrite forms selectively on regions of the substrate coated with a thin seed layer of SrTiO3, and describe the nanocomposite structure and properties. The formation of complex heterogeneous garnet-based films and structures expands the range of properties and applications of this important class of materials.

Incoherent Magnon Transport in Magnetic Insulators TianxiangNan; Tsinghua University, China

Magnon spin transport, with its low energy dissipation, has become a promising candidate for applications in information transmission. In this talk, I will present room-temperature measurements of magnon spin diffusion in ultra-thin epitaxial ferrimagnetic insulator $MgAl_{0.5}Fe_{1.5}O_4$ (MAFO) thin films. I will first show the observation of spin diffusion lengths > 0.8 μm at

room temperature in 6 nm films, with anisotropic spin diffusion lengths along different crystal axes, which can be attributed to the anisotropy in exchange stiffness. I will also show the magnon spin transport at near zero applied magnetic field where the sample forms a multi-domain state with 180° domain walls. We find, surprisingly, that the presence of the domain walls has very little effect on the spin diffusion – nonlocal spin transport signals in the multi-domain state retain at least 95% of the maximum signal strength measured for the spatially-uniform magnetic state, over distances at least five times the typical domain size. These findings provide additional approaches for controlling magnon transport via strain and magnetic domain walls, which opens new opportunities for designing magnonic devices.

SESSION EL03.13: Spintronics II
Session Chairs: Bhagwati Prasad and Caroline Ross
Thursday Afternoon, November30, 2023

1:30 PM *EL03.13.01
Structural Magnetic Properties Correlation in $(Gd_{1-y}Ho_y)_2Ti_2O_7$ and $Ho_2(Ti_{1-x}Ge_x)_2O_7$ Frustrated Pyrochlores VinodSingh[1] and KailashChandra[1,2]; [1]Delhi Technological University, India; [2]Motilal Nehru College, University of Delhi, India

The effects of Ho substitution at A site on the structural and magnetic properties of $(Gd_{1-y}Ho_y)_2Ti_2O_7$ (y = 0, 0.2, 0.4 and 0.6) single phasic pyrochlore oxides have been investigated. Magnetic Ho substitution reduces the size of crystallites as calculated from the WH graph, validating the reduction in structural ordering of the produced samples. The compounds show a tendency towards a heightened ferromagnetic interaction on Ho substitution owing to the ferromagnetic connections between the Gd and Ho cations. The fight between ferromagnetic (FM) and antiferromagnetic (AFM) interaction, which is linked to magnetic frustration and local structural disorder, is speculated to be influenced by this property. The θ_{CW} can be regulated by doping at the A site, as demonstrated by a substantial rise in the θ_{CW} for $Gd_2Ti_2O_7$ doped with Ho. This might be due to the larger spin angles of the Gd-O-Ho spin, which encourage FM interactions. Further, by partially substituting Ti with Ge (B site doping), the magnetic and structural characteristics of $Ho_2(Ti_{1-x}Ge_x)_2O_7$ (x = 0, 0.2, and 0.4) pyrochlore have also been investigated. Structural assessment has verified that impurity-free cubic type pyrochlore crystals form with a lattice constant that continuously lowers and follows Vegard's law. Further evidence for the pyrochlore phase's hardening of the phonon mode due to phonon anharmonic interaction came from Raman spectroscopy research. Magnetic investigations have revealed that $Ho_2Ti_2O_7$ elevated chemical pressure causes the ferromagnetic interaction to diminish. Furthermore, even when the temperature in both the (A and B site doping) series was reduced by up to 2K, the glassy pattern remained undetectable. It can be declared that doping at the B site controls magnetic characteristics more effectively than doping at the A site when comparing both of them. It would be stimulating to conduct further research on these system crystallographic modifications at temperatures where spin ices are known to freeze and lose their equilibrium.

2:00 PM *EL03.13.02
Novel Control of Magnetic Anisotropy in Ultrathin Ferromagnets by Interfacial Reconstruction DiYi; Tsinghua University, China

The manipulation of spin in magnetic systems has been of great interest as it has given rise to a rich spectrum of magnetic ground states and has enabled high performance magnetic memory and logic devices. Magnetic anisotropy (MA), which describes the tendency of magnetic moment vectors to prefer directions, plays an important role in determining these ground states. Here, we present two recent advances in controlling MA in ultrathin ferromagnets by interfacial reconstruction. In the first case, we show that the interface reconstruction in heterostructures comprised of monolayers of 3d and 5d transition metal oxides induces a strong perpendicular magnetic anisotropy. Due to the suppression of thermal fluctuations, we stabilize ferromagnetic order in monolayer manganite with superior performances, which is otherwise challenging in single-phase oxides. In the second case, we show that a tilted magnetic easy axis is induced and can be tuned from nearly in-plane to out-of-plane in ultrathin Co layer, by controlling the crystal symmetry at the interface. This enables the field-free spin-orbit torque switching of perpendicular magnetization components at room temperature with a relatively low current density and excellent stability.

2:30 PM EL03.13.03
Room-Temperature Magnetic Glassiness in Zinc Ferrite JuliaLumetzberger[1], VerenaNey[1], AnnaZakharova[2], NieliDaffe[2], DanielPrimetzhofer[3], FabriceWilhelm[4], AndreiRogalev[4] and AndreasNey[1]; [1]Johannes Kepler Universitat Linz, Austria; [2]SLS, Switzerland; [3]Uppsala University, Sweden; [4]ESRF, France

Zinc ferrite in thin-film form possesses a range of possible applications such as gas sensors, photocatalytic applications or as an interesting semiconducting material in spintronics with tunable magnetic properties including unconventional magnetic order due to intrinsic or extrinsic frustration. Zinc ferrite ($ZnFe_2O_4$) belongs to the family of normal spinels of the form AB_2O_4. In bulk form zinc ferrite is known to be antiferromagnetic with a low Néel-temperature [1]. The magnetic properties significantly change as a thin film, especially for a finite degree of inversion and/or off-stoichiometry where ferro(i)magnetic order up to room temperature can be found, e.g. [2]. In contrast, other studies report the existence of a spin-glass or cluster-glass behavior under various conditions in bulk [3] or in thin films [4] exhibiting a wide range of spin freezing temperatures. Here we present a systematic study of epitaxial, stoichiometric zinc ferrite thin films prepared using reactive magnetron sputtering over a wide range of preparation conditions which exhibit signatures of magnetic glassiness up to room temperature [5]. Using element-selective characterization with soft x-ray magnetic circular dichroism we can provide evidence for a finite degree of inversion accompanied by the formation of Zn on octahedral lattice sites as well as a finite magnetic polarization of Zn. In addition, hard x-ray linear dichroism allows a correlation of magnetic glassiness with disorder in the Zn cationic sublattice, which can be induced by increasing the sputtering power, thus further elucidating the microscopic origin for magnetic glassiness at unusually high temperatures exceeding room temperature.

2:45 PM EL03.13.04
Molecular Field Coefficient Modeling of Temperature-Dependent Ferrimagnetism in a Complex Oxide MielaGross, TingyuSu, JacksonBauer and CarolineA. Ross; MIT, United States

The temperature-dependence of the magnetic moment of a magnetically ordered material is fundamental to all aspects of its technological applications. In ferrimagnetic materials with multiple sublattices of magnetic ions coupled by exchange interactions with different strengths and signs, the magnetization can vary nonmonotonically with temperature and can pass through zero at a magnetization compensation temperature T_{comp}. The net angular momentum can also reach zero at the angular momentum compensation temperature T_A, which differs from T_{comp} if the sublattices have different Lande g-factors. Recent studies reveal fast magnetization dynamics near T_A, emphasizing its importance [1]. It is therefore useful to predict the temperature-dependent magnetic moment and angular momentum of a material with known site occupancy, or conversely to use the magnetization vs. temperature to identify the cation site occupancy.

In this work we designed and developed a Python computer code that models the magnetism of rare-earth iron garnets ($RE_3Fe_5O_{12}$, REIG) using a molecular field coefficient (MFC) approach. REIGs contain 8 formula units (160 atoms) per unit cell and the cations occupy three sublattices: tetrahedral Fe^{3+}, octahedral Fe^{3+}, and dodecahedral RE^{3+}. Following Dionne [2], the program calculates both the exchange interactions and the magnetic moment of each sublattice to determine the magnetization and angular momentum as a function of temperature. The model accounts for site occupancy on each sublattice including the effects of non-magnetic and magnetic substitutions, vacancies, Fe^{2+}, and deviations from the ideal RE:Fe stoichiometry by considering their effects on the net magnetization and the sublattice exchange coupling. Unlike previous iterative methods, our program recursively solves for the moment at each temperature which provides more accurate results with excellent match to magnetization vs temperature data for a range of bulk garnets. Using data of Tb-rich terbium iron garnet thin films with Tb:Fe = 0.86 from Rosenberg et al. [3], we show that the model is consistent with the excess Tb accommodated in octahedral sites (which contain $Fe_{1.52}Tb_{0.48}$) and vacancies (V) in the tetrahedral sites (which contain $Fe_{2.53}V_{0.47}$), giving an excellent match to the measured magnetization, T_{comp}, and Curie temperature, as well as to XPS, XMCD, and elementally resolved TEM data. This work provides accurate magnetic modeling of REIGs of a variety of compositions allowing for design and analysis of ferrimagnets with useful properties.

Polar Textures in Epitaxial $BaTiO_3$-Based Heterostructures on Silicon ValentinV. Hevelke[1,2], OlaniyanI. Ibukun[1,2], InesHaeusler[3], AdnanHammud[4], ChristophT. Koch[3], Dong-JikKim[1] and CatherineDubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany; [3]Humboldt-Universität zu Berlin, Germany; [4]Fritz Haber Institute of the Max Planck Society, Germany

In recent years, polar textures featuring curled polarization patterns (vortices, skyrmions, merons…) have been unraveled in ultrathin films, superlattices and nanostructures. The development of topological nanoelectronics on chips that would take advantage of such polar textures requires their integration on silicon.
I will discuss in this talk the growth and the resulting polarization patterns of $(BaTiO_3/SrTiO_3)_n$ superlattices epitaxially grown on silicon substrates. The heterostructures were synthesized by molecular beam epitaxy on 4 nm $SrTiO_3$-buffered Si (001). Various $BaTiO_3$ and $SrTiO_3$ thicknesses in the range of 2-5 nm were investigated. The superlattices were characterized by X-ray diffraction, scanning transmission electron microscopy (STEM) and piezoresponse force microscopy. We will show that the biaxial in-plane tensile strain imparted by the silicon substrate upon cooling has a strong impact on the crystalline structure and strain distribution as shown by the in-plane and out-of-plane lattice parameter profiles throughout the stacks (calculated from high angle annular dark field STEM images and geometrical phase analysis). The in-plane lattice parameter of both $SrTiO_3$ and $BaTiO_3$ layers increases continuously from bottom to top, and dislocations are present throughout the stacks. The out-of-plane lattice parameter of $BaTiO_3$ indicates an overall tensile strain (tetragonal *c*-axis $BaTiO_3$). The atomic displacements of Ti atoms relative to the center of the unit cell (as defined by the Ba or Sr atoms) were determined. From the resulting electrical dipole maps, periodic polar domains are observed in the $BaTiO_3$ layers as well as nanodomains of curled polarization. The textures observed at different layers of the superlattices will be discussed. Finally, we will show how polar bubbles can also be generated in $BaTiO_3$ thin films on $SrTiO_3$-buffered Si. The evidence of curled polarization nanodomains in $BaTiO_3$-based heterostructures gives promises for a future integration of topological polar nanodomains into nanoscale devices.

4:00 PM EL03.14.02
Polar Vortices in Microwave Electronics FlorianBergmann[1,2], BryanBosworth[1], NickJungwirth[1], EricMarksz[1], AaronHagerstrom[1] and NateOrloff[1]; [1]National Institute of Standards and Technology, United States; [2]University of Colorado Boulder, United States

Under the right lattice periodicity conditions, internal stress in $PbTiO_3$-$SrTiO_3$ superlattice thin films forces the polarization in the $PbTiO_3$ into a vortex structure. Often called Polar Vortices, theorists expect collective dynamics of Polar Vortices in the gigahertz range. Our group at NIST has experience characterizing thin films up to 1 THz with metallic transmission line structures deposited onto the thin film, producing dielectric and magnetic properties versus frequency. We designed an experiment on Polar Vortex thin films to quantify the electrical properties with devices both parallel and perpendicular to the vortex core. Our measurements show features that we have not observed in any other films, such as negative imaginary parts of the impedance or extremely large resistances per unit length. At this point, we are seeking engagement from the materials community to help understand our observations and how they might be coupled into new microwave electronics.

3D-Atomic-Scale Analysis of Magnetoelectric Multiferroic Topologies via Scanning Transmission Electron Microscopy and Spectroscopy Complemented by Atom Probe Tomography Shelly MicheleConroy; Imperial College London, United Kingdom

Magnetoelectric multiferroic higher order topologies are an emerging solution for future low-power spintronic and quantum devices, due to a combination of their atomic-scale tunable multi-functionality and mobility. In addition to their potential for next-generation interactive technology, topologies with spin to charge coupling are a fertile ground for the exploration and engineering of new states of matter. In our recent report we have shown the presence of vortex topologies present in room temperature magnetoelectric multiferroic $Bi_6Ti_xFe_yMn_zO_{18}$ thin films by atomic-scale scanning transmission electron microscopy (STEM) polarization mapping. We find these chiral polar textures at antiphase boundaries within the thin films. Such topologies related to crystalline defects should be analyzed three-dimensionally to truly understand their formation. In this presentation, will discuss the use of atom probe tomography (APT) combined with STEM and spectroscopies to analyze the Fe and Mn elemental segregation at topological defects.

For $Bi_6Ti_xFe_yMn_zO_{18}$ the magnetic cation partitioning increases the probability of nearest-neighbor magnetic interactions in the central unit cell layer by up to 90% compared to random distributions over the other available B-sites. Using atomic resolution STEM with corresponding energy dispersive X-ray (EDX) and electron energy loss spectroscopy (EELS) elemental mapping we can determine the location of Fe and Mn within the unit cell. Monochromated STEM EELS is used to probe the atomic scale crystal field splitting at the differet topologies and within the unit cell. As the topologies themselves are the active regions within such material systems, it is vital that we explore the higher order elemental segregation in full real space. We hence used APT's unique 3D characterization capability to move beyond the 2D projection of the elemental segregation knowledge, with an aim to unravel the magnetic cation partitioning of complex 3D vortices and associated crystallographic defect topologies. Theoretical calculations confirm the subunit cell cation site preference and charged topology energetics. We will discuss the opportunities APT characterization methods can bring to the field multiferroic higher order topology physics. Finally we will discuss recent advancements in MEMS based cryogenic microscopy stage and transfer design to investiagte the low temperature phases.

4:45 PM EL03.14.04
Ferroelectric and Chiral Domains in the Polar Vortex System PiushBehera[1], FernandoOrtiz[2], PeterMeisenheimer[1], PravinKavle[1,3], Ching-CheLin[1,3], JavierJunquera[2] and RamamoorthyRamesh[1,4]; [1]UC Berkeley, United States; [2]Universidad de Cantabria, Spain; [3]Lawrence Berkeley National Laboratory, United States; [4]Rice University, United States

Polar surface textures are a recent class of topological materials that host numerous unique physical properties such as chirality and collective sub-terahertz dynamics. These properties are directly linked to the fundamental structure of the vortices and their self-organization into a two-dimensional lattice. Here, we focus on how the fundamental structure of the polar vortices influences their mesoscale properties by first examining the intrinsic organization of the vortices at the atomic scale using planar transmission electron microscopy (TEM). By utilizing TEM, we observe three distinct domain wall variations, two of which separate domains with different chirality. Additional cross-sectional TEM measurements enhance our understanding of how the organization of the vortex lattice leads to a measurable net polarization both parallel and perpendicular to the vortex tube axis. Upon examining the vortex system at broader length scales, the vortices exhibit behavior similar to classical ferroelectrics, forming multiple domain variants. Through the usage of piezoresponse force microscopy and second harmonic generation (SHG) linear dichroism, we can clearly distinguish these ferroelectric domain variants and demonstrate that, on the mesoscale, the overall polarization aligns along the [110]pc axis. Furthermore, by comparing SHG linear dichroism with SHG circular dichroism, we can differentiate how these different ferroelectric domain variants are connected to the chirality of the vortex system, providing a pathway to control the chirality of the vortices using an electric field.

Fluctuating Domain Walls and Morphological Configurations in Chiral Magnetic Systems JeffreyBrock, RubenSaatjian and EricFullerton; University of California-San Diego, United States

The fluctuating nature of magnetic domain morphology transitions has been the subject of intense study, given that such behavior may offer a directly observable means of understanding the physics of underlying magnetic phase transitions. At the same time, stochastic processes in condensed-matter systems have attracted significant interest for neuromorphic computing applications. Recently, we have reported on a domain morphology transition that occurs in the limit of low ferromagnetic exchange stiffness in thin-films with substantial perpendicular magnetic anisotropy and a moderate interfacial Dzyaloshinskii-Moriya interaction [1]. The observed morphological transition was attributed to a severe reduction in the domain wall energy density. Building off these results, we discuss recent work in which we have employed temperature-dependent magneto-optic and AC susceptibility measurements to better understand the

dynamics of this morphological phase transition. Besides temperature-induced changes in the domain periodicity, these measurements have indicated that these systems exhibit two distinct types of temperature-dependent fluctuations – faster-scale fluctuations in the domain wall positions and slower-scale fluctuations in the configuration of the overall domain morphology. While the domain wall fluctuations demonstrate properties of Brownian motion modified by a sporadic pinning potential, the slower-scale morphological fluctuations exhibit characteristics typically ascribed to more solid-like, collective dynamics.

Manipulating Chiral-Spin Transport with Ferroelectric Polarization XianzheChen[1], XiaoxiHuang[1], Zhi(. Yao[2] and RamamoorthyRamesh[1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

A collective excitation of the spin structure in a magnetic insulator can transmit spin-angular momentum with negligible dissipation. This quantum of a spin wave, introduced more than nine decades ago, has always been manipulated through magnetic dipoles, (i.e., time-reversal symmetry). Here, we report the experimental observation of chiral-spin transport in multiferroic BiFeO3, where the spin transport is controlled by reversing the ferroelectricpolarization (i.e., spatial inversion symmetry). The ferroelectrically controlled magnons produce an unprecedented ratio of up to 18% rectification at room temperature. The spin torque that the magnons in BiFeO3 carry can be used to efficiently switch the magnetization of adjacent magnets, with a spin-torque efficiency being comparable to the spin Hall effect in heavy metals. Utilizing such a controllable magnon generation and transmission in BiFeO3, an all- oxide, energy-scalable logic is demonstrated composed of spin-orbit injection, detection, and magnetoelectric control. This observation opens a new chapter of multiferroic magnons and paves an alternative pathway towards low-dissipation nanoelectronics.

9:30 AM EL03.15.03
Novel Magnetic Topological Phases in BFO: A Computational Approach TizianaMusso[1], BinXu[2], YousraNahas[3], SergeiProkhorenko[3], DanielSando[4,1], NagarajanValanoor[1] and LaurentBellaiche[3]; [1]University of New South Wales, Australia; [2]Soochow University, China; [3]University of Arkansas, Fayetteville, United States; [4]University of Canterbury, New Zealand

As one of the most studied room-temperature multiferroics[1], the perovskite compound bismuth ferrite ($BiFeO_3$ - BFO) has intriguing magnetic structures, where a Dzyaloshinskii-Moriya interaction results in complex spin cycloids. BFO's appealing properties are not only photovoltaic, piezoelectric and optoelectronic, as different topological states have been recently found[2]. These particular phases provide a topological protection necessary for information storage technology[3].
In this work, a first-principles-based effective Hamiltonian approach[4] is used, in conjunction with Monte Carlo simulations, to investigate the magnetic properties of BFO under certain constraints.
First, fast quenching simulations of BFO under strain reveal the presence of magnetic antiferromagnetic (AFM) skyrmions, quasiparticles topologically protected that form stable spin textures[5]. The Pontryagin density has been computed to unambiguously identify the topological nature of the obtained swirling field structures[6]. These novel AFM skyrmion patterns have different morphologies and are preferentially located at the ferroelectric domain walls.
Subsequently, the topological structures obtained from cycloids with different initial propagation directions have been investigated, highlighting the interplay between polarization, cycloids and topological magnetic configurations.

Atomistic Polar Topological Structures in Quasi-1D $BaTiX_3$ (X = S, Se) BoyangZhao[1], Gwan-YeongJung[2], HuandongChen[1], GuodongRen[2], ShantanuSingh[1], TieyanChang[3], NickSettineri[4], SimonJ. Teat[4], Yu-ShengChen[3], RohanMishra[2] and JayakanthRavichandran[1]; [1]University of Southern California, United States; [2]Washington University in St. Louis, United States; [3]Argonne National Laboratory, United States; [4]Lawrence Berkeley National Laboratory, United States

Polarization vortices[1] and skyrmions in epitaxial heterostructures[2] arise from boundary condition engineering of ferroelectric materials. Currently, there are no other physical origin for such polar topological structures. In this work, we report the observation of high order ferroic phase transitions in hexagonal quasi-1D chalcogenides, $BaTiX_3$ (X = S or Se) *via* single crystal synchrotron X-ray diffraction. By refining the crystal structure of $BaTiX_3$ at different temperatures, we observe large displacements of Ti in the TiX_6 octahedral of $BaTiX_3$ along and across the quasi-1D chains of TiX_3. $BaTiS_3$ undergoes a series of symmetry defined TiS_6 dipole ordering from a room temperature $P6_3cm$ ferrielectric phase to a charge-density-wave $P3c1$ vortex-anti-vortex phase below ~ 250 K and then transforms into a chiral $P2_1$ phase below ~180 K. While $BaTiSe_3$ shows distinctive ferroic order than $BaTiS_3$, the breaking of the room temperature $P31c$ symmetry is accompanied by emergent correlated disorder ~200K, revealing a longer-range coupling of the ferroic chains in $BaTiSe_3$.
The observation of complex ferroic dipolar ordering in $BaTiX_3$ shows complex high order polar textures can be symmetry driven unlike the ferroelectric heterostructures. We presume the role of multipole interactions as the origin of these emergent polarization textures and note the accessibility of similar structural and electrical characteristics in charge density wave materials such as 1*T*-$TiSe_2$[3] and Ta_2NiSe_5[4]. Our work sets up complex charge density waves with d^0 filling as a playground for realizing and understanding quantum polar topologies.

Symmetry of Charge Density Waves and Response Tensors in AV_3Sb_5 Kagome Metals TuranBirol[1], EthanT. Ritz[1,2] and RafaelFernandes[1]; [1]University of Minnesota, United States; [2]Harvey Mudd College, United States

Space group symmetries and multipole moments allowed by them can be used to predict the macroscopic response of ferroic materials, including ferroelectrics, (anti-)ferromagnets, and multiferroics. In this talk, we apply similar ideas to charge density wave materials with time-reversal symmetry breaking imaginary charge density wave phases. The AV_3Sb_5 (A=K, Rb, Cs) Kagome metals undergo multiple charge density wave transitions in addition to hosting superconducting and topological phases.This charge ordering behavior may involve both bond distortions ("real" charge density waves) and time-reversal symmetry breaking loop currents. In this talk, we classify different charge density wave phases using magnetic space groups and their representations. By studying the allowed elements of various macroscopic response tensors, including piezomagnetic and magneto-optical tensors, we lay out experimental pathways to pin down the symmetry of the charge density wave phases in these systems and possibly observe novel nonreciprocal optical effects. We also comment on the implications of the possible Kerr rotation in Kagome metals.

EL03-virtual

6:30 PM *EL03.16.01
Crafting Novel Low-Symmetry and Topological Structures in Complex Oxide Thin Films Through Anisotropic Epitaxy and Superlattice Engineering NagarajanValanoor[1], DanielSando[2] and LaurentBellaiche[3]; [1]UNSW Sydney, Australia; [2]University of Canterbury, New Zealand; [3]University of Arkansas, Fayetteville, United States

Complex oxide thin films and superlattices provide an exciting playground for exploring and fine-tuning structure-property relationships. By playing with the electrical and mechanical boundary conditions through epitaxial strain, substrate orientation, and superlattice design, completely new phases of these materials – with enhanced or new functionality – are possible. In piezoelectric oxides, for instance, tuning the morphotropic phase boundary by strain offers a route to generating improved electromechanical responses. At the same time, there has been increasing interest in ferroelectric solitons – topologically protected particle-like polarization textures with great promise for beyond-CMOS technologies – which can form in ferroelectric oxide thin films through the competition among various degrees of freedom. However, while polar skyrmions have been extensively studied (e.g., in the $PbTiO_3$-$SrTiO_3$ (STO) system), such polarization textures have scarcely been demonstrated in multiferroics.
In this talk we show that epitaxial strain and orientation engineering, as well as careful control of mechanical and electrical boundary conditions through superlattice design, can be used to craft new phases and topological textures in the popular multiferroic $BiFeO_3$ (BFO). First, using "anisotropic epitaxy" (i.e., growing epitaxial films on extremely vicinal substrates) we create a low-symmetry phase of BFO that acts as a structural bridge between the rhombohedral-like and tetragonal-like polymorphs. Interferometric displacement sensor measurements reveal that this phase has a 2.4x enhanced piezoelectric coefficient compared with typical rhombohedral-like BFO.
Second, by combining BFO with STO in carefully designed superlattices, we demonstrate ferroelectric solitons in this popular multiferroic system. High-resolution piezoresponse force microscopy and Cs-corrected high-angle annular dark-field scanning transmission electron microscopy uncover a zoo of topologies, and polarization displacement mapping of planar specimens reveals centre-convergent/divergent topological defects as small as 3 nm. Phase field simulations reveal that some of these structures can be classed as "bimerons" with a topological charge of ±1, and effective Hamiltonian computations show that the coexistence of such structures can lead to non-integer topological charges, a first observation in a $BiFeO_3$-based system.
Our results once again highlight the versatility and power of epitaxy for the creation of novel phases in oxide thin films, and open new opportunities in multiferroic topotronics.

Investigation of Rare Earth Lean Sm-(Fe,Co)-Mo Alloys for Permanent Magnets YitongXu and GeorgeHadjipanayis; University of Delaware, United States

R-(Fe,Co)-Mo compounds with the $ThMn_{12}$ crystal structure have been studied recently as potential candidates for high-performance magnets, due to their low rare-earth (R) content which are considered as critical elements. The compounds with high Fe content, are expected to be strong magnets, because of their large magnetization M_s, high Curie temperature as well as strong uniaxial magnetocrystalline anisotropy when R=Sm. In this study, bulk alloys with composition $Sm_1Fe1_{0.5-x}Co_xMo_{1.5}$($x$ =0,1,2) were prepared with the tetragonal $ThMn_{12}$ structure. The effects of Co on the magnetic properties, including the Curie temperature, saturation magnetization M_s, anisotropy field, and energy product $(BH)_{max}$, have been investigated. It was found that the Curie temperature shows a linear increase with the Co substitution; also, an increasing Co content increases M_s but decreases the anisotropy field. In order to develop high coercivity, the cast samples were high-energy-ball-milled followed by hot-compaction at 650 °C under 275 MPa. Annealing of compacted samples was done from 700 to 1000 °C to optimize the magnetic properties. Our studies showed that the $Sm_1Fe_{10.5-x}Co_xMo_{1.5}$ alloy with x =1 has a coercivity H_c=2.8 kOe and the highest energy product ($(BH)_{max}$=2.8 MGOe) after annealing at 750 °C for 48 h, marking a 22% enhancement relative to the specimen without cobalt substitution. These properties are attractive for their future development into permanent magnets via sintering.

Surface-Sensitive and Bulk-Suppressed Raman Scattering by Transferable Nanoporous Plasmonic Membranes SebastianHeeg[1], RomanWyss[1,2], GünterKewes[1], MartinFrimmer[2], Karl-PhilippSchlichting[2], MarkusParzefal[2], EricBonvin[2], MartinF. Sarott[2], MorganTrassin[2], LalaHabibova[1], GiorgiaMarcelli[1], MarcelaGiraldo[2], JanVermant[2], LukasNovotny[2] and MadsWeber[3]; [1]Humboldt-Universität zu Berlin, Germany; [2]ETH Zürich, Switzerland; [3]Le Mans Université, France

Raman spectroscopy is a powerful technique to characterize materials. It probes non-destructively chemical composition, crystallinity, defects, strain and coupling phenomena. However, the Raman response of surfaces or thin films is often weak and obscured by dominant bulk signals. Here we overcome this limitation by placing a transferable porous gold membrane (PAuM) on top of the surface of interest. Slot-like nanopores in the membrane act as plasmonic slot antennas and enhance the Raman response of the surface or thin film underneath. Simultaneously, the PAuM suppresses the penetration of the excitation laser into the bulk, efficiently blocking the bulk Raman signal. Using graphene as a model surface, we show that these two simultaneous effects lead to an increase in the surface-to-bulk Raman signal ratio by three orders of magnitude. We find that 90% of the Raman enhancement occurs within the top 2.5nm of the material, demonstrating truly surface-sensitive Raman scattering. To validate our approach, we analyze the surface of a $LaNiO_3$ thin film. We observe a Raman mode splitting for the $LaNiO_3$ surface-layer, which is spectroscopic evidence that the surface structure differs from the bulk. This result underpins that PAuM give direct access to Raman signatures of surfaces and their structural properties.

Ultrafast Activation of Hidden Phases in Antiferroelectrics, Relaxors, Quantum Paraelectrics and Ferroelectric Nanostructures LaurentBellaiche; University of Arkansas, United States

One currently active and exciting research field explores the generation of "hidden" metastable states of matter by ultrafast optical excitation. Such states are referred to as hidden because they are not accessible via the tuning of thermodynamic variables, such as temperature or pressure. Optically-induced ultrafast transitions to hidden states have been found in superconductors (1), colossal magnetoresistance manganites (2), charge-density wave materials (3) and incipient ferroelectrics (4,5). A variety of optical excitation wavelengths have been used to trigger the transition to hidden phases, ranging from visible (3) to mid-infrared (1,2) to THz wavelengths (4,6). In an example most relevant to this Talk, ferroelectricity was induced in the quantum paraelectric $SrTiO_3$ by a THz optical pulse (4). These hidden metastable states often enable physical functionalities that do not exist in the equilibrium thermodynamic phase, such as novel electronic memory concepts (7).

The aim of this Talk is to demonstrate and explain why, via the use of first-principle-based atomistic effective Hamiltonians, that a variety of hidden states can be generated in antiferroelectrics, relaxor ferroelectrics, quantum paraelectrics and ferroelectric nanostructures, when applying THz pulses of electric fields [8]. Such hidden states can be of homogeneous nature in antiferroelectrics [9,10] *versus* of inhomogeneous character in relaxor ferroelectrics [11], while all having enhanced or novel physical properties and being also promising for neuromorphic computing. This talk will also report and discuss the ultrafast formation of ferroelectricity in quantum paraelectrics [12], as well as, of hidden states possessing electric topological defects, such as skyrmions or bubbles, in ferroelectric nanostructures [13].

7:50 PM EL03.16.05
Characterizing Polarization Switching Kinetics of Ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ at Cryogenic Temperature JiachengXu[1], JiajiaChen[1], RongzongShen[1], ChengjiJin[1], MingleiMa[1,2], HaojiQian[1], GaoboLin[1], YianDing[1], YanLiu[1,2], XiaoYu[1] and GenquanHan[1,2]; [1]Zhejiang Lab, China; [2]Xidian University, China

Properties of HfO_2-based ferroelectric at cryogenic temperature (T) are getting significant attention for various applications from high-performance computing to aerospace electronics. In this work, we characterize polarization (P) switching kinetics of $Hf_{0.5}Zr_{0.5}O_2$ (HZO) at cryogenic T down to 100 K. By nucleation limited switching (NLS) model with Lorentzian distribution fittings, the dependences of average switching time ($\log\tau_1$) and switching time distribution (ω) on T are extracted. As the T decreases from 300 K to 100 K, $\log\tau_1$ first rapidly decreases and then gradually stabilizes. Meanwhile, ω exhibits different trends under different applied electric fields (E), decreasing under low applied E while increasing under high applied E, eventually stabilizing at non-zero constants. Leakage, charge de-trapping, and imprint effect measurements are also carried out to reveal the possible mechanisms in the dependence of P switching kinetics on T. It is clarified that the less charge trapped by defects leads to the lower $\log\tau_1$ at lower T while the built-in E and domain wall motion induced by trapped charge result in the change of ω. With the further decrease of T (<100 K), due to the negligible charge trapping effect, $\log\tau_1$ and ω exhibited by HZO are saturated, indicating the intrinsic properties of ferroelectric domains, which are different from the prediction in previous literatures that $\log\tau_1$ and ω will linearly decrease as T decreases.
In this work, titanium nitride (TiN)/HZO(10 nm)/TiN structures are fabricated to study the switching kinetics. Firstly, the leakage measurements were carried out at different T. As the T decreases, the leakage current decreases (3.49×10^{-4}/1.21×10^{-5}/4.70×10^{-6}/2.66×10^{-6} A/cm at 300/200/150/100 K under 3.0 MV/cm, 500 ms pulse), resulting in less trapped charge. Then, after 1000 cycles of triangular waves (±4 MV/cm, 1 kHz) applied to fully release the trapped charge, P–E curves (±4 MV/cm, 1 kHz) at different T are readout for the first time. After a relaxing time (60 s), the P–E curves are readout for the second time. We found that, the shift of coercive E after relaxing (0.442/0.126/0.040/0.002 MV/cm at 300/200/150/100 K) becomes much weak at low T. These results show lower leakage and less imprint at lower T and imply charge trapping effect can be ignored at deep cryogenic T (<100 K).
Finally, the switching kinetics of HZO are measured using a pulse sequence at 300/200/150/100 K. The P variations divided by the spontaneous P ($\Delta P(t)/2P_s$) are extracted under various writing pulses (0.1 μs-1 ms, 0.5-4.0 MV/cm). The NLS model and the Lorentzian distribution are applied to fit all the experimental $\Delta P(t)/2P_s$ data. Lorentzian distribution includes two key parameters, i.e., $\log\tau_1$ and ω, representing the average switching time and half-width of the switching time distribution. For low applied E (1.5 MV/cm), the extracted $\log\tau_1$ and ω at T=300/200/150/100 K are -3.19/-4.66/-4.91/-5.06 s and 1.94/0.84/0.77/0.69, and the extrapolated $\log\tau_1$ and ω at T<100 K stabilize around -5.22 s and 0.60. For high applied E (4.0 MV/cm), the extracted $\log\tau_1$ and ω at T=300/200/150/100 K are -5.69/-5.87/-5.90/-5.90 s and 0.10/0.11/0.13/0.13,and the extrapolated $\log\tau_1$ and ω at T<100 K stabilize around -5.91 s and 0.15.
In summary, with the T decreases from 300 K to deep cryogenic, $\log\tau_1$ first rapidly decreases, attributed to the lower built-in E caused by charge trapping. Then it gradually stabilizes, representing the intrinsic switching speed of ferroelectric domains. ω decreases under low applied E, attributed to the more switching ferroelectric domains caused by the lower built-in E, while it increases under high applied E, due to the domain wall motion. Eventually ω stabilizes at non-zero constants, showing the intrinsic distribution of ferroelectric domains. These phenomena indicate that HZO will exhibit poly crystal properties described by NLS model as T down to deep cryogenic, which is different from the previous predictions.

Improvements in Ferroelectric Properties of $Hf_{1-x}Zr_xO_2$ Thin Film with Rapid Thermal Annealing under Alternating Electric Field ShoTanaka, TakumiHayakawa and MinoruNoda; Kyoto Institute of Technology, Japan

Various methods have been so far investigated to prepare the ferroelectric HfO_2 family film and to improve its properties. The origin of ferroelectricity of HfO_2 is considered to be the metastable orthorhombic phase, where, for example, this phase is thought to evolve during the process of cooling down in rapid thermal annealing (RTA) [1]. The volume fraction of the ferroelectric phase has a large relationship to the value of remanent polarization, so it is important to induce the o-phase as much as possible during the RTA. Regarding this, there are some reports of transformation from paraelectric tetragonal phase to the ferroelectric orthorhombic phase [2]. In this work, we newly propose applying an electric field on a HfO_2 family film during RTA process that would induce more effectively ferroelectric phases by way of field-induced phase transition, as hafnia is in the t-phase at high temperatures [3]. An alternating electric field was applied between a Pt substrate, contacting with a power supply, on the top electrode of HZO film capacitor and its bottom electrode. Hysteresis loops of P-E and J-E were measured at 1 kHz for samples RTA-annealed with and without electric field. The sample annealed with electric field showed nearly no imprint and larger remanent polarization by three times (~15 $\mu C/cm^2$) than that without the field with a rather large imprint. Furthermore, it was noted from our XPS results that not only the phase change but the distribution of oxygen vacancies and/or constituent atoms especially near the film surface and interface at $Hf_{1-x}Zr_xO_2$(HZO)/TiN lower electrode gives influence on the electrical and ferroelectric properties of the HZO film. Finally, we found that the annealing with electric field leads to an enhancement in the ferroelectric o-phase and uniform diffusion of oxygen vacancies.

Enhancing Functionality of Lead-Free Ferroelectric $BiFeO_3$-$BaTiO_3$ based Piezoceramics through Chemical Modification and Site Engineering SrishtiPaliwal, ProsunMondal and AkhileshK. Singh; Indian Institute of Technology BHU, Varanasi, India

The urgent need for lead-free piezoceramics with superior ferroelectric and dielectric properties at high temperatures has spurred extensive research efforts, particularly for demanding environments such as oil drilling, process monitoring, nuclear, and space exploration. Despite the dominance of lead-based piezoelectric ceramics in commercial applications, concerns for the environment and human health necessitate the development of viable alternatives. $BiFeO_3$-$BaTiO_3$ (BF-BT) is one such extensively studied system that has attracted a lot of attention because of its properties like multiferroicity, high Curie temperature etc. In this study, we address this challenge by employing judicious chemical modification to develop two lead-free binary solid-solution of $0.67\{Bi_{1.05}(Fe_{0.97}Ga_{0.03})_{1-x}Sc_xO_3\}$-$0.33(BaTiO_3)$ and $0.67(Bi_{1.05-y}La_yFe_{0.97}Ga_{0.03}O_3)$-$0.33(BaTiO_3)$ with x, y ≤ 0.07, through site engineering and the solid-state route using the air quenching sintering technique. The crystal structure analysis using X-ray diffraction (XRD) data reveals the pure perovskite phase formation. The Rietveld structure refinement confirms the presence of psuedocubic symmetry with space group Pm-3m as the majority phase. Microstructural analysis reveals a homogeneous and dense microstructure with a narrow grain size distribution of less than 3 μm. The temperature dependent dielectric studies show strong frequency dependence of the dielectric constant resulting in diffuse phase transition peaks which indicates the relaxor ferroelectric behavior. In addition, the small grain size, low remnant polarization and coercive field values also confirm the relaxor like behavior for both systems. Furthermore, the dielectric peaks maxima temperature (T_m) shift to lower temperature side on increasing concentration of Sc^{3+}. The freezing temperature (T_F) of ~ 633K was obtained for x=0.07 while T_F follows an upward trajectory as accounted by the Vogel-Fulcher model, with the highest point observed at around 551 K for the composition containing y=0.07. In contrast, the activation energy exhibits a contrasting pattern, gradually decreasing from about 0.61 eV to 0.07 eV. The synthesized materials display promising characteristics, including remnant polarization ranging from 2Pr~ 8-55 $\mu C/cm^2$) and coercive field (Ec) ranging from 2Ec~ 27-91 kV/cm among different compositions. Improved resistivity on the order of 1010 was observed in leakage current measurements under an applied field of 1 kV/cm. Notably, the dielectric permittivity corresponding to peaks at 10 kHz experienced a remarkable boost from 4100 to 21832 as the concentration of La doping increased from 1 mol% to 7 mol%. These findings highlight the enhanced functional attributes and temperature stability achieved through site engineering, paving the way for the development of lead-free piezoceramics with enhanced performance in a wide range of industrial applications requiring reliable operation under harsh conditions.

8:25 PM EL03.16.08
Giant Electromechanical Response from Defective Non-Ferroelectric Epitaxial $BaTiO_3$ Integrated on Si (100) SandeepVura[1], ShubhamK. Parate[1], SubhajitPal[2], UpanyaKhandelwal[1], RajeevKumar Rai[3], Sri HarshaMolleti[1], VishnuKumar[1], Rama SatyaSandilya[1], GirishPatil[1], MuditJain[1], AmbreshMallya[1], MajidAhmadi[4], BartKooi[4], SushobhanAvasthi[1], RajeevRanjan[1], SrinivasanRaghavan[1], SaurabhChandorkar[1] and PavanNukala[1]; [1]Indian Institute of Science Bangalore, India; [2]Queen Mary University of London, United Kingdom; [3]University of Pennsylvania, United States; [4]University of Groningen, Netherlands

Recently giant electromechanical (EM) responses have been observed in several defective systems due to the formation of site deficiency which is obtained either by creating geometrical or compositional modification. The idea of obtaining a giant EM response in the defective system gained tremendous attention owing to the observation of d_{33} value of ~200,000 pm/V even in centrosymmetric gadolinium-doped CeO_{2-x} films at milli Hz frequency owing to the mass migration of point defects under application of electric field leading to a local structural change from a cubic to tetragonal. Since large range motion of ions results in large EM response in Gd:CeO_2, its EM response is confined to very low frequency (~milli Hz). This response degrades to 25000 pm/V at 100 Hz and beyond that the response is almost zero, with different defect-induced mechanisms at play in different frequencies. Here we demonstrate silicon compatible Barium Titanate (BTO) system that shows an equivalent large electromechanical response at much higher frequencies (>1 kHz). These films are Barium and oxygen-deficient nature as revealed from XPS and TEM studies. X-ray Diffraction shows that the thermal expansion coefficient of these defective films is 3×10^{-5} (K^{-1}) one of the highest reported. We measure out-of-plane displacement while applying in-plane field using Laser Doppler Vibrometry (LDV) and report highest second order effective M_{31} (of the order 10^{-14} $(m/V)^2$)for any material at high frequencies (>1000 Hz). We further performed small signal and large signal impedance measurements and correlate them with our structural data from TEM and XRD. Through simulations, we assess the effects of joule heating in mechanical displacements and attribute the rest to defect-based electro-strictive behavior.

8:40 PM EL03.16.09
A ReaxFF Reactive Force Field for Studying Ferroelectricity in Mg-Substituted ZnO AlirezaSepehrinezhad and AdriVan Duin; Penn State, United States

Ferroelectric materials have emerged as a pivotal component in the realm of microelectronic devices, owing to their unique properties including robust spontaneous polarization, piezoelectric

and pyroelectric effects, and large dielectric constants. These materials have been used in nonvolatile memories, transducers, capacitors, and photovoltaic devices. Application of conventional perovskite ferroelectrics, however, faces prohibiting factors such as incompatible windows for synthesis and difficulties in scaling below 100nm. These limitations inspire looking beyond perovskite thin films. Recent research has attracted attention to the *Ferroelectrics Everywhere* hypothesis in the development of modern ferroelectrics. This hypothesis suggests that, in principle, one can observe ferroelectric behavior by distorting a polar structure through cation substitution, as long as the polar axes are re-orientable under an external electric field. In this study, we aim to demonstrate ferroelectricity in Mg-substituted ZnO slabs using the ReaxFF reactive force field. Specifically, we develop a ReaxFF reactive force field and utilize MD simulations to investigate reaction dynamics for $Zn_xMg_{1-x}O$ (ZMO). To develop the force field, we fit the force field parameters to a training set of data points from DFT calculations. The data points have been chosen to provide adequate descriptions of the phase transition path in ZnO. We then evaluate our force field against equations of state (compression and expansion) of ZMO from DFT derived data. The results show a strong agreement between DFT reference data and ReaxFF predictions. We then use the force field in NPT MD simulations to investigate ferroelectricity in the presence of an external electric field. Our findings show that Mg-substitution enables polarization reversal through lowering the coercive field. Specifically, an increase in Mg percentage consistently results in a decrease in coercive field. Moreover, we observe that coercive field magnitude in ZMO is strongly dependent to the temperature. In all cases, an increase in temperature is followed by a sharp drop in the coercive field. These findings would not only support the hypothesis of *Ferroelectrics Everywhere*, but also motivates how tunable ferroelectric properties of ZnMgO could be utilized in future applications.

Interfacing Neuronal Tissue with 3D Electrodes AndreasOffenhaeusser[1], JamalShihada[1,2], MarieJung[1,2], SimonDecke[1,2] and VivianaRincon Montes[1]; [1]Forschungszentrum Julich, Germany; [2]RWTH Aachen University, Germany

Neuronal signals obtained from 3D neural tissue using various - in vitro or in vivo - approaches lack the spatial resolution and high signal-to-noise ratio (SNR) required for a detailed understanding of neural network function and synaptic plasticity. To overcome these limitations, we used a highly customizable 3D printing process in combination with thin film technology and templated assisted electrodeposition to fabricate 3D-printed based microelectrode arrays on stiff and flexible substrates. We show devices with design flexibility and physical robustness for recording neural activity in different in vitro and in vivo applications: our microelectrode arrays successfully recorded neural activity in 3D neuronal cultures, retinal explants, and the cortex of living mice, thereby demonstrating the versatility of the 3D microelectrode platform while maintaining high-quality neural recordings. Customizable 3D microelectrode arrays provide unique opportunities to study neural activity under regular or various pathological conditions, both in vitro and in vivo, and contribute to the development of drug screening and neuromodulation systems that can accurately monitor the activity of large neural networks over time.

9:15 AM EL04.01.02
Three-Dimensional MnO2 Nanoflowers Integrated into Flexible Optoelectronic Biointerfaces for Safe and Effective Neuronal Photostimulation LokmanKaya[1], OnuralpKaratum[1], RidvanBalamur[1], Humeyra NurKaleli[1], AsimOnal[1], Sharadrao A.Vanalakar[2], MuratHasanreisoglu[1] and SedatNizamoglu[1]; [1]Koç University, Turkey; [2]Shivaji University, India

The utilization of optoelectronic biointerfaces for wireless and electrical control of neurons has garnered significant interest, particularly in the field of photovoltaic retinal implants. Three-dimensional pseudocapacitive nanomaterials with porous structures and large surface areas hold high promise for developing efficient optoelectronic biointerfaces that can effectively convert light into stimulating ionic currents because of their high electrode-electrolyte capacitance. In this study, we present the successful integration of flexible optoelectronic biointerfaces with three-dimensional manganese dioxide (MnO2) nanoflowers, enabling the achievement of safe and effective photostimulation of neurons. The synthesis of MnO2 nanoflowers involves a chemical bath deposition process on the return electrode, initially coated with a MnO2 seed layer using cyclic voltammetry. The resulting nanoflowers exhibit remarkable interfacial capacitance (>10 mF.cm-2) and photogenerated charge density (>20 μC.cm-2) even at low light intensity (1 mW.mm-2). Significantly, the MnO2 nanoflowers facilitate the generation of safe capacitive currents through reversible Faradaic reactions and exhibit no toxicity towards hippocampal neurons in vitro, making them a highly promising material for seamless biointerfacing with electrogenic cells. The functionality of the developed optoelectronic biointerfaces is validated through patch-clamp electrophysiology recordings conducted on hippocampal neurons in the whole-cell configuration and we observed repetitive and rapid firing of action potentials in response to light pulse trains. This study demonstrates the vast potential of electrochemically-deposited three-dimensional pseudocapacitive nanomaterials as a robust and versatile nanotool for optoelectronic control of neurons.

Ultra Low Impedance PEDOT:PSS Neural Electrode Array for Simultaneous Two Photon Imaging and Electrophysiology Analysis Hyun WooKim, Young UkCho and Ki JunYu; Yonsei University, Korea (the Republic of)

Understanding the intricate mechanisms of information processing in the brain requires precise electrophysiology recordings at the resolution of action potentials. Recent progress in optical technologies, notably the advancements in multi-photon microscopy, have brought about a paradigm shift in our capacity to observe and analyze neuronal activity. Integration of optical methodologies with electrical recordings assumes a crucial role in bridging the knowledge gap between animal models and human studies, which heavily rely on electrophysiological evaluations of brain activity. Nonetheless, this integration encounters obstacles such as the emergence of light-induced artifacts and the requirement for neural electrodes with low impedance. To address these challenges, we present transparent a poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate)(PEDOT:PSS)-based neural interface array. This PEDOT:PSS neural array merges transparency, adaptability, and biocompatibility facilitating simultaneous acquisition of local field potentials (LFPs) and action potentials from superficial cortical neurons. By utilizing a flexible polyethylene terephthalate (PET) substrate, we enhance the convenience of electrocorticography (ECoG) measurements while maintaining a cost-effective and straightforward manufacturing process.

Transparent PEDOT:PSS electrode array ensure the integration of two-photon microscopy and ECoG recordings within a single in vivo experiment. To further enhance the functionality of the PEDOT:PSS electrode array, we have analyzed the charge transfer enhancement mechanism and developed a three-step post-processing technique. This technique effectively reduces the impedance of the electrode to an impressive value of 5.8 kΩ (at lkHz) for a 50 × 50 μm*μm electrode surface area without the use of traditional metal components. The transparent, low impedance PEDOT:PSS microelectrode array allows for depth-resolved two-photon imaging below the cortical surface, while simultaneous recordings of LFPs from the cortical surface and neuronal calcium activity provide a comprehensive understanding of neural dynamics. Our PEDOT:PSS electrode array offers a platform for integrating optical modalities with electrophysiology, enabling a wide range of experimental possibilities. The successful integration of diverse in vivo optical imaging and electrical recording with PEDOT:PSS electrode recordings exemplifies the versatility of this technology. Whether applied to depth-resolved two-photon imaging or the chronic monitoring of LFPs and action potentials of cortical neurons, our PEDOT:PSS electrode array offers a seamless and non-invasive solution that contributes to the advancement of our comprehension regarding brain function. These findings highlight the potential of our PEDOT:PSS microelectrode array as a effective tool for seamless and artifact-free integration of optical and electrical modalities, opening new avenues for comprehensive neuroscience research.

Organic Bioelectronic Circuits and Artificial Neurons for Biosensing and Biointerfacing FabrizioTorricelli; University of Brescia, Italy

Organic bioelectronics based on organic mixed ionic-electronic materials and devices, can enable the direct communication and interfacing with ions, biomolecules, soft tissues, cells, and organs in the aqueous biological environment, opening opportunities for in-vitro and in-vivo applications. [1]
This talk will present emerging organic bioelectronics including technologies, devices and integrated architectures for enhanced applications. Starting from the fundamental properties of device operating principles and integrated bio-circuit configurations,[2,3] the talk will seamlessly move to a large set of applications including (i) multiscale ion detection,[4] (ii) selective multi-bio-marker detection at the single-entity limit,[5,6] (iii) real-time monitoring of cell layer integrity and tight junction modulation,[7] and (iv) artificial spiking neurons with electrobiochemical degrees of control for in situ neuromorphic sensing and biointerfacing.[8]
The talk will show the key achievements of a beautiful journey that I am doing with various multidisciplinary and geographically-distributed research groups, highlighting possibilities for next-generation multifunctional bioelectronics and neuromorphic bio-interfacing.

Enzymatic Polymerization of Thiophene-Based Oligomers for Soft Bioelectronic Interfaces XenofonStrakosas; Linkoping University, Sweden

The field of Bioelectronics aims to integrate electronics and biology, offering promising opportunities in various domains. However, a major hurdle in this field is the mechanical mismatch between rigid electronics and the soft nature of living tissues. To overcome this challenge, soft and flexible bioelectronic devices are being developed using microfabrication and printing techniques. Alternatively, biological processes polymerize small molecules to create intricate micromachines. Inspired by these biological processes, we utilize of thiophene-based oligomer building blocks and enzymatic processes for in vivo polymerization of organic conductors. By harnessing the advantages of this approach, we successfully achieved the in-situ formation of conducting polymer gels within living organisms. These gels exhibited soft mechanical properties that closely resemble those of natural tissues. Furthermore, we demonstrated the enzymatic construction of organic conductors in various tissues and their application as active materials in organic transistors. Our approach offers a solution to the limitations of conventional methods, providing opportunities for the development of novel, soft, and bio-compatible electronic interfaces. This advancement in Bioelectronics opens avenues for healthcare, bioengineering, and beyond.

11:15 AM EL04.01.07
Kirigami Electronics for Long-Term Electrophysiological Recording of Human Neural Organoids and Assembloids XiaoYang, CsabaForro, ThomasLi, YukiMiura, TomaszZaluska, Ching-TingTsai, SabinaKanton, JamesMcQueen, XiaoyuChen, SergiuPasca and BianxiaoCui; Stanford University, United States

Human stem cell-based organoids and assembloids have emerged as a promising platform to model aspects of nervous system development. Long-term, minimally invasive recordings in these three-dimensional (3D) multi-cellular systems are essential for developing disease models. Current technologies, such as patch clamp, penetrating microelectrodes, planar electrode arrays and substrate-attached flexible electrodes, do not, however, allow chronic recording of neural organoids in suspension, which is necessary to preserve their 3D architecture. Here, inspired by the art of kirigami, we develop flexible electronics that transition from a flat 2D pattern to a 3D basket-like configuration to accommodate the long-term culture of human neural organoids in suspension. We show that this novel platform named kirigami electronics (KiriE) integrates with and enables chronic recording of intact cortical organoids for 170 days while preserving their morphology, cytoarchitecture and cell composition. KiriE can be integrated with optogenetic and pharmacological stimulation and detect a disease-related hyperactive phenotype. Moreover, KiriE is compatible with simultaneous recordings from organoids in assembloid and can capture activity in emerging cortico-striatal circuits. Moving forward, this flexible electronics system could reveal disease phenotypes and the patterns of activity underlying the assembly of the nervous system.

11:30 AM EL04.01.08
High Aspect Ratio Au Nanotubes in Soft Bioelectronics YuyangLi and KlasTybrandt; Linköping University, Sweden

Soft bioelectronics offer a promising flexible and stretchable platform to engineer biomedical devices in healthcare applications, such as wearable health tracker, chronic neural interface probes, implantable electrophysiological sensors, electrical stimulator, etc. Much effort in decades has been devoted in materials science to the design of reliable soft bioelectronics. Typical flexible and stretchable devices utilize elastic polymers as substrate that are well conformable with human tissues, and fillers of conductive nanomaterials like carbon nanotubes (CNTs), Ag nanowires (NWs). These one-dimensional (1D) nanowires are proved to form highly percolated networks in the substrate, providing outstanding thermal, electrical, and mechanical properties. Of which Ag nanowires with high aspect ratio are easily accessible by facile large scale synthesis method. Up to now, Ag nanowires is one of the most popular materials as conductive fillers. Despite all of that, concerns of long-term biocompatibility hover around due to toxic Ag ions leaching from Ag nanowires-based devices, same on carbon nanotubes with plumonary toxicity. Researchers have turned to search for materials with high biocompatibility as well as uncompromised electromechanics properties.
Alternatively, Au nanomaterials show excellent optical-electrical properties and biological inertness. For instance, Au nanoparticles or nanorods could be obtained by well-developed synthetic routes, being applied in many biomedical applications such as cancer therapy, cell imaging, biosensing. Whereas, due to the low aspect ratio and poor percolation of Au nanoparticles, there is limited use in bioelectronics. The major challenge is that the insufficient conventional methods of synthesizing one-dimensional (1D) Au nanomaterials. The procedures are tedious for many

days with low yield, and includes toxic direction growth agent such as hexadecyltrimethylammonium bromide (CTAB), besides further purification needed to separate byproducts of nanoparticles and nanorods. The yielded Au NWs has limited aspect ratio, far less than that of Ag NWs. All these factors hinder the research and development of 1D Au nanomaterials based soft bioelectronics. Here we present a facile, large-scale, low-cost aqueous method to synthesis high aspect ratio Au nanotubes with controllable surface morphologies. It paves the way for future design and application of soft bioelectronics with high biocompatibility and electrical performance based on one-dimensional (1D) Au nanomaterials.

11:45 AM EL04.01.09
Self-Adhesive Organic Thin Film Transistors on Elastomeric Nanofilms ChikaOkuda, SunghoonLee, TakaoSomeya and TomoyukiYokota; University of Tokyo, Japan

Devices that can be intimately contacted with our skin are increasingly gaining attention because of their huge potential in collecting long-term vital data for future healthcare, nursing, or sports activities. One of the key components is flexible or stretchable transistors, since they are necessary for signal amplification close to the body [1], or sensor matrixes to collect spatial data [2]. Flexible transistors in ultrathin form, especially below few-100 nm-thick, can conform to the complex shape of the skin surface [3], whereas thicker elastomeric transistors can also attach to the skin by their elastomeric property. Although these devices can contact well to the human skin, stability of the device-skin contact and robustness needed improvement in order to achieve long-term signal collection. Nanofilms, which are below few-100 nm thick and are made of elastomeric materials, have shown sufficient stability of the device-skin contact and robustness to be worn on skin for over a week [4]. These elastomeric nanofilms has become a candidate for wearable devices' interface, but only electrodes have been fabricated on them. Fabrication of transistors on them has remained a challenge, due to difficulty in handling and physical damages that occur during the fabrication.

In this work, we report novel device structure and process of organic thin film transistors (OTFT) on elastomeric nanofilms. Total device thickness is only 0.5 μm, enabling the devices to have stable contact on any parts of the body. The substrate film is ultrathin with average thickness of ~200 nm, enabling the film to be self-adhesive requiring ~130 μJ/cm^2 for detachment from artificial skin. This film was fabricated by dip-coating electrospun polyurethane nanofibers into polydimethylsiloxane solution, according to ref.3. The fiber-reinforced structure enhances the robustness of the film. The film was then placed onto a flexible supporting substrate with release agent. Bottom gate was formed by thermally evaporating gold (50 nm) through a shadow mask, followed by chemical vapor deposition of parylene (200 nm) as the dielectric layer. Subsequently, organic semiconducting layer of dinaphthothienothiophene (DNTT) (30 nm) and gold contact electrodes (50 nm) were formed by thermal evaporation. Finally, OTFTs on nanofilms were delaminated manually from the supporting substrate to become free-standing state.

The fabricated transistors exhibited electrical characteristics comparable to those fabricated on conventional substrates. They showed excellent yield of 75/77, with mobility of 0.19 ± 0.02 cm^2/Vs and maximum on/off ratio of above 10^5. To demonstrate stability, devices were laminated and then delaminated from a glass substrate, which showed negligible effect on the electrical characteristics.

Wearable Ultrasound Technologies for Continuous Deep Tissue Monitoring ShengXu; University of California, San Diego, United States

The use of wearable electronic devices that can acquire vital signs from the human body noninvasively and continuously is a significant trend for healthcare. The combination of materials design and advanced microfabrication techniques enables the integration of various components and devices onto a wearable platform, resulting in functional systems with minimal limitations on the human body. Physiological signals from deep tissues are particularly valuable as they have a stronger and faster correlation with the internal events within the body compared to signals obtained from the surface of the skin. In this presentation, I will demonstrate a soft ultrasonic technology that can noninvasively and continuously acquire dynamic information about deep tissues and central organs. I will also showcase examples of this technology's use in recording blood pressure and flow waveforms in central vessels, monitoring cardiac chamber activities, and measuring core body temperatures. The soft ultrasonic technology presented represents a platform with vast potential for applications in consumer electronics, defense medicine, and clinical practices.

2:00 PM EL04.02.02
A Fully Integrated Wearable Ultrasound System to Monitor Deep Tissues in Moving Subjects MuyangLin, ZiyangZhang, XiaoxiangGao and ShengXu; University of California, San Diego, United States

Medical ultrasound is a powerful diagnostic and evaluation tool in hospitals and clinics due to its safety and versatility. Traditional ultrasound suffers from operator dependency and does not allow long-term usage. Recent advances in wearable ultrasound technologies have demonstrated the potential for hands-free data acquisition, but technical barriers remain as these probes require wire connections, can lose track of moving targets, and create data-interpretation challenges. Here we report a fully integrated autonomous wearable ultrasonic-system-on-patch (USoP). A miniaturized flexible control circuit is designed to interface with an ultrasound transducer array for signal pre-conditioning and wireless data communication. Machine learning is used to track moving tissue targets and assist the data interpretation. We demonstrate that the USoP allows continuous tracking of physiological signals from tissues as deep as 164 mm. On mobile subjects, the USoP can continuously monitor physiological signals, including central blood pressure, heart rate, and cardiac output, for as long as 12 h. This result enables continuous autonomous surveillance of deep tissue signals toward the internet-of-medical-things.

2:15 PM EL04.02.03
Conformable Ultrasound Patch for Cavitation Enhanced Transdermal Cosmeceutical Delivery AasthaShah and CananDagdeviren; Massachusetts Institute of Technology, United States

Increased consumer interest in healthy-looking skin demands a safe and effective method to increase transdermal absorption of innovative therapeutic cosmeceuticals. However, permeation of small-molecule drugs is limited by the innate barrier function of the stratum corneum. Here, we report a conformable ultrasound patch (cUSP) that enhances transdermal transport of niacinamide by inducing intermediate-frequency sonophoresis in the fluid coupling medium between the patch and the skin. The cUSP consists of piezoelectric transducers embedded in a soft elastomer to create localized cavitation pockets (0.8 cm^2, 1 mm deep) over larger areas of conformal contact (20 cm^2). Multiphysics simulation models, acoustic spectrum analysis and high-speed videography are used to characterize transducer deflection, acoustic pressure fields and resulting cavitation bubble dynamics in the coupling medium. The final system demonstrates a 26.2-fold enhancement in niacinamide transport in a porcine model *in vitro* with a 10-minute ultrasound application, demonstrating suitability of the device for short-exposure, large-area application of sonophoresis for patients and consumers suffering from skin conditions and premature skin aging.

Mapping the Human Brain with High Spatiotemporal Resolution ShadiA. Dayeh; University of California, San Diego, United States

Electrophysiological recording and stimulation are the gold standard for interrogating the nervous system for diagnostic and therapeutic purposes. Recording the human brain activity with microelectrode arrays enable broadband and high spatiotemporal resolution but are conventionally limited to a small cortical coverage. However, large cortical coverage together with the high spatiotemporal resolution are needed to advance our understanding of diseased and normal brain function to be able to develop effective therapies.
This talk will cover the challenges and latest developments in brain mapping and discuss the clinical translation of UCSD's multi-thousand channel platinum nanorod surface and depth microelectrode arrays to map the human brain activity. We will discuss considerations in the electrode-tissue interface for recording and stimulation and demonstrate mapping of functional units (cortical columns) across species including humans. Examples of large-scale microelectrode mapping of motor, language, and epileptogenic discharges from the human brain will be presented along with a perspective on future directions. Lastly, we will present the display of cortical activity directly from the surface of the human brain with the newly developed Brain-

intracranial electroencephalography-microdisplay (Brain-iEEG-microdisplay).

3:30 PM *EL04.02.05

Enhanced Photodetection and Resistant Switching in CVD Grown MoS_2: A Potential Neuromorphic Photo-memristor PukhrajPrajapat[1,2] and GovindGupta[1,2]; [1]National Physical Laboratory, India; [2]Academy of Scientific & Innovative Reserach, India

The rapid development of neuromorphic computing has stimulated the research of novel materials and technologies to emulate the remarkable capabilities of the human brain. Two-dimensional transition metal dichalcogenides (2D-TMDs) have become interesting options in this scenario because of their distinctive electrical and optical characteristics. For its potential use in photodetection and memristive devices, molybdenum disulfide (MoS_2) has drawn much attention among them. MoS_2 is a viable material for future neuromorphic computing systems due to its unique qualities, which include its effective light-matter interaction, atomically thin structure, and customizable electrical characteristics. To establish an approach for advancing a neuromorphic photo-memristor, we examine the few layers of growth of MoS_2 using CVD and explore the potential for boosted photodetection and resistive switching. Photoluminescence and Uv-Visible spectroscopy were used to characterize the optical characteristics of MoS_2, which demonstrated its potent excitonic emission and tunability concerning the number of atomic layers. The effective charge separation and transport in the atomically thin MoS_2 channel are responsible for the extraordinary photoresponsivity and low dark current displayed by the fabricated MoS_2 photodetectors. The enhanced photodetection performance was further demonstrated by measuring the responsivity under different light intensities (15mW to 2.85mW) and 532 nm wavelength. Additionally, the resistive switching behavior of MoS_2 was examined, which revealed potential memristive properties. The Au/ MoS_2/Au device exhibits typical bipolar switching behavior with a low working voltage, extended retention time, high resistance ratio (~103), and strong endurance (104 cycles), which has enormous potential for neuromorphic computing applications. The analysis revealed the possibility of producing energy-efficient, brain-inspired computing platforms thanks to the integration of photodetection and resistant switching in a single chip.

Investigation of Opto-Electrical, Mechanical and Surface Properties of AgNWs-PEDOT: PSS Based Transparent and Conductive Electrodes for Bio-Sensing Applications JostinV. Dcosta, SebastienSanaur and DanielOchoa; École des Mines de Saint-Etienne, France

Ultra-flexible organic photodetectors (OPDs) have experienced a rapid development in recent years, making them increasingly significant in the field of flexible electronics, wearable technology and medical applications. They have emerged as promising optoelectronic devices for several applications including biosensing. For example, OPDs in the field of biosensing are used to monitor vital signs such as, heart rate, oxygen saturation and blood glucose levels. When fabricated on ultrathin flexible substrates organic photodetectors provide conformal surface contact thus allowing for efficient light absorption and detection, thereby enhancing the sensitivity and the performance.
Transparent conductive electrodes (TCEs) are considered to be one of the most crucial components in OPDs as they play a significant role in improving their efficiency as they effectively take part in light transmission and charge extraction. Typically, TCEs are designed to exhibit high transparency in the visible spectrum thus allowing the incoming light to pass through them with minimum loss. The flexible nature of the TCEs will allow for the conformal contact on to curved or flexible substrates and thus allows the seamless integration of OPDs with biological tissues enabling for the continuous and real-time monitoring of the physiological parameters.
Among the various available materials, one dimensional AgNWs are perceived as a promising candidate for TCEs for flexible OPDs due to some of their remarkable properties such as low percolation threshold, high electrical conductivity, high optical transparency and excellent flexibility. However, their long-term stability is still challenging as AgNWs are susceptible to oxidation thus limiting their reliability in flexible devices. Hence to solve this issue the combination of AgNWs with conducting polymers such as poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT: PSS) as transperent hybrid electrode has been explored. PEDOT: PSS alone offers excellent chemical stability and can therefore further contribute to the stability of AgNWs by preventing from oxidation, thus maintaining the overall integrity of the film from various environmental degradation conditions. Moreover, the hydrophobic properties of PEDOT: PSS helps to shield the AgNWs from the detrimental effects of moisture such as oxidation and loss in electrical conductivity. Additionally, PEDOT: PSS when incorporated in AgNWs will help to reduce the interfacial resistance between the nanowires thus help in the overall stability and electrical conductivity of the film.
In this work, we have investigated the opto-electrical, mechanical and surface properties of silver nanowires/poly (3,4-ethylenedioxythiophene): poly(styrenesulfonate) (AgNWs-PEDOT: PSS) hybrid electrode fabricated on 5-µm ultrathin parylene C substrate. The fabricated electrode exhibits low sheet resistance of 27 Ω/Sq, and shows an average optical transmission of >85% throughout the visible spectrum which is suitable for optoelectronic applications. Besides the comparable work function of 5 eV with respect to standard ITO, the surface rms roughness of the electrode is effectively reduced from 8 nm to 4 nm by spin coating PEDOT: PSS as planarization layer. With a stable R/R0 ≈1 over continuous 50k bending cycles at a radius of curvature of 0.1 mm, the electrode exhibits excellent mechanical characteristics suitable for ultraflexible and wearable applications. Utilizing this electrode, we have realized an ultraflexible organic photodetector that can be conformally adhere to human skin for biosensing applications. The OPD is fabricated in normal atmospheric conditions that can withstand 5k bending cycles when bent at a radius of curvature of 0.2 mm while maintaining similar values in ON/OFF ratio under white light illumination.

4:15 PM EL04.02.07

Intrinsically Stretchable Transistor Array Based on Pure Liquid Metal Electrodes for Biophysical Signal Monitoring on Skin SeungkyuLee, Do HoonLee and SteveePark; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The human perception of auditory, tactile, and visual information is transformed into electro-physiological signals and transmitted to the brain, which processes these complex signals simultaneously. The development of electronic devices composed of intrinsic stretchable materials is essential to achieve seamless integration with the human skin and possess mechanical properties for human-machine interactions. The proposed research focuses on a stretchable transistor array, which consists of a flexible material-based output device and electronic circuits, providing opportunities for human-machine interaction.
This research can be explained from three aspects: process and fabrication, measurement characteristics, and applications. Firstly, from the perspective of process and fabrication, liquid metals can exist in a liquid state at room temperature due to their low melting points and can exist as very small particles (spherical). They possess intrinsic flexibility and high electrical conductivity due to being metallic. The particle size is around 2-3 µm, the flexibility is 300%, and the electrical conductivity is 3.4 x 10^6 S/cm. Coating pure liquid metals in film form on hydrophobic substrates is challenging due to their high surface tension. In this study, liquid metal particles are dispersed in two different hydrophilic solvents with different boiling points, and then coated on the substrate using the Marangoni flow principle. The boiling point of deionized water is 100 degrees Celsius, and the boiling point of ethyl acetate is 77.1 degrees Celsius. In the patterning of liquid metals through photolithography, the most crucial step is the etching process. To break the bonding between the thin metal oxide layer (approximately 5 nm) surrounding the liquid metal particles and the hydrophobic substrate, wet etching is conducted using an SC-2 (hydrochloric acid + hydrogen peroxide) solution. This is because gallium, which constitutes most of the liquid metal, is a metal and is etched by the reaction of hydrogen peroxide and hydrochloric acid. The resolution is <5 µm, and transistors using s-CNT (single-walled carbon nanotubes) and SEBS H10152 will be fabricated.
From the perspective of measurement characteristics, a comparison will be made with previously reported stretchable transistors. The ultimate goal is to achieve a transistor device with an on/off ratio of 10^5, an operating voltage of ~1V, a carrier mobility of 0.9 cm^2/Vs, and maximum stretchability of 200%. Due to its high resolution, this transistor device is expected to be the smallest among the reported ones, enabling highly integrated mass production. It is also expected to have the advantage of low power consumption from an energy consumption perspective. Lastly, from the perspective of applications, the fabricated stretchable transistor array is highly flexible and can be attached to the skin. Its array characteristics will be verified for complex tasks such as signal processing, involving very small electro-physiological signals. Monitoring the electro-physiological signals of the stretchable transistor device enables applications in health monitoring, medical treatments/implants, etc. The intrinsic liquid metal-based stretchable transistors allow for the processing of weak electro-physiological signals (in the sub-millivolt range) with minimal interference from skin or tissue deformation. They enable the conversion of spike signals into analog-to-digital signals, enabling signal processing.

4:30 PM EL04.02.08

Fiber-Type Neural Probe with Balanced Mechano-Electrical Properties for Prolonged Electrophysiological Brain Signals Recording ChihyeongWon[1], Ui-JinJeong[2], Il-JooCho[3] and TaeyoonLee[1]; [1]Yonsei University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Korea University, Korea (the Republic of)

Implantable neural probes that are inserted into the brain tissues are widely used in brain-machine interfaces (BMIs) for the analysis of brain circuits. They are implanted into specific brain regions such as Thalamus and Cerebellum, that generate neural signals related to electrophysiological information. Recently, flexible neural probes are developed to minimize the damage to brain tissues and nerves for reducing foreign body responses (FBRs) in the brain. To prevent FBRs between the probes and brain tissues, mechanical properties such as bending stiffness and Young's modulus of devices should be well matched with that of the brain. However, conventional flexible neural probes using a silicon substrate still induce damage in the brain due to their even high Young's modulus (> 1 MPa) than that of the brain (~ 1.8 kPa). Furthermore, the electrical properties of the devices such as conductivity and impedance could be deteriorated by focusing on only matching mechanical properties between the probes and the brain. Herein, we fabricated Au nanoparticles (AuNPs) embedded fiber-type neural probes with balanced mechanical and electrical properties for a long-term measuring brain signals. The fiber-type neural probe was fabricated by controlling the distribution of Au ions in polymeric networks to using osmotic pressure. After the Au ions were converted into AuNPs by the reducing agent, A core of the fiber-type neural probe was still remained as an original elastomer, and the AuNPs were formed on the exterior of the fiber. The proposed fiber showed remarkable electrical properties, including high conductivity (7.68×10^4 S/m) and low impedance (2.88×10^3 W at 1 kHz). In addition, the fiber exhibited brain tissue-like mechanical properties such as low Young's modulus (170 kPa) and low bending stiffness (22.2 N m^{-1}). We could successfully measure various electrophysiological signals from a mouse brain using a brain chip containing the developed fiber-type neural probe. Additionally, the fiber-type neural probe exhibited significantly reliable signal recording with an impedance of under 4 kW at 1 kHz over four months post-implantation with negligible FBRs in the brain. We suggest that the developed fiber-type neural

probe could be a crucial role in the field of neurological sciences and BMIs for understanding the mechanism of brain circuits and developing electronic devices in the treatment of chronic diseases.

4:45 PM EL04.02.09

A Perovskite Nanowire Array Based Spherical Bionic Eye with Filter-Free Color Vsion, In-Device Neuromorphic Signal Preprocessing and Adaptive Optics ZhenghaoLong and ZhiyongFan; The Hong Kong University of Science and Technology, Hong Kong

Bio-inspired vision systems that utilize curved detector geometry have the potential to create miniaturized cameras with a wide field of view and low aberration. Nonetheless, integrating color vision, in-device signal preprocessing, and adaptive optics into spherical artificial eyes has always been a challenge. Herein, we developed a bionic eye that integrates all of the above functions. The device contains a hemispherical artificial retina and an optical sub-system.
The artificial retina is based on a hemispherical perovskite nanowire array, which possesses in-device color distinguishing and neuromorphic preprocessing abilities. The device structure incorporates a SnO_2/NiO double-shell nanotube filled with ionic liquid in the core, which is located on top of a $CsPbI_3$/NiO core-shell nanowire. It has been observed that under shorter (blue) or longer (green and red) wavelength illuminations, the positive surrounding gate effect of NiO due to photo hole injection can be partially or fully balanced by electrolyte, respectively. Thus, the device can yield either positive and negative photocurrent under shorter or longer wavelength illumination, respectively. Additionally, the color selectivity of such a structure can be adjusted by applying a small external bias, which allows for the acquisition of more detailed color information in multiple measurements. We demonstrated the reconstruction and classification of color patterns based on the artificial retina. Meanwhile, photo-generated carriers can accumulate in the SnO_2/NiO structure, resulting in a self-powered synaptic photo response that we used to demonstrate the neuromorphic preprocessing of noise filtering. The in-device signal preprocessing, along with the self-powered feature, can significantly reduce energy consumption.
The optical subsystem includes a fixed lens, an artificial crystalline lens, and an artificial iris, all of which mimic the optics of a human eyeball. The artificial crystalline lens is a liquid crystal Pancharatnam-Berry lens. Compared to conventional glass lenses, it exhibits reduced geometrical aberration and a much smaller thickness. The artificial crystalline lens can be switched between light refraction mode and transparent mode, allowing for the tuning of the focal length of the optical subsystem. Similarly, the artificial iris is based on liquid crystal technology, and it has five rings of liquid crystal. The transparency of each ring can be individually controlled from 0% to 95%, which enables the overall aperture size to be adjusted from 3.14 mm^2 to 78.50 mm^2. The electronic optics, which has reduced thickness and geometrical aberration, can assist with miniaturization and expand the depth of field and dynamic range of the system.
Overall, we have designed and developed a distinctive hemispherical bionic retina and spherical eye device that possesses the missing capabilities of color vision, optical adaptivity, and energy efficiency in previous research. This device presents a new paradigm by integrating structural and functional traits that are similar to biological eyes, and it highlights the potential for further exploration and optimization of artificial visual systems with biomimetic functionalities that can enhance the efficiency of machine vision and robotics.

SESSION EL04.03: Poster Session I

Stacked One Selector-One Resistor 32x 32 Crossbar Array with Chalcogenide-Based OTS Selector for Neuromorphic Computing Su YeonLee, Hyun KyuSeo, Se YeonJeong and Min KyuYang; Sahmyook University, Korea (the Republic of)

Existing Resistive Random Access Memory (ReRAM) is a next-generation memory technology known for its high operating speed, low voltage operation, and higher density compared to other memory types. However, when implemented in a cross-point array structure, it can suffer from leakage currents that cause malfunctions in read and write operations. To overcome these limitations, structural changes were implemented by stacking a selector device on a resistor. The selector device utilizes an amorphous chalcogenide-based OTS (Ovonic Threshold Switching) technology.
By incorporating the amorphous chalcogenide-based threshold switching selection device onto the resistor (1R), it offers several advantages, including lower off-state current (Ioff) compared to MIT-based selector devices. This makes it an attractive and optimal choice for stacking ReRAM with a 1 selector 1 resistor (1S1R) structure. The 1S1R architecture employs a W/Ti/TaOx/Pt structure for the resistor (1R) and a W/GeSeTe/W structure for the selector (1S). This crossbar resistance memory architecture is suitable for non-volatile, high-density, and low-latency storage class memory applications.
The reliability of each device was thoroughly evaluated, and a suitable material for the 1S1R structure was selected. Moreover, the 1S1R structure holds potential for application in neuromorphic computing, a novel conceptual architecture that aims to develop low-energy, high-speed neurons and synapses. In neuromorphic computing, an artificial neural network consists of low-power computing devices (neurons) and reconfigurable storage devices (synapses). This architecture offers the significant advantage of performing Multiply-Accumulate (MAC) operations in parallel, thereby reducing data transmission time and energy consumption.
In this study, the researchers demonstrated sufficient device yield in a 32 x 32 crossbar array structure using an auto-probe technique. They also showcased reliable MAC behavior, simulating neuromorphic computing.

8:00 PM EL04.03.02

Engineering Cell and Nuclear Morphology on Nano Topography by Contact-Free Protein Micropatterning EinollahSarikhani[1], DhivyaPushpa Meganathan[1], KeivanRahmani[1], Ching-TingTsai[2], AbelMarquez-Serrano[1], XiaoLi[2,3], FrancescaSantoro[4,5,6], BianxiaoCui[2], LasseHyldgaard Klausen[7] and ZeinabJahed[1,1]; [1]University of California, San Diego, United States; [2]Stanford University, United States; [3]Xi'an Jiaotong University, China; [4]Istituto Italiano di Tecnologia, Italy; [5]RWTH Aachen University, Germany; [6]Forschungszentrum Juelich, Germany; [7]Aarhus University, Denmark

Platforms with nanoscale topography have recently become powerful tools in cellular biophysics and bioengineering. Recent studies have shown that nanotopography affects various cellular processes like adhesion and endocytosis, as well as physical properties such as cell shape.
To engineer nanopillars more effectively for biomedical applications, it is crucial to gain better control and understanding of how nanopillars affect cell and nuclear physical properties, such as shape and spreading area, and impact cellular processes like endocytosis and adhesion. In this study, we utilized a laser-assisted micropatterning technique to manipulate the 2D architectures of cells on 3D nanopillar platforms. We performed a comprehensive analysis of cellular and nuclear morphology and deformation on both nanopillar and flat substrates. Our findings demonstrate precise engineering of cellular architectures through 2D micropatterning on nanopillar platforms. We show that the coupling between nuclear and cell shape is disrupted on nanopillar surfaces compared to flat surfaces. Furthermore, we discovered that cell elongation on nanopillars enhances nanopillar-induced endocytosis. These results have significant implications for various biomedical applications of nanopillars, including drug delivery, drug screening, intracellular electrophysiology, and biosensing. We believe our platform serves as a versatile tool for further explorations, facilitating investigations into the interplay between cell physical properties and alterations in cellular processes.

8:00 PM EL04.03.03

Low Voltage Organic Light-Emitting Synaptic Transistors for Neuromorphic In-Display Processing Kwan-NyeongKim[1], HuanyuZhou[1], Dong-YoonKim[1], Hea-LimPark[2], YeongjunLee[3], Kyun KyuKim[3], Min-JunSung[1], YileiXu[3], SongZhang[3], Dae-GyoSeo[1], Gyeong-TakGo[1], JinwooPark[1], ZhenanBao[3] and Tae-WooLee[1]; [1]Seoul National University, Korea (the Republic of); [2]Seoul National University of Science and Technology, Korea (the Republic of); [3]Stanford University, United States

Organic neuromorphic electronics using flexible organic semiconductors pave the way for the development of energy-efficient and intelligent devices, particularly in wearable applications. To create user-friendly systems, wearable neuromorphic devices need to provide outputs that are easily recognizable to user through light-emitting devices. The previous approach of employing external processing units to transmit signals from neuromorphic devices to display devices can give rise to limitations similar to those encountered in conventional electronic systems. Organic light-emitting synaptic transistors (OLESTs) offer a potential solution by integrating the functions of synaptic processing and light-emission in a single device. Despite this advantage, high voltage operation (>30V) in previous light-emitting synaptic transistors remains a main challenge that requires further investigation and improvement.
Here, we present low voltage OLESTs achieved through the electrochemical doping of semiconducting light-emitting polymers (LEPs). By utilizing surfactant molecules, we enhance the ion transport in the LEP channel, resulting in low turn on voltage ($|V_{DS}|$=2.0V at $|V_{GS}|$=1.0V that is lower than band gap of LEP (Eg=2.17eV) due to spontaneous band bending during the OFF state. With the low switching and channel voltage (2.5V), the synaptic plasticity with luminescent outputs was demonstrated. Finally, we show neuromorphic in-display processing using a sensory neuromorphic display system. This system utilizes a hierarchical structure consisting of temperature sensor, spike generator, and OLEST to provide intuitive visible warning signals to patients suffering from sensory disabilities. Our results present a new approach for the realization of user-friendly neuromorphic display systems in intelligent wearable electronics.

8:00 PM EL04.03.04
Biocompatible Multilayered Encapsulation of Organic Light-Emitting Diodes for Optogenetic Applications SukyungChoi, Jin-WookShin, Jong-HeonYang, KukjooKim, Chun-WonByun, Dae-HyunAhn, Yong HeeKim and Sang-DonJung; Electronics and Telecommunications Research Institute (ETRI), Korea (the Republic of)

Organic light-emitting diodes (OLEDs) are gaining significant attention in the field of bioelectronics due to their advantages as thin and flexible light sources. However, OLEDs are highly susceptible to moisture and oxygen, making the development of protective encapsulation crucial. While conventional glass-based encapsulation has been suitable for rigid devices, it is not suitable for flexible bioelectronics that require flexibility. As a result, there has been extensive research on the application of thin inorganic or organic-inorganic hybrid encapsulations. Due to the unstable nature of OLED devices at temperatures above 100 degrees Celsius, low-temperature processes are required to develop encapsulation. In our study, we formed a high-density Al_2O_3 film using atomic layer deposition and deposited SiO_xN_y using low-temperature plasma-enhanced chemical vapor deposition to create a thin inorganic bilayer encapsulation. To enhance the biocompatibility of the device, we deposited parylene-c on the upper layer of the SiO_xN_y using chemical vapor deposition. The OLED device was fabricated as a blue-emitting component for optogenetic applications, specifically for stimulation using channelrhodopsin-2. The stability of the OLED devices was verified by dipping them into a phosphate-buffered saline solution, and it was observed that the OLEDs with a bilayer inorganic encapsulation of Al_2O_3/SiO_xN_y exhibited significantly superior stability compared to OLEDs with only an Al_2O_3 encapsulation. However, it was found that the bilayer inorganic encapsulation of Al_2O_3/SiO_xN_y alone exhibited cell toxicity, making it unsuitable for bio applications. To address this issue, parylene-c was introduced to assess cell viability. It was confirmed that OLED devices with an encapsulation of Al_2O_3/SiO_xN_y/parylene-c demonstrated biocompatibility. HEK-293 and L-929 cells were used to assess biocompatibility, and both relative cell counting and MTT tests revealed cell viability of over 80%, demonstrating a high level of biocompatibility. Finally, the feasibility of optogenetic experiments was demonstrated by applying the OLED devices to neuronal cells.

8:00 PM EL04.03.05
Uncooled Self-Powered Hemispherical Biomimetic Pit Organ for Mid-to Long-Infrared Imaging YuchengDing and ZhiyongFan; The Hong Kong University of Science and Technology, Hong Kong

Infrared (IR) vision is a highly desirable capability for various applications, including medical instrumentation, surveillance, environmental monitoring, robotics, and space exploration. Among the few species with this exceptional visual capability, snakes stand out due to their advanced infrared perception assisted by pit organs. Inspired by the pit organ structure, we present a biomimetic hemispherical infrared imaging device that overcomes the limitations of conventional planar IR image sensors.
Our innovative device employs high-density ionic thermoelectric polymer nanowire arrays as sensing nerve cells, demonstrating a notable voltage response to temperature variations in test objects. Unlike planar IR image sensors, which typically have a limited field of view (FoV) of less than 90° and require multiple lenses due to the Petzval field curvature, our hemispherical design effectively eliminates imaging aberrations and simplifies the optical system. This approach minimizes IR transmittance loss, preserves detection sensitivity, and reduces the form factor of the IR devices.
We successfully demonstrate an infrared sensor array with 625 pixels on a hemispherical substrate, achieving an ultrawide FoV of up to 135°, significantly larger than that of the pit organ. Furthermore, our device can image body temperature objects without the need for a cooling system or external power supply, thanks to the thermoelectric effect that enables a self-powered working mode. The device exhibits high responsivity (0.5 mV for a 40°C object at a 5-cm distance) and a reasonable response rate of 0.69 s.
Despite the challenges associated with fabricating devices on curved substrates, our biomimetic hemispherical polymer-based ionic thermoelectric (PIT) image sensor effectively mimics thermal receptors in pit organs. Aided by an IR-absorbing layer, the PIT image sensor can detect and image mid- to long-wavelength IR light at room temperature. We also demonstrate the device's potential for practical applications, such as staring imaging of human hand gestures and heated symbols with approximately 60°C temperature.
In conclusion, our hemispherical infrared imaging device not only mimics the pit organ both structurally and functionally but also surpasses it in terms of the density of the nanowire array. This work paves the way for the design and fabrication of a new generation of high-performance, bioinspired IR imaging devices based on emerging ionic thermoelectric materials, offering significant improvements over conventional IR sensing technologies.

8:00 PM EL04.03.06
Photopatternable OECTs for Scalable and High Resolution Organic Electronics Charles-ThéophileCoen and Yoerivan de Burgt; Technische Universiteit Eindhoven, Netherlands

The conjugated polymer PEDOT:PSS has been at the forefront of research in the field of organic mixed ionic-electronic conductors (OMIECs) thanks to its excellent conductivity, flexibility and biocompatibility. This material has found applications ranging from biosensing to neuromorphic computing.

Patterning OMIECs has however been one of the main challenges toward miniaturization and scalability of organic electronics. As these materials are sensitive to conventional photoresists, traditional microfabrication processes have to be adapted, leading to poorer reproducibility, scalability and resolution.

Nonetheless, the development of new materials and techniques in recent years, such as orthogonal photoresists and photopatterning, have led the way toward highly integrated organic circuits. Photopatterning of OMIECs offers a rapid and chemically compatible process. Two distinct strategies, namely interpenetrating network and direct crosslinking, are being investigated for the fabrication of organic electrochemical transistors (OECTs). Similarly, these two approaches are employed for patterning a solid-state electrolyte, enabling the creation of fully photopatternable solid-state and high performance OECTs. This type of device has great potential for applications in neuromorphic computing, such as hardware accelerators and artificial spiking neurons, and biosensing, including multiplexed electrode array and in-line trans-epithelial electrical resistance measurement.

8:00 PM EL04.03.07
Memristor Device Requirements Analysis and Update Thresholding Strategy for Accurate Neuromorphic Resistor (1R) Array Programming GihoLee and JeehwanKim; Massachusetts Institute of Technology, United States

Neuromorphic computing, which draws inspiration from the functioning of the brain, offers several advantages such as minimizing data transmission, reducing power consumption, and enabling parallel computation. These remarkable properties of neuromorphic computing are expected to have a wide range of applications, including artificial intelligence (AI), scientific computing, and security. Particularly, neuromorphic computing powered by a memristor crossbar array has demonstrated promising capabilities as an AI inference accelerator, with various on-chip deep neural network inference demonstrations showing comparable inference performance to software-based approaches.
One common approach, known as the one-transistor one-resistor (1T1R) system, has been widely adopted to achieve precise programming of individual memristors and overcome the sneak path issue, thereby enhancing computing precision. However, this 1T1R system introduces compromises in terms of power consumption, computation speed, and design simplicity. These limitations can be addressed by employing the simplest one-resistor (1R) system. However, the effective utilization of the 1R system requires precise adjustment of the conductance values of each memristor on the cross-points. This task is often challenging due to the presence of asymmetry, selectivity, sneak path, and stochasticity in the conductance update process.
In this study, we address this issue by developing the simplest automatic programming algorithm, which involves iterative conductance read and update sequences. Subsequently, we analyze the requirements of memristor devices for achieving high programming accuracy. We establish the relationships between array size and various requirements, such as the interconnect-to-memristor conductance ratio and illustrate how selectivity enhances the convergence speed. Additionally, we observe that the update asymmetry of memristor devices negatively affects programming performance when the target conductances deviate from the symmetry point of the memristors. To overcome this challenge, we demonstrate a simple update event thresholding algorithm that significantly improves the programming accuracy of an actual asymmetry device model. This requirement analysis and programming strategy have the potential to assist the 1R memristor array system in addressing programming challenges and implementing an ideal AI inference accelerator.

8:00 PM EL04.03.08
Optically and Electrically Modulated Optical Neuromorphic Transistor Based on Oxide Semiconductor with MgO_X Oxygen Vacancy Forming Layer SujinLee, Min SeongKim, Hyung TaeKim, Young WookKim, Seok MinHong and Hyun JaeKim; Yonsei University, Korea (the Republic of)

As the Internet of Things (IoT) and artificial intelligence (AI) robot technologies have been developed, object recognition with artificial visual perception system is required to process massive data from the continuous light inputs in the environment. For the artificial visual perception system, an optical neuromorphic transistor (ONT) was proposed which combined the functionalities of an optical sensor and neuromorphic device to remove data movement between sensory and data storage components, minimize the required area for the system, and reduce the power consumption. The synaptic current of the ONT was modulated by the wavelengths and intensities of the light inputs, enabling the precise control of the synaptic weight at a low voltage. However, there was a limitation of the ONT in realizing the depression characteristics since the synaptic current showed an exponential decay rather than exhibiting various discrete states simply by removing the light inputs. To overcome this limitation, an additional input source was necessitated along with the light inputs. In this regard, an optically and electrically driven dual-functional neuromorphic transistor (DNT) was introduced which showed the potentiation characteristic by light inputs and the depression characteristic by electrical spikes.
To achieve the aforementioned characteristics, we presented an oxygen vacancy forming layer (VFL) consisting of magnesium (Mg) which was introduced between the channel and the gate insulator of the amorphous indium-gallium-zinc oxide (a-IGZO) DNT. Since Mg has a high binding force with oxygen, the VFL attracted oxygen in the front channel, resulting in the formation of magnesium oxide (MgO_X) during the thermal treatment after the a-IGZO deposition. In other words, the VFL facilitated the creation of oxygen vacancies (V_Os) in the front channel. Since the V_Os acted as subgap states for visible light absorption and carrier trapping/de-trapping centers, the VFL conferred the potentiation and depression characteristics to the a-

IGZO DNT by light inputs and electrical spikes, respectively. To validate the optoelectronic characteristics with visible light inputs, the transfer characteristics of the a-IGZO DNT without and with VFL were measured without and with red light (635 nm) irradiation. The a-IGZO DNT with VFL showed improved optoelectronic characteristics including the maximum value of photoresponsivity (Max. PR), photosensitivity (Max. PS), and detectivity (Max. D*) from 1.51×10^{-4} to 1.13×10^{2} A/W, 1.34×10^{2} to 1.22×10^{6}, and 2.69×10^{4} to 2.93×10^{11} Jones compared to those of the a-IGZO DNT without VFL under red light irradiation with the light intensity of 5 mW/mm^2, respectively. In addition, to confirm the short-term plasticity characteristics, the synaptic current was measured over time by applying red light with the light intensity of 5 mW/mm^2 and the electrical spike with 10 V. As a result, it was confirmed that the a-IGZO DNT with VFL showed the potentiation and depression characteristics by light input and electrical spike, respectively.

Development of a Hand Tremor Monitoring System for Quantitative Diagnosis Criteria of Parkinson's Disease ChiwonSong, ChanPark, JeongbeomKang, CheoljeongPark, ByeongjunLee, JungminKim, HaranLee and Seong J.Cho; Chungnam National University, Korea (the Republic of)

Parkinson's disease is a neurodegenerative disorder that affects millions of people worldwide. One of the most common symptoms of PD is hand tremor, which is caused by involuntary muscle contractions. The frequency of hand tremor in PD patients is typically between 4 and 6 Hz. The current gold standard for diagnosing PD is the Movement Disorder Society Unified Parkinson's Disease Rating Scale (MDS-UPDRS). However, the MDS-UPDRS is a subjective assessment that is prone to human error. In addition, the MDS-UPDRS only assesses the severity of tremor, not the frequency. To address these limitations, we developed a new hand tremor monitoring system. Our system consists of a lightweight and flexible circuit, a portable device, and a flexible strain sensor. The flexible strain sensor has a skin-like Young's modulus (0.08 MPa), high readability (25,000 cycles), sensitivity (GF: 6.1 at 30% strain, which is the fracture strain of skin), self-adhesion, and a flexible circuit that experiences almost no change in electrical signal at 50% bending strain. We used our hand tremor monitoring system to assess the frequency and amplitude of hand tremor in a clinical trial of PD patients. The results showed that our system was able to accurately quantify the frequency and amplitude of hand tremor in PD patients. The development of our hand tremor monitoring system is a significant step forward in the diagnosis and management of PD. Our system can be used to objectively assess the severity of hand tremor, which can help clinicians to make more accurate diagnoses and to monitor the progression of the disease. In addition, our system could be used to develop new treatments for PD.

8:00 PM EL04.03.10
Tactile Neuromorphic Display Enabled by Block Copolymer Structural Color KyuhoLee, YeeunKim and CheolminPark; Yonsei University, Korea (the Republic of)

The development of tactile stimuli interactive display with a memory function in a single device is highly desired and holds promise for potential applications such as intelligent artificial electronic skin (e-skin) and human-machine interfaces. In this work, we report for the first time a tactile neuromorphic display integrated into a single device enabled by block copolymer (BCP) structural color capable of a dual output of optical signals by combining the functionality of reflective mode display with a synaptic transistor that allows for the sensing, storing, learning and visualizing the number and magnitude of external tactile stimuli. The proposed device is based on an ion-gel gated transistor with a dome-shaped gate electrode and periodically ordered block copolymer (BCP) lamellae which serve as both tactile-interactive color-tunable gate dielectrics and ion-moving pathways. The electrically switchable structural color (SC) of BCP is ascribed to the movement of hydrated Li+ ions to an electric field. As the structural color returns to its original state due to ion diffusion when the electrical field is removed, the conductance retention feature of the synaptic device can be observed intuitively through the display. Furthermore, we fabricated 4X4 arrays of tactile neuromorphic display (TND) devices to propose a novel dual personal locking device that can detect information using wavelength and current. The new locks are prohibited from being accessed if the pressing time and pressure of the pattern are different, even if the path of the pattern is known, by taking advantage of the difference in pressing time and pressure depending on the individual.

8:00 PM EL04.03.11
Retina-Inspired Ferroelectric-Based Photonic Synapses TingyuLong[1], HuanyuZhou[1], JaewanKo[2], DaehanKang[1], EojinYoon[1], Gyeong-TakGo[1], HyojunChoi[1], MinhyukPark[1], JoonaBang[2] and Tae-WooLee[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Photonic synapses, combining sensing and processing in a single device, have received a lot of attention from photonic computing and neuromorphic computing in recent years. In particular, photonic synapses using ferroelectric polarization are receiving much attention due to their unique bidirectional polarization characteristics. However, there are few papers related to substituting ligands of quantum dots with ferroelectric material. Here, a photonic synapse using ferroelectric polarization is reported. The device shows some crucial synaptic functions, including paired-pulse facilitation, short-term potentiation, and long-term potentiation. Most importantly, compared to conventional ligand capped QDs, it is shown that the long-time retention is improved from 11% to 23%. It is expected that the development of this photonic synapse device will facilitate the next paradigm of neuromorphic electronics.

8:00 PM EL04.03.12
Synaptic Thin-Film Transistors Employing Titanium-Oxide-Based Dual-Channel ChohyeonPark[1,2] and Jung-WookLim[1,2]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]University of Science and Technology, Korea (the Republic of)

Implementing neuromorphic computing systems in hardware has gained significant attention as an alternative to conventional Von-Neumann computer architecture, offering energy-efficient processing of large amounts of data. This study focuses on characterizing titanium-oxide-based synaptic thin-film transistors (TFTs) with a dual-channel structure, aiming to emulate biological synaptic behavior.
The dual-channel structure of the titanium-based synaptic TFTs consists of titanium oxide (TiO_2) and indium-titanium oxide (InTiO) prepared by plasma-enhanced atomic layer deposition (PEALD), which exhibit compatibility with the complementary metal-oxide-semiconductor (CMOS) process. In addition, different photo-sensitivity[1] according to different energy bandgaps of each channel allows for synaptic behavior modulation based on the wavelength of the incident light.
Experimental results show various optical and electrical synaptic behaviors in the titanium-based dual-channel synaptic TFTs due to the different lifetimes of captured carriers at each interface. Moreover, various characteristics include excitatory postsynaptic currents, paired-pulse facilitation, and potentiation/depression of synaptic weights. These phenomena arise from trapping the carriers at the dielectric and channel interfaces. It provides potential applications for artificial synapses employing a dual-channel approach, paving the way for advancements in neuromorphic computing systems.

In Vitro Implementation of Reconfigurable Logic-in-Memory using Crossbar Neuronal Networks YongheeBae, Kyo-SeokLee, Sun-MiLee and Kyung-HwaYoo; Yonsei University, Korea (the Republic of)

The proposal of a logical neural network by McCulloch and Pitts, along with Hebb's postulate of spike-timing-dependent plasticity (STDP) for learning, has greatly influenced the field of brain-inspired computing research. In order to examine the impact of these concepts on the computational principles of real neurons, researchers constructed 4x4 crossbar neuronal networks on multi-electrode arrays (MEA) using a microfluidic structure made of polydimethylsiloxane (PDMS). By recording neural activity spatiotemporally with MEA, it was observed that STDP learning caused a shift in the threshold voltage (V_{th}) required to activate neurons, as well as changes in the response time determined by the interval between the stimulus onset and the arrival of the evoked spike. Additionally, the crossbar neuronal network exhibited well-defined connections between neurons, enabling the successful implementation of reconfigurable AND/OR logic gates through STDP learning. These findings demonstrate the feasibility of implementing reconfigurable logic-in-memory in crossbar neuronal networks.

8:00 PM EL04.03.14
Synaptic Memory Properties of Micron-Scale Geopolymer-Based Memristors Mahmudul AlamShakib, ZhaolinGao and CaterinaLamuta; University of Iowa, United States

Memristors are electric components capable of emulating the memory and computational properties of biological synapses by remembering the current that flows through them. They are considered artificial synapses when they mimic the memory and sensing properties of biological synapses. Enormous efforts have been given to discover the most suitable memristor materials for different applications. Here we present the synaptic memory properties of geopolymer memristors. These properties make them excellent candidates for the development of artificial synapses, which represent the building blocks of neuromorphic computing. We recently demonstrated memristive properties of geopolymers, inexpensive ceramic materials obtained from alkaline activation of amorphous aluminosilicate precursors. We also proposed a physics-based model to describe the role of electroosmosis in the memristive properties of geopolymers. We followed-up with the demonstration of synaptic functions by geopolymer memristors. However, the samples were in millimeter scale. In this study, we present the synaptic functions of geopolymer memristors manufactured at micrometer scale. We have developed a simple fabrication method to device multiple geopolymer memristors with the help of double-sided adhesive layer sandwiched between two printed circuit boards (PCS). The memristors were analyzed with the help of single-channel pulsed excitations for Short-Term Plasticity (STP) and Long-Term Plasticity (LTP) behaviors. Additionally, Spike-Timing-Dependent Plasticity (STDP) in terms of Long-Term Potentiation (LTP) and Long-Term Depression (LTD) are also observed by stimulating the geopolymer memristors with pairs of pre-synaptic and post-synaptic pulses. All 4 types of Hebbian learning behaviors are demonstrated. Finally, Spike-Frequency-Dependent

Plasticity (SFDP) properties such as Paired-Pulse Facilitation (PPF) and Depression (PPD), Post-Tetanic Potentiation (PTP), and History-Dependent Plasticity are demonstrated. The reported findings pave the way for the use of geopolymers in novel and low-cost neuromorphic computing applications like analog switching, memristive neural network, computer vision, etc.

8:00 PM EL04.03.15
Direct Electrical Biointerfacing with Bioadhesive Polymer Semiconductors NanLi and SihongWang; University of Chicago, United States

Polymer semiconductors have shown distinct promise for merging human-machine interfaces, owing to their solution processability and flexible mechanical nature. Polymer semiconductors-based organic electrochemical transistors (OECTs) as an advanced type of sensing devices, are highly desired for direct electrical biointerfacing due to their low operation voltage, high sensitivity, and signal-to-noise ratio. To interface with wet and dynamically moving tissues, conventional suturing causes tissue/device damage and cannot achieve good conformability; having the adhesive property will ease the attachment process and help achieve a conformable contact and high spatial sensing resolution.

Here, we develop an intrinsically bioadhesive semiconducting polymer by creating a rationally designed polymer network with interpenetrating semiconducting polymers and adhesive brush polymers to realize both high normalized maximum transconductance and good adhesion on wet biotissues. Benefiting from the brush polymer design, the semiconducting polymer network possesses soft and viscoelastic mechanical properties, moderate water absorption, and controllable swelling, which synergically contribute to the adhesion on wet tissue surfaces. In addition, the semiconducting material shows abrasion resistance, high stretchability, and good biocompatibility. Furthermore, we fabricated an intrinsically bioadhesive and stretchable OECT and further demonstrated its use for monitoring electrophysiological signals consistently and reliably on wet heart surfaces and in vivo muscles.

CMOS-Compatible Linear and Symmetric Electrochemical Protonic Synapse Device with HfO2 Electrolyte LonglongXu, MantaoHuang and BilgeYildiz; Massachusetts Institute of Technology, United States

Analog programmable resistors, as key components of hardware artificial neural network hardware, can help solve the high-energy-consumption challenge of conventional hardware in artificial intelligence applications. Three-terminal proton-based electrochemical synapse device, working as programmable resistors, are operated by the reversible electrochemical insertion and extraction of protons, modulating the channel conductance with nonvolatile conductance states. Achieving fast, energy efficient, and CMOS-compatible electrochemical synapse devices remain a challenge. Previous organic electrolytes in ionic synapses are not CMOS-compatible although having high proton conductivity. CMOS-compatible solid-state electrolyte with high proton conductivity is important for the integration of the synapse device for future applications. Meanwhile, achieving highly linear and symmetric conductance change are significantly important in order to improve the inference accuracy after the training process of hardware neural networks.

Herein, we investigated proton-based electrochemical ionic synapses using CMOS-compatible binary oxide Hafnium oxide (HfO2) as the electrolyte. HfO2 has a low electronic conductivity and high electric breakdown field, which can facilitate good retention and lower writing energy consumption. The devices are fabricated by an all-sputtering process, with shadow mask for patterning. It has reactive sputtered WO3 as channel material, sputtered HfO2 as electrolyte, Cr/Au as source and drain contact, and Palladium hydride as the gate and hydrogen reservoir.

The synapse devices can be programmed with hundreds of distinguishable conductance state with 0.1-10 microseconds, 1-2V voltage pulses. The conductance change exhibit repeatable and almost ideally symmetric and linear behavior for potentiation and depotentiation. The writing energy consumption of the device can be as low as ~100 femtojoule/um2 per pulse.

This work not only achieved high performance programmable resistor, but also proved that undoped HfO2 can work as a proton electrolyte, which is important in making protonic electrochemical device CMOS-compatible. We are now investigating thin film binary oxides proton kinetics including conductivity and proton conducting mechanisms. The next stage also includes further improving the device performance by scaling down and engineering the proton conduction properties of HfO2 by structure modification.

8:00 PM EL04.03.17
Sub-Nanometer Interface Modifications for Conductance Modulation in Proton-Based ECRAM Devices JordanMeyer, MantaoHuang and BilgeYildiz; Massachusetts Institute of Technology, United States

Three-terminal electrochemical random-access memory (ECRAM) devices have gained interest for use as resistive elements in neuromorphic computing architectures, with promising nonvolatility, reversibility, and symmetric operation through solid-state ion intercalation of the channel. Engineering these ECRAM devices to be both fast and energy-efficient remains difficult, as even proton-based devices display operating voltages above 1 V and programming speeds on the order of µs, above the desired ns programming speeds. Recent advances in high ionic conductivity electrolytes and decreasing electrolyte thickness have decreased the gap in operating voltages, but as electrolytes become increasingly thin, other optimizations are needed.

Modification of the interface between electrolyte and channel remains largely unexplored in ECRAM. Lithium-ion-based ECRAM devices may benefit from many of the same interface strategies used in solid-state lithium-ion batteries since the material systems are similar. For proton-based devices, much less is known about the interface reaction in solid-state proton transport. How device operation responds to interface modification may give insight towards faster, low-power ECRAM devices. This work reports attempts to modify the interface in a proton-based ECRAM device between the archetypal channel material WO_3 and proton-conducting electrolytes, HfO_2 and phosphosilicate glass, with sputtering of a range of metals and metal oxides. Differences in conductance modulation across interface-modified devices are presented, which could be relevant for the low operating voltage regime where interface-limited kinetics start to manifest. Electrochemical impedance spectroscopy (EIS) is employed to study charge-transfer features in symmetric cell configurations. Surface modification of WO_3 thin films is also examined with X-ray photoelectron spectroscopy (XPS) and sheet resistance measurements. In doing so, we demonstrate that some tunability of ECRAM device operation is possible using CMOS-compatible sputtering with sub-nanometer interface modifications.

Nanoparticles as Drug Delivery Vehicles for TLR7 Agonists and Their Influence of Anti-Inflammatory Activity KiShawndaA. Parker; JSNN, United States

Nanoscale materials play an integral role in delivery of drugs to their targets. This project focuses on understanding how nanoparticles impact drug performance at the interface. Systemic Lupus Erythematosus (SLE) is an autoimmune disease that negatively influences the function of organs throughout the body. SLE is triggered by the toll-like receptor (TLR) gene TLR7, which is located on chromosome X and is responsible for activation of the immune system. TLR7 agonists have been effective in stimulating innate immune cells and can lead to anti-inflammatory activity. Consequently, the targeted delivery of TLR7 agonists to cells is an important process in the treatment of SLE. The design and synthesis of well-defined magnetic particles with nanoscale dimensions is opening new avenues in understanding their fundamental chemical and physical properties, and their biocompatibility for effective use as drug carriers. Our work describes a novel facile procedure for the synthesis of homogeneous isotropic and anisotropic magnetic and biocompatible nickel nanoparticles. These nanoparticles were produced using a wet-chemical process and characterized by transmission electron microscopy (TEM), high-resolution transmission electron microscopy (HRTEM), selected-area electron diffraction (SAED), powder x-ray diffraction (XRD), energy dispersive spectroscopy (EDS) and thermogravimetric analysis (TGA). While there is significant interest in using magnetic nanoparticles for biological applications, little is known about their size-dependent interactions with biological cells. We demonstrate the impact of TLR agonists anchored to magnetic nickel nanoparticle surfaces and the influence on the particle-cell interactions. We further compare the effect of anchoring TLR7 agonist molecules on magnetic nanoparticle surfaces relative to polymer nanoparticle surfaces and study their effect on cells. The results indicate that the surface and molecular orientation of the attached molecules play a significant role in cell interactions. The underlying mechanisms of these interactions will be discussed.

8:00 PM EL04.03.19
Gradient-Free Learning in Organic Neuromorphic Devices SimoneSpolaor and Yoerivan de Burgt; Eindhoven University of Technology, Netherlands

Organic electronics is paving the way towards a new generation of low-power, bio-compatible neuromorphic computing devices, implementing hardware neural networks that can directly interface with living matter. However, the lack of learning algorithms that work efficiently for online, in hardware learning still hampers their computing power and scope of application.
On the one hand, offline learning on digital hardware requires precise computational modeling of the physical properties of the devices and limits the energy efficient computations done in hardware to the inference phase. On the other hand, conventional learning algorithms used to train software neural networks are difficult to implement in hardware, due to memory constraints, necessity to calculate gradients and share weight information across the whole network.
Here, we apply a gradient-free optimization algorithm, named Simulated Annealing, to train a network of electrochemical neuromorphic organic devices (ENODe) and perform classification tasks. The Simulated Annealing algorithm does not rely on gradient information, and it is co-designed to exploit the ENODe physical properties (e.g., number of conductance states, state-retention time, energy, and time required per state-switch). This novel learning algorithm could be employed to achieve online learning on emerging organic neuromorphic systems, enabling multi-sensory integration and actuation in biological environments.

Self-Assembled Networks at Avalanche Criticality in Ag-hBN Platform AnkitS. Rao[1], SoorajSanjay[1], MajidAhmadi[2], AnirudhVenugopalrao[1], NavakantaBhat[1], BartKooi[2], SrinivasanRaghavan[1] and PavanNukala[1]; [1]Indian Institute of Science, India; [2]University of Groningen, Netherlands

Systems and networks which exhibit brain-like behavior can analyze information from intrinsically noisy and unstructured data with very low power consumption. Such characteristics arise due to the critical nature and complex interconnectivity of the brain and its neuronal network. We demonstrate that a system comprising of multilayer hexagonal Boron Nitride (hBN) films contacted with Silver (Ag), that can uniquely host two different self-assembled networks, which are self-organized at criticality (SOC). This system shows bipolar resistive switching between high resistance (HRS) and low resistance states (LRS). In the HRS, Ag clusters (nodes) intercalate in the van der Waals gaps of hBN forming a network of tunnel junctions, whereas the LRS contains a network of Ag filaments. The temporal avalanche dynamics in both these states exhibit power-law scaling, long-range temporal correlation, and SOC. These networks can be tuned from one to another with voltage as a control parameter. For the first time, different neuron-like networks are realized in a single CMOS compatible, 2D materials platform.

8:00 PM EL04.03.21
Identification of VCM Switching Mechanism and Synaptic Characteristics of CMOS-Compatible Memristors FeiQin[1], YuxuanZhang[1], Han WookSong[2] and SunghwanLee[1]; [1]Purdue Unviersity, United States; [2]Korea Research Institute of Standard and Science, Korea (the Republic of)

Memristors are being increasingly recognized as prospective components in the realm of brain-like computing applications. However, gaining insights into their switching procedures, especially concerning valence change memristors (VCM), continues to be an actively debated issue due to the complexities involved in the direct visualization of conductive filaments via microscopy. In this work, we focus on an in-depth understanding of the switching behaviors and mechanisms of VCM, with an emphasis on the promising role of SiO_2-based memristors in neuromorphic computing. Firstly, our study presents findings on CMOS-compatible SiO_2-based memristors, showcasing an impressive on/off ratio exceeding 10^5. We delve into an extensive analysis utilizing COMSOL Multiphysics simulations, aiming to illustrate the evolution of the oxygen vacancy-based conductive path in these memristors throughout the SET process. Furthermore, the theoretical findings are corroborated experimentally via electrochemical impedance spectroscopy, enabling the interpretation of the switching behavior in the context of the equivalent circuit. A core part of our study is the evaluation of synaptic characteristics with pulse measurements which were then integrated into neural networks for image recognition tasks, using the MNIST and Fashion MNIST datasets as benchmarks. In essence, this work provides an encompassing view of the fundamentals about VCM's switching mechanism as well as a potential application of low-cost and CMOS-compatible memristors towards neuromorphic computing.

Driving Flexible Electronics by Hybrid Materials RodrigoF. Martins and ElviraFortunato; FCT UNL, Portugal

Printable electronics and flexible electronics are key areas of development worldwide, once offer the potential to add functionality to everyday objects at very low costs that would be difficult with conventional technologies. This was pushed by the large success of organic electronics over the past few decades due to their attractive features such as low process temperatures, good mechanical flexibility, light weigh, and the possibility to use a wide range of substrates and being recyclable. Besides that, we can prepare these devices using inexpensive solution processes over large areas. These benefits offered by printable and embedded electronics have been recognized in many sectors. Nevertheless, the bottleneck here is the low electronics performance so far achieved.
On the other hand, metal oxide electronic materials are quite attractive since they are reliable, able to be processed at low temperatures and present excellent electronic performances at 1-2D scales, providing so a large variety of different and possible applications, going from low costs to high complex systems able to compete with silicon in applications like transparent electronics, optoelectronics, magneto electronics, photonics, spintronics, thermoelectrics, piezoelectrics, power harvesting, hydrogen storage and environmental waste management.
In terms of production techniques RF magnetron sputtering has been well established and has demonstrated high-performance devices, as ALD. However, these require complex equipment, especially if we are targeting low-cost applications. In contrast, the solution process has many advantages such as large-area deposition, roll-to-roll capability, easy control of composition, atmospheric processing, and low cost.
In parallel, we have been observing a rapid and growing interest in the utilization of biological materials for a wide range of applications. One of the most representative examples is cellulose, not only in the form of raw material mainly for pulp and paper production but also in the development of advanced materials/products with tailor-made properties, especially the ones based on nanostructures, for low-cost and disposable applications. In this presentation we will review the main applications of vegetal and bacterial cellulose in electronics, either as substrate (passive) or as a real electronic material (active), considering the expertise as well as the major developments already done at CENIMAT|i3N in Paper Electronics.

Device Physics and Switching Speed in Polymer-Based Artificial Synapses: Towards "Iontronics"AlbertoSalleo; Stanford University, United States

Polymer-based artificial synapses have shown outstanding performance in terms of switching speed, switching energy and endurance. Indeed, devices that can switch with 20 ns pulses and can undergo a read-write cycle in under 1 µs have been demonstrated. Furthermore, we have shown that they can be switched billions of times with no degradation. These are very unusual featured for organic semiconductors, which are usually plagues with slow speeds and weak reliability. In order to understand the origins of this performance we have developed a suite of operando characterization techniques that allow to study the materials structural evolution during biasing. We show that the highest performance devices are permeated with electrolyte in the form of neutral pairs, essentially acting as internally-gated transistors. Furthermore, we show that despite intercalating and expelling large ions, switching occurs with minimal structural disruption. These features may enable the operation of a broader category of "iontronic" devices that rely on ionic motion yet achieve high speeds compatible with electronics.

8:45 AM *EL04.04.02
Neuromorphic Computing and 2D Materials for Neural Interfaces DuyguKuzum, MehrdadRamezani, MadisonWilson and AshwaniKumar; University of California, San Diego, United States

The next leap in implantable neural interfaces requires technological advances in materials, devices, and computing paradigms. Holistic approaches integrating optical and electrical sensing modalities using 2D materials can overcome spatiotemporal resolution limits of neural sensing as well as open up new avenues for non-invasive neural recording. Integration of sensing, computation on neuromorphic interfaces can enable real-time processing of neural signals for compact, low-power and high-throughput brain machine interfaces. Here, I present this vision, its challenges, and discuss recent advances in the areas of transparent neural interfaces for multimodal recordings, neuromorphic approaches for on-chip neural processing and computational co-design at the system level for minimally invasive neural interfaces.

9:15 AM EL04.04.03
Organic Neuromorphic Electronics for Local Learning and Control in Robotics ImkeKrauhausen[1,2], PaschalisGkoupidenis[2] and Yoerivan de Burgt[1]; [1]Technische Universiteit Eindhoven, Netherlands; [2]Max Planck Institute for Polymer Research, Germany

Biological systems learn by interacting directly with the environment and receiving positive and negative feedback from many different stimuli that influence the formation of dynamic associations inside their neuronal systems. These associations are encoded within the neuronal connections of the brain, specifically in the strength of the synaptic connection between neu-

rons. Recently, the organic electrochemical transistor (OECT) has emerged for its use as artifi-cial synapse showcasing volatile and non-volatile tunable dynamics that emulate synaptic plasticity. This allows the mapping of (artificial) neural networks into hardware-based circuits as well as the development of specialized neuromorphic chips mimicking the efficient structure and function of the human brain. Organic neuromorphic electronics also operate on low voltage which make them ideal for integration in energy-restricted environments such as autonomous robots [1-6].
In this work, we aim to create a small-scale locally trained organic neuromorphic circuit con-nected to a robot. The robot is able to respond to different input signals adaptively and form behavioral associations based on its interaction with the environment. This on-chip adaptable integration of multiple stimuli with low-voltage organic neuromorphic electronics opens the way towards stand-alone, brain-inspired circuitry in autonomous and intelligent robotics.

9:30 AM EL04.04.04
An Organic Spiking Neuron with Unconventional Form-Factor for Energy Efficient, Neurotransmitter-Mediated, In-Sensor Pre-Processing Functions Giovanni MariaMatrone[1], XudongJi[1], AbhijithSurendran[1], ZacharyLaswick[1], GangYe[2], FrancescaSantoro[3], Yoerivan de Burgt[4] and JonathanRivnay[1]; [1]Northwestern University, United States; [2]Shenzhen University, China; [3]Forschungszentrum Juelich, Germany; [4]Technische Universiteit Eindhoven, Netherlands

The fundamental mechanisms of signal communication within the human body rely on the spiking frequency of action potentials.[1] Through biological receptors and afferent neuronal cells, stimuli from the external world are encoded into a spiking pattern and transmitted to the central nervous systems where they are processed via interneurons: the “sensory coding” mechanisms. The fundamental goal of neuromorphic electronics is to emulate the architecture of the human brain to enable parallel computing with high energy efficiency[2] and local processing, thus advancing intelligent systems interfacing with the human body[3].
Recently, organic materials have been employed to build electronic circuits that mimic both the spiking behaviour of neurons[4–6] and their synaptic transmission[7] thus replicating afferent neurons and interneurons functions. Indeed, a combination of bioelectronic devices may recreate a “neuronal pathway” that in nature relies on the cooperation of spiking (neurons and interneurons) and non-spiking elements such as mechano-chemical sensors (receptors), and neuromodulator junctions (chemical synapses)[8]. Although the most recent neuromorphic circuits emulate biological functions which are deemed essential for basic signal processing and computation capabilities (mimicking some retinal functions), i) these systems power consumption is 2-3 order of magnitude higher than the brain processors, ii) their footprint is still on a scale (tens of mm) impeding meaningful in-sensor applications, iii) the electrochemical detectors for neurotransmitter still show sensitivity and selectivity not suitable for tissue interfacing.
Here it is presented an integrated neuromorphic platform that replicates both afferent neurons “sensory coding” and synaptic transmission.
Exploiting a vertical transistor architecture comprising stacked n-p type polymer films, complementary inverters are fabricated with a lateral footprint of 50 mm and requiring low drain voltage (0.05 V), thus building an independent spiking unit. To allow neurotransmitter-mediated synaptic transmission with high sensitivity, a novel biohybrid synapse is developed exploiting a referenced-ENODe architecture[9]. This system allows the detection of neurotransmitters, such as dopamine and serotonin, with a sensitivity approaching sub-nanomolar concentrations and enhancement selectivity, facilitating tissue coupling and potentially avoiding molecular cross-talk.
Moreover, the total neuromorphic system energy consumption, as predicted by electronic circuit simulations, is reduced to 1 nJ[10], with a synaptic transmission contribution depending on the device lateral dimension and an energy-per-spike depending on the materials selection and the dimension of the vertical inverters. Moreover, the integrate-and-fire neuron footprint is reduced to 200mm x 200mm. This system constitutes a fundamental building block for programmable neural pathways. It is compatible with in-sensor application footprint and sensitivity requirements for locally executing bio-inspired pre-processing functions while its unconventional architecture allows to dynamically communicate with the nervous system.

Overcoming the Trade-Off Between Electrochemical Doping Efficiency and Retention Time in Electrolyte-Gated Organic Synaptic Transistors Min-JunSung[1], Dae-GyoSeo[1], JingwanKim[2], Ho EonBaek[2], Gyeong-TakGo[1], Seung-JeWoo[1], Kwan-NyeongKim[1], HoichangYang[3], Yun-HiKim[2] and Tae-WooLee[1,1,1]; [1]Seoul National University, Korea (the Republic of); [2]Gyeongsang National University, Korea (the Republic of); [3]Inha University, Korea (the Republic of)

The electrochemical doping efficiency and retention time of long-term potentiation (LTP) are essential for superior device performance such as fast operation speed, high on/off current ratio, and high state retention in electrolyte-gated organic synaptic transistors. However, these characteristics exhibit a trade-off relationship in general; faster and more efficient electrochemical doping can induce faster de-doping of ions, which is directly related to lower state retention, and vice versa. This work introduces an effective strategy to increase retention time while maintaining efficient electrochemical doping. Our approach involves blending two polymer semiconductors (PSCs) that have the same backbone but different types of side chains. Polymer synaptic transistors (PSTs) that used the blend film showed stronger potentiation under weaker presynaptic spikes and retained LTP longer than PSTs that used only one of the PSC films. We attribute this change to the increased redox activity of the blended PSC, which was confirmed by several electrochemical characterizations. Unlike the common belief in this field, this work is the first to enhance retention time in PSTs with neither increasing the crystallinity of polymer film nor sacrificing the electrochemical doping efficiency. This method provides an effective way to tune synaptic properties for various neuromorphic applications.

Memristive Technologies for Ultrasensitive and Advanced Bio/Chemical Sensing Systems IouliaTzouvadaki; Ghent University, Belgium

Memristive technologies coupled with biological processes opened new perspectives in the role of bio-inspired sensors, bringing a new versatile approach for label-free and specific transduction with ultra-sensitivity. These emerging technologies hold great promise as intelligent bio-interfaces opening application perspectives in the biomedical field, particularly for implantable and lab-on-a-chip devices.

The recent developments on transduction and processing of chemical biomarkers of neural and endocrine functions will be discussed as well as the critical perspective on the future applicability of memristive devices as pivotal building blocks in advanced biosensing systems.

11:00 AM *EL04.04.07
Elucidating the Resistive Switching Mechanisms Taking Place in $La_2NiO_{4+\delta}$-Based Devices by *In Situ* and *Operando* Spectroscopic TechniquesMónicaBurriel; University Grenoble Alpes, CNRS, Grenoble INP, LMGP, France

Resistive switching (RS) devices have attracted increasing attention for their application as non-volatile memories and neuromorphic computing systems. In my talk, I will focus on the design of novel memristive heterostructures using a perovskite-related oxide with high oxygen mobility and p-type semiconducting electronic transport, namely $La_2NiO_{4+\delta}$ (L2NO4). Dense L2NO4 thin films were grown using pulsed-injection metal-organic chemical vapor deposition (PI-MOCVD) under optimized conditions. While our first studies were dedicated to epitaxial planar devices on single-crystal substrates, [1][2] we then moved towards industrial-relevant substrates and thus fabricated vertical devices with polycrystalline L2NO4 films on Si-based CMOS-compatible wafers.[3] The electrical response of these devices could be tuned both by changing the electrode materials and the amount of point defects (oxygen interstitials) of the sandwiched film. The chemical, structural, microstructural characterisation of the films will be presented, showing the high crystal quality, together with the change in Ni oxidation state and the

concomitant change in resistivity after annealing. Furthermore, by several electrical characterization measurements, the key role played by the oxygen interstitials on the initial resistance state, the initialization step, and the memristive characteristics of the devices will be presented and discussed. An analog bipolar counter-eightwise RS behavior with multiple resistance states has been proven using continuous sweeps and voltage pulses.
However, to ensure that the TiN/ L2NO4/Pt devices are suitable for use in the neural networks (NN), certain additional properties should be investigated. Firstly, the device should exhibit reversible long-term potentiation/depression to enable learning in NN. In addition, requirements such as low current, low switching time, high endurance, and retention should also be met. Here we explore the possibility of device optimization by alternating varying both fabrication and measurement conditions for TiN/ L2NO4/Pt devices. The use of post-deposition annealing allows tuning the memristive properties of the device, and potentially eliminating the forming process. On the other hand, we show that with adjustment of the pulse length and voltage amplitude the process of multilevel resistive switching can strongly influenced. We demonstrate highly reproducible long-term potentiation and depression in TiN/ L2NO4/Pt structures achieved with short voltage pulses, which allows the potential use of these devices as artificial hardware synapses in spiking neural networks.
Selected devices were further analyzed by X-ray absorption spectroscopy (XAS) using synchrotron radiation. Changes in the Ni K-edge were measured for different annealings, in different regions of the device and under *in situ* and *operando* conditions, allowing for a better understanding of the RS mechanisms taking place in the device. Furthermore, gradual changes in conductance after the application of repetitive DC sweeps, which can be regarded as the evolution of the synaptic weight between neurons, were obtained for these novel L2NO4-based devices. These results were complemented with *in situ* transmission electron microscopy (TEM) measurements combined with Electron Energy Loss Spectroscopy (EELS) carried out for "lamella-devices" using an adapted TEM sample holder, which allowed for the observation of chemical changes for different resistance states. These results go a step further towards the comprehension of the intricate switching mechanisms taking place, and open the door to the use of L2NO4-based memristors as artificial hardware synapses in spiking neural networks.

Single-Nanoparticle Based Memristors for Neuromorphic Computing SabrinaArtmeier[1], JonathanHiltz[2], JonathanG. Veinot[2] and MarcTornow[1]; [1]Technical University of Munich, Germany; [2]University of Alberta, Canada

During the last years, neuromorphic computing has emerged as a fascinating and important research area. As one of its key elements, which would mimic the biological synapses, memristors are among the most promising device candidates [1]. Due to their energy-efficient operation, which can be in the order of picojoule per synaptic event [2] and the perspective to solve the von Neumann bottleneck problem [3], these devices have become an extensive research topic. Important current directions of research and engineering include device down-scaling and 3D-integration. To address these challenges, single nanoparticle (NP) - based memristive devices offer a promising route as they can be chemically synthesized with a high yield [4; 5] and may form functional heterogeneous aggregates by bottom-up directed self-assembly [6].
In order to study the memristive electrical properties of oxide NPs, we have developed a nano-lithographic process to individually and permanently contact single nanoparticles by embedding them in-between two electrodes. Our fabrication process can be employed to investigate oxide nanoparticles of different material composition, shape and size.
A highly appealing active layer material for memristive devices is tungsten oxide [7]. In our research, we were able to chemically synthesize tungsten oxide NPs of size ca. 90x90x15 nm^3 [8]. Our studies of these NPs included different contact material combinations such as Ti/Au-Ti/Au, Ti/Pd-W and Ti/Pd-TiN. Electrical characterization was performed in DC mode (range ~± 4 V) where the results showed a forming-less and stable, gradual resistance switching behavior for hundreds of cycles. Pronounced potentiation and depression behavior was visible as a hysteresis with an in- or decreasing current, respectively, after repeated voltage sweeps for one fixed bias polarity. To mimic the function of a biological synapse, some devices were also investigated under pulsed operation, where the pulse parameters are currently adapted in a way to optimize device learning and forgetting behavior. We discuss the possible mechanism of the observed resistance switching in terms of conducting oxygen vacancy paths in the tungsten oxide, which can be reversibly strengthened or weakened.
As our studies are eventually aiming towards a directed self-assembly of nanoparticles, we have also undertaken first experiments to facilitate such aggregation via tailored surface functionalization. Via coating of our NPs with phosphonic acid molecules [9] comprising hydrophobic endgroups, we were able to demonstrate the formation of homogeneous, directed face-to-face agglomerates in hydrous environments. These agglomerates indicate a successful replacement of the initial capping layer by the phosphonic acid molecule layer. To support this hypothesis, element-specific analysis methods such as XPS are used alongside with scanning electron microscopy. As the second endgroup of the phosphonic acid molecules is variable, this process is anticipated to allow for the fabrication of the desired, heterogeneous NP stacks.

2D Drift-Diffusion-Reaction Model of Organic Electrochemical Transistors for Biosensing and Neuromorphic Hardware Simulations UgoBruno[1,2], BjornLussem[3] and FrancescaSantoro[1,4,5]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Napoli Federico II, Italy; [3]University of Bremen, Germany; [4]Forschungszentrum Jülich GmbH, Germany; [5]RWTH Aachen University, Germany

Organic electronics, and in particular electrolyte-gated transistors, witnessed an exponential growth in the last decades, enabling a collection of different applications, ranging from biosensing to flexible digital circuits[1].
In particular, PEDOT:PSS-based organic electrochemical transistors (OECTs), have come to play an important role for their natural ionic-to-electronic signal transduction and biocompatibility[2].
In addition, thanks to the development of inexpensive, tuneable and energy efficient devices, organic neuromorphic engineering emerged as a promising approach to overcome conventional silicon technology limitations[3]. Notably, neuromorphic OECTs were shown to exhibit non-volatile and reproducible memory[4], and the first biohybrid synapse was demonstrated, in which an artificial neuron could communicate with dopaminergic cells[5].
As complex electrochemical mechanisms take place during doping/de-doping processes of OECT, several models were developed over the years[6,7], in order to guide device design of such complex devices. Still, while correctly describing several featured of such devices, these modelling approaches rely on a 1D approximation of the transistor channel, neglecting import dynamics of ions and holes. Furthermore, a clear model of a neuromorphic OECT is still missing.
Here, starting from a newly developed 2D drift-diffusion model of an OECT[8], we present a numerical model of a PEDOT:PSS-based neuromorphic OECT, working at the border with biology. First, drift-diffusion-reaction equations are solved, to describe redox reactions happening at the gate/electrolyte interface, and the subsequent faradic charge transfer that dopes/de-doped the OECT.
In particular, dopamine oxidation, and the subsequent hydrogen release in the electrolyte of the OECT, were simulated.
Notably, the model predicts a dependence of the faradic reaction on the composition of the electrolyte, as it directly affects the voltage drop at gate/electrolyte interface, that drives the whole faradic reaction. In addition, experimental data are provided, validating the model.
Lastly, charge trapping is implemented in the model, enabling the simulation of a biohybrid synapse, in which PEDOT:PSS is de-doped by hydrogen ions in a non-volatile manner.
The proposed model aims to provide a tool to guide the design of the novel generation of organic sensors and neuromorphic hardware, enabling the modelling of the devices working at the interface with biological systems.

Time-Dependent Programming of Electrochemical Synapses Enabled by Nonlinear Voltage Kinetics BilgeYildiz, MantaoHuang, JuLi and JesusA. del Alamo; Massachusetts Institute of Technology, United States

The rapid rise in energy demand for computing motivates the search for new computing paradigms.The exploration and development of new architectures with brain-guided learning rules have the potential to offer substantial enhancements in energy efficiency and performance. Spiking neural networks (SNN) are one of such promising architectures for achiving highly energy-efficient machine intelligence.To effectively implement SNNs in hardware,one of the key components are programmable synaptic devices capable of time-dependent weight updates. Recent advance ofelectrochemical ionic synapses (EIS) has shown their promise as programmable synaptic weights indeep learning accelerators due to their exceptional energy efficiency and low variability. Here we propose a passive local circuit and crossbar array architecture that implements timing-dependent weight update of EIS in a parallel and asynchronous way, leveraging the intrinsic nonlinear kinetics of EIS.Our architecture accommodates a diverse range of STDP (spike-timing-dependent plasticity) learning rules, with time scales controllably ranging from milliseconds to nanoseconds. Moreover, the architecture offers the flexibility to choose different learning rules within the array, emulating the behavior ofsynaptic pathways in biological brains.This approach holds potential applicability across a wide range of ions and material systems for EIS, potentially enabling SNN hardware implementations with high energy efficiency and high throughput.

2:00 PM *EL04.05.02
Neuromorphic Organic Electronic Devices for Neural Signal Sensing, Recording and *In Situ* ProcessingFabioBiscarini; University di Modena e Reggio Emilia, Italy

Organic electronic neuromorphic components and devices operated in electrolytes are being investigated in vitro and in vivo as tools for selective bio-sensing, as their frequency response is strongly affected by the dopamine content of the operational electrolyte,[1] and as signal recroding and signal processing units, thanks to their frequency response which enables low-power computation at the hardware level.[2,3]

These properties stem from the inherent matching of the relevant timescales, as well as the chemical nature of the active layer and its strong interactions with neurotransmitters on the one hand, and, on the other hand, the similarity between the signal processing logic paradigms in the brain and in organic neuromorphic devices. Nonetheless, the implementation of neuromorphic devices and concepts in neuroelectronic interfaces designed specifically for translation comes with number of practical and conceptual hurdles which should be addressed, at both sides of the biotic/abiotic interface.

In this presentation, I will discuss some of the hurdles to translation of neuromorphic devices to clinical settings, showing experimental examples of recordings of electrical and chemical signals, and present some device layouts and material processing strategies for overcoming them.

A Phototransistor Leads to Artificial Synaptic Behaviors by Controlling Off-Current under Illumination SeungmeKang[1], ByungchulJang[2], SunyoungSohn[3] and HocheonYoo[1]; [1]Gachon University, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of); [3]Sangji University, Korea (the Republic of)

Organic phototransistors (OPTs) can amplify electrical output signals without additional devices and provide tunable optical spectral response. A lot of research is being conducted using the characteristic that the electrical characteristics of the OPT change depending on the light. Recent studies investigate the properties of these OPTs for various applications such as photodetectors, image sensors and neuromorphic devices. Here, we propose an organic semiconductor-based OPT device in which the off-current increases when light is applied to the OPT. The structure of OPT is a single transistor using p-type organic semiconductor dinaphtho[2,3-b:2′,3′- f]thieno[3,2-b]thiophene (DNTT) as a channel layer by thermally depositing it on a SiO_2/Si substrate. In addition, the photoresponse was improved by doping the entire surface of the material 2,2',2"-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole) (TPBi) used as the hole transport layer of the organic light emitting diode (OLED). As a result, when the electrical characteristics of a single DNTT transistor were checked, an increase in off-current could be observed only under illumination of 300 nm to 400 nm, which is the DNTT photoresponse region. On the other hand, the TPBi-doped DNTT phototransistor shows an increase in off-current in all broadband wavelength ranges from 400nm to 1000nm. In addition, the change of current over time, we imitated artificial synaptic behavior by applying a relatively slow light response speed. As a result, a recognition rate of over 70% was achieved in all wavelength bands.

3:45 PM EL04.05.04
Symmetric Electrochemical Ionic Synapses (EIS) Based on Mg^{2+}-Intercalation MirandaSchwacke, PjotrsZguns, JesusA. del Alamo, JuLi and BilgeYildiz; Massachusetts Institute of Technology, United States

Neuromorphic accelerators for deep learning applications, as well as other energy-efficient, brain-inspired computing hardware, can be enabled by low power programmable resistors which act as artificial synapses. Here we focus on artificial synapses in which the channel resistance is programmed by reversible electrochemical intercalation of small ions, allowing for dynamic doping of the channel. These devices are referred to as electrochemical ionic synapses (EIS). The use of protons as the working ions in EIS has enabled very fast and energy-efficient devices but limits the long-term retention of devices without encapsulation in ambient air. This motivates the search for an alternative working ion which is stable once intercalated into channel materials in air without requiring encapsulation. Here we provide a proof-of-concept for EIS based on intercalation of Mg^{2+} ions into tungsten trioxide (WO_3).
These proof-of-concept devices are symmetric, with Mg_xWO_3 serving as both the ion reservoir and channel materials. Increasing the Mg content x in Mg_xWO_3 from x = 0 to 0.3 continuously increases the electronic conductivity over several orders of magnitude. *Ex-situ* characterization of the channel confirms that the change in channel conductance is due to intercalation of Mg^{2+} ions and reveals the structural and chemical changes taking place in WO_3 during Mg^{2+} ion insertion. Compared to H_xWO_3, the conductance of Mg_xWO_3 rises much faster at low ion concentrations. Additionally, unlike H-EIS, Mg-EIS has good retention in air without any encapsulation. Computational results suggest that this stability is not thermodynamic but is enabled by very slow kinetics and/or the blocking nature of Mg-O reaction products. Mg^{2+} as a working ion with WO_3 as the channel material is a promising materials system for improving the retention of EIS devices without the need for encapsulation.

4:00 PM EL04.05.05
Vertical Bilayer Anti-Ambipolar Transistors for Tunable Electrochemical Neurons ZacharyLaswick, AbhijithSurendran, Giovanni MariaMatrone and JonathanRivnay; Northwestern University, United States

The human brain deploys a complex network of interconnected spiking neurons featuring a variety of electrophysiological characteristics to perform complex classification and recognition tasks[1,2,3]. Although machine learning algorithms implemented on traditional von Neumann electronics have emerged for diverse computing applications, they lag behind biological calculators in terms of performance and power consumption[1]. This “technological gap” stems from the brain’s massively paralleled event-based processing of information, via interconnected neuronal

networks, and the high specificity of its circuital elements, via neuronal diversity, which neuromorphic devices attempt to mimic[1,4]. Advancements in organic neuromorphic devices over the last few years has led to several circuits that mimic neuronal spiking behaviors, but these systems are limited by complexity, large device footprints, high power consumption, and show limited customizability[1,4,5,6,7,8].
Replicating the vast diversity of neurons with a scalable fabrication strategy is a critical step towards the development of large scale organic artificial neural networks that can approach the computational capabilities and functionality of the brain[1]. Recently, neuromorphic systems have been developed based on the integrate and fire neuron model, which uses conventional organic electrochemical transistors(OECTs), and the hodgkin-huxley (HH) neuron model, which uses anti-ambipolar OECTs (aaOECTs), that can exhibit bio-mimetic spiking behaviors with low power requirements. However, these platforms are generally limited by single device footprint and, for the HH-based systems, by the customizability of the aaOECTs characteristics including peak position, width, and threshold voltage [4,7,8].
Here, a novel vertical aaOECT that can be used in spiking circuits to reduce size footprint and introduce a full control of neurons characteristics, including spiking threshold, refractory period, and frequency, is presented. The vertical aaOECT is fabricated through a bilayer in-series combination of accumulation and depletion modes p and n-type OMIEC materials. To demonstrate the applicability in spiking circuits, the aaOECT is used within the bio-realistic HH model leading to decreased neuron footprint. Neuronal customization is achieved through material selection, which reliably alters the aaOECTs characteristics, with a full control over the peak position, width, and threshold voltage.
This device formulates a critical tool for the creation of large scale organic artificial neural networks that are not only significantly reduced in size, due to the vertical structure, but also customizable in neuron characteristics, thereby providing a fundamental step towards diverse bio-mimetic and interconnected networks of neurons.

4:15 PM EL04.05.06
Emulation of Synaptic Plasticity on a Metal Oxide-Based Ion-Gated Synaptic Transistor for Neuromorphic Computing RaminKarimi[1], LuanP. Camargo[1,2], JoseR. Herrera[1] and ClaraSantato[1]; [1]Polytechnique Montreal, Canada; [2]State University of Londrina (UEL), Brazil

The bottleneck of the von Neumann architecture has driven the development of neuromorphic computers. These computers utilize chip architectures that combine memory and processing within a unit, enabling them to perform intelligent and power-efficient computations. Unlike traditional architectures, neuromorphic computers mimic the structure and functionality of the human brain, allowing for parallel processing and improved efficiency in handling complex tasks.
Metal Oxides (MOs) are materials composed of metal elements bonded with oxygen. By leveraging their unique electronic structure, composition, crystallinity, morphology, intrinsic and/or extrinsic defects, and doping, it is possible to tailor their properties for synaptic behavior in ion-gated transistors (IGTs).
In this study, we used titanium dioxide (TiO_2) and tungsten trioxide (WO_3) as channel materials. TiO_2 is earth-abundant with non-toxicity, high stability under ambient conditions, and biocompatibility. The typical crystalline phases include anatase and rutile with a tetragonal crystal structure. WO_3 can exist in different crystal structures, including orthorhombic, monoclinic, and hexagonal phases. The current modulation in MO IGTs arises from both electrostatic and electrochemical processes. The crystal structure of the metal oxide is anticipated to have an impact on ion permeability, leading to variations in doping, channel conductivity, and redistribution time of the anions in the IGT channel. The time-resolved measurements indicate that the application of gate-source voltage (V_{gs}) pulses to WO_3 IGTs results in a drain-source current (I_{ds}) that is almost twice as high compared to TiO_2-based IGTs. Furthermore, the response time of WO_3-based IGTs is longer than that of TiO_2-based IGTs. As a consequence, WO_3-based IGTs display a more prominent transition between short-term plasticity (STP) and long-term plasticity (LTP), indicating superior synaptic performance.
The current modulation in ion-gated transistors (IGTs) is investigated also by changing the gating medium (including solvent-in salt media).
The addition of Li to the ionic medium ([EMIM][TFSI]) of metal oxide IGTs can play a crucial role in modulating the conductivity and synaptic plasticity of the transistor.
When Li ions are incorporated into the channel material or adsorbed at the interface between the transistor channel and the ionic medium, they can influence the diffusion dynamics and mobility of ions within the channel. This leads to an increase in the conductivity of TiO_2 and WO_3 channels by almost 100 percent after applying V_{gs} to the gate.
This affects the ion redistribution and de-doping processes, leading to changes in the synaptic behavior of the transistor. In particular, when Li ions are readily diffusible back into the ionic medium after the removal of the low amplitude gate bias (under 1 volt), STP was observed. On the other hand, if the Li ions are intercalated into the channel material and do not diffuse back spontaneously, LTP effects were exhibited and response time increased.
In this sense, understanding metal oxide materials in IGTs and effectively tuning the presence and dynamics of Li ions through pulse parameters offers opportunities for tailoring the synaptic properties and performance of these transistors in developing new integrated circuits and neuromorphic devices.

4:30 PM EL04.05.07
Complementary Internal Ion-Gated Organic Electrochemical Transistors (C-IGT) DuncanWisniewski and DionKhodagholy; Columbia University, United States

Bioelectronic devices capable of accurately and safely interfacing with physiological systems for the capture, monitoring, processing, and stimulation of neural systems are required in both medicine and research. Because of the ionic flux-based communication system used by neurons in the brain tissue signal transduction is required for devices to observe neural activity through an electrical interface. This creates the need for organic mixed-conducting based transistors and sensors for measurement and recording of neuronal signals and systems. To use these sensors effectively conformable and scalable systems must be created for interfacing with both biology and existing technology. Current integrated circuit technology relies on a complementary approach of balanced N-type and P-type devices for improvements in power efficiency and scalability. Here we demonstrate a method to create transistors with N-type functionality, transistor action in the first quadrant and resistor like in the third quadrant, from P-type materials which usually express the opposite behavior, modulating in the third quadrant and acting as a resistor in the first quadrant. These opposing behaviors enabled a complementary logic device with an output voltage range similar to the input voltage dynamics. Additionally, similar channel material and geometry resulted in equal impedances between the two transistors yielding a higher power efficiency and fabrication density. To create these devices the transistor geometry was analyzed in terms of relative size to establish performance thresholds for different types of operation, including N-type, P-type, high power, and high speed. Transistors were characterized in terms of asymmetry, voltage required for complementary operation, speed, and gain. Using designs informed by the characterization of channel contact asymmetry we then fabricated circuits including amplifiers and logic gates for digital systems. These CIGT circuit designs have a broad range of applications in bioelectronics including wearable electronics, neural interfacing, and therapeutic implants.

4:45 PM EL04.05.08
Implementation of Memristive Devices with Self-Rectifying and Analog Switching by Modulation of Dual Schottky Barriers KeonheeKim[1,2], Jae GwangLim[1,2], YeonjooJeong[1], JaewookKim[1], SuyounLee[1], Joon YoungKwak[1], JongkilPark[1], Gyu WeonHwang[1], Kyeong-SeokLee[1], SeongsikPark[1], Hyun JaeJang[1], Byeong-KwonJu[2], Jong KeukPark[1] and InhoKim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

The rapid advancement of artificial intelligence (AI) has created a demand for computing architectures capable of meeting its complex processing requirements. Traditional von Neumann architectures are facing challenges in meeting these demands, prompting the exploration of alternative technologies. Neuromorphic computing has emerged as a promising candidate to address this challenge. Memristive devices have gained significant attention as potential artificial synapses for neuromorphic computing hardware. While numerous studies have been conducted, further improvements are needed across various aspects of memristive devices.
This study emphasizes the significance of analog switching with highly linear updates in synapse weights as a critical parameter. Additionally, the high self-rectifying characteristics of memristive devices were explored to suppress crosstalk in memristive neural networks, thereby enhancing scalability. We propose a memristive device consisting of Cu/TaO_x/IGZO/Pt with dual Schottky barriers at the interfaces TaO_x/IGZO and IGZO/Pt, respectively. TaO_x serves as a switching layer, and IGZO as a current limiting layer. The energy barrier at the interface of IGZO/Pt induces a self-limiting effect in a positive bias. Limiting the current prevents excessive formation of Cu conductive filaments, thereby leading to analog synaptic switching. Another energy barrier at the interface of TaO_x/IGZO tunes the overall filament size by limiting the current, providing self-rectifying characteristics as well. Oxygen stoichiometry in both oxide layers was found to be a key factor to modulation of the dual Schottky barriers. The memristive devices with optimally controlled dual barriers offer high linearity in synapse weight updates, long retention time as well as high self-rectifying ratio. We discussed the origin of the energy barrier modulations induced by the control of oxygen stoichiometry. Lastly, we implemented a small-scale crossbar array and demonstrated vector matrix multiplication, showing its potential as a next-generation application.

Visible Light-Driven IGZO Optoelectronic Synaptic Transistors with Subgap State Enhanced by Sonication YoujinSeo, JusungChung, SujinJung, Sung MinRho, Min SeongKim and Hyun JaeKim; Yonsei University, Korea (the Republic of)

With the remarkable advancements in artificial intelligence (AI) and the internet of things (IoT), adeptly managing vast amounts of data has become imperative. However, conventional von Neumann architecture has intrinsic limitations such as high power consumption and data bottlenecks due to its reliance on sequential processing. As an alternative, neuromorphic computing has emerged which emulates the complex operations of the human nervous system. Similar to the parallel connection of neural synapses, neuromorphic computing enables the simultaneous execution of tasks like memory storage, reasoning, and learning while minimizing power consumption.
Among various neuromorphic devices, interest in optoelectronic synaptic transistors (OST) that regulate synaptic weight through the control of channel conductance has recently attracted attention due to wide bandwidth making them suitable for handling large amounts of data, low power consumption, and low susceptibility to surrounding signals.
As a emerging candidate for channel material of OST, indium gallium zinc oxide (IGZO) has been attracted due to its low off-current, high photosensitivity, and large persistent photoconductance (PPC), which is responsible for neuromorphic characteristics. However, it is not feasible for IGZO-based OST to be driven by the entire range of visible light, resulting from the wide optical bandgap of IGZO (~ 3 eV). This limitation hinders the scalability of IGZO-based OST for various optical applications and recent research has focused on creating subgap states within the bandgap to expand the light absorption range.
Herein, we introduce complete visible light-driven OST by inducing subgap states in IGZO through a facile sonication method. This sonication process induces the cavitation phenomenon, the rapid collapse of bubbles, and the generation of shock waves, resulting in hydroxyl radicals. The interaction between IGZO and hydroxyl radicals leads to the formation of subgap states near the valence band maximum of IGZO. The optoelectronic properties of IGZO-based OST with subgap state enhanced by sonication (SES) are measured under red (635 nm), green (532 nm), and blue (405 nm) light irradiation. SES shows optoelectronic characteristics of the IGZO-based OST such as photoresponsivity of 1324.4 A/W, photosensitivity of 3.21×10^9, and detectivity of 1.12×10^{13} Jones under red light irradiation of 635 nm with the light intensity of 5 mW/mm^2, respectively. Moreover, It is confirmed that IGZO OST with SES demonstrated neuromorphic characteristics such as pair-pulse facilitation (PPF), short term memory (STM), and long term memory (LTM). A maximum PPF index value of 150 % is shown for red-light pulses at 1 mW/mm^2 with time interval of 1 s. Light pulses are applied with the wavelength of 635 nm, pulse width of 0.5 s, and pulse number of 5, varying different light power density from 1 mW/mm^2 to 5 mW/mm^2. STM behavior is demonstated, when red lihgt pulses are applied with light power density of 1 mW/mm^2. However, LTM behavior is confirmed, when the same input pulses are applied with light power density of 5 mW/mm^2.. The transition of STM-to-LTM occurs though repeated input pulses, depending on light power density.
As a result, a facile method is demonstrated to improve the optoelectric performance of IGZO OST by controlling the photoresponse characteristics. This research proposes the introduction of a facile sonication fabrication for inducing subgap states in a-IGZO and suggests the implementation of an IGZO-based OST operating in the entire range of visible light, indicating the potential application in enhancing the functionality of artificial visual cells.

8:00 PM EL04.06.02
Bio-Interface for Actuation and Neuromorphic Devices MuhammadYunusa[1], MertcanHan[1], Muhammad TurabAli Khan[1], ErdostYildiz[1], AndrésRodríguez-Camargo[2], AmirrezaAghakhani[3], BettinaV. Lotsch[2] and MetinSitti[1]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Max Planck Institute for Solid State Research, Germany; [3]Universität Stuttgart, Germany

Intrinsically soft materials are increasingly developed for biosensors and interfaces for neuromorphic bio-hybrid devices. Here, we developed new memristors material solution for soft and adaptive neural interfaces using a hybrid approach through the combination of organic polymers and inorganic liquid metals (such as gallium-indium). We have demonstrated the photo-charging mechanism and memristive behavior of such material interface with sensing and actuation capabilities. The electrically and thermally conducting inorganic liquid metal provides the possibility to design devices based on soft and deformable particles for integration with biological interfaces. Polymer conjugated micro- and nanodroplets of liquid metals are biocompatible as are previously been used in drug delivery and phagocytosis. The new approach presented in this work will provide a new material platform for biological interfaces, neural stimulation and neuromorphic computation.

8:00 PM EL04.06.03
Enhancing RRAM Device Performance: A Design of Experiments Approach AlirezaMoazzeni, Md TawsifRahman Chowdhury, SakirKarakaya and GozdeTutuncuoglu; Wayne State University, United States

Oxide-based Resistive Switching Random Access Memory (RRAM) devices hold significant promise as candidates for next-generation memory technology and novel brain-inspired computing applications. Among these, TaO_x ($1<x<2.5$)-based RRAMs have achieved substantial attention due to their promising performance in terms of durability and low energy consumption. However, these devices still suffer from instability and endurance degradation issues which hinder their large-scale adoption. One critical parameter is the forming voltage, which significantly influences resistive switching activation, device energy efficiency, and overall RRAM reliability but high forming voltage can increase the parasitic capacitance discharge which accelerates the degradation in the higher number of consecutive ON/OFF cycles. Intrinsic properties of TaO_x switching films such as film stoichiometry and oxygen vacancy profile play a pivotal role in shaping RRAM device performance metrics. The stoichiometry engineering of oxide films, enabled by varying the deposition parameters of a sputtering system, offers substantial advantages in optimizing RRAM behavior. However, the multitude of controllable and uncontrollable experimental parameters and potential interdependencies render this task challenging. In this work, we study the optimal processing conditions for sputtered TaO_x films that will yield the desired device metrics compatible with the algorithm requirements of neuromorphic computing. We employ a 2-level design of experiments (DOE) approach to examine the interactive impact of oxygen content on TaO_x films by varying the oxygen pressure and deposition power. Furthermore, we demonstrate how this set of parameters impact critical device performance metrics such as forming and set/reset voltages, the type of resistive switching (bipolar or unipolar, among others), initial resistance, memory window, and the endurance variation coefficient.

8:00 PM EL04.06.04
Double Dry-Etching Microfabrication of Flexible Neural Probes with Homogenous Glassy Carbon Microelectrodes and Interconnections RabiaFatima[1], AustinBroussard[1], DanielRivera[1], BingchenWu[2], Emma-BernadetteFaul[1], DavisBailey[1], XinyanT. Cui[2] and ElisaCastagnola[1]; [1]Louisiana Tech University, United States; [2]University of Pittsburgh, United States

Glassy carbon (GC) has only recently been considered for implantable neural interfaces, mainly due to a key advanced technology that allows for pattern transfer and integration of pre-pyrolyzed GC electrodes into flexible circuits. Hybrid GC multielectrode arrays (“hybrid” GC-MEAs), with GC microelectrodes and metal interconnections, have shown promising performance in neural applications, such as highly sensitivity in multi-site neurotransmitter detection, and high quality acute single-unit recordings. Hybrid GC-MEAs on thin flexible SU-8 substrate have also been demonstrated to reduce tissue damage and inflammation compared to stiff silicon probe, showing that the flexible substrate preserves a healthy neural tissue interface that can facilitate long-term sensing measurements. However, the mechanical contact between the metal interconnects and the GC electrodes may not withstand prolonged and aggressive electrical stimulation and mechanical stresses in a chronic application.
Using GC as a homogenous material for both electrodes and interconnects eliminates this concern. MEAs with both electrodes and interconnects from a single and homogeneous GC layer (“all” GC-MEAs) have been previously fabricated and have shown outstanding electrochemical stability. However, their fabrication required a complex double-pattern lithography process that is a potential limitation for device miniaturization.
Here, we introduce an alternative double dry-etching process for the fabrication of “all” GC-MEAs and “all” GC-fibers with miniaturized features. First, we pattern the SU-8 precursor on a Si3N4 wafer followed by pyrolysis (900°C in an inert atmosphere) to obtain GC electrodes and interconnections. Dimensions of trace width (5µm) and thickness (2-3µm) are optimized to ensure practical conductivity (1.21±0.26 Ω/sq). Second, we lithography pattern the SU-8 insulation of the device and we protect its features with a sacrificial hard mask. Then, we etch the 2µm Si_3N_4 layer using CF_4 reactive ion etching (RIE), where not protected, leaving the Si exposed. Finally, we use a purely chemical isotropic XeF_2 etching, taking advantage of the > 100:1 Si versus Si_3N_4 selectivity, to release the Si_3N_4 insulated devices from the Si wafer.
The new double dry-etching process enables the batch fabrication of “all” GC-fibers and “all” GC-MEAs on ultra-thin substrate with miniaturized features. The bare GC microelectrodes of these “all” GC devices demonstrated promising electrochemical sensing capability in the detection of tonic dopamine levels using square wave voltammetry, *in vitro* and *in vivo* in the dorsal striatum of mouse brain. Next step will be the investigation of their chronic electrochemical and electrophysiological sensing performance.

Visible Light Stimulated Optoelectronic Synaptic Transistor via Solution Processed Vertically Diffused Cd Doped IGZO Jun HyungJeong and Seong JunKang; Kyung Hee University, Korea (the Republic of)

Inspired by the human visual system, optoelectronic synaptic transistors have recently received a great deal of attention as a promising candidate for next-generation neuromorphic computing systems. To fully leverage the advantages of such systems, it is essential to address the challenges of developing low-cost, large-area, and solution-processable optoelectronic devices that can maintain long-term stability. In this study, we introduce an indium gallium zinc oxide (IGZO) based optoelectronic synaptic transistor by doping cadmium(Cd) using vertical diffusion process. By employing visible light stimulation, we successfully demonstrated a fundamental synaptic properties of the device, including excitatory post-synaptic current (EPSC), paired-pulse facilitation (PPF), and short-term plasticity(STP) to long-term plasticity(LTP) conversion. In addition, the Cd dopant act as an n-type dopant, resulting in improved electrical characteristics, such as field-effect mobility and on/off current ratio. Our findings offer a promising approach for advancing the development of visible light optoelectronic synaptic transistors for next-generation neuromorphic computing systems.

8:00 PM EL04.06.06
Expanding Dynamic Range of Ionic Liquid Based Physical Reservoirs by Utilizing High Molecular Design Flexibility AsahiArai, YumengZheng and KentaroKinoshita; Tokyo University of Science, Japan

In recent years, there has been a growing focus on reservoir computing (RC) due to its adaptability to edge computing. RC is composed of input, reservoir, and output layers, and is characterized by learning only in the readout part [1]. Furthermore, RC in which the reservoir is replaced with actual physical system is referred to as physical RC (PRC). Accordingly, PRC allows for physical implementation of the reservoir layer and is suitable for fast and low-load learning for time-series data processing. However, the time scale of input signal that can process is limited depending on the relaxation time peculiar to the selected physical system. We focus on ionic liquids (IL) that offer high molecular design flexibility, enabling fine- and wide-tuning of dynamics time scales.
In this study, we showed that the time constant of reservoir could be tuned by employing IL as a physical reservoir and controlling the dielectric relaxation time. In addition, we successfully expanded the dynamic range of PRC for short-term memory (STM) tasks [2] by mixing ILs or parallelizing IL reservoirs with different dielectric relaxation times.
IL reservoirs with EL/IL/EL structure were formed by supplying IL onto a gap between a pair of gold electrodes (ELs) deposited on a SiO2 substrate. We employed four types of ILs with different cations of [$C_n$mim$^+$] (n = 2, 4, 6, 8) each while fixing the anion to [Tf_2N^-], in which the alkyl side chain length of the cation systematically becomes long with increasing n. Positive and negative triangular voltage pulses, which were defined respectively as binary data of “1”and “0”, were injected into the structure. The width (t_w) of the pulse was set in the range of 1-10 μs. We conducted STM tasks using the current response to the random binary data input, and estimated the performance of IL reservoirs as a function of t_w.
Impedance measurement revealed that the dielectric relaxation time of [$C_n$mim$^+$][Tf_2N^-] (n = 2, 4, 6, 8) increased with increasing the length of the cation alkyl side chain. Furthermore, it was confirmed that t_w at which each IL reservoir exhibits the best STM performance closely matches the dielectric relaxation time of each IL. This result enables us to optimize the STM performance of IL reservoirs by selecting IL with the dielectric relaxation time that is similar to t_w. However, once the IL is determined, it is difficult to learn input signals with t_w that is far from the dielectric relaxation time of the IL.
Then, we configured an IL reservoir by connecting all the IL reservoirs for n = 2-8 in parallel, which is called a parallel reservoir hereafter. The STM performance of the parallel reservoir was significantly improved in all the range of t_w compared to that of each single IL reservoir. This is thought to be the result that four IL reservoirs with different time constant provide feature vectors which are linearly independent to each other, creating a higher-dimensional feature vector space.
The above results suggest that a single reservoir which includes multiple relaxation time constants can process input signal with high performance over a wide range of t_w. Therefore, we evaluated the STM performance of an IL reservoir in which ILs for n = 2 and 8 were mixed at a ratio of 4:1, which is called a mixed IL reservoir hereafter. Although not as good as the parallel reservoir, the STM performance of the mixed IL reservoir improved over all the rage of t_w compared to those of single IL reservoirs. It is interesting that by mixing two different types of IL, STM performance can be cooperatively improved without interfering with each other's learning.
The present study indicates the feasibility of wide dynamic range PRC with a single physical reservoir device.

8:00 PM EL04.06.07
Neuromorphic Applications Realized by a Free-Standing Multilayer Molybdenum Disulfide Memristor AmirhosseinHasani[1,2], AminAbnavi[2] and MichaelAdachi[2]; [1]Montana State University, United States; [2]Simon Fraser University, Canada

Recently, there has been growing interest in ultra-thin two-dimensional materials called transition-metal dichalcogenides (TMDs) for their potential use in compact electronic and optoelectronic devices. These materials are appealing because of their extremely thin structure and high data storage capacity. In this study, we introduce a type of memristor created using suspended multiple layers of molybdenum disulfide (MoS2). This memristor exhibits a substantial current on/off ratio of around ~1000 and maintains stable retention of data for at least ~3000 seconds. By adjusting the intensity of light shining on the suspended MoS2 channel, we can further enhance the on/off ratio to approximately 10^5. Additionally, we demonstrate that these devices can replicate essential functions of the human brain related to memory, both short-term and long-term. We found that short-term memory (STM) can be transformed into long-term memory (LTM) by increasing the power of the light stimulus, the duration of the light pulses, and the number of pulses. Our electrical measurements, conducted in both vacuum and ambient air conditions, suggest that the observed change in resistance in these memristors is due to the presence of oxygen and water molecules on both sides of the MoS2 channel. Consequently, our free-standing two-dimensional MoS2-based memristors offer a facile approach to creating energy-efficient and reliable resistive switching devices suitable for neuromorphic applications.

8:00 PM EL04.06.08
Self-Rectifying and Artificial Synaptic Characteristics of Amorphous Ta_2O_5 Thin Film Bilayer Memristor BumjooKim, In-SuKim and SahnNahm; Korea University, Korea (the Republic of)

Amorphous Ta_2O_5 (ATa_2O_5) film has different electrical properties depending on the growth conditions. ATa_2O_5 film, which was grown under the Ar/O_2 atmosphere with a high O_2 pressure, has insulating property and thus it can be used as a tunneling barrier. ATa_2O_5 film, which was grown under O_2 deficient condition, shows resistance random access memory (ReRAM) characteristic, indicating that it can be used for switching layer. ATa_2O_5 film for tunneling barrier was grown on TiN/SiO_2/Si (TSS) at room temperature and annealed under oxygen condition by RTA. ATa_2O_5 film for bipolar switching was grown on tunneling barrier. Self-rectifying characteristics were observed in an ATa_2O_5 bilayer memristor. The current conduction of this ATa_2O_5 bilayer memristor in the high-resistance state (HRS) is explained by Schottky emission, direct tunneling, and Fowler–Nordheim (FN) tunneling. In the low-resistance state (LRS), this ATa_2O_5 memristor shows insulating behavior, indicating that oxygen vacancy filaments were not formed. The current conduction of this memristor in the LRS was attributed to direct tunneling and FN tunneling. Moreover, ATa_2O_5 bilayer exhibited artificial synaptic properties. Therefore, the ATa_2O_5 bilayer memristor can be used as an artificial synapse for neuromorphic computing.

8:00 PM EL04.06.09
Improvement of Information Processing Performance in the Ionic Liquid-Based Physical Reservoir Device by Thermal and Electrical Pretreatment YukiKubo[1,2], MasaharuYonezawa[1,2], HisashiShima[2], YasuhisaNaitoh[2], HiroyukiAkinaga[2], ToshiyukiItoh[3], ToshikiNokami[4] and KentaroKinoshita[1]; [1]Tokyo University of Science, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Toyota Physical and Chemical Research Institute, Japan; [4]Tottori University, Japan

Edge computing, where AI processing is carried out in the edge domain, is attracting considerable attention because it is expected to provide more energy-conservative information processing and more rapid (real-time) feedback of the processing results compared to a conventional cloud-based computing. The various machine learning models for edge AI, which is required to satisfy both of low processing cost and high performance, have been proposed.
One of the promising learning models that satisfies these requirements is reservoir computing (RC), which has a very simple network structure consisting of input, reservoir, and read-out layers. Physical reservoir computing is a device implementation of RC, which use the actual physical phenomenon as a reservoir, a-nonlinear data transformation layer. So far, a wide variety of physical systems have been investigated as the physical reservoir device (PRD) [1]. PRD can effectively handle time series data (TSD) by selecting the PRD having appropriate dynamics according to the time scale of the input signal.
We have developed PRD using faradaic currents generated by the redox reactions in metal ion doped ionic liquids (ILs), which is hereafter represented as IL-PRD [2]. The advantage of IL-PRD is to have the relaxation time constant around hundreds of milliseconds with adjustability and is suitable for processing TSD generated with biological activities. We have previously clarified that the information processing capability in IL-PRD was influenced by various parameters such as an input signal asymmetry [2], electrode size [3], water content in IL [4], and temperature [5]. Herein, we present the significant improvement of the information processing capability in IL-PRD by the simultaneous applications of thermal and electrical stimuli.
The present IL-PRD had a pair of input and output terminals made of a Pt thin film. The electrode size was 100 μm x 100 μm, and the electrode spacing was 124 μm. To clearly define the location at which the redox reactions take place, those terminals were covered by the insulating SiO_2 layer excepting the electrode area. A droplet of [C_4mim][Tf_2N] doped with 0.4 M Cu ions was placed over the electrode to form a Pt/IL interface. TSD consisting of “0” and “1” was input to the device as a triangular voltage pulse (TVP) (pulse height ±3.0 V, pulse width 500 ms),

and the output current was measured. The signs of the TVP for “0” and “1” were defined to be negative and positive, respectively.
The information processing capability was evaluated by performing a short-term memory (STM) task. In the present study, the output current dataset for the STM task was obtained under three different conditions. In condition 1, the dataset was acquired at room temperature (RT), i.e., without applying thermal stimulus. In condition 2, IL-PRD was heated to 100°C as a thermal stimulus and cooled down to RT without applying electrical stimulus, followed by the dataset acquisition at RT. In condition 3, IL-PRD was heated to 100°C and the external voltage was applied at 100°C before the dataset acquisition at RT. The atmosphere during the experiment under those conditions 1, 2, and 3 was high vacuum. The memory capacity (MC), which is a quantitative measure for the STM task accuracy, was 1.72, 1.68, and 2.38 under the conditions 1, 2, and 3, respectively. Namely, the learning performance was improved by about 40% by the simultaneous application of the thermal and electrical stimuli. This result suggests that thermally enhanced electrochemical reaction causes the change in IL and/or Pt/IL interface and improved the learning performance.

Preparation and Characterization of $Hf_{0.5}Zr_{0.5}O_2$-Based Flexible RRAM Device TurgunN. Boynazarov, HoJinLee, JoonbongLee and TaekjibChoi; Sejong University, Korea (the Republic of)

Flexible substrate-based non-volatile devices are even more desired than before for foldable tools and electronics. However, the use of flexible substrate and high-temperature growth of the $Hf_{0.5}Zr_{0.5}O_2$ thin films constitutes the main obstacles to using this kind of heterostructure in flexible computing devices. Here, we report the $Hf_{0.5}Zr_{0.5}O_2$ (HZO)-based flexible resistive random access memory (RRAM) fabrication process by water etching-based oxide membrane lift-off and the following transfer. We have fabricated HZO/$La_{0.7}Sr_{0.3}MnO_3$(LSMO)/$Sr_3Al_2O_6$ (SAO) on SiO_2/Si substrate by using pulsed laser deposition, in this case, we used SAO as a sacrifice layer for transferring HZO/LSMO heterostructure on a metal-coated PET flexible substrate. The RRAM device exhibited forming free bipolar switching characteristics with low power consumption and when it comes to practical applications, the ON/OFF ratio and long-term stability are two crucial concerns regarding flexible RRAM. Excellent RRAM performance in the bent state with radii of curvatures of 12, 10, and 8 mm. In addition, our flexible device shows memristor behavior by measuring multilevel switching. This study provides a promising candidate for flexible memory devices and wearable electronics. When it comes to practical applications, the ON/OFF ratio and long-term stability are two crucial concerns regarding flexible RRAM. Here, we report transfer method-based HZO deposition at a high temperature on silicon samples and transfer.

8:00 PM EL04.06.12
Crystalline $NaNbO_3$ Thin Films Grown on a $Sr_2Nb_3O_{10}$ Seed Layer at Low Temperature for Self-Rectifying and Self-Powered ReRAM Devices SahnNahm, In-SuKim and BumjooKim; Korea University, Korea (the Republic of)

Crystalline $NaNbO_3$ (NN) thin films were deposited on a $Sr_2Nb_3O_{10}$/TiN/Si substrate at 300 °C. The $Sr_2Nb_3O_{10}$ (SNO) nanosheets served as a template to form the crystalline NN films at low temperatures. When the NN film was deposited on one SNO monolayer, the NN memristor exhibited normal bipolar switching characteristics, which can be attributed to the formation and destruction of oxygen vacancy filaments. Additionally, the NN memristor with one SNO monolayer exhibited artificial synaptic properties. However, the NN memristor deposited on two SNO monolayers exhibited self-rectifying bipolar switching properties and two SNO monolayers behaved as a tunneling barrier in the memristor. The conduction mechanism of the NN memristor with two SNO monolayers in the HRS is attributed to Schottky emission, direct tunneling, and Fowler–Nordheim (FN) tunneling. Hence, the NN self-rectifying switching memory device with SNO multilayer can be attributed to fabricating high-density cross-bar devices. Moreover, the piezoelectric energy harvester (PEH) was fabricated using the [001]-oriented NN film grown on SNO/Ni at 250 °C and the NN ReRAM devices have been operated using the NN thin film PEH.

Rotating Janus Particles using Electric Field Gradients Ji-YoungLee, PatrickA. Sullivan and LeilaDeravi; Northeastern University, United States

Rotating particles using electric fields offers a platform to induce dynamic colors for display applications. We explore the rotational behavior of Janus structures comprising a metal and a dielectric material with different geometries, including matchstick-like and snowman-like configurations. We combine numerical analysis with experimental validation to gain insights into their dynamics. We investigate how different particle geometries influence rotational behavior under an applied electric field and highlight the role of high frequencies on the angular velocity and electric torque showing promise for controlling particle asymmetry for displays.

8:00 PM EL04.06.14
Integration of Local Neuromorphic Circuits in Soft Robotic Systems to Realize Learning and Memory BobHuisman[1], Yoerivan de Burgt[1] and BasOvervelde[2,1]; [1]Eindhoven University of Technology, Netherlands; [2]AMOLF, Netherlands

Organic electrochemical transistors (OECT) have shown to be promising components for neuromorphic computing. In particular, their ability to control stable conductance states over a large range, which can be used to emulate the synaptic weight in artificial neural networks (ANN); an important component in translating the network from digital to hardware, as to reduce operation power and to circumvent the von Neumann bottleneck. Simultaneously, the field of soft robotic systems has achieved inherently adaptive actuators by using compliant, soft materials, which makes them promising candidates to be used in non-conventional environments and for complex applications. However, they are typically pre-programmed and are subsequently not capable of adapting their behavior on longer time scales. Additionally, the weight and size of typical robotic learning systems do not make it suitable for integration in soft systems. Our goal is to integrate local neuromorphic circuits, as an alternative platform to achieve decentralized learning and memory in soft robotic systems for performance optimization and environment adaptability. Typical software-based ANN learning algorithms make use of backward propagation and gradient descent, the latter being particularly hard to achieve in hardware. A possible alternative route for the hardware-based ANN is to make use of a physical neural network (PNN), where the physical processes and local rules of the circuit are utilized to train the network.

The Impact of Sc-Substitution on the Switching Behavior in AlN-Based Memristor Devices SeokgiKim, JimyeongYu and SungkyuKim; Sejong University, Korea (the Republic of)

Aluminum Nitride (AlN) has garnered significant interest as an active material for memristor devices due to its outstanding characteristics such as a tunable bandgap by doping, chemical/thermal stability, and high electrical resistivity (~ 10^{14} Ω-m). [1],[2] Since memristor devices for artificial intelligence learning must ensure low power consumption, fast write speed, and long-term stability, it is important to clearly identify the switching behavior and control the electrical path in active materials. [3] However, the strong electric field is required to generate the set state, and permanent breakdown by Joule heating occurs due to the high barrier of AlN/metal Schottky junction. [4] Therefore, it is necessary to lower the Schottky barrier *via* elemental doping and form the robust conductive path by soft breakdown for realizing a stable AlN-based memristor with multilevel resistance.
In this study, we fabricated the vertically stacked Au/$Al_{0.7}Sc_{0.3}N$/Cu device with a modified active layer in which 30% of Al sites is substituted with Sc to prevent permanent breakdown in Au/AlN/Cu device. The yield of Au/AlN/Cu is lower than Au/$Al_{0.7}Sc_{0.3}N$/Cu by 23% because of the excessive Joule heating induced by high forming voltage of AlN causes permanent breakdown. The irreversible migration of nitrogen ions in AlN active layer leads to the degradation of conductance. Compared to AlN-based device, Sc-substituted AlN (AlScN) with a 15% reduced bandgap exhibits a low forming voltage of 6.0 V due to Schottky barrier lowering. In addition, AlScN with a thickness of 30 nm shows stable switching behavior at a reduced set voltage of 2.1 V and a reset voltage of -1.3 V formed by relatively weak soft breakdown. We directly observed conductive path composed of nitrogen vacancies in a AlScN layer using atomic-resolution transmission electron microscopy. In addition, the resistance at low resistive state gradually decrease at the elevating temperature from 300 K to 400 K, indicating typical semiconductor behavior. Under various compliance current conditions ranging from 0.1 mA to 10 mA, all resistance states were maintained for a duration of 10^5 seconds at a read voltage of 0.3 V without noticeable degradation. The analog switching characteristics of AlScN and AlN devices were measured by applying a 10 us positive/negative voltage pulse for potentiation/depression, and statistical values of non-linearity factors (NL) were obtained for its quantification. Compared to the average NL of AlN devices is 0.67, the average NL of AlScN devices is 0.36, which is explained by the reversible movement of nitrogen ions in AlScN matrix. Modification of junction properties by elemental substitution provides a specific method to improve the reliability of AlN-based memristor devices for future neuromorphic computing.

Leveraging Electrochromic Polymers for Organic Electrochemical Synaptic Devices by Unraveling Polymer-Ion Interactions. HeejungRoh[1], ShuwenYue[1], HangHu[2], KeChen[2], HeatherJ. Kulik[1] and AristideGumyusenge[1]; [1]Massachusetts Institute of Technology, United States; [2]Purdue University, United States

Owing to low-power, fast and highly adaptive operability, as well as scalability, electrochemical random-access memory (ECRAM) technology is one of the most promising approaches for neuromorphic computing based on artificial neural networks. Despite recent advances, practical implementation of ECRAMs remains challenging due to several limitations including high write noise, asymmetric weight updates, and insufficient dynamic ranges. Here, inspired by similarities in structural and functional requirements between electrochromic devices and ECRAMs, we demonstrate high-performance, single-transistor and neuromorphic devices based on electrochromic polymers (ECPs). To effectively translate electrochromism into electrochemical ion memory in polymers, we systematically investigate polymer-ion interactions, redox activity, mixed ionic-electronic conduction, and stability of ECPs both experimentally and computationally using select electrolytes. The best-performing ECP-electrolyte combination is then implemented into an ECRAM device to further explore synaptic plasticity behaviors. The resulting ECRAM exhibits high linearity and symmetric conductance modulation, high dynamic range (~1 mS or ~6x), and high training accuracy (> 84% within 5 training cycles on a standard image recognition dataset), comparable to existing state-of-the-art ECRAMs. This work offers a promising approach to discover and design novel polymer materials for organic ECRAMs and demonstrates potential applications, taking advantage of mature knowledge basis on electrochromic materials and devices.

Flexible Electrochemical Neural Probes for *In Vivo* Recording of NeurotransmittersMonaAbdelmonem, SinaGharahtekan, AbdulrahmanAl-Shami, FarbodAmirghasemi, AliSoleimani and MaralMousavi; University of Southern California, United States

Catecholamines are a significant focus in research because they play a critical role in the brain's "reward" system, although their precise function is not yet fully comprehended. The quantification of catecholamines are vital as they regulate all cognitive processes in the brain and
can aid in early detection, diagnosis, monitoring, and therapeutic interventions for complex neural disorders. Implantable neural interfaces are essential in expediting progress in neuroscience research and the practical application of clinical neurotechnologies. Electrochemical
sensors offer several advantages for measuring catecholamines, including high sensitivity and selectivity, rapid response time, minimal sample preparation, non-invasiveness, and portability. The proposed design will be used to create the sensor. It includes a working electrode and a reference electrode with a reference membrane. The reference electrode is shared between the platinum electrodes and will be formed on a parylene C substrate that is 10-20 μM thick. The
platinum electrodes have a 100-200 μM radius and a thickness of approximately 200 nm. The sensing membrane will be applied to
the circular area of the platinum contact using drop-casting.
For in vivo recording, parylene's flexibility is essential because it enables implanted devices to adapt
to the shape of the brain or muscles and move with it without harming the surrounding tissue. While many in vitro catecholamine sensing electrodes utilize coatings made of enzymes, aptamers, and antibodies to increase their sensitivity, these coatings are prone to biofouling and quick degradation, reducing the sensor's lifespan in vivo. As a result, we are using a label-free surface-modified Pt electrode, which has been shown to be durable during long-term implantation, Figure 1. The
expected peaks potential for different catecholamines are: Epinephrine (EP): around 0.1-0.3 V, Norepinephrine (NE): around 0.1-0.2 V, Dopamine (DA): around 0.2-0.4 V. We utilize cyclic voltammetry and square wave voltammetry for direct electrochemical detection of catecholamines.
We are depositing a sensing membrane comprising an ionophore on the working electrode for acetylcholine and pH.

Improved Charge Trapping of Synaptic Flash Memory by TiO_2 Reinforcer Seong HyunLee, LeeWangjoo, JinhaKim, Jeong WooPark and DongwooSuh; Electronics and Telecommunications Research Institute, Korea (the Republic of)

I. Introduction
As AI computing has come a long way in the last decade, synaptic devices in artificial neural networks (ANNs) are recently drawing more attention due to the role of connection between neurons. Among synaptic devices, flash memory has been thoroughly investigated because of high density of data storage and low-voltage operation. However, even conventional flash memory like $SiO_2/Si_3N_4/Al_2O_3$ (SONOS) device still has a serious issue of nonlinear responses limiting the ability to deal with complicated input patterns. In order to improve the linearity, synaptic devices should have a large window of conductance to afford various input signals. In the present study we suggest new solution to subdue the nonlinearity by enhancing charge trapping.

II. Main Body
2.1 Experimental
The present synaptic devices were fabricated on Si(100) wafers using ETRI's CMOS fab. Based on thermal oxide of 500 nm, deposition of polysilicon atop and ion implantation were performed in a row to make channel and source/drain. Dielectric complex including tunneling and blocking oxide was formed as SiO_2(3 nm)/Si_3N_4(3 nm)/TiO_2(2 nm)/Si_3N_4(3 nm)/Al_2O_3(9 nm) using plasma enhanced atomic layer deposition at 300°C. The incorporation of TiO_2, an additional charge-trapping layer in the middle of Si_3N, is the main feature of the solution suggested. Finally, we adopted TiN and aluminum as gate and electrode materials, respectively.
Transfer properties of the implemented devices were measured using parameter analyzer for single and multiple pulse condition while keeping both programming (PRM) and erasing (ERS) voltages fixed. Input signal was a square-type pulse with duration of 2 sec in single pulse. On the other hand, we investigated conductance change under multiple pulses to simulate real ANNs by applying 10^6 pulses with both duration and interval of 10 msec

2.2 Results and Discussion
We extracted from measured transfer curves conductance change between PRM and ERS states of TiN/Al_2O_3/Si_3N_4/SiO_2/poly-Si (TANOS) and TiN/Al_2O_3/Si_3N_4/TiO_2/Si_3N_4/SiO_2/poly-Si (TAXOS) devices. Both devices show much lower PRM and ERS voltage (9 V) than conventional SONOS device (~ 20 V). Furthermore both devices show largest conductance span near the gate voltage of 1 V, which is small enough to reduce the burden of power issue.
The difference of conductance △G between PRM and ERS states are compared both for TANOS vs. TAXOS and single vs. multiple pulse condition, respectively. As a result, the conductance span of TAXOS is superior to TANOS both for single ($\triangle G_s = 3.6x10^4$ S vs. $1.7x10^2$ S) and multiple pulse condition ($\triangle G_m = 1.5x10^4$ S vs. $2.6x10^3$ S). The conductance span of TAXOS is one to two orders of magnitude higher than that of TANOS. The increased DG can keep more input signals contained in TAXOS device improving the linearity aforementioned. Furthermore, the wide tunability of conductance enables TAXOS synapse to catch even smaller change of input signals facilitating more accurate learning in ANNs.
This improvement of conductance span in TAXOS is attributed to TiO_2 layer. TiO_2 has large dielectric constants of tens to hundreds depending on crystalline structure, thereby it can be regarded as a reinforcer of charge-trapping. Although we have not yet fully understood the trapping mechanism, its electron-deficient stoichiometry may be able to enhance the charge trapping capacity.

III. Conclusions
We suggested new synaptic flash device of TAXOS that enhances charge-trapping capacity due to TiO_2 layer. TAXOS shows larger conductance span (tens to hundreds times) between PRM and ERS states than TANOS, which would be able to improve linearity in synaptic response. Through this study we noted that very high-k electron-deficient TiO_2 plays a role of reinforcer in charge-trapping operation despite a necessity to explore theoretical mechanism yet.

8:00 PM EL04.06.19

$MoTe_2$ Neuromorphic Memory Devices Enabled by Metal Ion Intercalation Rifat HasanRupom[1], MoonyoungJung[2], DongseokSuh[2] and WonbongChoi[1]; [1]University of North Texas, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Two-dimensional transition metal dichalcogenides (TMDs) have attracted a lot of attention as neuromorphic memory devices due to their phase-tuning properties at the atomic-level structure. Among 2D TMDs, Molybdenum ditelluride ($MoTe_2$) has shown a phase tuning property between its 1T' and 2H phases by a minimal energy change. We developed a large-scale $MoTe_2$-based synaptic memory device for neuromorphic computing by a simple sputtering and post-lithiation process. We observed that lithiation on sputtered $MoTe_2$ results in phase segregation by forming Te crystal structure, which has a negative effect on the phase tunability towards synaptic memory. We have developed a method for stabilizing $MoTe_2$ crystal structure under metal ion intercalation by using a passivation layer. When compared to non-lithiated pristine amorphous $MoTe_2$, the lithiated $MoTe_2$ effectively enhances I_{on}/I_{off} hysteresis current from 5 to $>10^2$ at lower sweep voltages of 5V with Pico joule power consumption. We will discuss the fundamental mechanism of phase transition by metal-ion intercalation and its neuromorphic characterization by stabilizing the phase in $MoTe_2$ in addition to the $MoTe_2$ synaptic memory device performance.

8:00 PM EL04.06.20

Tuneable Conductance Quantization in Crossbar Cu/Ta_2O_5/Pt Resistive Random Access Memory Devices UtkarshMisra[1,2], Vikas K.Sahu[2,3], Amit K.Das[2], Ajimsha

RohiniSreedharan[2] and PankajMisra[2,3]; [1]University of South Florida, United States; [2]Raja Ramanna Center for Advanced Technology, India; [3]Homi Bhabha National Institute, India

Given the current demands of data-intensive and cost-efficient computing, there exists a need of a memory device that could offer low operating power in-memory computation capabilities and can redefine von Neuman computer architecture while still exhibiting compatibility with the current CMOS fabrication infrastructure. In the past decade, resistive random access memory (ReRAM), has emerged as a promising candidate for the logic-in-memory devices due to its excellent properties such as scalability, low power operation, multiple logic states, fast switching and CMOS compatibility. In addition, quantized conduction in ReRAM devices arising due to size quantization, presents an opportunity to realize high-bit multilevel resistive switching for ultra-high-density memory systems with in-memory computation applications. For device showing quantized conduction, the conductance (G) of the device can be expresses as $G=nG_0$, where n is integer or half integer, and G_0 is the fundamental unit of conductance (G_0 ~ 77.5 µS). Here, we report reliable and repeatable resistive switching behavior in crossbar Cu/Ta_2O_5/Pt ReRAM devices based on electrochemical metallization (ECM) , wherein quantized conductance has been observe, investigated, and tuned in reset switching events.
The Cu/Ta_2O_5/Pt devices in 8×8 crossbar geometry were fabricated on SiO_2/Si substrates using RF magnetron sputtering. Platinum bottom electrodes of thickness ~ 20 nm and line width and separation ~ 250 µm were patterned using a metal shadow mask, followed by ~100 nm thick Ta_2O_5 thin film. After the deposition of the Ta_2O_5 layer, about 45 nm thick copper line electrodes as top electrode were patterned again using the shadow mask orthogonal to the bottom electrode, forming an array of 64 individual RRAM devices. The devices showed robust bipolar resistive switching, where the set switching voltage was found in the range of ~ 0.6-0.8V and reset voltage ~ (-) 0.5 to (-) 0.8V for 150 switching cycles at compliance current (I_C) of 200 µA. The mean resistances of the low and high resistance states were ~8.4 kΩ and ~828 kΩ, with variability of ~ 0.39 and 6.6 respectively. The reset currents were always found to be smaller than the compliance current confirming the ECM mechanism of the resistive switching, wherein the conducting filament (CF) is considered to have formed of Cu atoms which leads to low operating power per switching event. The variation in compliance current resulted in change in lateral dimension of the CFs leading to different low resistance states.
Furthermore, integral and half integral quantized conduction (QC) sates were clearly observed in the crossbar Cu/Ta_2O_5/Pt devices, where the number and magnitude (n) of the quantized states were found to ~6 and 3.5, respectively at I_C of ~ 200 µA. The distribution of the conductance was Gaussian which were centered at1 G_0, 1.5 G_0, 2 G_0, 2.5 G_0, 3 G_0, 3.5 G_0. The magnitude and number of the QC states were found to increase from ~2.5 to 3.5 and from 4 to 6, respectively as the I_C increased from 50 to 200µA. The increase in number and magnitude of QC steps with I_C was explained considering the fact that thicker CF obtained at higher I_C, when undergoes a gradual rupture during reset process, results in larger number of QC steps compared to a thinner CF. The diameter of the CF was calculated theoretically considering resistance contributions from Ohmic, Maxwell and Quantum point contact to the resistance of the low resistance states, and found to increase with increasing compliance current. In future work, the synaptic behaviour of Cu/Ta_2O_5/Pt devices for artificial learning will be explored via spike-time-dependent-plasticity, potentiation and depression characterisations. The observation of QC states in the ECM based crossbar Cu/Ta_2O_5/Pt device, and I_C controlled tuneability of magnitude and number may be useful for next generation high storage density resistive memory and electronic synapses for neuromorphic computing.

8:00 PM EL04.06.21
Closed-Loop Neuromorphic OECTs for Autonomous Reinforcement Learning in Robotics UgoBruno[1,2], DanielaRana[3,4], ChiaraAusilio[1], OttaviaBettucci[5], SimonMusall[3], ClaudiaLubrano[3,4] and FrancescaSantoro[1,3,4]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Napoli Federico II, Italy; [3]Forschungszentrum Jülich GmbH, Germany; [4]RWTH Aachen University, Germany; [5]University of Milano-Bicocca, Italy

Neuromorphic platforms are emerging as new computational paradigm[1], with the ultimate goal of building artificial neural system, by replicating the efficiency of the brain in terms of parallel computation.
Such technologies can mirror several aspects of the brain, by exploiting complex circuits[2] or by exploiting unique features of innovative materials[3].
Among the plethora of the available materials and structures, organic electrochemical transistors (OECTs) have emerged as ideal candidates in the building of complex neuromorphic systems, able to interface with living organisms[4] and to learn autonomously[5].
Notably, PEDOT:PSS-based OECTs have been employed in the implementation of the first biohybrid synapse. Here, cells cultured *in vitro* could directly communicate with such artificial neurons by means of neurotransmitters, emulating a biological chemical synapse[6].
In this scenario, while successfully recapitulating several features of the synaptic communication, current neuromorphic devices process information in an open-loop fashion, failing in the recapitulation of the intricate, redundant and closed-loop communication of the brain, that makes the human nervous system so fault-tolerant and energy efficient.
The present work demonstrates autonomous reinforcement learning mediated by biological-inspired signals, in a closed-loop neuromorphic system. Here a neuromorphic OECT will ultimately learn how to drive a robotic harm, in order to grasp objects of different sizes.
The OECT can communicate with a silicon microcontroller to drive the 3D-printer robotic hand that is required to execute the task of grasping a ball. A pressure sensor provides a feedback on the outcome of the task. If the OECT cannot elicit a complete grasp, a punishment signal is sent in the form of a dopaminergic signal, that oxidized the PEDOT:PSS channel of the transistor, changing its conductance and modifying the grasp. Conversely, if the grip is correctly executed, a reward signal is supplied.
In addition, even when the difficulty of the task is increased by changing using a progressively smaller object, the neuromorphic system can adapt and learn again to grasp the target. Notably, such learning is non-volatile.
In light of this, the present work paves the way towards a novel generation of hybrid devices able to combine decades of development of silicon-based technologies with innovative features of organic neuromorphic devices.

8:00 PM EL04.06.22
A Vacuum-Deposited Polymeric Dielectric for Intrinsically Stretchable Carbon Nanotube Transistors Ja HoonKoo; Sejong University, Korea (the Republic of)

Stretchable devices based on high-performance inorganic materials require the use of stretchable device designs such as wavy interconnects and kirigami structures, which sacrifices the device density to achieve stretchability and complicates circuit design. For applications that require high resolution or complex circuit designs in stretchable formats, the inorganic-based stretchable devices based on the device design strategy are thus not suitable. Another strategy to achieve stretchability is to construct the devices using intrinsically stretchable materials, but significant progress is required as devices based on these materials generally exhibit low electrical/optoelectronic performance as compared to the inorganic-based devices. This is particularly due to the absence of a high-quality stretchable dielectric material that exhibit nanometer-scale thickness for easy gate control and excellent insulating/mechanical performances at the same time. As such, common stretchable dielectrics used for intrinsically stretchable devices exhibit micrometer-scale thickness, resulting in poor gate controllability and high operation voltages. In many cases, these stretchable dielectrics are solution-processed, susceptible to organic solvents, and have low dielectric constants, which are not desirable fabrication of high-performance devices. Through this work, we report the development of nanoscale stretchable dielectric layer which is compatible with the current microfabrication tools such as photolithography, etching, and consequent film deposition. The dielectric layer can be deposited using vacuum-deposition technique (initiated chemical vapor deposition), thus allowing for excellent thickness controllability and high areal uniformity. Our nanoscale stretchable dielectric film with ~160 nm thickness exhibits high chemical, mechanical, and thermal stabilities. Wafer-scale transistor arrays employing the developed dielectric, semiconducting carbon nanotube networks (as channel), and Au nanomembranes exhibit comparable electrical performance as those fabricated using inorganic dielectric layers (Al_2O_3 layer deposited with atomic layer deposition), but with intrinsic stretchability (up to 40% strain).

8:00 PM EL04.06.23
Integration of Synaptic Optoelectronics and Quantum Dot Light-Emitting Diodes for The UV Visualization Moon KeeChoi; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Synaptic photodetectors demonstrate photon-triggered synaptic plasticity, offering potential enhancements in image recognition rates by improving image contrast. However, the visualization and recognition of concealed ultraviolet (UV) patterns remain challenging due to significant background noise. In this study, drawing inspiration from the all-or-none potentiation of synapses, we introduce an integrated device comprising synaptic phototransistors (SPTrs) and quantum dot light-emitting diodes (QLEDs) to address this issue. This device aids in noise reduction and the visualization of UV patterns through on-device preprocessing. The SPTrs transform noisy UV inputs into a weighted photocurrent, which is subsequently applied to the QLEDs as a voltage input through an external current-voltage–converting circuit. The QLEDs' threshold switching characteristics result in amplified current and visible illumination in response to suprathreshold input voltage, while nearly zero current and no visible illumination occur below the threshold. Utilizing the SPTr-QLED preprocessing for image data can effectively enhance image contrast, thereby facilitating high-accuracy image recognition

8:00 PM EL04.06.24
Porous Organic Semiconductors for Geneless Optical Fine Tuning of Intracellular Reactive Oxygen Species in Endothelial Cells CamillaMarzuoli[1,2], MiryamCriado-Gonzalez[3],

LucaBondi[4], GabrieleTullii[1], CarlottaRonchi[1], EdgarGutierrez-Fernandez[3], ElenaGabirondo[3], HaritzSardon[3], Daniel EnriqueMartinez Tong[5], JaimeMartin[3,6,7], MarcoMalferrari[4], StefaniaRapino[4], TobiasCramer[4], DavidMecerreyes[3] and Maria RosaAntognazza[1,5]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]POLYMAT, Spain; [4]Università di Bologna, Italy; [5]UPV/EHU, Spain; [6]Universidade da Coruña, Spain; [7]Basque Foundation for Science, Spain

An imbalance in cellular redox status is intrinsically linked to the onset and progression of numerous diseases. [1] In fact, Intracellular Reactive Oxygen Species (ROS) concentration plays a crucial role in the control and fine tuning of several physiological functions, from cell proliferation to differentiation, from migration to metabolic activity, to specific functionalities.[2] As a consequence, a strong interest towards the concept of 'redox medicine' has been emerging in the few latest years.[2]
Current available treatments to modulate the cell redox balance rely on the employment of chemically controlled methods. However, this strategy often fails to achieve accurate spatial and temporal control, is not reversible and is unsuitable for fine-tuned control of sub-cellular organelles. Employing optical excitation as a stimulus to finely modulate intracellular ROS concentration at non- toxic levels offers the opportunity to overcome these limitations, but requires the development of novel, photoelectrochemically active transducers.
To support the development of new tools for precise, non-toxic, non-invasive and on-demand modulation of intracellular ROS concentration it is therefore necessary to develop new biocompatible materials, characterized by highly tunable electrochemical efficiency and good stability in a biological environment.[4,5] Moreover, stimulation protocols should be as minimally invasive as possible.
Here, we propose a novel strategy, based on the use of semiconducting polymers. We demonstrate that photoelectrochemically active organic semiconductors potentially satisfy all these requirements and their application for bio-hybrid interfaces could lead to a reliable new medicine.
In more detail, our strategy is based on the development novel porous nanomaterials with an enlarged surface area that enhances their opto-electrochemical properties.[6] To that aim, graft copolymers, made of poly(3-hexylthiophene) (P3HT) and poly(lactic acid) (PLA) P3HT-g-PLA, are synthesized and employed for the fabrication of both porous thin films and porous nanoparticles (NPs). We employ FT-IR, TEM, AFM, DLS and water contact angle measurements to provide extensive characterization of morphology and composition. Importantly, sizable enhancement of photo-electrochemical efficiency is successfully achieved in porous P3HT-g-PLA materials, in both films and NPs, as demonstrated by photocurrent and Scanning Electrochemical Microscopy measurements.
Human Umbilical Vein Endothelial cells (HUVECs) are employed here as a physiologically relevant cell model. In endothelial cells, in fact, ROS production can regulate several aspects of vascular function, including angiogenesis. [7,8]
Internalization of porous NPs in HUVECs is successfully reported at different concentrations. For both thin films and NPs, intracellular, optically-modulated ROS production is demonstrated with high specificity and yield. Future work will aim at clarifying the functional interplay among biophysical pathways connecting intracellular ROS modulation, ion channels activation and Ca^{2+} dynamics, focusing on the potential application of these porous materials for therapeutic angiogenesis.

Development and Evaluation of Bioelectrode Array Devices for Monitoring Lower Back Pain SeiichiTakamatsu, NaotoTomita and ToshihiroItoh; The University of Tokyo, Japan

In recent years, wearable devices like Fitbit and Apple Watch have gained popularity for health monitoring. Advances in e-textile technology have made fabric devices equipped with arrayed bioelectrodes particularly suitable for whole-body muscle activity monitoring. Specifically, it is suggested that back pain can be prevented or measured by capturing FRP signals in the lumbar region. Due to the need for monitoring in daily life, the longevity of these devices is becoming increasingly important. While there has been progress in developing long-lasting electrodes with low noise, the issue of electrode adhesion has remained a challenge. In this study, we propose a new method for securing electrodes using hot-melt sheets and have confirmed its effectiveness. Our results demonstrate that this approach ensures the electrodes do not detach, allowing for reliable electromyographic measurements. The device proposed in this study has a multi-layered structure in which various functional materials are laminated onto fabric. The composition of each layer. In the manufacturing process, silver paste is first screen-printed onto a polyurethane film (DUS-202, Seadam Co., Ltd.) to form the wiring layer. This wiring layer is then thermally bonded to the fabric using a hot-melt sheet (SHM101-PUR, Seadam Co., Ltd.). On top of that, another hot-melt sheet with holes opened in the via regions is thermally bonded to serve as the insulating and adhesive layer. Next, fabric cut into electrode shapes using a laser cutter is thermally bonded, and conductive plastic PEDOT:PSS and ionic liquid gel are then impregnated into this fabric piece and cured. We conducted mechanical characteristic evaluations as well as performance assessments as an electromyography (EMG) measuring device on the fabricated device. When wearing and using the device, it is anticipated that force will be applied to the electrodes from various directions, and it is required that the electrodes do not peel off under such conditions. Therefore, we evaluated the strength of the electrodes using tensile-shear tests and T-peel tests. During the evaluation, we prepared a sample based on the actual electrode structure by adhering a polyurethane film to a piece of fabric (10 mm x 30 mm) using a hot-melt sheet (10 mm x 10 mm). Another layer of fabric with electrode material applied was then attached using another hot-melt sheet. We also conducted tests on samples before the electrode material was applied for comparison. The strength was determined by clamping 10 mm x 10 mm sections on both ends of the fabric and investigating the relationship between the pulling amount and the load using a benchtop load tester (FTN1-13A, Iko Engineering Co., Ltd.).To assess the EMG measurement performance, the fabricated device was attached to the lower back and the lumbar EMG was measured. In the adhesive strength evaluation tests, two key findings emerged. First, when subjected to pulling forces, the fabric itself broke at around a strain level of 1.2 without any delamination at the adhesive interface. This indicates that the electrodes have sufficient tensile strength. Second, delamination began to occur when the strain exceeded 1, and the load plateaued. The peel strength was around 40 N before the electrode material was applied, and approximately 20 N after its application. Despite the reduction in peel strength due to the ionic liquid gel, it was confirmed that the electrode could withstand the types of force it would encounter in wearable use. In lumbar electromyography (EMG) measurements using the array electrodes, the data corresponded to a known physiological phenomenon. It is generally understood that no lumbar EMG activity is observed when maintaining a bent-over posture. This was confirmed in the current study, where a clear disappearance of EMG activity was observed between the 5 to 10-second interval, compared to the periods before and after.

8:00 PM EL04.06.26
Multilevel Resistance Modulation of Au-Nanodot Embedded Self-Rectifying Memristor for Neuromorphic Hardware Tae GyunPark[1], JihunKim[1], Young JaeKown[1], Hae JinKim[2] and Cheol SeongHwang[1]; [1]Seoul National University, Korea (the Republic of); [2]Myongji University, Korea (the Republic of)

The memristor-based materials have been researched as next-generation computing devices due to their simple metal-insulator-metal (MIM) structure and ease of device fabrication. The memristive crossbar array (CBA) is effective for the implementation of multiply-and-accumulate (MAC) operations by simply collecting current at the single bit line (BL) from the multiple biased memristors through word lines (WLs), which follows Kirchhoff's current law (KCL). Since the memristive CBA consists of multiple BLs, the multiple MAC operations can be performed in parallel, proving a more efficient computing device for ca. neuromorphic system as the size of the CBA increases.[1, 2]
Despite the promising structural advantages of memristive CBA for MAC operations, the non-ideal characteristics, such as sneak current, line resistance, variations, and electroforming, hinder more practical applications. Such a problem can be mitigated by introducing additional selecting devices, known as selectors or transistors, to the memristors.[3] However, engineering the electrical characteristic to match the appropriate operational voltage and the current level is challenging, especially when processing variation exists throughout the CBA structure. Another aspect to consider for MAC operations is energy consumption. Introducing other three-terminal devices, however, often induces higher operational current levels in the range from several hundred μA to mA and the operational voltage, resulting in significant additional energy consumption in the larger CBA structure.
To alleviate the difficulties, self-rectifying memristor (SRM)-based CBA is introduced that uses a bi-layered oxide structure instead of introducing the additional selecting devices and has a much lower operation current level with a range of sub-μA to nA. Since the switching mechanism is governed by trap-rich and insulating layers with Schottky contact, the electroforming process is not required in the CBA structure, and the reversed current is significantly suppressed to prevent the sneak current.[4, 5]
However, SRM-based CBA still requires additional control in cycle-to-cycle variations and retention of states, resulting from the variation in the electronic trapping and detrapping in trap levels, which are essential parameters to determine the accuracy of the MAC operations and multilevel states in the implementation of the artificial synapse.
In this work, nanometer-sized gold nanodots (Au NDs) were formed at the interface of switching and rectifying layers to promote the electric field concentration in alignment with trap states. Enhancing the electric field concentration improves the overall cycle-to-cycle variations and retention characteristics. The conduction model to explain the improvement from Au NDs in $Pt/Ta_2O_5/HfO_x/TiN$ structure is proposed based on the experimental result from the modulation of the size and position of Au NDs with transmission electron microscope (TEM) analyses. With conductive atomic force microscopy analysis and the finite element method simulations, the distribution of the internal electric field and the current density could be verified inside Au-NDs embedded SRM. Finally, the demonstration of MNIST classification in neural network application using eight stable states (3-bit) of the SRM-based CBA shows improved accuracy compared to non-inserted Au NDs SRM.

Reconfigurable Logic Circuits Based on Organic Electrochemical Neuromorphic Devices Myung-HanYoon; Gwangju Institute of Science and Technology, Korea (the Republic of)

Owing to the increasing demands of data-intensive applications, there exists an imperative need for next-generation electronic systems that are energy-efficient and possess low power consumption, facilitated by innovative architectures. In this study, we present the development of reconfigurable circuits built on organic neuromorphic devices. Our research focused on leveraging the learning capabilities of an organic electrochemical diode to execute multiple logic functions through high-performance reconfigurable logic circuits. A key feature of these devices is the tunability of their conductivity state, which can be modulated in response to the polarity of the drain-source voltage (V_{DS}), while the selective activation of various elements is governed by the manner in which the input voltage (V_{logic}) is utilized. Consequently, such manipulation facilitates the transition from an undefined state to selectively performing as either an AND or OR gate within the same hardware configuration. Additionally, it was demonstrated that the capacity for more sophisticated operations by integrating learnable AND and XOR circuits to construct a half-adder. We expect that our findings will provide an efficient approach toward novel digital circuitry through on-chip learning, thus surmounting the efficiency bottleneck that exists in conventional computing systems.

9:30 AM EL04.07.02
Characteristics of the Thermodynamics of Novel Ag-Cation Controllable Diffusive Memristors for Artificial Neuron Application MoonkyuSong, SangheonLee and SanjayK. Banerjee; Microelectronics Research Center, The University of Texas at Austin, United States

Introduction: Diffusive memristors are essential elements for neuromorphic computing applications due to their ideal electrical characteristics such as high off-state resistance and a steep turn-on slope [1]-[2]. However, it is difficult to have characteristics with a large on/off ratio and a fast switching speed at the same time with conventional devices. Here, we reported a method to solve this problem using combination of Al_2O_3 metal oxide solid electrolyte layer and engineered defective graphene monolayer. We have also verified this characteristic through thermodynamic analysis for artificial neuron application.

Device Description: The devices for this study were fabricated using the same method as presented in our previous paper [3]. Silver active metal layer was deposited by e-beam evaporation on a SiO_2/Si wafer, followed by patterning with lift-off method. For the filament-control graphene interlayer, chemical vapor deposition (CVD) of graphene on copper foils was done, and then, CVD graphene was transferred onto a SiO_2 / Si substrate with Ag bottom electrode using poly (methyl methacrylate) (PMMA) support layer. After the transfer of the graphene layer, the PMMA was removed with acetone. A hydrogen electrochemical reaction process and vacuum anneal were performed after the transfer process to form the defective area in the graphene and remove PMMA residue on the graphene film, and then the Al_2O_3 layer was deposited by atomic layer deposition (ALD). Finally, Pd inert metal was defined as the top electrode (TE). To analyze the characteristics of the thermodynamics of Ag-cation controllability with our system, MATLAB, and COMSOL Multiphysics were performed with the Ag-based threshold switching device measured parameters.

Results and Discussion: The DC current–voltage characteristics of Ag/Graphene-based novel diffusive memristor were performed. The initial states of devices were normally in the off-state and their resistances were about 10^{12} ohms at 0.1 V. When a graphene layer is placed between the active metal (Ag) and oxide electrolyte layer (Al_2O_3), the off-current was found to maintain its low value until the conductive filament is fully generated and the memristor is changed from off-state to on-state. The off-current of the novel memristor was ~10^{-13} A. The on-current was~ 10^{-3} A, with self-compliance characteristics, as reported in our previous paper [3]. To elucidate the self-compliance characteristics, we investigated the dynamics of conductive filaments with limited Ag cation concentration using our defective graphene. We utilized MATLAB and COMSOL Multiphysics to calculate the relationship between chemical potential and filament radius during the turn-on process. The filament dynamics during turn-on were analyzed based on the minimization of free energy, which comprises thermal energy, electrostatic energy, surface chemical energy, and volume chemical energy. We calculated each term in the free energy equation using our device structures, and the total free energy was obtained by summing up these terms. The radius of the conductive filament was found to have the minimum value at the intersection of the thermal energy and volume chemical energy terms. This indicates that the radius of the filament can be fixed, resulting in the achievement of self-compliance characteristics at this fixed point. This limitation can be related to the filament dissolution time which makes the fast reset speed for artificial neuron applications.

9:45 AM EL04.07.03
Lego-Like Heterogeneous Integration of Memristor Arrays using Optical Communication Min-KyuSong, HyunseokKim, JunminSuh and JeehwanKim; Massachusetts Institute of Technology, United States

Conventional integration technologies have encountered issues including material deterioration due to the physical interaction between chips, fixed operation modes owing to the permanent connections to a single sensor, and limited data processing capabilities due to constraints when adding processors for various computing needs. In this study, we developed an innovative, reconfigurable 'Lego-style' 3D integration platform. This platform uses optoelectronic devices to facilitate communication between AI processors. We integrated freestanding GaAs/InGaP membranes into each chip via an epitaxial lift-off (ELO) process. Communication between chips was enabled by optical transmission between GaAs LEDs and InGaP photodiodes. By eliminating electrical interconnects, we not only avoided interference from physical contact, but also significantly enhanced chip configuration flexibility. We further incorporated memristor arrays into each stackable chip, serving as AI hardware accelerators and greatly improving processing efficiency. This innovative approach overcomes the limitations observed in previous 3D heterogeneous integration methods. By using this novel 'Lego-style' 3D heterointegration process based on a GaAs/InGaP stack, edge computing systems integrated with various sensors can provide infinite modality, exceptional computational efficiency, and adaptability for a variety of computing tasks.

Impact of Low-Voltage Resistive Switching Devices on Neuromorphic Computing ArkaMukherjee, SrikrishnaSagar and BikasC. Das; IISER Thiruvananthapuram, India

The human brain is the most efficient machine around us in size, power efficiency, self-learning capability, decision-making, and simultaneous data storage and processing. Additionally, our brain performs all operations analogously by consuming energy of about 1 – 100 fJ per synaptic event. Even though the conventional computer works much faster than the brain, the von Neumann bottleneck and memory wall issues limit the performance and energy efficiency due to the physically separated storage and processing unit. After discovering the memristor (MR), a two-terminal device with multiple conducting states at a particular bias voltage, efforts are already underway toward developing machines similar to brain functionality. Despite massive progress in semiconductor technology, it is still challenging to mimic the functionality of synapses and neurons, the basic building blocks of our brain. Memtransistor (*mem*T), a gate-controlled memristor or memory transistor, is also coming up rapidly to the limelight for mimicking functionalities of synapses and neurons more controlled way as the building block of the artificial brain. Among various approaches, the redox-controlled MR and *mem*T are becoming very attractive to accomplishing the desired metrics for developing efficient neuromorphic computing tools. In this talk, I will introduce a few unconventional redox reaction-dependent molecular MR and organic *mem*T devices that are very efficient for data storage and mimic various synaptic and neural functions electronically.

11:00 AM *EL04.07.05
Emergence of Neuromorphic Devices using Conductive Materials of Various Ion Species KazuyaTerabe, TakashiTsuchiya and TohruTsuruoka; NIMS, Japan

The development of hardware-oriented artificial intelligence (AI), such as information terminals and brain computers that operate with small size and low power consumption, is expected to develop into the next generation of information technology. In order to realize such hardware-oriented AI systems that do not rely on conventional supercomputers and complex programs, new concept devices with diverse functions, such as memristive and neuromorphic devices, should be required. To this end, it is necessary not only to further develop conventional semiconductor devices with characteristics suitable for digital arithmetic processing, but also to create novel devices that operate based on new principles.
As you know, material properties can be significantly altered by slightly changing the composition and arrangement of its constituent atoms. Therefore, we have been actively searching for interesting nanophenomena arising from the control of composition and atomic configuration in nanostructures. Such nanostructure control can be achieved using ionic nanoarchitectonics techniques, which allow local control of ion transport and electrochemical reactions occurring at and near solid interfaces or surfaces. We have used the ionic nanoarchitectonics to create a variety of devices with unique electrical, magnetic, and optical functions and performance that cannot be obtained with conventional semiconductor devices [1,2]. Some neuromorphic devices such as a decision-making device, artificial synaptic devices, multifunctional on-demand device, artificial vision device and physical reservoir devices [3] have been fabricated using ion-conducting materials of various ion species. This talk will focus on the creation of various neuromorphic devices by ionic nanoarchitectonics using conductive materials of various ion species such as proton ions, lithium ions, silver ions, copper ions, and oxide ions.

11:30 AM EL04.07.06
Tuning the Redox Properties of a Conducting Polymer for OECT-Based Zn Sensing: From Template to Target TommasoNicolini[1,2,3], ShekharShinde[4,3,2], ReemEl-Attar[5,6,3], DamienThuau[5,2,3], MamatiminAbbas[5,3,2], JochenLang[7,6,2], EricCloutet[4,3,2] and AlexanderKuhn[1,2,3]; [1]Institut des Sciences Moleculaires, France; [2]Bordeaux INP, France; [3]Centre National de la Recherche Scientifique, France; [4]Laboratoire de Chimie des Polymère Organiques, France; [5]Laboratoire de l'Intégration du Matériau au Système, France; [6]Université de Bordeaux, France; [7]Chimie & Biologie des Membranes et de Nano-objets, France

Due to their ionic and electronic conducting capabilities, as well as their mechanical properties, conducting polymers have been at the forefront of organic bioelectronics,[1] especially when integrated as active materials in organic electrochemical transistors[2] (OECTs). Importantly, these devices allow developing analytical methods for a specific target mainly based on either amperometric or potentiometric sensing[3]. Molecules or ionic species in solution can be quantified selectively and with high sensitivity due to the intrinsic amplification power of OECTs. Their sensing capabilities[4] are based on the interaction of an analyte with either the channel or the gate electrode and the resulting modulation of the transistor readout, i.e. the drain current, I_d. Since the electrochemical doping/dedoping process is intimately governed by ion-aromatic backbone coupling[5], some interest has been devoted to achieve selectivity towards ions of biological interest by using ion selective membranes[6a-c] or through direct chemical modification of the conducting polymer[7a-c]. In one of these latter examples[7a], OECT-based membrane-free specific cation sensing has been achieved by implementing poly(3,4-alkoxy thiophene) (PEDOT) derivatives with added functionality at the gate electrode of an OECT through electropolymerization. Here, we present a novel conducting polymer allowing the selective sensing of Zn when implemented in the channel of an OECT. Interestingly, we use the target cation during electropolymerization to impart planarity and order to the polymer layer to modulate its electrochemical and electrical properties. This is the first instance of a OECT-based Zn-specific sensor and the limit of detection obtained is one order of magnitude lower than what has been achieved with membrane-free devices for other cations ($\approx 10^{-6}$ mol L^{-1} vs. $\approx 10^{-5}$ mol L^{-1}). These results hold the promise to develop analytical methods for *in-vitro* and *in-vivo* applications investigating the numerous biological processes involving Zn^{2+}.

11:45 AM EL04.07.07
Effects of Gamma on the Switching Performance of MoS_2 Based Resistive Random Access Memory (RRAM) Devices ArunNimmala[1,2], SakshiKapoor[1] and J. P.Singh[1]; [1]Indian Institute of Technology Delhi (IIT-D), India; [2]Indian Institute of Technology Delhi,, India

Metal–Insulator–Metal (MIM) structures of a Non-volatile memory (NVM) devices were fabricated by sandwiching Molybdenum disulfide (MoS_2) thin film in between two metal electrodes. The top and bottom metal electrodes were deposited by using the thermal evaporation and the oxide layer was deposited by spin coating drop casting technique. A controlled resistive switching Resistive of random-access memory (RRAM) device structures such as Ag (or Au, Pt)/ MoS_2 /Au (or ITO)/Si were fabricated and I-V characteristics for the pristine and gamma-irradiated devices with a few low doses were measured. The X-ray diffraction (XRD), Field emission scanning electron microscopy (FESEM) analysis measurements were performed to determine the crystallinity and stoichiometry of these films. The effects of gamma irradiation on the switching properties of these RRAM devices have been studied. The study also indicates the significance of radiation damage and reliability of these devices beyond a critical fluence. The electrical properties of these devices such as switching endurance cycling, retention time, and resistance ratio studied by using Agilent B1500 semiconductor device analyzer will be discussed in detail at the conference.
Key words: Resistive switching, 2-D materials, Gamma irradiation, RRAM, Endurance and Retention test.

SESSION EL04.08: Emerging Materials for Neuromorphic Engineering II

1:30 PM *EL04.08.01
Organic Neuromorphic Electronics for Sensory Coding and Biohybrid Systems Yoerivan de Burgt; Technische Universiteit Eindhoven, Netherlands

Neuromorphic engineering takes inspiration from the efficiency of the brain and focusses on how to utilise its functionality in hardware. Organic electronic materials have shown promising solutions for the manipulation and the processing of biological signals, with applications ranging from bioinformatics to brain-computer-interfaces and smart robotics.

This talk describes state-of-the-art organic neuromorphic devices and provides an overview of the current challenges in the field and attempts to address them. I demonstrate two device concepts based on novel organic mixed-ionic electronic materials and show how we can use these devices in trainable biosensors and smart autonomous robotics.

Next to that, organic electronic materials have the potential to operate at the interface with biology. This can pave the way for novel architectures with bio-inspired features, offering promising solutions for the manipulation and the processing of biological signals and potential applications ranging from brain-computer-interfaces to bioinformatics and neurotransmitter-mediated adaptive sensing. I will highlight our recent efforts for such hybrid biological memory devices and artificial neurons.

2:00 PM *EL04.08.02
Advances and Challenges in ECRAM-Based Resistive Crosspoint Arrays for AI Computation SeyoungKim; Pohang University of Science and Technology, Korea (the Republic of)

Artificial Intelligence (AI) technology, which heavily relies on deep neural networks, is having a significant impact on both business and society, transforming our daily lives. To support the

ever-increasing computation demands for AI applications, there has been a growing interest in novel analog computing architectures enabling massively-parallel neural network computation by adopting cross-point arrays of emerging non-volatile memory devices. Both device-level and system-level research efforts are actively pursued to achieve the promised power-efficiency and substantial performance improvements. Among various cross-point device candidates, electrochemical random-access memory (ECRAM) has recently attracted researchers owing to its 3-terminal nature and superior programmability [1-3]. In this talk, I will first introduce our recent device specification study when different training algorithms, optimized for practical resistive memory devices, are used to train neural networks in resistive cross-point arrays [4]. This quantitative study is expected to provide a guide for material and device research. I will continue the discussion on the recent advances and challenges in implementing large ECRAM-based cross-point arrays for analog AI computations with the consideration of the non-ideal device characteristics such as limited retention time and selector-less array-level operations.

2:30 PM EL04.08.03
Biomimetic Electrochemical Eye Based on Organic Optoelectronic Synapse KeChen and JianguoMei; Purdue University, United States

The human eye possesses remarkable abilities in sensing images, including a wide field of view, high resolution, sensitivity with minimal distortion. Moreover, the information captured by human eyes can be sent to the brain for processing, enabling image recognition and learning. Having biomimetic eyes or vision systems with such characteristics is highly desirable, particularly in fields like robotics and visual prostheses. Currently, most artificial eyes rely on rigid and brittle silicon electronics, which poses challenges for non-invasive implantation and seamless integration with soft biological tissues. In contrast, organic semiconducting materials have demonstrated biocompatibility, mechanical flexibility, and responsiveness to biological media, making them a promising candidate for the next generation of artificial eyes. In this talk, we present an organic electrochemical eye (E-eye) consisting of a high-density array of optically switchable synaptic devices. Within the device, light can control the insertion of ions into the photoactive layer, allowing for the modulation of multiple nonvolatile conductance states and the replication of ion flux-regulated synaptic activities observed in living systems. The device exhibits an unprecedented light-induced on/off ratio ($>10^4$), a wide range of wavelength detection (400-980nm), and high biocompatibility. Furthermore, we demonstrate the image-recognition capability of our E-eye by successfully distinguishing optical patterns projected onto it. This research has the potential to lead to the development of a biomimetic intelligent eye, which could find applications across a wide range of technologies.

2:45 PMBREAK

3:15 PM EL04.08.04
A Novel Electrical Bias Technique to Recover Degraded ReRAM Arrays for Deep Learning Fabia FarlinAthena[1,2], NanboGong[2], RamachandranMuralidhar[2], PaulSolomon[2], EricM. Vogel[1], VijayNarayanan[2] and TakashiAndo[2]; [1]Georgia Institute of Technology, United States; [2]IBM T.J. Watson Research Center, United States

Resistive Random Access Memory (ReRAM) arrays based on HfO_x have shown promise for in-memory computing in deep neural network (DNN) training. A modified SGD algorithm [1, 2, 3], together with a co-optimized ReRAM material, can achieve respectable accuracy on a reduced Modified National Institute of Standards and Technology (MNIST) database classification task, approaching a floating point baseline [4]. However, as these arrays are used over time, they begin to degrade, which reduces their efficacy and impacts the performance of the systems that rely on them. As these arrays are leveraged for complex tasks like deep neural network training, the degradation issue becomes increasingly acute.

In an effort to better understand the degradation phenomena, we turned towards employing a 3D atomistic simulator that enables the simulation of processes such as bond breakage, ion and vacancy diffusion, and trap-assisted electronic tunneling between vacancies. The filament formation and subsequent switching are also simulated, providing valuable insights into the degradation process and the potential for recovery.

Building on this foundation, a unique electrical bias technique has been proposed to address the degradation issue and restore the precision of a deteriorated ReRAM array. We noticed that post-fatigue, the devices in the ReRAM array exhibited increased resistance and a diminished number of observable states. Our proposed electrical bias technique efficiently addresses both these challenges, reducing resistance and amplifying the number of states, thereby restoring the ReRAM array's accuracy to its initial pre-fatigue level.

In practice, this carefully controlled recovery method has demonstrated impressive results. The accuracy after recovery using the biasing technique reaches 98% on a reduced MNIST classification task, closely approaching the results from a floating point baseline, a notable benchmark in the field.

In summary, the proposed method offers a promising solution to a pervasive issue in neuromorphic computing. It underscores the potential for rejuvenating the performance of worn-out ReRAM crossbar arrays employed in in-memory deep neural network training. In addressing the immediate problem, it also significantly enhances the durability and reliability of these indispensable systems, promising more precise and reliable results over time. Moreover, this breakthrough sets a new direction for future developments in neuromorphic computing, paving the way for more resilient and enduring memory solutions that can withstand the rigorous demands of advanced computing tasks.

Electrically Tunable Stochastic Devices via Magnetic Fluctuations in V-Doped WSe_2Dinh LocDuong[1,2]; [1]Montana State University, United States; [2]Department of Physics, Montana State University, United States

Fluctuations are ubiquitous in magnetic materials and provoke random telegraph noise (RTN) that can be used for spiking neuron devices, random number generators, probability bits, and neuromorphic computing. Two-dimensional (2D) magnetic materials are thought to possess inherently stronger fluctuations than their three-dimensional (3D) counterparts, which yield weaker fluctuations that are more difficult to control with external forces. This has been demonstrated in 2D van der Waals (vdW) $CrBr_3$ utilizing the magneto-optic Kerr effect, but electrical measurement of these fluctuations has not yet been demonstrated. Moreover, these fluctuations only appear over a narrow range of transition temperatures centered around 22 K. For practical applications, such magnetic fluctuations in 2D materials should be well-described and electrically tunable across a wide range of temperatures, but there has been limited progress to date on this front. Here, we report magnetic fluctuations in a vdW-layered semiconductor with a magnetic dopant by investigating the giant RTN of resistance across the vertical tunnel junctions of a graphene/V-WSe2/graphene (Gr/V-WSe2/Gr) device. We identify bistable magnetic states from discrete Gaussian peaks of the RTN histogram, which were further confirmed by $1/f_2$ features in the noise power spectrum. We detect three fluctuation categories in the resistance change: small changes from the intralayer coupling between magnetic domains at high temperatures, anomalous large resistance changes over a wide range of temperatures, and persistent large resistance changes originating from magnetic interlayer coupling at low temperatures. This device reveals high-amplitude RTN in resistance as large as 40% with a well-defined bistable state that can be tuned by magnetic and electric fields.

3:45 PM EL04.08.06
Nonvolatile Electrochemical Random-Access Memory Enabled by Phase Separation JingxianLi and YiyangLi; University of Michigan, Ann Arbor, United States

Electrochemical random access memory (ECRAM) is a promising recently developed device for analog computing. Like resistive random access memory (RRAM), ECRAM also stores and switches information through ion migration and the resulting change in valence and electronic conductivity. ECRAM is a three-terminal memory cell that electrochemically shuttles oxygen vacancy point defects between two transition metal oxides with a solid electrolyte sandwich. ECRAM enables analog, continuous retention state switching (~100 states) by deterministically modulating oxygen vacancy concentration. In the past, ECRAM suffered from poor retention, about several hours at room temperature and several minutes at 85C, substantially less than >10 years at 85C standard for most nonvolatile memory.

In this work, we utilize new materials that not only meet, but vastly exceed the 10 year retention time metric. We hypothesize that the poor retention in the previous ECRAM results from using solid solution materials; in contrast, our phase separating materials enable multiple equilibrium states and thereby substantially improve e retention in ECRAM. Moreover, our results

show that a nonvolatile ECRAM with a retention time more than 12 hours at 400C, exceeds the performance of the best nonvolatile memory cell. Our work shows that harnessing phase separation can provide a powerful means to enable nonvolatile ECRAM to attain the necessary retention times and ECRAM's ability to electrochemically move point defects within solids for both analog and high-temperature memory.

4:00 PM EL04.08.07
Correlation Between Transient Response and Neuromorphic Behavior in P3HT based-Ion Gated Transistors. RaminKarimi and ClaraSantato; Polytechnique Montreal, Canada

Ion-gated transistors (IGTs), by perceiving dynamically the environment, can be studied and exploited as synaptic transistors in neuromorphic computing.
Depending on the permeability of the semiconducting channel to ions, IGTs undergo volumetric (three-dimensional) or electrostatic (field-effect, two-dimensional) doping, which leads to a wide range of response times. Long-term memory and high-speed data processing are essential for neuromorphic computing.
We propose a method to modulate the response time and synaptic plasticity of IGTs made up of poly (3-hexylthiophene, P3HT) gated by the [EMIM][TFSI] ionic liquid. We report on the effect of the frequency of the (gate-source voltage) V_{gs} pulses, the number of applied V_{gs} pulses, and the pulse duration time on the IGT response time. By increasing V_{ds} from -0.2 V to -1 V, we observed that the response time halves using a 200 ms-long square step V_{gs} = -0.5 V pulse. Moreover, increasing V_{gs} from -0.5 V to -1 V increases the response time by 27% in V_{ds} = -1 V. The methodology also includes the effect of the V_{gs} sampling time on the accuracy of electric measurements.
Our results shed light on the impact of various aspects of the input voltages on establishing the response time behavior and synaptic functions in organic IGTs, to reach low-power and fast-switching neuromorphic devices.<quillbot-extension-portal></quillbot-extension-portal>

A Bio-Mimicking Synaptic Tactile Sensor Based on SWCNT Transistors YanHuang, AngusHawkey, ElisaFresta and JanaZaumseil; Heidelberg University, Germany

The skin is the largest organ in the human body, with a network of receptors that are essential for our perception of the surrounding environment. Among various receptors, the Merkel cell acts as the mechanoreceptor, and it forms a synapse called Merkel cell-neurite complex with an afferent neuron. With this complex, a tactile stimulus applied on the skin can be sensed, preprocessed, and then transmitted to the brain. To mimic the function of Merkel cell neurites, several devices such as sensors and synaptic transistors usually need to be integrated together. In this work, a synaptic tactile sensor capable of sensing and memorizing the stimulus in one device is demonstrated to imitate the main functions of the Merkel cell neurite. The synaptic sensor is based on a single-walled carbon nanotube (SWCNT) transistor with a surface patterned polymeric ionic gel as the solid electrolyte. We find that ions can be released from the ionic gel into the transistor channel when the ionic gel is compressed. Modulation of the post-synaptic current of the device is realized by electrochemically doping SWCNTs under presynaptic pressure spikes. Due to the unique morphology of SWCNTs and slow ion motion in the ionic gel, long-time conditioning up to 24 hours can be achieved. For sensing performance, the device also shows a high gate sensitivity (~14.24 kPa^{-1}) in a wide sensing range (~30 kPa). By combining the functions of mechanical sensors and synaptic transistors, the space and energy efficient design in this work can facilitate the development of next-generation electronic skin and artificial neuron systems.

Enabling The Formation of High Impedance Supported Lipid Bilayers on PEDOT:PSS for Biosensing Applications JeremyTreiber[1], ZhongmouChao[2], ReeceMcCoy[3], SusanDaniel[2], RoisinOwens[3] and AlbertoSalleo[1]; [1]Stanford University, United States; [2]Cornell University, United States; [3]University of Cambridge, United Kingdom

Supported lipid bilayer (SLB) electrochemical sensors are a promising platform to study analyte-ligand interactions that occur at the cell surface. Utilizing an organic mixed conductor, such as PEDOT:PSS, as the SLB supporting material has enabled this technology to be used for detection of biomolecules at physiological relevant concentrations by measuring impedances. However, currently there is a lack in understanding of how the PEDOT:PSS surface facilitates SLB formation; a challenge which leads to significant device reproducibility issues. This talk will share our progress in investigating the PEDOT:PSS surface chemistry using x-ray photoelectron spectroscopy and correlating this to electrochemical impedance spectroscopy data of SLBs on microfabricated PEDOT:PSS electrodes. Results will be shared that show how we obtain a high yield of viable SLB devices by controlling aspects of the fabrication process, post-fabrication surface treatments, and electrolyte choice. This progress establishes guidelines necessary to realize high impedance SLBs on PEDOT:PSS electrodes.

Doping-Induced Assembly Interface for Non-Invasive *In Vivo* Local and Systemic ImmunomodulationBaoningSha[1,2]; [1]Columbia University, United States; [2]Shenzhen Institute of Advanced Technology, China

Peripheral neural interfaces exhibit considerable potential in the treatment of diseases by modulating both local and systemic immune responses. However, the mismatch between static electronic components and the dynamic, intricate tissue organization of the peripheral nervous system results in interface failure, hindering progress in circuit research and clinical implementation.

Jet-injectors are preferred by diabetic patients for insulin administration over syringes due to their enhanced diffusivity and reduced scar formation. By leveraging the diffusivity of jet-injection and in vivo polymerized neural interfaces, we aim to interface with the finely structured reticular nerve plexus, which has been demonstrated to possess unique capabilities in peripheral-central circuitry, such as systemic anti-inflammation, anxiety, and social disorders. However, recent in vivo polymerization systems are incompatible with this inherently diffusion-promoting injection method, as precursors, enzymes, and surfactants diffuse into the tissue and ultimately hinder the polymerization process.

To address these challenges, We developed a versatile, monocomponent cocktail strategy for the in vivo assembly of biodegradable, self-adaptive neural interfaces to achieve both local and global immunomodulation. To accomplish this regulation, we employed a propulsionary flow-enhancing method—jet-injection—to interface with a series of reticular nerve plexuses. Additionally, we engineered ROS-triggered catalytic doping nanosheets with inherently low diffusivity to counteract tissue diffusion during jet-injection. MXene, a semi-metal, has been extensively investigated for its conductivity and catalytic properties. We harnessed MXene's catalase activity to catalyze the in vivo doping system, reconciling the conflict between catalyst and conductivity. Furthermore, we functionalized MXene with de-doped conductive polymer (CP)–PEDOT and dopant–benzenesulfonic acid. The doping of de-doped PEDOT is mediated by the ROS-MXene cascade, which occurs when the injection induces local microdamage, increasing ROS metabolites in tissue and subsequently triggering PEDOT doping by MXene. This doping process enhances the π-π interaction between nanosheets, driving in vivo assembly. Additionally, we employed a tissue cross-linking compound, PDA, to connect de-doped PEDOT and benzenesulfonic acid dopant, controlling spontaneous non-catalytic doping. This approach also allows nanosheets to form dynamic bonds during assembly, including hydrogen bonds, coordination bonds, cation–π interactions, and π–π interactions, further reducing diffusion.

Our neural interface can be deployed within 10 seconds, and the π-π mediated assembly process, along with the metabolic oxidation of MXene, enables biodegradation of the interface. The neural interface, established with the sciatic nerve, can promote peripheral tissue recovery through local regulation via electrical stimulation. In freely moving mice, the neural interface activated the vagal anti-inflammatory axis at ST36, releasing noradrenaline, adrenaline, and dopamine from adrenal chromaffin cells while reducing TNF and IL-6 levels in serum. We demonstrate that catalytic doping and cross-linking around peripheral tissue create degradable, self-adaptive interfaces with reticular nerve plexuses in peripheral-central circuitry.

Unraveling the Relationship Between Molecular Weight and Long-Term Plasticity in IGOSTs HyunhaengLee[1], Gyeong-TakGo[1], Min-JunSung[1], JaehoLee[2,1], HyunwooPark[3,1], Tae-LimChoi[3,1] and Tae-WooLee[1,1,4]; [1]Seoul National University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]ETH Zürich, Switzerland; [4]SN Display Co., Ltd., Korea (the Republic of)

Ion-gel Gated Organic Synaptic Transistors (IGOSTs) have been widely researched as a building block of neuromorphic computing due to low-energy consumption, large dynamic range, and high linearity. To realize hardware neural network using IGOSTs, long-term retention of updated synaptic weight is necessary. However, fast back diffusion of doped ions in semiconductor channel is the main limitation from achieving long-term retention. Poly(3-hexylthiophene-2,4-diyl) (P3HT) semiconductors can have high crystallinity, which allows long-term ion trapping. Therefore, fine control of morphology can be a solution to improve ion trapping time in semiconductor channels.

Here, we investigated the effect of molecular weight on morphology to achieve long-term retention of P3HT IGOSTs. The materials were synthesized through Living Anionic Polymerization, in which the molecular weight is controlled by degree of polymerization with extremely low polydispersity. As the chain length increased with molecular weight, the high-crystalline fibril morphology shifted to less-crystalline granular morphology which can show higher on current and transconductance due to elongated chains. The long-term plasticity of IGOSTs exhibited dependence on molecular weight, with distinct contributions from two different morphologies. High-crystalline fibril morphology in smaller molecular weight samples impeded ion back-diffusion, resulting in longer retention time. However, in higher molecular weight samples, granular morphology prolonged the retention time by promoting enhanced intergranular connectivity. This work could provide a fundamental understanding of the relationship between molecular weight and morphology of P3HT to achieve long-term retention for use in next-generation neuromorphic computing.

Dynamic Machine Vision with Retinomorphic Photomemristor-Reservoir Computing HongweiTan and Sebastiaanvan Dijken; Aalto University, Finland

Dynamic machine vision requires recognizing the past and predicting the future of a moving object based on present vision. Current image sensing and machine vision technologies accomplish this by analyzing massive frame-by-frame image sequences in multiple hardware blocks and complex software algorithms, engendering redundant data flows, high energy consumption, and latency. Photomemristors, or optoelectronic memristors, originally proposed for photosensing, processing, and memory functions [1], are ideal candidates for dynamic machine vision tasks. In recent years, photomemristors have been studied in neuromorphic vision and processing systems for static image classification [2-5] and human action recognition [5]. However, motion recognition and prediction within a compact dynamic sensing system, which is crucial for dynamic machine vision technology, has been elusive until very recently. Here, I will summarize a brief history of photomemristor, and show our recent works on photomemristors for sensing, processing, and memory. Then I will focus on the implementation of motion recognition and prediction in recurrent photomemristor networks [6]. In the retinomorphic photomemristor reservoir computing system, a retinomorphic photomemristor array, working as a dynamic vision reservoir, embeds past motion frames as hidden states into the single present frame through inherent dynamic memory. The informative present frame facilitates accurate recognition of past and prediction of future motions with machine learning algorithms. This in-sensor motion processing capability eliminates redundant data flows and promotes real-time perception of moving objects. Potential applications of the retinomorphic photomemristor-reservoir computing system include video analysis, autonomous driving, and robotic vision.

Soft and Stretchable Wireless Skin Patch for Electrophysiological Recording AlexandreTessier, AnanZhang and Shideh KabiriAmeri; Queen's University, Canada

Developing soft and stretchable electronics that perform reliably during daily activity without limiting the users' physical movements during daily activities is a challenge. In most cases to improve stretchability of inherently rigid electronic components of a circuit, the use of off-the-shelf components in conjunction with stretchable interconnects to mitigate the strain is one method to address this issue. Several strategies have been reported to make such a hybrid platform including utilizing serpentine metal films on stretchable substrates, coating metal, or conducting films on pre-stretched polymers, using liquid metal filled microfluidic channels, etc. While such methods have indeed proved effective when low range of strain is applied, they fail at high level of strain. Further, the fabrication process for most of these methods often require microfabrication and access to clean-room facilities which is costly and time consuming.
Here we report a wireless skin patch for electrophysiological recordings such as electrocardiography (ECG) and electromyography (EMG). This patch consists of self-adhesive stretchable sensor and circuit patches. The circuit consist of highly soft and stretchable interconnect with more than 600% stretchability and includes conditioning, wireless communication, and power circuits. Over 60,000 cycling test of the interconnects under 30% of strain showed no change in electrical conductivities of interconnects. Further, the fabrication process is low coast, scalable and done using bench top equipment.

In conclusion our approach is a low cost, time effective method of wireless circuit patches for electrophysiological recording. The low modulus and stretchability of the circuit patch allows the integration of ultrasoft sensors that can conform to the microscopic feature of skin and enables long term, mobile, low motion artifact, high quality health monitoring.

Analysis of Charge Transport in Narrow Amorphous $Ge_2Sb_2Te_5$ Line Cells Stressed and Stabilized at Room TemperatureABM HasanTalukder, Md Tashfiq BinKashem, HelenaSilva and AliGokirmak; University of Connecticut, United States

Phase change memory (PCM) is considered as one of the most promising non-volatile memory technologies because of its high scalability, high endurance cycles, and long retention time [1]. The large resistivity contrast between amorphous and crystalline phases of phase change materials such as $Ge_2Sb_2Te_5$ (GST) opens up the possibility for multi-level-cell (MLC) operation to reduce the cost per bit. However, resistance in the amorphous phase spontaneously increases over time, known as resistance drift, making it difficult to implement MLC operation. We reported earlier on the stabilization of resistance drift by accelerating the drift with high-field stresses at cryogenic temperatures ($\leq$ 200 K) [2] and established a charge transport model [3]. In this work, we have demonstrated the acceleration and stabilization of resistance drift by applying high field sweeps at room temperature in narrow GST line cells with ~ 20-50 nm width and 20 nm thickness. Also, we performed analysis on the charge transport in these cells at a temperature range 300 K – 80 K.
We amorphized the GST cells using a ~200 ns rectangular pulse of 1.5 V amplitude at 300 K and monitored the resistance drift immediately (~ 1 s) after amorphization for an hour. Then we applied two high-field voltage sweeps with current compliance set to < 1 μA not to cause any self-heating in the device. We observe a substantial acceleration in resistance drift during the high-field stresses. The device displays a slightly negative drift coefficient when we monitored the resistance drift after the stress. The device resistance reduces to the pre-stress level after 25 days. When another stress sweep is applied, the resistance comes back up to the previously stressed/stabilized level. We analyzed the I-V characteristics measured at temperatures 300 K to 80 K for different charge transport parameters and how they relate to the acceleration in resistance drift and stabilization with high field stresses.
Since we do not expect substantial self-heating to occur in the whole of the device at < 1 μA, thermally induced structural relaxation is very unlikely to happen in the whole of the device. We expect that acceletation and stoppage of resistance drift is due to relaxation of the charges left in the traps within amorphous GST when devices were quenched [4].

Resistance Drift and Percolation Transport in Phase Change Memory Md Samzid BinHafiz, Md Tashfiq BinKashem, ABM HasanTalukder, Raihan SayeedKhan, HelenaSilva and AliGokirmak; University of Connecticut, United States

3D integration of electronic memories led to enormous storage capacity with substantially reduced cost, new processor architectures, and artificial neural network and artificial intelligence (AI) implementations dramatically improved performance and application space. However, the speed of typical data-heavy computations are still limited by memory access latencies between CPU and DRAM (dynamic random access memory), flash memory and magnetic drive[1]. The next stage of improvements is expected to come from monolithic integration of memory and logic, and complementing silicon CMOS with new capabilities, which is likely to include devices with dynamic materials. The emerging resistive non-volatile memory (RRAM) technologies, such as phase change memory (PCM)[2], conductive bridging RAM (CBRAM)[3] and magnetic RAM (MRAM)[4], [5], offer the possibility of monolithic integration of processor and high-performance non-volatile memory.

PCM devices utilize reversible changes in resistance of a small volume of material (1000s of atoms) as it is thermally switched between amorphous and crystalline phases, which makes PCM (i) operable using signal polarity for set and reset, (ii) virtually immune to read disturbance, (iii) insensitive to point defects and thermodynamically stable down to ~ $(5\ nm)^3$ scale, (iv) have a large memory window (orders of magnitude) at a very desired resistance range for CMOS[6].

The resistance of the reset (amorphous) state of the PCM cells increases over time, widening the memory window but hinders multi-bit-per-cell PCM. Although resistance drift has been commonly attributed to structural relaxation, resistance drift at lower temperatures (below 100 K) and its response to high-field stress and photoexcitation suggest an electronic origin to resistance drift. This is a promising finding for the potential mitigation strategies for resistance drift and the viability of multi-bit implementations of PCM[7, 8] including neuromorphic computing.

In this study, we use our experimental results to construct a finite element model that captures electronic transport in amorphous $Ge_2Sb_2Te_5$ (GST)[9] and investigate potential mitigation strategies. We model local hole-traps that are activated in time with a temperature dependent probability. The remaining fixed charges lead to local potential variations, which then give rise to formation of percolation paths in time. The changes give rise to resistance fluctuations (noise) along with the increase in resistance. Once the steady state is reached, resistance drift stops. Our experimental results show that the resistance drift can be dramatically accelerated with application of high-field stresses, which can be explained by acceleration of activation and removal of trapped holes in the amorphous material.

***N*-Heterocyclic Carbenes (NHCs) as Conductive and Stable Anchors for Au-Based Hybrid Materials and Devices**FranziskaLissel[1,2]; [1]Technische Universität Hamburg-Harburg, Germany; [2]Leibniz Institute for Polymer Research, Germany

Gold nanoparticles (Au NPs) have unique surface plasmonic resonances (SPR) and promise a broad variety of optical applications in sensors and imaging,[1] while combining them with organic components can give electronically functional hybrid materials.[2] Protecting surface ligands, carrying one or more functional anchor groups with a high affinity for gold, are needed to stabilize the Au NPs and prevent their irreversible aggregation. Thiols are ubiquitously used, yet the thermal instability and comparably low conductance of the S-Au contact limit the applications of the resulting Au NPs.[3] *N*-heterocyclic carbenes (NHCs) have been used in surface chemistry as an high-performing alternative to sulfur-based ligands[4]: The NHC-Au linkage shows excellent stability under conditions that destroy the S-Au bond (e.g. high temperature, variable pH, and electrochemical redox), and is furthermore highly conductive.

We use NHC anchors as robust and conductive anchors to bind charge-conducting conjugated polymers (CPs) to Au NPs to obtain electronically functional hybrid materials.[5] Br-NHC-Au-X (X=Br, Cl) complexes were synthesized, converted to Grignard monomers and used for a chain-growth Kumada polymerization to obtain regioregular poly-3-hexylthiophenes (P3HT) with a low polydisperity index. Direct reduction gave spherical Au NPs with P3HT as surface ligands. The presence of the NHC on the surface was confirmed by XPS. The P3HT-NHC@Au NPs have a remarkable thermal stability up to 24 h in 100 °C toluene solutions, while Au NPs stabilized by sulfur-based PEG fully degrade under the same conditions. Also, continuous CV scans show only a slight decay of peak current after 50 cycles, indicating the good electrochemical stability of P3HT-NHC@Au NPs. To investigate the conductive linker, electrochromism (EC) experiments were carried out. P3HT is electrochromically active, and one can assume that binding the polymer to Au NPs via a conductive NHC anchor group will increase the electrochromic response speed, allowing to estimate the organic/inorganic electron transfer of P3HT-NHC@Au NPs. We found that blending 10% of P3HT-NHC@Au NP into P3HT films improves the responsive speed signiffcantly, from 1.21/1.05 s for neat P3HT to 0.79/0.52 s for the blend.

Probing Photosynthetic Light Harvesting with a Single Photon QuanweiLi[1], KaydrenOrcutt[1], RobertCook[1], JavierSabines-Chesterking[2], AshleyTong[3], GabrielaSchlau-Cohen[3], XiangZhang[1], GrahamFleming[1] and K. BirgittaWhaley[1]; [1]University of California, Berkeley, United States; [2]Joint Quantum Institute, United States; [3]Massachusetts Institute of Technology, United States

The process of converting light energy into chemical energy via photosynthesis sustains most of life on earth. However, fundamental questions remain open regarding the initial steps of photosynthesis, despite advances over the past several decades in understanding the dynamics of energy transfer in photosynthetic systems using ultrafast spectroscopies. Here, by developing a photon-counting quantum light spectroscopy that probes photosynthetic light harvesting with a single photon at a time, we experimentally demonstrate that photosynthesis begins and proceeds with a single quantum of energy [1]. We report the observation of individual single-photon absorption and emission events in spatially distinct regions in photosynthetic systems. We show that a complex material system can be prepared and studied with only a single excitation, without perturbation by other photons or averaged over many simultaneous excitations. The experiments were carried out on an ensemble of pigment-protein complexes light-harvesting 2 from purple bacteria *Rhodobacter sphaeroides* under ambient conditions in vitro. Our results advance a true microscopic mechanism of energy conversion in photosynthesis at a fundamental single quantum regime, beyond the semi-classical picture of spectroscopy, and open a new domain of experiments using quantum light to probe complex material systems.

Some Notes on Mixed Memristor-Resistor Model as Defined in [1]KazimierzJ. Plucinski; Military University of Technology, Poland

Edge network entropy as defined in [1] - inspired by the Shannon based entropy - proposed by Pershin et al [2] is analyzed, where the entropy is a measure of the number of possible configurations of a system. Notes on the Interpretation of the decrease of entropy as the consequence of the decreased number of equal resistance paths available in the network and the emergence of fewer low resistive paths for the current flow.are presented.

Heterogeneous Integration of Memristive HfO_2 Devices on 2D Van Der Waals Materials for Neuromorphic Computing ReginaDittmann; PGI-7, Germany

Based on their large dynamic range in resistance with analog tunability, memristive devices can act as ultra-dense, low power synapse in neuromorphic circuits. HfO_2 is one of the most common material for the use in redox-based memristive devices. It is usually grown on Si wafers or even integrated in the back-end of line of a CMOS process. In order to transfer Memristive HfO_2 cells to flexible or even biological substrates, we investigated to co-integrate HfO_2-based on graphene. The graphene serves as conductive bottom electrode and/or enables the transfer to arbitrary substrates.

To this end, we investigated both, the van der Waals epitaxy of HfO_2 thin films on graphene and the remote epitaxy on graphene-covered, lattice-matched Y-stabilzed ZrO_2 (YSZ) substrates. We identified a growth window for the pulsed laser deposition of HfO_2 that preserves the graphene transferred to thermally oxidized Si wafers. This enabled us to successfully fabricate memristive HfO_2 cells with graphene bottom electrode on both substrates. Based on the crystalline growth of the HfO_2 on SiO_2 and the forming-free switching behaviour, likely caused by an oxygen deficiency of the HfO_2, we conclude that graphene acts as diffusion barrier for both, Si and oxygen. Therefore, the growth on graphene offers high potential for the heterogenous integration of HfO_2 thin films on arbitrary substrates.

Accurate Predictions of the Stark Shifts of Nitrogen-Vacancy Optical Frequencies in Diamond RodrickKuate Defo[1], AlejandroRodriguez[1], EfthimiosKaxiras[2] and StevenL. Richardson[3,2]; [1]Princeton University, United States; [2]Harvard University, United States; [3]Howard University, United States

Accurate prediction of the Stark shift of the optical frequencies of nitrogen-vacancy centers (NV^-) in diamond is generally hindered by uncertainties regarding the background environment. The nitrogen-vacancy center in diamond has, however, proven to be a very useful probe of the electric field within materials, which is important to determine to predict proper operation of semiconductor devices and performance of solid-state single-photon emitters embedded within the semiconductor devices. In this talk, we demonstrate accurate computation of the average electric field measured at the location of NV charged defects in diamond. Far away from the surface, we achieve this result by evaluating the leading-order contribution to the electric field, which comes from the Dirac delta function contribution to the dipole field generated as a result of the presence of the neighboring substutional N (N_C) defects that induce the ionization of the NV^- centers. Our results use density-functional theory (DFT) and the principle of band bending. Our work has the potential to aid both in the prediction of the functioning of semiconductor devices and in the prediction and correction of the spectral diffusion that often plagues the optical frequencies of solid-state single-photon emitters upon repeated photoexcitation measurements.

12:40 PM EL02/EL04/EL06.11
Exploring the Interplay of Electro-Mechanical and Electro-Optical Signals in Neuristors UpanyaKhandelwal[1], Rama SatyaSandilya[1], RajeevKumar Rai[2,1], Deepak.[1], SmrutiR. Mahapatra[1], DebasishMondal[1], NavakantaBhat[1], SushobhanAvasthi[1], SaurabhChandorkar[1] and PavanNukala[1]; [1]Indian Institute of Science, India; [2]University of Pennsylvania, United States

Neuristor systems, as electro-mechanical counterparts, provides a valuable approach to explore and replicate the dynamics of biological neurons. Among them, VO_2 neuristors, characterized by insulator-to-metal transition (IMT) and negative differential resistance (NDR), have demonstrated diverse neuronal signals in the electrical domain. In this study, we investigate the intriguing behaviors of tonic spiking and tonic bursting in VO_2 neuristors, revealing their coupled electro-mechanical signals and unveiling additional electro-optical oscillations.
The emergence of electro-mechanical and electro-optical oscillation arises from significant changes in the electrical, optical and mechanical properties of VO_2 during its phase transition from an insulator to a metal driven by joule heating. Laser interferometry is employed to analyze films with different thickness, allowing us to distinguish the contributions of optical and mechanical oscillations. Additionally, an analytical model is developed to effectively characterize these dynamics.
Our work highlights the multifaceted nature of self-oscillating neuristors, showing their coupled electro-mechanical and electro-optical behaviors. This research opens up the possibilities for utilizing neuristors as alternatives to conventional piezoelectric materials in MEMS applications and as potential replacements for Pockel's materials in electro-optic applications. By bridging the gap between biological neurons and engineered systems, neuristors offer versatile building blocks for bio-inspired electronics and opto-electronic technologies.

Retinomorphic Motion Detector and Supercapacitors Based on Organic Semiconductors Tse NgaNg; University of California, San Diego, United States

Organic retinomorphic sensors offer the advantage of in-sensor processing to filter out redundant static background and are well suited for motion detection. To improve this promising structure, here we studied the key role of interfacial energetics in promoting charge accumulation to raise the inherent photoresponse of the light-sensitive capacitor. Specifically, incorporating appropriate interfacial layers around the photoactive layer was crucial to extend the carrier lifetime, as confirmed by intensity-modulated photovoltage spectroscopy. Compared to its photodiode counterpart, the retinomorphic sensor showed better detectivity and response speed due to the additional insulating layer, which reduced the dark current and the resistor-capacitor time constant. Lastly, three retinomorphic sensors were integrated into a line array to demonstrate the detection of movement speed and direction, showing the potential of retinomorphic designs for efficient motion tracking.
In addition to discussing the development of organic optical sensors, this presentation will also show the use of the same class of organic semiconductors in energy storage applications, in particular for redox supercapacitors as portable power sources. We developed multifunctional structures, which combine load-bearing and energy-storage functions in one, resulting in weight savings and safety improvements. We demonstrated a gradient electrolyte design to facilitate high ionic conductivity at the electrode-electrolyte interfaces and transitioned to a composition with high mechanical strength in the bulk for load support. The gradient design enabled the multilayer structural supercapacitors to reach state-of-the-art performance matching the level of mono-functional supercapacitors. Finally, the structural supercapacitor was made into the hull of a model boat to demonstrate its multifunctionality.

11:00 AM EL05.01.02
Bioinspired Compound Eye Camera for High-Resolution and Depth-Based Sensing Applications SehuiChang[1], Min SeokKim[1], Gil JuLee[2] and Young MinSong[1]; [1]GIST, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

Machine vision has advanced to provide high-performance imaging for various fields in electronics and robotics such as smartphones, surveillance, and autonomous vehicles. The capabilities of high resolution, a small form factor, and functional imaging (e.g., depth extraction, object detection, etc.) are of major interest to modern vision platforms. However, conventional camera designs show an intrinsic trade-off between miniaturization and high-performance, including a wide field of view and low aberrations. In particular, a camera design requires multiple lenses to be compatible with a commercial planar CMOS sensor in order to compensate for optical aberrations (e.g., field curvature). This complexity of lens design originates from offsetting against an inherently curved focal plane, which eventually hinders the miniaturization of entire system.
Meanwhile, natural eyes carry out high-performance and functional imaging specialized to their natural habitat, despite having a compact, simple configuration of the ocular structure. For instance, the fish eye provides a wide field of view via a single spherical lens and a curved retina, and the eye of a fiddler crab enables clear imaging both on land and in water via a flat, graded refractive index microlens array. Thus, various animal eyes can inspire the development of enhanced vision systems with novel camera design strategies. Insect compound eye, inter alia, has inspired in various artificial vision systems due to their unique features of wide field of view with low aberrations, high sensitivity to motion, and infinite depth of field. However, most artificial compound eye cameras suffer from two major issues: low resolution caused by the use of a curved photodetector array, or limited field of view caused by the use of a planar image sensor.
Here, inspired by insect compound eyes, we propose a high-resolution compound eye camera for depth-based sensing applications. The artificial compound eye camera consists of a curved microlens array (cMLA), a tapered fiber bundle (TFB), and a commercial CMOS imager. The cMLA was fabricated using flexible polymer, polydimethylsiloxane (PDMS), to achieve the curvature of the MLA through a repeated molding process with a precisely machined flat MLA metal mold and a 3-D printed base mold, enabling wide field of view imaging. To relay sub-images of each microlens in the cMLA onto the planar image sensor plane, we utilized the TFB as a relay optics, which is tapered and polished to form each individual fiber facet perpendicular to its optical axis on its curved and flat sides. The fabricated systems demonstrated high-resolution imaging via the TFB with over 2 million fibers and the commercial sensor, while the entire microlenses of the cMLA provides focused images. Since each individual microlens is matched with ~5 thousands pixels, the acquired image data from the cMLA can provide depth information of objects by calculating disparities among adjacent microimages, while achieving wide field of view imaging. Unlike conventional light field cameras, the proposed artificial compound eye has a curved shape MLA. Therefore, geometrical calibration was conducted to convert the world coordinate into the camera's spherical coordinate for restoring the visual data in 3-dimensional space. By collecting and processing the image data of angular and distant objects, it is expected that the proposed camera system will pave the way for the development of bioinspired artificial vision specialized in depth sensing applications.

11:15 AM *EL05.01.03
Optics in Animal Eyes and Their Applications in Vision System Young MinSong; Gwangju Institute of Science and Technology, Korea (the Republic of)

The development of bioinspired artificial cameras, through the application of optics and photonics, offers innovative designs inspired by diverse natural vision systems. The superior optical characteristics of these bioinspired devices often outperform traditional imaging systems, boasting heightened visual acuity, expanded field of view, unrestricted-wavelength imaging, enhanced aberration correction and depth of field, along with exceptional motion sensitivity. The evolution of soft materials, ultrathin electronics, and adaptable optoelectronics has ushered in an era of opportunity for crafting artificial eyes that closely emulate biological vision systems. This tutorial zeroes in on the recent progress and continuous efforts in the arena of bioinspired artificial eye research and development, specifically highlighting optical components and image sensors. The discussion kick-starts with an exploration of the structures of two key types of eyes from nature, namely, the single-chambered eye and the compound eye. The tutorial then progresses to delve into the recent developments in bioinspired optic components and image sensors, enveloping subjects like materials, optical and mechanical design approaches, and integration strategies.

11:45 AM EL05.01.04
Pupil-Scalable and Light Attenuating Soft Artificial Iris using Gradient Controlled Photochromic Effect Actuated by External Light Hafiz SaadKhaliq, AsadNauman, Young-MinCho, Jae-WonLee and Hak-RinKim; Kyungpook National University (KNU), Korea (the Republic of)

The constriction and dilation of human pupil diameter in reaction to the changes in ambient light are governed by the masculine components present in the iris tissue. This iris-mediated reflex mechanism controls the amount of light that reaches the retina, producing sharp and glare-free visual perceptions. Nonetheless, in cases where the iris is deficient in its inherent light-modulating capabilities due to congenital abnormalities or accidental damage, it can harm the retina's function and give rise to significant impairment in visual effects. The existing artificial iris designs documented rely on external circuitry to enable their activation or light-actuated mechanical opening and closing of the aperture. Moreover, with the development of photochromic materials, few groups presented remotely controlled artificial iris with chemical change at molecular level switching with no circuitry and mechanical movements involved. Meanwhile, the lack of a non-tunable aperture and dynamic response of reported artificial iris for active light regulation makes them difficult for practical implications. In this study, we present a novel artificial iris that exhibits dynamic light-regulating properties and can also scale its aperture size. In addition, iris patterns of different shapes are integrated, imitating the behavior of the different human iris. This innovative design enables the photochemical adjustment of light transmission and pupil size, leading to dynamic adaptation to diverse external lighting conditions. The cross-linking density of a hydrogel matrix containing a light-responsive photochromic dye is manipulated in a radially decreasing fashion. This radial control over cross-linking of hydrogel/photochromic dye composite is accomplished by employing a gradient-patterned UV light curing technique. The UV curing was achieved using UV curable resin mixed in the photochromic solution. The UV light is gradiently patterned using inject printed gray-scale patterns on transparent PET film as a photomask. This controlled cross-linking density results in varying switching speed of photochromic dye at the same UV intensity to realize the scalable aperture and hence the light transmission. The suggested self-regulating artificial iris exhibits the potential for customization in terms of color dyes and patterns, allowing for the replication of diverse iris colors and patterns mimicking specific regional and ethnic characteristics of the iris. Moreover, our proposed artificial iris shows consistent performance at body temperature under several on/off switching cycles with fast switching speeds.

SESSION EL05.03: Liquid Crystal Elastomer Optics
Session Chairs: Cindy Harnett and Juejun Hu
Tuesday Morning, November28, 2023
Hynes, Level 2, Room 203

10:30 AM *EL05.03.01
Fully Solid, Dynamic Optical Filters via Mechanical Reconfiguration of Liquid Crystalline Materials TimothyWhite; University of Colorado, United States

Electrochromic devices have found widespread use in automotive, aerospace, and architectural implementations. This talk will detail our recent research of liquid crystalline compositions in which the selective reflection can be tuned, broadened, and switched by mechanical, thermal, or electrical stimuli. Enabled by the modularity of the formulation of the cholesteric liquid crystal phase, filters can be prepared throughout the electromagnetic spectrum (VIS, NIR, SWIR, MWIR).

11:00 AM *EL05.03.02
Pixelated Camouflage from Cholesteric Liquid Crystalline Elastomers ShuYang; University of Pennsylvania, United States

In nature, there are full of creatures that will dynamically change their shapes and appearances to closely match their respective environments for camouflage, signaling, or energy regulation. Reflective structural colors can greatly enhance the appearance of their skin patterns, which are largely controlled by pigmented chromatophores. Meanwhile, bioorganisms are often sensitive to polarized light for navigation or communication. Cholesteric liquid crystalline elastomers (CLCEs) can assemble liquid crystal molecules into a helix, forming a 1D photonic crystal that can reversibly change the reflected colors upon mechanical deformation. Here, we demonstrate pneumatic inflation of the thin CLCE membranes with pixelated channels to achieve broadband color shift from near-infrared to ultraviolet wavelengths, where each channel is individually programmed as a color "pixel". We also 3D print CLCE filaments as color-changing smart wearables.

11:30 AM EL05.03.03
Reversible Selective Phase Patterning of Liquid Crystal Elastomer by Laser-Induced Dynamic Crosslinking Seok HwanChoi[1], Kyung RokPyun[1], HuijaePark[1], Deog-GyuSeo[1], SangminSong[2] and Seung HwanKo[1,1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Liquid crystal elastomers (LCEs) offer remarkable potential in various fields by enabling reversible transitions in mechanical and optical properties across polydomain, monodomain, and isotropic phases. However, the focus on the monodomain-isotropic phase transition has limited their applications to mechanical systems like soft robots and artificial muscles, overlooking their optical capabilities. This limitation arises from the absence of a local phase patterning method that can simultaneously pattern isotropic phases as well as monodomain and polydomain phases, hindering the utilization of LCEs in optical approaches. Furthermore, the lack of reversibility in conventional programming methods has impeded the widespread adoption of LCEs. To overcome these challenges, we introduce a novel laser-based technique termed laser-induced dynamic crosslinking (LIDC) for reversible selective phase patterning in LCEs.

LIDC leverages the precision and control offered by laser technology to achieve high-resolution patterning across various phases, enabling transmittance modulation while remaining compatible with conventional techniques. By crosslinking LCEs above the nematic-isotropic transition temperature (T_{NI}), the mesogenic units are immobilized, allowing for selective confinement in the isotropic configuration even upon cooling below T_{NI}, thus facilitating optical transmittance. Careful manipulation of laser parameters enables precise control over the degree of confinement and modulation of the optical and phase transition properties, including T_{NI} and ΔH, in LCE films. Combining LIDC with mechanical alignment methods enables the generation of patterns encompassing isotropic, polydomain, and monodomain phases within a single LCE film, facilitating visible patterns and actuation.
To introduce reversibility, allyl sulfide functional groups are incorporated into the LCE networks. Laser irradiation at higher power and temperature induces a relaxation process through the switching of bonds between allyl sulfide groups, leading to network reconfiguration and opaqueness upon cooling. The introduction of additional photoinitiators allows for repeated procedures, empowering LIDC to generate adaptive LCEs that can be configured into desired phases or used to create complex monolithic patterns that can be subsequently erased if necessary. Additionally, by incorporating allyl sulfide functional groups, T_{NI} is effectively reduced to near body temperature, expanding the thermal stimulus-responsive properties of LCEs for lower-temperature applications.
To demonstrate practical applications, particularly in human-related or skin-attachable contexts, we showcase a functional implementation of LIDC for easy information entry and deletion in LCE films, with information encryption triggered by body temperature. These findings open new avenues for the development of LCEs with enhanced versatility, functionality, and real-world applicability, paving the way for advanced applications across diverse fields.

11:45 AM EL05.03.04
Flexible, Fully Solid Tunable Filters via Cholesteric Liquid Crystalline Elastomer Stimuli-Response AlexisT. Phillips and TimothyWhite; University of Colorado Boulder, United States

Stretchable, soft optical materials are currently being explored for use in automotive, aerospace, and the wearable device industries as actuators, sensors, and light modulators. Cholesteric liquid crystalline elastomers (CLCEs) are a unique class of soft materials that self-organize into a helicoidal structure. The periodic nature of the hierarchical organization of these materials produces a 1-D photonic bandgap where periodicity in the refractive index causes the elastomer to exhibit selective reflection. This talk will entail the synthesis of CLCEs with high optical quality, a tunable modulus and reflection wavelengths. Stretchable, tunable light filters will be prepared that control light in the Visible-MWIR regions of the electromagnetic spectrum. We will detail how the tunability and polarization of the reflection can be controlled by the inherent optical and material properties of the elastomer and how the optical properties can be switched in response to mechanical, photothermal, and electrical stimuli.

SESSION EL05.04: Structural Optics with Soft Materials
Session Chairs: Michael Ford and Juejun Hu
Tuesday Afternoon, November28, 2023
Hynes, Level 2, Room 203

1:30 PM *EL05.04.01
Electrically Tunable Structural Colors of Cholesteric Liquid Crystals OlegD. Lavrentovich, KamalThapa, OlenaS. Iadlovska and SergijShiyanovskii; Kent State University, United States

Cholesteric liquid crystals are soft materials capable of selective reflection and transmission of light thanks to a spatially varying refractive index associated with the helicoidal twist of the optic axis. An attractive feature of cholesterics for optical applications is that the pitch and, thus, the wavelength of reflected and transmitted light can be tuned by temperature or chemical composition. However, the most desired mode of pitch control, by electromagnetic fields, has been elusive. This presentation reports on a cholesteric liquid crystal with an oblique helicoidal structure, abbreviated as Ch_{OH}. In the heliconical Ch_{OH} structure, the local director twists about a single axis but remains tilted to this axis (rather than being perpendicular to it, as in a conventional cholesteric). The Ch_{OH} forms when a chiral liquid crystal with a low bend elastic constant is acted upon by an electric (or a magnetic) field. The field tunes the pitch and the conical tilt angle without destroying the single-harmonic mode of periodic variation of the effective refractive index. As a result, a simple device in the form of a thin Ch_{OH} slab confined between two plates with transparent electrodes shows an extraordinarily broad range of electrically tunable robust selective reflection with structural colors reversibly shifting from ultraviolet to visible and infrared. For the oblique incidence of light, the slab shows total reflection with a tunable wavelength. The electric field controls both the bandwidth and the wavelength of reflection and transmission. The structure can also be used for electrically tunable retarders. The work is supported by the National Science Foundation grants ECCS-1906104 and ECCS - 2122399.

2:00 PM *EL05.04.02
Responsive Soft Photonic Materials from Cellulose Nanocrystals MarkMaclachlan; University of British Columbia, Canada

Cellulose nanocrystals (CNCs) extracted from biomass such as cotton and wood pulp form stable colloidal suspensions in water. Above a critical concentration, the CNCs spontaneously form a chiral nematic liquid crystal. In the chiral nematic structure, the CNCs are organized into pseudolayers, whose orientation rotates with a helical pitch, *P*. This chiral nematic organization is retained in dried films of CNCs. When the pitch of the chiral nematic structure in the solid film corresponds to the wavelength of visible light, the materials exhibit selective diffraction of light and appear brightly iridescent.[1] Moreover, the color of the material can be tuned by changing the helical pitch.

Our group has been active in using CNCs as a template to construct novel chiral nematic mesoporous materials with photonic properties.[2] We have succeeded in preparing silica,[3] organosilica,[4] and polymeric materials[5] through self-assembly or templating methods.
In this presentation, I will discuss our recent explorations of the liquid crystalline properties of CNCs, including shape-memory photonic materials[6] and elastomers with tunable optical properties.[5,7,8]

3:00 PM EL05.04.03
All Water Processing for Multilayered Biomaterial-Based Nanostructures with High Refractive Index Contrast and Selectively Responsive Structural Color TaehoonKim[1], JunyongPark[2] and FiorenzoOmenetto[1]; [1]Tufts University, United States; [2]Kumoh National Institute of Technology, Korea (the Republic of)

Transparent multilayered nanocomposites, known as distributed Bragg reflectors (DBRs), offer effective light modulation control, making them vital for next-generation photonic materials and devices. While inorganic multilayer structures have been successfully manufactured using vacuum deposition techniques, the emergence of biopolymers as eco-friendly alternatives with advantages such as biocompatibility, flexibility, and stimuli-responsiveness presents new opportunities. However, substantial challenges remain in achieving high-resolution biopolymer-based DBRs suitable for optical functions, which require control down to the single nanometer scale.

Here, we present a fabrication strategy using aqueous SF and aqueous metal oxide (ZrO_2) precursor solutions to address these challenges. Control over the structural polymorphism of SF to tune its physicochemical properties. By inducing crystallization in the silk film, the coated silk layer becomes water-insoluble, enabling consecutive coating of the ZrO_2 precursor solution without dissolving the underlying film. The slightly hydrophobic surface of the crystallized silk film hinders spin coating coverage of the metal aqueous solution due to its high surface tension. To overcome this wetting issue, we utilize the amphipathic nature of SF heavy chains. Adding a small amount of amphiphilic SF to the aqueous Zr solution dramatically improves surface coverage.

Through this optimized solution processing approach, we successfully demonstrate silk-ZrO_2 DBRs with a high index contrast ($\Delta n \sim 0.42$@500 nm). The resulting DBR structure consists of eight pairs of silk/ZrO_2 bilayers, exhibiting uniformity and high reflectance of up to 85% at visible wavelengths. Additionally, by controlling the structural polymorphism of SF through UV light, the thickness and swelling behavior of the silk film can be modulated, enabling the fabrication of photo-patternable and stimuli-responsive DBRs.

These results showcase the potential of biopolymer-based multilayer structures for photonic applications, highlighting the importance of solvent design, large refractive index contrast, and precise control over layer thickness and roughness. The developed silk-ZrO_2 DBRs offer opportunities for diverse applications such as structural colors, colorimetric sensors, optical communication, and optoelectronic devices. Furthermore, we demonstrate the feasibility of utilizing stimuli-responsive silk polymorphism for structural color-based encryption, which holds promise for applications in colorimetric sensors and anti-counterfeiting technologies.

3:15 PM EL05.04.04
Solid-Phase Structural Coloration from Cholesteric Phases of Hydroxypropyl Cellulose-Parameter Space for a Full Color Palette HongningRen, TadeuszBalcerowski, CamranAli, JordiBures and Ahu GumrahDumanli; University of Manchester, United Kingdom

Hydroxypropyl cellulose (HPC) is a sustainable, cost-efficient and biocompatible cellulose derivative which can self-assemble into cholesteric mesophases at highly concentrated water solutions. Such cholesteric solutions reflect iridescent and metallic colors in the visible range (1,2,4). Retaining the vibrant coloration in the solid phase for the HPC has been widely studied by offering cross-linkers that are mostly toxic such as glutaraldehyde (3, 4), with the assistance of acid catalysts and the exact mechanism of cross-linking is still a subject of debate and ongoing research.
In this presentation, we will discuss the mechanisms behind retaining the solid-phase structural coloration in the HPC without cross-linking and by controlling the parameter space during the evaporation process to achieve a full color palette.(5) Our investigation revealed that during the evaporation process, at the early stages of the evaporation the HPC readily forms a disordered dense skin that controls the balance between the kinetic arrest of the cholesteric order and its thermal expansion. Increasing the sample thickness, applying higher curing temperatures, and exposing the samples to higher humidity during the evaporation all result in red-shift in the pitch values and the final coloration. Furthermore, we will also showcase our new findings which stems from the idea of implementing the steric repulsion that leads to fabricating solid phases of HPC with predictable coloration by adding linear dicarboxylic acids to the solution. The dicarboxylic acid additives causes further steric interactions between the cholesteric layers. Therefore changing the aliphatic chain length of the acid from 3 to 5 by using malonic acid (MA), succinic acid (SA) and glutaric acid (GA) allows an additional fine tuning ability at the molecular level for the color manipulation.

3:30 PM EL05.04.05
Xanthan-Induced Gelation in Cellulose Nanocrystal Suspensions: Tuning of the Self-Assembly and Optical Purity TadeuszBalcerowski and Ahu GumrahDumanli; University of Manchester, United Kingdom

Cellulose nanocrystals (CNCs) are anisotropic nanoparticles that can undergo chiral self-assembly in aqueous suspension to produce vibrant structurally colored films with a helicoidal nanostructure resembling the cholesteric structures found in natural systems. Above a critical concentration, CNC suspensions form a cholesteric liquid crystal phase and small clusters of order called tactoids, with a periodicity (pitch) determined by the colloidal interactions between the CNCs, and further parameters affecting the dynamics of the evaporation. Upon further drying, the CNCs undergo kinetic arrest, which allows their helicoidal ordering to be preserved in the solid state. The color and the angular dependence in these films can be tuned using numerous experimental parameters. Such films can be used to produce optically active components or processed further. In this study, we explore two differently processed CNC colloidal suspensions and their interactions with a food-grade gelating agent with the aim to explore the onset of the gelation point. The Xanthan gum used here is produced by the fermentation of simple sugars by the bacteria *Xanthomas campestris*. While the presence of the complex polysaccharide gum brings flexibility to the CNC films, the films also demonstrate remarkable color uniformity and loss of iridescence due to the entrapment of the CNC tactoids into encapsulated structures to combine a surface texture and scattering of visible light within the co-assembled structure. In this talk, I will explain how in the evaporation stage Xanthan advances the onset of gelation and provides colloidal stability, thus restricting the expected phase separation into smaller-scale events as compared to pure CNC films. This work sheds new light on the gelation mechanisms in hybrid CNC systems, their interaction with an additive of alike chemistry, and self-assembly in a phase-stabilized environment.

3:45 PM EL05.04.06
Reflectin and Cellulose-Based Bragg Reflectors with Chiral Photonic Response Luz Carime GilHerrera, JiaxinHou, TadeuszBalcerowski, DerrenHeyes, ErikoTakano, JonnyBlaker, NigelScrutton and Ahu GumrahDumanli; University of Manchester, United Kingdom

Structural colors in nature are generated by elaborate hierarchical nanostructures, which have been exploited for the fabrication of functional bio-inspired photonic materials for sensing applications. One attractive model system for this is the structural coloration in cephalopods, which is achieved by the multilayer interference of periodically stratified reflectin platelets in iridophores that act as Bragg reflectors. Such multi-layered structures have the ability to respond to chemical stimuli via a complex response mechanism involving the change in the multilayer periodicity and absorbance through chromophores. While there are studies focused on using the reflectins in synthetic multilayered constructs, such optical materials are not scalable and the angular and polarisation response cannot be tuned easily. Here we designed a multilayered hybrid material system that is built by layer-by-layer (LbL) processing of reflectins and cellulose nanocrystals (CNCs). CNC films exhibit fascinating optical properties, mainly due to their chiral nematic structure and birefringence. The optical response of this hybrid system combines the chiral response from CNCs and is amplified by the addition of reflectins. LbL processing allows us to explore several parameters, such as dependence on the concentration, layer thickness, and the dynamics of cellulose suspension, in order to achieve optimal structural color-producing systems. The reflectance of these systems was analyzed by using an optical model based on the 4×4 Berreman matrix method (Mathematica®). In addition, the effect on the retention of the chiral optical response of the CNC by the building up of the thin film was evaluated. Our findings define the optimal points and the limitations of the optical response from these multilayer systems. The multilayer construct with thin layered reflectin and CNCs at the gelation point suggests that the chiral response is affected by the ability to retain the helicoidal morphology during the LBL process and can be non-uniform. Our results show good agreement between the theoretical model and experiments. Overall, we will demonstrate that the unique optical properties of cellulosic materials can be combined with the dynamic coloration imparted by reflectin and this study will potentially broaden the application of these chiral photonic systems.

4:00 PM *EL05.04.07
Mechano-Responsive Color-Changing Photonic Materials BenjaminMiller, AndrewBlair, MaxThomsen and MathiasKolle; Massachusetts Institute of Technology, United States

Color-changing photonic materials are promising candidates for the design of colorimetric sensors and wearable technology, which can for instance be used to quantify the pressure exerted on a patient's body with compression bandages. While efforts in research groups across the world have resulted in many interesting lab-scale implementations of dynamic photonic materials, the scalable and economically viable production of such materials with high throughput is still a challenge that remains to be addressed. This presentation will be focused on a scalable optical manufacturing approach for the generation of highly stretchable, color-changing photonic sheets on the square-meter scale. The design space that is accessible with this technique with regards to controlling the materials spatio-spectral reflection behavior, its angular scattering characteristics, and its strain-induced color dynamics will be discussed in detail. Potential application scenarios, including medical textiles will be presented.

4:30 PM EL05.04.08
Living Optical Networks for Light Redistribution Inspired by Orchid Leaves GiuliaGuidetti and FiorenzoOmenetto; Tufts University, United States

Plants and animals have developed sophisticated hierarchical systems that integrate physicochemical material properties with functional micro- and nanostructures to effectively manage energy, motion, and species survival. These biological systems, besides providing cues on bottom-up manufacturing of technological structures, can offer insight on strategies for efficient energy management. In this study, we investigate the light harvesting and redistribution capabilities of tropical orchid leaves, which employ a cell-based optical network. Unlike regular orchid

leaves, the outer epidermal cells of these leaves exhibit a distinctive hexagonally packed short-range order lattice and rounded shape, facilitating optical cross-communication. By replicating this optical network within a tunable biopolymer matrix, we can fabricate versatile devices such as omnidirectional light couplers, wavelength selective optical networks, and cryptographic systems including all-optical unclonable security tags. To reproduce this propagation mechanism, we mimic the leaf structure using free-standing silk fibroin films. The response of the bioinspired cell-based optical networks can be controlled through functionalization achieved by selective doping with pigments and absorbers, as well as by modulating the silk protein conformation. We explore the structure-function relationship of the bioinspired optical networks using finite-difference time-domain optical modelling, revealing that the lateral redistribution of light through cross-communication is not only geometrically but also wavelength dependent.

4:45 PM EL05.04.09
Photonic Crystals Built by Time in Ancient Roman Glass GiuliaGuidetti[1], RobertaZanini[2], GiuliaFranceschin[2], MauroMoglianetti[2], TaehoonKim[1], NathanielCohan[3], LisaChan[3], JohnTreadgold[3], AriannaTraviglia[2] and FiorenzoOmenetto[1]; [1]Tufts University, United States; [2]Center for Cultural Heritage Technology, Istituto Italiano di Tecnologia, Italy; [3]Carl Zeiss Microscopy LLC, United States

Ancient glass artifacts, though not inherently soft materials, display intriguing optical phenomena resulting from environmental-induced physico-chemical transformations over time. Iridescence is a common optical signature and one of the distinctive signatures of glass aging that is often observed on the surface of excavated glass. This study presents the optical investigation of a Roman-era archaeological glass fragment, employing a correlated optical-morphological and elemental analysis approach. Specifically, the studied ancient glass fragment exhibits structural color through surface weathering resulting in iridescent patinas caused by silica reprecipitation in nanoscale lamellae with alternating low and high density. This archaeological artifact reveals an unusual hierarchically assembled photonic crystal with extremely ordered nanoscale domains, high spectral selectivity and reflectivity (~90%). When taken individually, these silica multilayer lamellar domains resemble Bragg-stacks with narrowband reflection; however, when taken collectively they behave like a gold mirror. Optical characterization paired with nanoscale elemental analysis further underscores the high quality of this structure providing a window into this sophisticated natural photonic crystal assembled by time. Significantly, this highly reflective patina consists of a rare example of a self-assembly, pH-driven fabrication process that involves top-down processes (glass network dissolution) followed by bottom-up nano- to micro-scale structuring (silica nanoparticles nucleation, growth, and assembly in ordered Bragg stacks) in a natural structure. The characterization of this Roman glass fragment opens new perspectives on the insights and inspiration provided by analyzing ancient materials at the nanoscale, enabling observations of phenomena occurring across temporal windows that are otherwise challenging to replicate with currently available artificial aging approaches.

Highly Sensitive Mid-Wavelength Infrared Linear Polarizers Based on Waste from Petroleum Refining Process WoongbiCho[1,1], JehwanHwang[2], Sang YeonLee[3], ZahyunKu[4] and Jeong JaeWie[1,1]; [1]Hanyang University, Korea (the Republic of); [2]Purdue University, United States; [3]Inha University, Korea (the Republic of); [4]Air Force Research Laboratory, United States

Infrared (IR) optics play a key role in detecting invisible objects in darkness as well as small gas molecules. For gas detectors in industries and night vision in the military, IR polarizers can provide high-resolution images by selectively reflecting the transverse electric (TE) field and transmitting the transverse magnetic (TM) field. In this presentation, we introduced a low-cost yet high-performance waste-based metal wire grid IR polarizer by deposition of Au on the sulfur-rich polymer-based 1D nano-gratings integrating with a spacer layer. For IR transparent materials, the sulfur-rich polymer is employed due to its economic feasibility and thermal/solution processability. The sulfur-rich polymers are synthesized through inverse vulcanization of elemental sulfur (S), waste from the petroleum refining process. To design an effective polarizer structure, we first simulated the variation of optical properties like transmission of TM and TE (T_{TM} and T_{TE}), and extinction ratio (ER), according to the geometries including pitch, height, a ratio of width and pitch, Au thickness, and spacer layer thickness. Then, we realized the sulfur-rich polymer-based polarizer having the simulated geometry by spin-coating, thermal nano-imprinting (NIR), and followed Au deposition. In detail, we precisely controlled spacer layer thickness from 50-5100 nm via spin-coating by tailoring the spin speed, and the concentration of sulfur-rich polymer solution. The high-fidelity 1D nano-grating was prepared by applying the systematically controlled thermal NIL conditions (temperature, pressure, and time), which are obtained by considering both temperature-dependent viscoelasticity and the correlation between time and pressure. Finally, the sulfur-rich polymer-based polarizer exhibited remarkably high T_{TM} of 0.59, and ER of 5.19×10^3 at 4 μm.

Controlling Optical Response of Hydrogel using Metallic Microstructures Fabricated with High-Speed Scanning of Femtosecond Laser Pulses KenKashikawa, HirofumiTomikawa, HiroakiOnoe and MitsuhiroTerakawa; Keio University, Japan

A temperature-responsive hydrogel shows reversible volume-phase transitions in response to changes in their surrounding temperature. By containing metal nanoparticles as light absorbers inside the temperature-responsive hydrogel, the hydrogel`s transmittance can be changed by photo-thermal conversion of the metal nanoparticles stimulated by light irradiation. The multi-photon photoreduction (MPR) method can spatially and selectively fabricate metal microstructures consisting of metal nanoparticles inside the hydrogel. In the MPR method, metal microstructures can be fabricated by femtosecond laser pulses inside the hydrogel containing metal ions. However, temperature-responsive hydrogels are thermally affected by the irradiation of femtosecond laser pulses at high repetition rates during the structure fabrication process which induce an undesirable volume phase transition, resulting in the hindrance of fabricating the arbitrarily designed structures. In this study, we fabricated microstructures consisting of multiple gold thin lines inside a poly (N-isopropylacrylamide) (PNIPAM) hydrogel by laser scanning at high scanning speed and multiple times (hereinafter called “multiple scans”) by using a galvanometer scanner system. Under the experimental conditions of low scanning speed at a single time (hereinafter called “single scan”), the density of gold nanoparticles in the gold microstructures was low and the lines formed curls, curves, and/or kinks. On the other hand, under the experimental conditions of high scanning speed and multiple scans, the density of gold nanoparticles in the gold microstructure was high and straight lines without curls and curves were fabricated. The temperature around the irradiated area during laser pulse irradiation was measured by a thermography camera (T865, FLIR), and it was confirmed that the maximum temperature at high scanning speed with multiple scans was lower than that at low scanning speed with a single scan. Next, transmittance control by light stimulation was performed using the PNIPAM hydrogel with the fabricated gold microstructure. The two laser diodes with wavelengths of 520 nm and 405 nm were used as a stimulating light and a signal light, respectively. When the stimulating light was illuminated to the fabricated gold microstructure, the transmittance of the signal light in the PNIPAM hydrogel significantly decreased. Furthermore, the rate of the decline in the hydrogel`s transmittance of the signal light and the response time of the hydrogel around the gold microstructure during irradiation of the stimulating light depended on the laser parameters during the structure fabrication process. The gold microstructures fabricated with high scanning speed and multiple scans showed the lowest transmittance and the fastest response time during the stimulated light irradiation in this experiment. This result is attributable to the higher density of gold nanoparticles in the gold microstructures fabricated with high scanning speed and multiple scans than in the microstructures fabricated with low scanning speed with a single scan. In the case of high scanning speed and multiple scans, the hydrogel around the fabricated gold microstructure is easier to reach the phase transition temperature. In conclusion, we experimentally demonstrated that gold microstructures can be simply fabricated into the temperature-responsive hydrogel by scanning femtosecond laser pulses with a high scanning speed and multiple scans. The fabricated gold microstructure can increase the degree of the hydrogel’s transmittance change and shorten the response time of the hydrogel.

Highly Selective Sensors for Carbonyl Groups via Ion-Pairing Dyes with Wide Visible Spectrum DonghyunKim, JinhoLee, ChungseongPark, EuichulShin and Il-DooKim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In sensor research, achieving selectivity to distinguish between different materials is crucial for sensor performance and practical application, albeit adding complexity to the sensor design. Here is a straightforward method to achieve selectivity: adjusting the amount of amine mixed into the sensor. Through visual observation, we can create a color change sensor that enables easy differentiation of carbonyl groups with similar structures (such as ketones, carboxylic acids, and aldehydes). This color change sensor generates different pH and chemical environment changes when exposed to different carbonyl materials, and these changes are detected using ion-pairing dyes with a broad range of colors. Notably, this change is particularly noticeable under high humidity conditions, allowing for the differentiation of concentrations at the ppm level. This feature enhances its potential use as an exhalation sensor in high-humidity environments. The presence of acetone in human breath is closely associated with fat burning, and the concentration of acetone at the ppm level varies depending on the extent of burning. Consequently, after transforming the sensor into nanofibers through electrospinning, it can be employed in a healthcare system capable of sensitively detecting acetone in human breath. Moreover, its high selectivity for acetone clearly distinguishes it from other gases produced through exhalation.

Structural Coloration in Water Droplets Containing Suspended Clay Mineral Nanosheets YueYu, PauloH. Michels Brito and Jon OttoFossum; NTNU, Norway

Na-fluorohectorite (Na-FHt), a synthetic clay mineral which spontaneously forms nematic phases of single 1-nm-thick nanosheets when immersed into water, show structural coloration. Our previous work has demonstrated that two single nanosheets pinned together by Cs^+ (so-called Double Layers, DBLs) produce bright and non-iridescent structure coloration. In the present study, we demonstrate experimentally that a single acoustic levitated water droplet (with diameter around 2mm) containing clay DBL nanosheets can easily and rapidly present structure coloration. The color changes during droplet evaporation as the clay DBL concentration increases. In addition, we observe droplets with similiar volume placed on non-wetting and wetting surfaces respectively. This study paves the way further for sustainable structural coloration design at the microscale.
Key words: nematic gel, structure, optical properties, environmental confinement, droplets and film

Temperature-Dependent Self-Assembly Remodeling by a Polyether Perylene Diimide in Water AdrianFernandez[1], MireyaMcKee[2], PedroRodriguez[1], SarahWeisbrodt[1], KrystalOjiemuada[1] and SeanM. Kerwin[1]; [1]Texas State University, United States; [2]The University of Texas at Austin, United States

We report a novel Perylene diimide (PDI) bearing polyether side chains that displays reversible, temperature depended remodeling of two spectroscopically distinct self-associated forms. We describe the synthesis of this PDI (TEL-045) and its self-association behavior in solution as determined by UV/Vis, fluorescence, and resonant light scattering spectral analysis. TEL-045 forms monomeric, emissive species in solution in organic solvents. In aqueous solution, TEL-045 undergoes self-association to produce a non-emissive state. As the temperature of aqueous solutions of TEL-045 are increased, the degree of self-association increases, leading to LCST behavior and a new type of self-associated, emissive species. This reversible, temperature-dependent switching between H- and J-type self-association of this simple, a non-chromophore-modified PDI leads to marked changes in fluorescence enabling temperature-sensing and other applications.

Near-Infrared Light Guidance Through a Long Length Hollow Core Polymer Optical Waveguide from a 3D Printed Preform MahmudurRahman and MustafaOrdu; Bilkent University, Turkey

Hollow-core polymer optical fibers have great significance due to wide range of applications, such as short distance data transmission, wideband light guidance, and chemical and biomolecule sensing. In this study, a novel hollow-core optical fiber design was proposed for visible and near-infrared light guidance. The fiber was drawn conventionally using thermal drawing tower using a 3D printed polymer preform. Light guidance was demonstrated through the air core surrounded by six-pointed star cladding tubes up to 57.8 cm with the lowest propagation loss of 0.11 dB/cm between 1.1 µm to 1.3 µm wavelength range.

Stretchable and Durable Electroluminescent Devices with Exceptional Luminance using In-Plane Electric Field and Ionogel Electrodes SeongkyuSong and Soon MoonJeong; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The advantages of in-plane electric field-driven electroluminescent devices (IP-ACEL) over coplanar devices include reduced light loss and increased brightness due to the electrodes being embedded within the emissive layer. Previous research showed that using conducting fibers and silver nanowires as electrodes improved luminance, but had limitations in stretchability and transmittance [1,2]. In this study, we addressed these limitations by developing transparent and highly stretchable ionogel electrodes for IP-ACEL devices, resulting in bright, stretchable, and durable ACEL devices. Our ionogel electrodes-based IP-ACEL device achieved a maximum brightness exceeding 3,000 cd/m^2, the highest reported among flexible/stretchable type ACEL devices. Furthermore, the IP-ACEL device exhibited exceptional durability, enduring 5000 cycles of repeated stretching, and provided protection against various external factors such as water and light. This approach enhances device performance and holds potential for applications in sustainable light sources, soft robots, and actuators.

The User-Friendly Foveated LED Smart Contact Lens for Realistic Metaverse JieunYeo, SehuiChang and Young MinSong; GIST, Korea (the Republic of)

With the advancement of semiconducting technologies including optoelectronic devices and displays in internet of things (IoT) era, there is growing attention to realize a hyper-connected society where various subjects such as people, objects, and systems. A “metaverse” is of interest to seamlessly blend virtual and real world spaces, which enables users to experience not only a sense of reality but also a virtual information without constraints of space and time. In this regard, the demonstration of a hyper-realistic virtual space that blurs the boundary between real and virtual space has become crucial factor in the display technologies. The augmented reality (AR), the one of the major visualization technologies of metaverse, is a technology that synthesizes information of virtual objects or spaces onto the scene of the real world through the device. However, the most devices such as head-mounted display (HMD) for the AR have limitations of the need for additional displays and cameras to integrate virtual objects or information into the real world due to the blockage between the user and outer physical space during wearing the HMD. In addition, the HMD causes cybersickness, generating the discomfort to users due to visual occlusion and discrepancies between sensory inputs and visual stimuli. Thus, there is an emerging demand for alternative technologies that can effectively alleviate user’s fatigue and seamlessly integrate metaverse visualization into daily life. Many studies in sunglasses-type displays to improve the large and heavy volume of HMD have been demonstrated, but fundamental issues (e.g., cybersickness) are remaining challenges. In this study, we present the foveated LED smart contact lenses system by incorporating transparent LED displays into the center of contact lenses. These smart contact lens-based technologies aim to achieve ultra-realistic virtual space that naturally blend the boundaries between the real world and the metaverse in user-friendly way.
The foveated imaging function in smart contact lens shows the maximum image quality in the main visual fields relating to the user's gaze, while having the background area in relatively low image quality to increase the user's immersion and reduce data processing speed. The foveated LED smart contact lens was designed by inserting the LED pixels to the human eye model through the commercial ray tracing software. The lens design was optimized with a basis of optical properties of the conventional contact lens polymer; refractive index (1.4-1.5), thickness (100-150 um), and radius of curvature (8.5-8.9 mm). In particular, LED displays should be designed small enough not to cast their shadows on the retina, and the LEDs are assumed that emitted light goes in the vertical direction of the LED device along the waveguide structure, unlike general LEDs emit light in radial direction under the substrate. When the fovea area was set as a detector region, the curvature of the lens and the LED greatly affected the image formation of the fovea. At a curvature of 8.6-8.9 mm, which is mainly used as the RoC for commercial contact lenses, small images are focused on areas outside of the fovea. However, if the contact lens is flattened than this curvature, it occurs user’s discomfort to actually wear it. Therefore, the LEDs is placed to flat only the center of the lens by dividing the layer, because the area occupied by the LED is sufficiently small, which is effective rather than controlling the curvature of the entire lens. As a result, we designed an optical system of the foveated LED smart contact lenses that is user-friendly and enables a realistic metaverse implementation. The proposed system is expected to open the way for the development and commercialization of user-friendly AR devices for metaverse.

Optical Physically Unclonable Function Based on Electrospun Fluorescent Random Fibrous Media MinSeokKim, Joo HoYun, SeungkyuChoi, Dong HyunSeo and Young MinSong; Gwangju Institute of Science Technology, Korea (the Republic of)

Physical Unclonable Functions (PUFs) are unique cryptographic mechanisms derived from non-deterministic random variables introduced during their fabrication process. PUFs have garnered significant interest in recent years, especially in combating counterfeit activities and ensuring privacy and confidentiality of sensitive information. Among the different categories of PUFs, those exploiting optical principles have gained prominence due to inherent benefits like high entropy, complex output patterns, and strong resistance against modeling and replication-based attacks. The use of random lasers provides an especially attractive aspect of optical-based PUFs that distinguishes it from conventional laser-based PUFs systems. This emission is a phenomenon of Anderson light localization, which occurs when light undergoes intense scattering within a disordered medium. However, the fabrication of large-scale random media that can induce random lasing remains a formidable challenge due to economic viability. In this study, we propose an innovative solution by capitalizing on electrospinning. We demonstrate the feasibility of fabricating an optical PUF device that incorporates random lasing properties using this method and investigate its potential use in security applications.
For implementing the optical PUFs, we employed the electrospinning technique to generate nano/microfibers. We created a solution by dissolving 2 g of polymethyl methacrylic acid (PMMA) in 9 g of dimethylformamide (DMF) and acetone, stirring it at 60 °C for eight hours. To acquire emission properties within the 560 nm to 640 nm, we used 4-(dicyanomethylene)-2-methyl-6-

(4-dimethylaminostryl)-4H-pyran (DCM) dissolved in a 2 mM solution at 60 °C for two hours. This solution then underwent the electrospinning process through a 23 gauge nozzle, applying a high voltage of 14 kV and maintaining a dispensing rate of 1 mL/hr. The process resulted in the fabrication of random microfibers, with homogeneous diameter distribution and thickness. Despite uniform diameters, the fabricated samples showed different optical properties due to variations in fiber structures at separate locations within the sample.
To verify the occurrence of random lasing, we initiated an optical stimulation procedure using a UV laser with a wavelength of 355 nm with 10 Hz repetition rate. The laser was concentrated on the fabricated sample using a convex lens. The wavelength information of the resulting random laser was collected using an objective lens and a spectrometer. We gathered wavelength data, which showed random peaks within the 580 nm to 620 nm range, indicating the occurrence of random lasing. We further processed the data to leverage the peaks acquired from optical PUF devices, removing the spontaneous emission with post-processing.
Utilizing a De-biasing method, we extract random bits from the PUFs, thereby significantly enhancing the uniformity of the digitized data. To validate the uniqueness and reproducibility of the bits generated from the PUFs, we calculated the Hamming distance and applied the NIST Randomness Test Suite (NIST SP 800-22). The random laser-based PUFs show excellent performance in terms of randomness, uniqueness, and reproducibility. With an inter-Hamming distance near 0.5, there was a high level of differentiation between bits produced from different samples. Notably, the intra-Hamming distance approached zero, indicating the high reproducibility of the random laser-based PUF. This research brings to light the potential of creating large-scale optical PUFs with random lasing properties, offering a promising direction for future cryptographic applications.

8:00 PM EL05.05.10
Production of Stimuli-Responsive Microlens Arrays by Photografting Surface-Assembled Hydrogel Prepolymers JohnKapitan[1], GraysonMinnick[2], BrennanWatts[1], NengjianHuang[1], MarkRose[1], RuiguoYang[2,2,2] and StephenA. Morin[1,2,2]; [1]University of Nebraska-Lincoln, United States; [2]University of Nebraska–Lincoln, United States

Hydrogels garner much interest due to their broad applicability to a wide range of fields such as soft robotics, biomaterials, and adaptive optics. Current manufacturing procedures for hydrogels, specifically those at the micro- and nanoscale, require the use of time consuming and expensive equipment. Moreover, often these microsctructured hydrogels (microgels) lack strong interfacial adhesion to support materials limiting their applications. We developed a manufacturing scheme for hydrogel prepolymers that: 1) uses mechanically-driven coalescence to assemble prepolymer droplets into well-defined geometries and morphologies and 2) creates robust bonds with an elastomer support substrate using a “graft from” polymerization scheme. We used this technique with several hydrogel systems to manufacture large arrays of highly ordered microgels in minutes. The size and periodicity of the hydrogels was easily controlled by changing the surface chemical template. Hydrogel arrays demonstrated robust adhesion to the surface versus hydrogels assembled on surfaces without the necessary moieties for covalent attachment. Despite the strong adhesion the attached hydrogels maintained their stimuli responsive nature. We demonstrated optically dynamic hydrogel arrays whose refractive index could be adjusted by external stimuli, such as solvent or heat. We quantified the change in refractive index by measuring the magnification of an image projected through a hydrogel array. These microlens arrays can be applied as optical sensors in soft robotics or lens elements in wearable electronic devices.

8:00 PM EL05.05.11
Universal Self-Aligned Waveguide for an Amphibious Imaging System Inspired by the Compound Eye of the Fiddler Crab Hyuk JaeJang, JieunYeo and Young MinSong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Compound eyes of arthropods (e.g., insects) have remarkable features such as a wide field-of-view and high sensitivity to motion detection. [1] These characteristics are due to their unique optical unit, ommatidium, which consists of a corneal lens, crystalline cone, and rhabdom. In nature, the ommatidia have diversely evolved with their environments, such as a corneal lens for optical power and crystalline cone for optical guidance. Researchers have attempted to mimic the functionality of natural ommatidia using photosensitive polymer materials to create artificial ommatidia. [2] However, previous studies have not considered the effects of different environments, such as air and underwater, on the imaging performance of these artificial ommatidia.
In typical optical systems, the refractive power of curved lenses is affected by the external refractive index (RI), leading to a loss of focusing power. In other words, curved lenses are not efficient in gathering optical rays when exposed to changing environments. Some imaging systems have addressed this limitation by modifying the lens shape or displacement (e.g., liquid lens). However, these optical accommodation systems tend to be bulky and complex, which is not suitable for compact configurations. To achieve more efficient vision in both air and water, an imaging system requires accommodation-free optical component. The fiddler crab, a semi-terrestrial crab, has compound eyes with flat corneal micro-lenses that possess a graded RI. Unlike traditional curved lenses, which rely on changes in shape or displacement for optical accommodation, the fiddler crab's flat micro-lenses maintain consistent optical power across various environments without the need for accommodation.
Here, inspired by the fiddler crab's eye, we introduce an amphibious artificial ommatidium with self-aligned waveguide. The artificial ommatidium comprise a self-written waveguide (i.e., crystalline cone) and a flat micro-lens array (MLA) (i.e., corneal lens), achieved through a process involving the use of ultraviolet (UV) curing properties of a photosensitive polymer material (SU-8) and the light-focusing capability of the MLA. Prior to fabricating the SU-8 MLA, a polydimethylsiloxane (PDMS) mold with a sidewall was created using a quartz MLA mold etched through reactive ion etching. The temperature of the SU-8 material was gradually increased from 65 °C to 120 °C to ensure complete solvent evaporation, followed by spin-coating of an optical adhesive (Norland optical adhesive, NOA) onto the fabricated SU-8 MLA. Upon UV light irradiation, the exposed region underwent photo-crosslinking via post-exposure baking, resulting in an increase in RI. Meanwhile, the unexposed region experienced thermal-crosslinking through hard baking, leading to a reduction in RI (~0.008). Consequently, this process turned out to be RI change between a core and cladding structure for the waveguide ($\Delta n = 0.029$), with an additional spin-coating step to cover the outer layer.
We successfully implemented the universal self-aligned waveguide by using flat MLA and the RI difference between the photo/thermal-crosslinked regions. The optical performance of the artificial ommatidium was evaluated, demonstrating its amphibious imaging capability. This amphibious artificial vision system represents a significant advancement in imaging applications, particularly in the field of amphibious motion detection.

Optical Fiber Probe based on Plasmonic Hydrogels for Continuous Glucose Sensing IsrarAhmed, AmalAlGhaferi and HaiderButt; Khalifa University, United Arab Emirates

In recent years, the prevalence of diabetes mellitus (DM), a chronic metabolic disorder caused by excessive blood glucose levels, appears to have increased globally. Diabetes is not lethal, but its complications can result in serious illness or death. Consequently, cost-effective, rapid, and dependable sensing is required for diabetes control. Optical fiber sensors based on nanocomposite photonic hydrogel functionalized with phenylboronic acid (PBA) were developed here for continuous glucose monitoring. Optical fiber sensors were created by polymerizing PBA-based hydrogel on the tip of a commercial fiber. Subsequently, Au nanoparticles were incorporated into the polymerized OF sensor by immersing the sensor in a nanoparticle solution. In the physiological glucose range (0 - 20 mM), glucose sensors were studied using transmission and reflection modes. The transmission spectrum of the OF sensor exhibited a 27 percent variation. Also, a minor shift of 5 nm was seen in the SPR when the glucose concentration varied from 0 to 20 mM. An increase in the reflectance spectrum was also seen when glucose concentrations rose. These OF sensors were measured to have a rapid reaction time of 20 seconds and a saturation time of 3 minutes. Ultimately, the sensor's usability was validated using a smartphone readout. For this reason, the photodiode of a smartphone was utilized, and the change in optical power for various glucose concentrations was evaluated. These OF sensors may benefit continuous glucose monitoring systems in diabetic care.

Quantum Chemical Study of Electrogenerated Chemiluminescence Cell of Rubrene Solution with an Assist Dopant NobuhikoAkino[1], EmiriKato[1], RyoichiIshimatsu[2], JunMizuno[3] and TakashiKasahara[1]; [1]Hosei University, Japan; [2]University of Fukui, Japan; [3]National Cheng Kung University, Taiwan

Recently, electrogenerated chemiluminescence or electrochemiluminescence (ECL) cells have been considerable attention for the use in future displays due to their simple device structure and also easy fabrication process.[1,2] In the previous study, we have shown that the ECL performances of 5,6,11,12-tetraphenyltetracence(rubrene)-based device was significantly improved by using 4-(di-*p*-tolylamino)-4’[(di-*p*-tolylamino)styryl]stilbene (DPAVB) as an emitting assist dopant, compared with the performance of device without it.[3] For example, the maximum luminance of the device with an emitting assist dopant was improved to 292 cd/m^2 at 6.0 V, which is approximately 3.4 times higher than the luminance of the device without it (86.2 cd/m^2 at 5.5 V).
From the cyclic voltammograms (CVs), both the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) of DPAVB are shallower than HOMO and LUMO of rubrene. Based on the energy level configuration of neutral molecules, it seems energetically unfavorable for an electron on HOMO of rubrene radical anion to DPAVB radical cation in order to form the excited states of rubrene. The mechanism of the improvement in device performance has not been clear enough and it has been desired to understand deeply for further improvements.
In this study, we have utilized the quantum chemical calculations to shed some light on the mechanism in the device with an assist dopant. The geometry optimizations of molecules are performed using the density functional theory at the level of B3LYP and the solvent effects are incorporated using the polarizable continuum model (PCM). The calculated energy levels of the radical anion of rubrene and the radical cation of DPAVB are modified from the levels of the neutral molecules. Their relative positions support the energetically efficient electron transfer

from the former to the latter leading to the excited states of rubrene and the neutral state of DPAVB, which results in the luminance improvement in ECL device.

Soft, Side Emitting Optical Fibers by Multimaterial Printing AránzazuDel Campo[1,2]; [1]INM–Leibniz Institute for New Materials, Germany; [2]Saarland University, Germany

Side-emitting optical fibers are used to illuminate large volumes of non-transparent material. Introducing a customized side-emission profile is a major challenge in the fabrication of side-emitting optical waveguides, requiring modulation of the guiding and emitting properties along the fiber length. This is particularly difficult to realize in continuous processing of soft materials. In this work we use extrusion-based multimaterial printing to generate segmented hydrogel optical fibers with tailored side emission. We print fibers with segments of different optical properties by switching between a waveguiding ink and its mixture with scattering particles. The method allows printing segment lengths below 500 microns. The length of the segments can be tailored by controlling the switching time between inks during printing, thereby achieving desired side-emission profiles along the fiber length. The presented technology and material combination allows unprecedented flexibility for designing optical fibers with customizable optical properties using simple processes and medical materials.

8:30 AM EL05.06.02
Thermally Reconfigurable Double Emulsions Droplets with Tunable Morphologies and Spherical Aberrations ZhangWu[1], BrendanDeveney[1], WenyunWang[1], StefanoAime[2], MathiasKolle[3], JoergG. Werner[4] and DavidWeitz[1]; [1]Harvard University, United States; [2]ESPCI – Paris FR, France; [3]Massachusetts Institute of Technology, United States; [4]Boston University, United States

Reconfigurable emulsions engineered with specific structure designs, present a promising avenue for achieving customized properties and advanced optical functionality. Tri-phase reconfigurable emulsion droplets hold significant promise as micro-lenses with the potential to revolutionize optics and photonics applications. Here we introduce a novel type of triple-phase emulsions characterized by thermally reconfigurable shells, consisting of hydrocarbon and fluorocarbon components. These components exhibit temperature-dependent miscibility and are stabilized with unique velcro-mimicking surfactants, resulting in the formation of solid-like water/oil interfaces and water-in-oil-in-water double emulsions at a high temperature above the critical point. We assess the viscoelastic properties of these interfaces by characterizing the droplet deformation as they flow through sinusoidal channels, essentially functioning as a rheometer within polydimethylsiloxane devices. Upon temperature change, the hydrocarbon and fluorocarbon components within the oil shell undergo phase separation, causing the droplets to adopt a new morphology of inner water core and hydrocarbon phase engulfed by fluorocarbon shell. The droplet morphologies can be fine-tuned by adjusting the hydrocarbon-fluorocarbon volume ratio and micelles used in the outer water phase, giving rise to diverse and exotic structures. We also perform two-dimensional ray-tracing simulations of visible light traversing through those morphologies to calculate the longitudinal and transverse spherical aberrations to inform the design and selection of fluid lenses for various applications, paving the way for expanding the scope of optical applications and future transformative technologies.

8:45 AM EL05.06.03
Evolution of The Geometry and Optical Anisotropy as Cellulose is Wet-Spun PabloB. Sánchez[1], JianyiDu[2], JavierPáez[1] and PabloOtero[1]; [1]University of Vigo, Spain; [2]Massachusetts Institute of Technology, United States

It is critical to monitor the structural evolution of complex fluids for an optimal manufacturing performance. Thus, we increase the understanding of the underlying physics which drives the structural modifications and contribute to identify the variables triggering changes in the material properties. Also, in situ measurements facilitate the continuous optimization of the manufacturing process.

Since cellulose undergoes thermal degradation before melting, its processing requires a solvent media with the ability of dissolving cellulose without causing major harm to the polymer chains. The resulting dissolution, often named spinning dope, show slow dynamics with a significant shear thinning behavior which becomes larger as we increase cellulose concentrations. Under extension, spinning dopes experience strain softening behavior followed by a strain hardening trend as the strain grows larger (Sanchez et al, Biomacromolecules, 2022). The spinning dope is extruded through a nozzle as it is pulled by a rotating rod, so it undergoes combined shear and extensional strains. Immediately after, it is coagulated in water which acts as an anti-solvent and triggers the formation of a hydrogen bond network. While cellulose regenerates into a fiber, polymer chains aligned, and the formation of the hydrogen bond network induces a birefringent response in the material which depends on the spun material and the process variables. Traditionally, the performance of the spinning process is evaluated by measuring the target properties of the fiber (e.g. tenacity or elongation) and iterating over the spinning parameters in a heuristic loop which tends to be time consuming and neglects the insights of the different stages involved in the fiber formation. This approach seeks to establish a relation between the source material and the produced fiber and to optimize the process variables. However, information about the chemical and conformational changes undergone by the spinning dope are not accessible.

In this work we propose a new framework to determine the evolution of the fiber geometry and optical anisotropy along the spinning process by measuring diameter and birefringence at the selected points along the process. With this aim, we have built a customized spin-line enabling an easy-control of the critical variables involved in the spinning process: draw ratio and residence time. Then, a self developed optical device comprised of a charge couple device (CCD) and a liquid-crystal (LC) compensator with tunable retardation for rapid and accurate birefringence measurements was designed and built together with the spin line (Sanchez et al, Carbohydrate Polymers, 2023). Results substantiate the microstructural variation as the extensional strain increases. Noticeably, the drawing process occurs almost instantaneously at the nozzle while the fiber coagulation takes several minutes to be completed. Birefringent response grows linearly with the draw ratio and diminishes tenderly with the residence time proving the material relaxation when strain is not imposed. Superposition techniques were successfully applied to capture and describe the effect of draw ratio and coagulation time in terms of shifting factors. Finally, the fiber geometry and optical anisotropy obtained “in situ” are discuss together with the rheological analysis of the spinning dope and the mechanical properties of the obtained fibers.

Thermally Drawn Soft Optical and Electrical Fibers as Wearable Sensors and Microrobots XiaotingJia; Virginia Institute of Technology, United States

Highly stretchable optical and electrical fibers have attracted significant attention in recent years due to their broad applications in wearable sensors, human–machine interfaces, and biomedical implantable devices. However, the scalable fabrication of submillimeter soft optical and electrical fibers with complex structures has been a challenge. Here we present a thermal fiber drawing method for the scalable fabrication of soft optical and electrical fibers with complex geometries and demonstrate the application of these fibers as wearable sensors and microrobots. This method allows for the production of hundreds of meters of continuous soft fibers per draw, and the resultant fibers can have optical, electrical, magnetic, and microfluidic functionalities within a submillimeter diameter. We first demonstrate an opto-electrical fiber sensor which can sustain at least 580% strain and up to 750% strain with a helix structure. The electrical fiber sensor simultaneously exhibits ultrahigh stretchability (400%), high gauge factors (≈1960), and excellent durability during 1000 stretching and bending cycles. We also show that the stretchable step-index optical fibers facilitate the detection of bending and stretching deformation through changes in the light transmission. By combining both electrical and optical detection schemes, multifunctional fibers can be used for quantifying and distinguishing multimodal deformations such as bending and stretching. Next, we demonstrate a soft robotic fiber that integrates navigation, sensing, and therapeutic functions at a submillimeter scale. These fiber robots consist of ferromagnetic, electrical, optical, and microfluidic components, and can navigate through complex and constrained environments, such as artificial vessels and brain phantoms. Moreover, we utilize Langendorff mouse hearts model, glioblastoma microplatforms, and in vivo mouse models to demonstrate the capabilities of sensing electrophysiology signals and performing localized treatment. Additionally, we demonstrate that the fiber robots can serve as endoscopes with embedded waveguides. These fiber robots provide a versatile platform for targeted multimodal detection and treatment at hard-to-reach locations in a minimally invasive and remotely controllable manner. These studies demonstrate the potential of using thermal fiber drawing as a versatile and powerful platform for fabricating soft optical and multifunctional fiber devices for a variety of applications.

Soft Multi-Material Optical Fibers and Metasurfaces: Innovative Fabrication Approaches and Novel Applications FabienSorin; Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland

The ability to realize advanced photonics systems on soft and deformable substrates can find tremendous opportunities in sensing and monitoring, health-care, soft robotics and smart textiles. The materials and processing challenges associated with imparting large, flexible and stretchable surfaces with state-of-the-art photonic performance remain however significant. Today, most existing photonics systems rely on rigid materials, with fabrication approaches that are not well adapted to soft substrates such as elastomers. In this talk, I will present novel fabrication strategies that we have been developing that rely on understanding and controlling viscous flow at various scales, from the fluid dynamics of optical fiber thermal drawing, to the nano-fluidics associated with thin-film dewetting[1-6]. Both approaches, while seemingly very different, exhibit an interesting interplay between viscosity and surface tension, that can be elucidated via in-depth rheological analysis, thermomechanical characterization, and modeling. First, I will present the template dewetting of thin optical glass layers on textured flexible and stretchable substrates as a novel approach to realize advanced optical metasurfaces on stretchable substrates[2,4]. Examples of structures and applications will include index and biosensing, second-harmonic generation, and soft metalenses. I will then make a parallel with thermal drawing, the fabrication process used to make optical fibers. I will show that an in-depth analysis of the rheological, thermomechanical and fluid dynamic aspects of this technique reveal similar features as dewetting, and has expanded the range of materials compatible with this approach. I will insist in particular on the recent ability to draw thermoplastic elastomers[1], metallic glasses[3], as well as of complex and multi-functional optical fiber architectures with either mechanical[5] or magnetic[6] actuation. These advances in materials an processing is paving the way towards advanced state-of-the art soft optics systems with multi-functionalities for applications in surgical diagnosis and intervention, wearable, soft robotics, bio-sensing and smart textiles.

Optofluidic Skins for Sustainable Buildings RaphaelKay[1], J. AlstanJakubiec[2], CharlieKatrycz[2], BenjaminHatton[2] and JoannaAizenberg[1]; [1]Harvard University, United States; [2]University of Toronto, Canada

Indoor climate control is among the most energy-intensive activities conducted by humans; more than 25% of the energy and 50% of the electricity we consume globally is spent heating, cooling, and lighting interior spaces to keep humans comfortable. At the core of this footprint is a fundamental design flaw in architecture: human comfort is predominantly curated internally, using air conditioners, furnaces, and electric lights. As an entirely different approach to keeping humans comfortable, a building ‘skin’ capable of achieving climate control directly could drastically reduce the use of the indoor heating, cooling, and lighting systems that drive energy consumption and greenhouse gas emissions globally. However, to date, the development of such a universally configurable building platform remains an unresolved scientific challenge.

Looking orthogonally to typical solid-state approaches, we have turned to a new class of material to achieve versatile climate control along the surfaces of buildings: liquids. Compared to solids, liquids have two important functional advantages. First, they flow. Liquids can be easily transported, overlapped, and exchanged, while quickly and reversibly filling the extents of their containers. Second, liquids can much more readily be tuned, and are able to hold a range of particles and molecules relevant to the manipulation of solar radiation. Taken together, the versatility of liquids allows us to explore a new set of optofluidic strategies for more comprehensively controlling environmental sunlight.

We develop simple fluidic devices capable of general solar configurability, and we treat rationally selected liquids as injectable solar filters, introducing them in different combinations and sequences to spatiotemporally regulate temperature and daylight distributions indoors. Altogether, using optical experiments and simulations, we demonstrate how a simple fluidic platform can synergistically control the amount, color, and position of transmitted sunlight over time – a universal solar toolkit not realized in traditional building technologies.

Importantly, because this fluid-based toolkit can curate much of the internal climate at the external skin, the need for indoor operational energy usage can be massively reduced. Compared to available alternatives, models demonstrate that our liquid wrappings can decrease heating, cooling, and lighting energy consumption in buildings by over 40%, suggesting the emergence of a liquid design paradigm toward net-zero buildings.

10:45 AM EL05.06.07
From Aberration Correction Elements to Liquid Space Telecospes-Theoretical Modeling of a Pinned Liquid Film in a Finite Domain IsraelGabay[1], VesnaBacheva[2], AntonioRamos[3], MoranBercovici[1] and AmirGat[1]; [1]Technion–Israel Institute of Technology, Israel; [2]Cornell University, United States; [3]University of Seville, Spain

Expanding beyond traditional applications in lubrication and coatings, thin liquid films now play pivotal roles in soft actuators and adaptive optical elements. These novel uses usually involve a finite volume of liquid within an impermeable domain, straying from the common models that mostly considered infinite or periodic boundary conditions. For example, researchers recently presented an adaptive optofluidic element that is based on a deformable membrane driven by an underlying layer of liquid enclosed with an impermeable chamber.The dynamics of these devices, due to the constraints of global mass conservation and a pinning boundary condition, significantly differ from those of infinite or periodic films. Mathematically, this constitutes non-self-adjoint problems. A theoretical framework is thus required in order to predict the performance of such devices.

In this work, we present a combined theoretical and experimental study to tackle this problem. We provide a time-dependent analytical solution for the linearized non-self-adjoint system that emerges from these boundary conditions. Our solution in the small deformations regime (i.e., the linearized equation) is particularly suitable in the context of diffractive optical components, which feature surface topography variations on the scale of a visible light wavelength. Unlike self-adjoint problems, this problem demands special attention to properly reconstruct the solution based on the system's eigenfunctions. Although our derivations primarily focus on a free interface, they apply directly to cases with a membrane under tension dominant regime and can readily be extended to include elastic bending of the membrane.

We compare our solutions with common models for self-adjoint thin-film problems, such as a pinned film in a permeable domain or periodic boundary conditions. We show that while the initial dynamics are almost identical, the boundary conditions eventually influence both the film topography of the entire domain and its response time. To validate our model, we designed an experimental setup that subjects a thin liquid film to a prescribed normal force distribution using dielectrophoresis, and measures the film deformation in real-time using high-frame-rate digital holography. The experimental results are in good agreement with our model, demonstrating that confined films behave differently from what existing self-adjoint models could predict.

Thin films in a finite domain have potential use as optical elements also in the other extreme of length scales; we are currently collaborating with NASA to explore their use for creating space telescopes on the scales of tens of meters. Aspects such as liquid settling time as stability under accelerations are particularly important for these applications and our model provides non-intuitive insights which guides the design. In my talk, I will also present our analysis for such applications and the most up-to-date experimental results on scaled-up systems that we are constructing.

11:00 AM EL05.06.08
Soft Waveguide Segments for Deformation Sensing TramNguyen[1], MichaelHan[2] and CindyK. Harnett[2]; [1]Hollins University, United States; [2]University of Louisville, United States

This presentation looks at soft optical waveguides made from oils and gels for their potential in measuring curvature along paths that bend and twist. Mapping curvature along a path helps capture the shape of soft deformable objects. The focus of this presentation is on creating a defective segment in an otherwise transmissive optical waveguide, a segment with a light transmission level that is highly sensitive to deformation. Optical methods like this one are increasingly popular in soft robotics because their all-polymer construction matches the mechanical characteristics of the surface, and optical signals are less susceptible than electrical signals to temperature drift and electromagnetic interference. Aside from a few recent examples of distributed optical sensors, most examples are point sensors with one highly sensitive section, or integrating sensors that report deformation at an unknown location along the waveguide.

In the first implementation to be discussed, we change a point sensor into a deformation mapper by moving a sensitive segment along the waveguide. Here, the deformation-sensitive section is an air bubble in an oil-filled tube routed along a surface. Loss of total internal reflection at the air bubble means that when the bubble is positioned at a sharp curve, the overall transmission of the channel drops more than when the bubble is in a straight section. The signal is dominated by events at the sensitive segment, while the rest of the waveguide serves as a high transmission signal delivery channel. By circulating the oil through the waveguide with a pump, the sensitive segment is scanned over the waveguide to map out its local curvature, whether that curvature is caused by the static waveguide path layout or by dynamic bending motions of the underlying surface. We demonstrate that the scanned bubble is able to detect and localize the bending location of a soft robotic limb to within approximately 4 cm.

However, the scanned bubble method has a speed limit determined by the Weber number. Scanning faster than a few cm/s causes the air bubble to break up leading to an unreliable signal. Soft segments of silicone or hydrogel are investigated as an alternative low-index segment that can be scanned around the waveguide faster without breaking up. A related topic included in this presentation is verifying the location of scanned segments with a closed loop method. Measuring volumetric oil displacement gives segment location when things are flowing smoothly, but it is possible for solid segments to get stuck. We therefore investigate light reflection as a method to locate segment edges in the liquid core waveguide.

Twist is another aspect of path shape that isn't captured by a rotationally symmetric, cylindrical soft waveguide segment. We discuss soft waveguide segments with non-circular cross sections for their ability to detect left- and right-handed twisting along the waveguide path. In this example, the application is monitoring the state of a reconfigurable soft robotic actuator.

11:15 AM EL05.06.09
Highly Integrated Multi-Material Optical Fibers for Soft Robotics StellaLaperrousaz, AndreasLeber and FabienSorin; École Polytechnique Fédérale de Lausanne, Switzerland

Soft robotics is rapidly growing as a prominent research field, in particular when considering the development of safe biomedical devices where compliance is key to safely interact with delicate tissues and interfaces. While this is an attractive prospect, innovative scalable fabrication strategies are required to enable the incorporation of advanced functionalities into soft and compliant devices. In particular, the fabrication of soft systems with small diameters and high aspect ratios, that integrate optical but also electrical, microfluidics or actuation attributes, remains challenging. To alleviate this challenge, we propose to rely on the unique attributes of the thermal drawing technique. Despite being mostly known for the scalable production of optical fibers, thermal drawing can actually be adapted to yield 10s of meters long soft elastomeric fibers with intricate architectures and extremely high aspect ratios.[1] In that regard, thermal drawing is a promising processing platform to realize highly integrated soft optical fibers imparted with multiple actuation and sensing modalities for soft robotics.
In this talk, we will present the thermal drawing of soft catheter-like fibers that can integrate optical waveguides but also microfluidic channels or electrical wires. [2] We will first show how a careful analysis of the rheological attributes and mechanical compliance enables to select the best suited materials to realize a hybrid fiber structure with rigid conventional optical fibers embedded in an elastomeric cladding. Then, we will introduce a first example of application of such multifunctional architectures where autonomous fiber movement and obstacle avoidance are achieved through a closed-loop control based on the continuous measurement of reflected light intensity. In addition, the collected proximity signals can be used to map the surrounding environment in 3D, endowing the fiber with imaging capability. Moreover, the potential of thermal drawing to produce highly integrated fibers will be demonstrated through a complex design incorporating optical guides, but also metallic wires and microfluidic channels. This specific soft optical fiber is thus able to perceive and adapt to its environment, but also to stimulate, record or deliver fluids to spatially distributed targets.
Finally, we will explore the integration of sensing elements into soft optical fibers. More specifically, thanks to an in-depth rheological study, we identified soft electrically conductive composites compatible with the thermal drawing process.[3] These piezoresistive composites can provide information about the fiber bending state and detect bending angles as small as 5°. By combining conventional rigid optical waveguides and soft piezoresistive composites into thermally drawn fibers, soft robotic fibers can accomplish both exteroception and proprioception.
The advanced soft optical fibers we will present could be envisioned as the next generation of steerable endoscopes and catheters, endowed with multiple advanced functionalities, and thus promote the development of safe minimally-invasive procedures.

Characterization of Clear Urethane Plasticizer for Use in Optical Waveguide Strain Sensors in Soft Robotics John GarrettWilliamson, CarolineSchell, ScottHolmstrom, PeterLoPresti, MichaelKeller and JoshuaSchultz; University of Tulsa, United States

One of the key challenges in soft robotics is proprioceptive sensing due to the robots' deformability and infinite degrees of freedom. Most often, soft robots rely on motion capture systems, which require external hardware like cameras. One of the proposed benefits of soft robots is their ability to navigate unstructured environments, however, the nature of these environments often leads to occlusions that interfere with motion capture sensing. Recently, researchers have proposed methods to integrate sensors into the robot body which have the potential to perform better in these environments; examples include galinstan and other liquid-metal resistive strain sensors. However, these sensors are prone to oxidizing, leading to hysteresis in sensor measurements over time.
We propose using optical strain sensors to sense motions within the robot body. These sensors are made by cladding a fiber made of clear, stretchable, high refractive index material with a low refractive index material. Light travels differently along the length of the fiber when it is deformed by stretching, bending, or locally applying lateral pressure. Prior work in this area has established methods to differentiate deformation modes based on the intensity and time of flight through these fibers.
Optical fiber strain sensors have little hysteresis or degradation over time, they are indifferent to electromagnetic interference and have large bandwidth. However, prior efforts to implement these sensors have been hampered by a mechanical mismatch between the core and cladding materials. One of the more stretchable versions of this type of sensor is made from aurethane core material with silicone cladding. Most optically clear urethanes, however, are somewhat stiff. Clear Flex 30™ made by *Smooth-On* is a clear urethane with lower stiffness than most optically clear urethanes. It has been used in soft robotics in our work and the work of others. It is commercially available in shore hardnesses of 30, 50, or 90 A. Usually, the silicone is picked to match this material's mechanical properties as closely as possible. This avoids issues like fiber slip and non-uniform robot inflation due to the fibers acting as a local reinforcement to the robot wall. Matching silicone cladding stiffness to the urethane core fiber limits the material design options. Higher stiffness robots allow for greater lifting capacity, while lower stiffness robots are more deformable. It is also sometimes desirable to match the stiffness of something like human skin or an object to be manipulated.
To address these issues, new formulations of optically clear urethanes were created to match the mechanical properties of a range of cladding or substrate materials. Optical and mechanical analyses of urethanes modified with a commercial plasticizer (*Smooth-On* So-Flex II™) were performed to measure the basic properties of the new formulations and to determine suitability for sensing applications. Digital image correlation tensile testing shows that this additive can modify the 100% modulus from 380 kPa for the unmodified material to 200 kPa at a concentration of 20% by weight in Clear Flex 30™. At that concentration, spectrophotometer testing shows negligible optical loss compared to the unmodified material meaning the additive does not negatively affect usable fiber length. A refractive index test at 632.8 nm found that the refractive index of the modified material differed from the unmodified material by 0.01, dropping from 1.48 to 1.47. Further testing will establish a larger spectrum of refractive indices. A tensile specimen made of Dragon Skin 10™ silicone cladding and a Clear Flex 30™ core with So-Flex II™ showed adequate total internal reflection for a 12 cm long sensor; having approximately 0.14 dB additional loss under 50% strain.

1:45 PM EL05.07.02
Fatigue-Resistant Hydrogel Optical Fiber Enables Peripheral Nerve Optogenetics During Locomotion XinyueLiu[1,2], SiyuanRao[3,2], WeixuanChen[3], KaylaFelix[3], JiahuaNi[2], AtharvaSahasrabudhe[2], ShaotingLin[1,2], QianbinWang[3], YuanyuanLiu[4], ZhigangHe[5], PolinaAnikeeva[2] and XuanheZhao[2]; [1]Michigan State University, United States; [2]Massachusetts Institute of Technology, United States; [3]University of Massachusetts Amherst, United States; [4]National Institutes of Health, United States; [5]Harvard University, United States

We develop soft and stretchable fatigue-resistant hydrogel optical fibers that enable optogenetic modulation of peripheral nerves in naturally behaving animals during persistent locomotion. The formation of polymeric nanocrystalline domains within the hydrogels yields fibers with low optical losses of 1.09 dB cm^{-1}, Young's modulus of 1.6 MPa, stretchability of 200%, and fatigue strength of 1.4 MPa against 30,000 stretch cycles. The hydrogel optical fibers permitted light delivery to the sciatic nerve, optogenetically activating hindlimb muscles in Thy1::ChR2 mice during 6-week voluntary wheel running assays while experiencing repeated deformation. The fibers additionally enabled optical inhibition of pain hypersensitivity in an inflammatory model in TRPV1::NpHR mice over an eight-week period. Our hydrogel optical fibers offer a motion-adaptable and robust solution to peripheral nerve optogenetics, facilitating the investigation of somatosensation with implications in motor recovery and pain management.

2:00 PM *EL05.07.03
Toward Noninvasive Simultaneous Arterial and Venous Oxygenation Monitoring with an Optical E-Tattoo NanshuLu; The University of Texas at Austin, United States

While noninvasive arterial blood oxygenation (SaO2) is easily estimated using peripheral pulse oximeters, noninvasive venous blood oxygenation (SvO2) monitoring is still a critical unmet

medical need. Critical conditions that lead to inefficient extraction of oxygen from the blood, such as sepsis or shock, can only be detected by analyzing the oxygen content of the venous blood. A fundamental assumption of photoplethysmography (PPG) and pulse oximetry is that only the arterial blood induces a pulsatile or alternating current (AC) signal. As a result, by analyzing only the pulsatile absorptivity changes of the tissue, arterial blood oxygenation alone will be isolated. However, this assumption may not hold outside of peripheral vasculature. Recent work has suggested that a venous pulse can be measured with a reflectance PPG probe placed over the jugular vein. A significant obstacle for simultaneous SaO2 and SvO2 extraction is the anatomic proximity of the artery and vein, thus leading to crosstalk. We characterize this crosstalk with simulation, in vitro, and in vivo experiments. We have devised a soft wearable optical e-tattoo sensor that simultaneously measures the arterial and venous pulses and used it to characterize how the PPG waveform morphology changes when the PPG sensor is shifted laterally over the carotid artery and jugular vein. We hypothesize that the venous and arterial pulses can be used to simultaneously extract SaO2 and SvO2, thus enabling noninvasive oxygen consumption estimation. This work offers a potential solution for minimizing the crosstalk through spatial filtering.

3:30 PM *EL05.07.04

Flexible Integrated Photonics for On-Chip Sensing Based on Cascaded FSR-Free Cavities LanLi[1], YeLuo[1], ChunleiSun[1], MaoliangWei[2], HuiMa[2], ZequnChen[1], JialingJian[1], JunyingLi[2], KathleenRichardson[3] and HongtaoLin[2]; [1]Westlake University, China; [2]Zhejiang University, China; [3]University of Central Florida, United States

High spatial resolution mechanical sensing within compact 3D space is important in healthcare, industrial automation, aerospace engineering, and intelligent robotics. Flexible optical sensors have received increasing attention due to their high sensitivity and measurement accuracy, electromagnetic interference immunity, and ability to conform to three-dimensional shapes. Compared to fiber and free-space flexible mechanical sensors, waveguide-integrated sensors exhibit superior performance due to their compact footprint, excellent sensitivity, high spatial resolution, scalability, and integration capability with electronics and other functional components. Here, we present a new flexible photonic integrated sensor concept that utilizes cascaded one-dimensional (1D) photonic crystal (PhC) micro-cavities. Due to the free-spectral-range (FSR) merit of the cascaded cavities, which eliminates restrictions on wavelength spacing, wavelength-division multiplexing technology has been utilized to fully utilize a wide band of optics. Additionally, mechanical sensing signals, like strain and position information, can be embedded into wavelength-dependent resonant dips, facilitating high spatial resolution quasi-distributed-strain sensing and two-dimensional shape sensing. The integrated photonic sensors exhibit ease of scalability, high sensitivity, and compact footprint, holding novel opportunities for on-chip and conformal sensing with high sensitivity and spatial resolution.

4:00 PM *EL05.07.05

Soft, Flexible and Biocompatible Technologies for Optical Sensing and Stimulation in Biomedical Applications JeroenMissinne[1], XavierDe Becker[1], FedericoPazzaglia[1], WouterVan Lysebettens[1], AnastasiiaBabych[1,2], JeroenSpanoghe[2], MarijkeVergaelen[2], RobrechtRaedt[2], PieterBauwens[1], SandraVan Vlierberghe[2], JanVanfleteren[1] and GeertVan Steenberge[1]; [1]Imec and Ghent University, Belgium; [2]Ghent University, Belgium

Light-based therapies and optical sensing are rapidly gaining interest in the biomedical field. Currently, new therapeutic or diagnostic concepts are mainly relying on relatively large optical components made of standard rigid materials. For example in preclinical research, silica optical fibers are used for light delivery to and from brain tissue for both biosensing (fiber photometry, optoacoustic imaging,…) and therapy (optogenetics, optopharmacology,…). However, to bring these techniques to a clinical setting, the required technologies need to be made more biocompatible. Currently, chronic implantation of rigid large probes evokes gliotic scar formation, demyelination and neuronal loss near the probe. In addition, these biological responses have a negative influence on the efficacy and durability of triggered interventions. Therefore, small and soft probes are needed to limit gliotic scarring and cellular damage upon probe implantation. We address this need by developing miniaturized, soft wearable and implantable technology.
We give an overview of our technologies for realizing soft waveguides allowing guiding light to stimulate deeper regions (e.g. in the brain), and technologies for integrating miniature sources and detectors on flexible foils allowing non-invasive stimulation or on-body sensing.
To match mechanical properties of tissue, we investigate several (optically transparent) waveguide materials, ranging from ‘standard’ optical polymers (e.g. Ormocers®, epoxies), poly-dimethylsiloxane (PDMS), to ultra-soft hydrogels. Depending on the material of choice, and waveguide design (single mode or multimode), standard lithography, laser direct-write lithography, soft-lithography or moulding techniques are being used. We will report on planar multimode (stretchable) PDMS waveguides with low propagation loss for operation from near-UV (405nm), over visible, up to near-infrared wavelengths and planar single mode waveguides made of hybrid UV-curable polymers (OrmoClear®). Furthermore, the optically clear hydrogel materials that are under development (tuning mechanical, optical, biological properties) will allow even further improvements in softness of implantable waveguides.
While softness and flexibility are desired for long term implantation, a higher rigidity is required to successfully implant the probes. We are tackling this challenge from different angles, i.e. from the material science side (e.g smart coatings) and the technological side (e.g implantation aids).
For future wearable operation, implantable waveguides will need to be equipped with recording electrodes, driving electronics and light sources. Our focus is on combining such light sources in the least obtrusive way together with the flexible waveguides relying mainly on thin bare die (e.g. LEDs and VCSELs) integration on flexible foils. Similar in-house technologies can be applied to integrate the electrodes and driving circuitry. Alternatively, without waveguides, such patches can serve as standalone phototherapeutic minimally invasive flexible devices (e.g. for cortical stimulation or for skin monitoring).
Although the presented soft technologies have a wide applicability, our current focus is on optogenetic or optopharmacologic therapies of the brain e.g. in the context of epilepsy.

4:30 PM EL05.07.06

Flexible Carbon Nanotube-Based Optical Sensor Sheet Integrated with Ultra-Thin Organic Circuits ReiKawabata[1,1], KouLi[2], TeppeiAraki[1,1], MihokoAkiyama[1,1], NorikaTakahashi[2], DaikiSakai[2], YutoMatsuzaki[2], MinamiYamamoto[2], LeoTakai[2], YutoAoshima[2], NozomiMatsuoka[1,1], NaokoKurihira[1], TakafumiUemura[1], YukioKawano[2,3] and TsuyoshiSekitani[1,1]; [1]Osaka University, Japan; [2]Chuo University, Japan; [3]National Institute of Informatics, Japan

Flexible optical sensors have attracted considerable attention in the development of wearable and shape-adaptable devices for health monitoring, non-invasive inspection, and biochemical analysis [1–5]. This study develops an ultra-flexible optical sensor using carbon nanotube (CNT) films and organic circuits to detect wavelengths from near-infrared to THz. Owing to their formation on ultra-thin polymer substrates, the CNT films demonstrate a 21-fold increase in sensitivity when compared to those fabricated on rigid thick substrates; further, they exhibit durability against bending and crumpling. The CNT films are connected to organic circuits comprising organic thin-film transistors (OTFTs), with which CNT signals are selected and amplified. The functional CNT films are integrated into a flexible optical sensor as an active matrix, facilitating internal imaging from any surface using a broadband light, including THz.
Flexible photodetectors have been intensively developed in recent years; for example, thin-film inorganic semiconductors, metal halide perovskites, and organic semiconductors have been employed as photodetector materials, demonstrating excellent sensitivity and flexibility [2–4]. While these flexible photodetectors are limited to detecting ultra-violet to near-infrared light, the detection of mid-infrared to THz for non-invasive inspection and chemical analysis is crucial. To address this issue, CNTs have garnered significant attention as flexible photodetectors; they can detect a broad range of electromagnetic waves (from visible light to millimeter waves) using the photothermoelectric effect at room temperature [5,6]. However, CNT optical sensors have been developed predominantly as single-element or small-scale sensors with low integration density. These types of sensors require signal processing via external circuits and spatial scanning for highly sensitive imaging, thereby limiting their portability, scalability, and scanning speed for imaging devices.
In this study, CNT films are fabricated on ultrathin Parylene substrates and exhibit broadband optical response from near-infrared to THz. The CNT films exhibit a 21-fold increase in sensitivity when compared with those on thick rigid substrates owing to the suppression of heat diffusion by an ultra-thin film. Furthermore, the photoresponse of CNT films is stable after bending and crumpling. The CNT films are connected to an organic amplifier and a matrix circuit that is constructed using OTFTs with the channel layer of dinaphtho [2,3-b:2′,3′-f]thieno [3,2-b]thiophene. The organic amplifier circuit exhibits a 10-fold gain and successfully amplifies the THz detection signals. Finally, the active matrix is designed for a flexible broadband imager for non-invasive internal inspection from the surface of an object.

Stretchable Light-Emitting Polymers and OLEDs Based on Thermally Activated Delayed Fluorescence (TADF) SihongWang; The University of Chicago, United States

The vast amount of biological mysteries and biomedical challenges faced by humans provide a prominent drive for seamlessly merging electronics with biological living systems (e.g. human bodies) to achieve long-term stable functions. Towards this trend, one of the key requirements for electronics is to possess biomimetic form factors in various aspects for achieving long-term biocompatibility. To enable such paradigm-shifting requirements, polymer-based electronics are uniquely promising for combining advanced electronic functionalities with biomimetic properties. Among all the functional materials, stretchable light-emitting materials are the key components for realizing skin-like displays and optical bio-stimulation. In this talk, I will mainly introduce our research in imparting stretchability onto “third-generation” electroluminescent polymers that can harness all the excitons through thermally activated delayed fluorescence (TADF), thereby with a theoretical near-unity quantum yield and high OLED efficiency. Our developments of fully stretchable OLED devices show the promise of achieving all the desired EL and mechanical characteristics, including high efficiency, brightness, switching speed, stretchability, and low driving voltage.

8:45 AM EL05.08.03
Structural Inclination for Next-Generation Mechano-Responsive Smart Windows HaominChen[1], GunhoChang[2], TaeheeLee[2], KwonhwanKo[2], SeokhwanMin[2], JonghwaShin[2], Jung-WukHong[2] and SeokwooJeon[1]; [1]Korea University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

By implementing smart window technologies to regulate temperature and lighting conditions, an estimated 50% reduction in energy consumption for building services can be achieved. Promising candidates for smart windows are mechano-responsive membranes that exhibit tunable transmission through strain-controlled light scattering.

However, the state-of-the-art light scatterers have encountered a bottleneck. Achieving appreciable contrast still necessitates large strains which require additional space, occupying more than 15% of the original window area. Furthermore, recent improvements in contrast and strain reduction have come at the cost of complexity in composition and fabrication. Therefore, a new design principle is urgently needed to simultaneously achieve high visibility, strong regulation of irradiation, low operational lateral strains, and simplicity in composition and fabrication at a low cost.

One potential solution lies in manipulating pore sizes within a 3D structure through out-of-plane compression. The reversible opening and closing of pores provide the scatterer with opacity when released and transparency when compressed, accommodating changes in the in-plane area. This working mechanism inherently addresses the issue of large areal changes. The performance of a compression-driven scatterer relies on the optical density in the released state and its sensitivity to compressive strains. To tackle this, submicron 3D structures with inclined pores are proposed for the new scatterer. The array of submicron pores induces strong multiple scattering of visible light, resulting in a high optical density in the released state and thus a high achievable transmittance contrast. A novel 3D patterning technique based on a slanted exposure angle enables the realization of tailorable inclination angles in submicron structures. Experimental and multi-physics simulation results demonstrate that the inclined structures redistribute local compressive strains, facilitating pore closure and significantly increasing transmittance for a given compression. Scatterers based on the inclined 3D structures achieve high transmittance of 96% and an unprecedented transmittance contrast of 95%, all while experiencing minimal areal strains during operation. Compared to conventional driving modes, the out-of-plane compression mode brings the scatterer closer to practical use, enabling localized modulation of transmittance by selectively compressing specific positions of the scatterer that need to be transparent. The design principle and fabrication technique presented in this work for the compressive strain-responsive scatterer are expected to drive advancements in smart windows, transparent displays, and flexible pressure sensors.

Highly Efficient UV-Absorbing and Anti-Reflective PDMS Film for Improving Stability of Perovskite and Organic Photovoltaics. Han binLee and Hyo JungKim; Pusan National University, Korea (the Republic of)

Perovskite solar cells and polymer-based organic solar cells(OSCs) have emerged as promising next-generation solar cell technologies due to their high efficiency, utilization of low-cost materials, and large-area fabrication capabilities. Despite these advantages, the commercialization of these solar cells faces significant challenges, primarily concerning module reliability and lifespan. Notably, both perovskite solar cells and OSCs exhibit high sensitivity to the surrounding environment, including heat, moisture, and UV rays. Exposure to UV light has been identified as a cause of decomposition in perovskite solar cells, leading to the generation of ionized lead and interfacial separation. Additionally, UV light exposure has been associated with a burn-in phenomenon in organic solar cells. The importance of UV light blocking to prevent degradation has been reported through many research results.
Hence, it is imperative to ensure stability against UV rays in order to successfully commercialize next-generation solar cells. Recently, the integration of UV-blocking materials into coatings and films has emerged as a promising strategy to address this issue of stability by effectively blocking UV light. Despite the significant improvement in a device, it leads to unavoidable photoconversion energy loss by blocking the UV region light. Consequently, the concept of blocking UV for stability requires additional techniques for keeping high photoconversion efficiency.
To overcome the inherent problem in this concept, we suggest an easily detachable multifunctional film for UV blocking without photoconversion energy loss. The multifunctional film was fabricated by incorporating a UV-blocking material(2,2'-dihydroxy-4-methoxybenzophenone) with polydimethylsiloxane(PDMS). By incorporating a UV absorber into the PDMS film, we could successfully block UV region light(< 380nm). As mentioned, the UV blocking induced the decrease of PCE of perovskite solar cells by 3.2% compared with reference cells. The decrease in PCE was compensated by the light-trapping effect from the surface texturing of the PDMS films. For the surface texturing, we used the soft lithography technique using a structured Si mold through Cu-assisted chemical etching. The light trapping effect was estimated by FDTD simulation and confirmed by the optical properties of textured films. The reflectance of structured PDMS decreased by ~ 4% compared with a flat PDMS surface. To increase the transmittance of the visible light region, we designed double-layered PDMS films, i.e., pure PDMS layer/UV block material embedded PDMS layer films. Our final multifunctional film was attached to the glass side of perovskite solar cells and showed 0.8% increased PCE compared with the reference cell. The UV-blocking effect was confirmed by 20 days test (10 days outdoor + 10 days UV irradiation). The solar cells with multifunctional PDMS films retained over 87% of their initial efficiency after 20 days test, in contrast to the rapid UV degradation observed in solar cells without the UV-blocking PDMS film.

Dynamic, Remote-Controllable Electroactive Hydrogel Waveguide Architectures Oscar AlejandroHerrera Cortes; McMaster University, Canada

Remote-controllable waveguide architectures inspired by living organisms with unique flexible, camouflage and light guiding properties, were fabricated using self-trapped beams of incoherent light. Made of electroactive hydrogels, light-guiding structures are generated through a nonlinear, self-inscription process that utilizes visible beams from light-emitting diodes (LEDs). Due to irreversible refractive index changes experienced by photoinduced chemical reactions, these self-trapped beams permanently inscribe cylindrical waveguides along their paths. Taking advantage of this phenomena, we can fabricate macro-scale remote controllable waveguide structures in the form of planar rectangular prisms and arrays of cylindric waveguides. We can also fabricate micro-scale structures for remote actuation, in the form of rectangular prisms embedded with thousands waveguide units. By applying and varying external electric fields, we can dynamically control the bending, angular orientation, and rotation (up to 360°) of these pliant light-guiding structures. This allows precise, remote control of the waveguided light output.

3D-Structured Soft Microwave Plasmonic Resonators via Direct Ink Writing of Stretchable Conductors Hoon YeubJeong and SeungjunChung; Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Beyond previous physical contact-based sensing technologies, emerging wireless sensing has gained significant interest in wearable electronics applications, particularly in monitoring human motion and acquiring data. However, existing wireless sensor systems face reliability and stability concerns when monitoring dynamic human motion due to the prevalent use of rigid integrated circuits (ICs) and wireless modules, along with complex wiring of electronic components. In this regard, developments of skin-attachable wireless sensor systems integrated with soft components are highly desirable. Recently, 2-dimensional (2D) flexible plasmonic resonators have been proposed to skin-attachable wireless sensors, but the coupling of their resonance to the lossy medium prevent from forming the robust resonances. Besides, additional initial calibration process is required due to the different dielectric properties of each individual and attached part. To address these challenges, we propose a novel approach: fully soft 3-dimensional (3D) plasmonic resonator structures enabling decoupled resonance from lossy substrates and the human body, thereby demonstrating reliable wireless sensing onto the human body.
In contrast to conventional 2D plasmonic resonators, our 3D plasmonic resonator structures allow resonance formation in a lossless free space. This achievement can be advanced by introducing an additional ground plane at the bottom of the resonators, enabling a perfect decoupling between the resonance and the lossy medium. Furthermore, we employ omnidirectional 3D printing to realize these 3D soft resonators using intrinsically stretchable conductor composites. Their composition and rheological properties were optimized to ensure that the conductivity and mechanical robustness of the stretchable conductor should be high enough to formulate high-quality factor resonance under mechanical deformation. Moreover, for the structural integrity of 3D free-form printed features, we introduced the emulsion phase into the conductive composite ink that achieves high storage modulus and yield stress, so the printed

resonators can maintain their own shapes after printing. In addition, high conductivity (10,000 S/cm) and low resistance variation during stretching (1.5 at 100 % strain) were successfully achieved by optimizing the ink formulation. This innovative material and fabrication method enables us to realize miniaturized free-form 3D resonator structures, which exhibit superior functionality and a high degree of design freedom compared to conventional 2D resonator structures.
We demonstrate highly robust wireless wearable strain sensors based on fully soft 3D microwave plasmonic resonators. The decoupling of resonance ensures that the resonant frequency shifting of these sensors is solely perturbed by geometric parameters, thereby enabling stable wireless strain sensing. A key merit of this approach is eliminating the initial calibration process, and compensating different dielectric properties among individuals or attachment parts. Our works will pave a promising pathway to develop lossless microwave metamaterials and resonators in wearable electronics, and we will present the state-of-the-art results of 3D-printed free-form plasmonic resonators opening up new avenues for highly efficient wireless sensing of human motion.

10:15 AM EL05.08.07
Unlocking Transparency in 3D Printing of Polysiloxanes MichaelFord, ColinLoeb, LemuelX. Pérez Pérez, StuartGammon, HawiGemeda, A. MelodyGolobic, AugustHonnell, JustinErspamer, EricB. Duoss, TomWilson and JeremyM. Lenhardt; Lawrence Livermore National Laboratory, United States

Silica-polysiloxane inks have been developed for 3D printing, but their opaqueness has limited their potential in some applications. We addressed this limitation by precisely adjusting the base polysiloxane composition to achieve transparency. When solidified, these inks transmit about 90% of 700 nm light through 1 cm, showcasing useful transparency. We explored the dependence of the ink's rheological properties on silica particle distribution, showing that these properties are influenced by silica functionality, weight content, and processing. This understanding enables precise control over printing and object quality. Furthermore, our research also unveiled a thermochromic effect, where ink opacity changes with refractive index mismatch and temperature. This effect was explored in further detail and will be highlighted in this talk. To demonstrate practicality, we successfully printed encapsulants for LEDs, scintillators, and microfluidic mixing devices. These transparent inks find applications in advanced lighting and cutting-edge medical devices.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS- 850030

Polymer-Based 4D-Printed Fresnel Lenses for Thermal Sensing Applications MuradAli and HaiderButt; Khalifa University of Science and Technology, United Arab Emirates

The demand for additive manufacturing is on the rise in the optical industry. Notably, 3D printing overcomes the majority of the limitations inherent in traditional processes. 3D printing allows for the rapid and cost-effective design and fabrication of complex geometries. Here, we demonstrate the fabrication of polymer-based functionalized optical devices (4D Fresnel lenses) for the first time using a computer-aided design for 3D printing based on the digital light processing (DLP) technique. The fourth dimension is introduced by adding the thermochromic pigment powders (blue, green, and red) to a transparent resin that utilizes spectral color response to variations in temperature as an external stimulus. The thermally active powder added two functionalities to Fresnel lenses: selective color filtering at room temperature and thermal sensing (25°C to 32°C). Using homemade experimental setups, the printed lenses were assessed for light focusing performance and thermal sensing. Contact angle measurements revealed the hydrophilic nature of the lens material, while XRD confirmed no other phase formation during photopolymerization. The surface topography of lenses was investigated using scanning electron microscopy (SEM) and atomic force microscopy (AFM) characterizations that confirmed the surface integrity of our printing process (often used for lenses, (λ/4 to λ/10). As a potential alternative to traditional optical devices, such as glass Fresnel lenses, 3D printing offers custom-built polymer-based optical devices with optimized materials for optical sensing applications.

10:45 AM *EL05.08.09
A Novel Electrochromic Platform that Integrates Dielectric Elastomers and Photonic Glasses MingXiao; Sichuan University, China

Electrochromic materials can change colors upon a voltage, which are based on either pigmentary or structural colors. The color changes of pigments originate from changes of absorption bandgap due to electrochromic redox reactions, while the structural color changes are caused by voltage-driven rearrangements of colloidal particles. So far, both types of electrochromic materials involve currents running through the materials and side electrochromic reactions, which limits cycling and performance lifetime. To address this issue, we develop all solid electrochromic materials by integrating dielectric elastomers and structural colors. We assemble colloidal particles in elastomers in ordered (photonic crystals) and disordered (photonic glasses) patterns to produce structural colors. With the voltages on, opposite charges accumulate on the two surfaces of elastomer composites, creating a Maxwell force to compress the elastomer without any currents running through the materials. The elastomers expand in area and shrink in thickness, leading to variations in spacing between colloidal particles and thus color changes. We achieve dramatic, rapid, and reversible color changes up to 10 Hz. The color of the photonic glass elastomer is not angle-dependent as typical photonic crystals. This avoids inhomogeneous colors when new curvatures are created with out-of-plane deformations, like wrinkling or buckling. To reduce the voltage and expand the color change range, we fabricate elastomer composites with lower modulus (~150 kPa) and higher stretchability (~ 250%) using lower volume fraction of silica nanoparticle and introducing a secondary aliphatic acrylate precursor into the matrix. We believe this novel electrochromic material will find wide applications in wide-angle color display, color-changing robots, military camouflage, and smart windows.

11:15 AM EL05.08.10
Unravelling the Governing Factors for Cholesteric Self-Assembly of Polysaccharides CecileChazot, SimonaG. Fine and EleanorC. Grosvenor; Northwestern University, United States

Thanks to their earth abundance and their ability to self-assemble in photonic crystals that can selectively reflect circularly polarized light, cholesteric polysaccharides have been investigated as the basis for colorimetric sensors responding to humidity, pressure, temperature, and other stimuli. However, cholesteric self-assembly requires a gel-like state, achieved by suspending the biopolymer in a strongly hydrogen-bonding solvent. Efforts to stabilize the cholesteric order in the solid-state have relied on controlled solvent evaporation or polymerization. However, the effects of polysaccharide chemistry and solvent-polymer interaction on the formation and solid-state retention of the cholesteric phase remain understudied. In this talk, we explain how different thermodynamic and chemical factors influence the self-assembly and optical properties of cholesteric mesophases constructed from suspensions of polysaccharides, such as cellulose ethers. Through a systematic data analysis framework we developed, we elucidate structure-property relationships linking solubility, viscosity, and hydrogen bonding to the cholesteric pitch and resulting optical properties. Then, we discuss how chemical factors such as molecular weight and repeat-unit chemistry affect kinetics of liquid-crystalline self-assembly and stabilization of the cholesteric order in a solid form. These relationships are expected to assist in the large-scale deployment of polysaccharide-based sensors with direct colorimetric assessment of temperature, mechanical strain, or humidity.

Soft Matter Infrared Photodetectors JarrettVella[1], AnthonyBenasco[2] and StefanNikodemski[3]; [1]Air Force Research Laboratory, United States; [2]NRC RAP at Air Force Research Laboratory, United States; [3]KBR, United States

Infrared detection in the shortwave (1000-3000 nm), midwave (3000-5000 nm) and longwave (8000-14000 nm) regions has traditionally been dominated by compound semiconductors such as indium antimonide and mercury cadmium telluride, among others. These materials must be epitaxially grown and cooled to cryogenic temperatures before use. Alternative materials such as strained layer superlattices that are thermoelectrically cooled have been developed but still have complex and costly deposition processes. We have developed a new class of infrared photoconductive detectors active between 1000-14000 nm using disordered, soft matter semiconductors: conjugated polymers. Using both solution processing and vapor phase deposition, conductive polymers with direct, shortwave infrared bandgaps or degenerately doped effective bandgaps have been incorporated into IR detectors whose performance approaches that of inorganic compound semiconductor-based devices, but at room temperature and with no optimization. We have observed several unique morphologies, ranging from solid films to intercolated wires to isolated platelets, all of which function as effective infrared detectors for blackbody radiation. An extensive study was also undertaken to understand how deposition parameters affect electronic transport properties in the photoconductive films.

Morphology-Directed Light Emission from Fluorescent Janus Colloids for Pathogen Sensing BradleyD. Frank[1], AgataW. Baryzewska[1], SaraNagelberg[2], MathiasKolle[2] and LukasZeininger[1]; [1]Max Planck Institute of Colloids and Interfaces, Germany; [2]Massachusetts Institute of Technology, United States

Pathogen sensors which are accurate, sensitive, cost-efficient, quick, and with minimal training are a continuing healthcare need. The chemical orthogonality of Janus droplets connects nano-scale chemical events into a structural response that is sensitive, inexpensive, and quick. Utilizing this chemo-morphological coupling, the detection of e.g., antibodies, pathogens, enzymes, PFAS, and metal ions, have been reported. While the connection between environmental change and droplet morphology is established, a method for simple and quick measurement of polydisperse samples is required, which would enable the deployment of Janus emulsion-based sensors without the need for precise droplet generation. Spherical Janus colloids with a morphology-tunable interface can totally internally reflect light dependent on morphology. Gravity-aligned Janus droplets with an internal refractive index contrast induce environmental and structural effects that contribute mutually to programmable optical behaviors. We investigate total internal reflection at the internal droplet interface, and the resulting morphology-determined anisotropy of both incident and emissive light. Using this angular emission, we present a ratio-metric sensing scheme to measure monolayers of polydisperse emulsion droplets responding to their chemical environment. Using this ratio-metric sensing scheme, these droplets were successfully used to detect three pathogenic bacteria from polydisperse emulsion droplets generated on-site, selectively, sensitively, and quickly. The reference-free detection of droplet morphology from macro-scale measurement has implications for the transduction of many existing surfactant chemistries. further understanding of directed anisotropic emission by spherical colloids has broad implications for the translation of nano-scale physical or chemical events into readily available macro-scale information.

3:15 PM EL05.09.03
Photoclickable Biopolymer for Soft, Spectrally-tunable and Reconfigurable Fluorescent Optical Patterning NicholasA. Ostrovsky-Snider, AmandaCode and FiorenzoOmenetto; Tufts University, United States

Patterned fluorescence has many applications in cell-tracking, fiducial markers and cryptography. Incorporating fluorescent patterning into soft and non-planar optics can be challenging with current rigid optical materials and planar fabrication techniques. Silk fibroin is a soft biomaterial that is highly transparent in the visible range with fair transmission in the near-UV and near-IR, and as such has been a proven optical material for waveguides, diffractive and refractive optics, photonic crystals and more[1]. To make a patterned fluorescent material silk can be functionalized with methacrylate groups that allow it to participate in 2,5-diaryl tetrazole photoclick reactions. These photoclick reactions are catalyst-free, light-mediated, “click” reactions that produce highly fluorescent pyrazoline adducts from non-fluorescent reactants[2]. In this work we have synthesized a library of photoclick-able tetrazoles with varying emission characteristics and environmental responses and integrated them into soft silk-based materials including films, hydrogels and nanoparticles. These materials display intense fluorescence and can be both implanted and patterned within biological media. The tunable secondary structure conformations of silk provide further control of the patterning, with selective wettability enabling diffusion restriction of the tetrazoles which act as a physical masking process. Alternatively, the intentional formation of di-tyrosine crosslinks acts in an auto-masking function to create soft and conformal photomasks well-tuned to the tetrazole excitation wavelength. The interplay of these mechanisms allows us to achieve complex multispectral patterns in multiple material formats of broad utility.

3:30 PM EL05.09.04
TDDFT Study of Light Emitting Materials in OLEDs NobuhikoAkino; Hosei University, Japan

Recently, organic light emitting diodes (OLEDs) have been utilized in smartphones, large-size displays and solid-state lightings due to their desirable characteristics such as self-emission, high-speed response, light weight and so on. For the light emitting materials in OLEDs, the emission spectrum profile is one of the most important material properties as it determines not only the emission color, but also the device efficiency. Especially for the display applications, the material with sharp spectral profile is essential to achieve a better color gamut and also to avoid any loss by the energy filter. Hence, it has been highly desired to simulate the spectrum profile, that is, not only the peak wavelength of absorption and/or emission, but also its overall spectrum shape.
In order to study the spectrum profile of materials, the time dependent density functional theory (TDDFT) has been employed [1]. This is one of the most prominent and widely used methods for calculating excited states of medium-to-large molecules, and it is recognized as a powerful tool for studying electronic transition of molecules. The TDDFT code used in this study is based on the real-space and real-time (RSRT) formalism [2]. One of the advantages of this real-space and real-time formalism is that one can keep the code simple and understand physical meanings as directly as possible. Since this formalism is suitable for large-scale parallel computing, its MPI parallelized code has been developed and be applied to large molecules depending on the computer resources. Furthermore, the use of maximum entropy method has also been studied to extract spectrum peak information with limited real-time data [3].
This RSRT approach has been applied to some typical organic materials such as poly-(9,9'-dialkyl-fluorene) as a fluorescent material, tri(2-phenylpyridinato)iridium(III), $Ir(ppy)_3$, as a phosphorescent material, and 4CzIPN and DABNA-1 as a thermally activated delayed fluorescent (TADF) materials. The results have been suggesting that although some redshift of the peak wavelength is observed, the simulated spectral profiles agree very well with the experimentally observed profiles [4,5].
In the presentation, with utilizing both the RSRT-TDDFT and commercial quantum chemical software, TADF molecules will be studied in order to obtain design rules and possibly new molecules with desired spectrum profile in RGB region.

Interfacial Triboelectricity Lights Up Phosphor-Polymer Elastic Composites: Mechanism of Bright Unwearying Mechanoluminescence in ZnS Microparticle-Embedded PDMS Films Sung JunLim and Soon MoonJeong; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The composite of copper-doped zinc sulfide phosphor microparticles embedded in polydimethylsiloxane elastic polymer (ZnS:Cu-PDMS) has received significant attention over the past decade due to bright and durable mechanoluminescence (ML), but the underlying mechanism of this unique ML remained largely unclear. Here, we present a set of empirical and theoretical findings which prove that the ML of ZnS:Cu-PDMS composite is an electroluminescence (EL) of ZnS:Cu phosphor microparticle induced by triboelectricity generated at the interface of ZnS:Cu microparticle and PDMS matrix. We found that ZnS:Cu microparticles exhibiting bright ML are coated with alumina (AlOx), an oxide with strong positive triboelectric properties, and the friction between this oxide coating and PDMS, a polymer with strong negative triboelectric properties, produces interfacial triboelectricity sufficient to turn on the EL of ZnS:Cu microparticles. Moreover, when changing the composition of this interface, the composite ML varies in a way that the ML intensity is proportional to the amount of interfacial triboelectricity. Based on these findings, we suggest a theoretical model that elucidates the ML process of phosphor-polymer elastic composite. Understanding such a mechanism will play a crucial role in exploring and advancing new materials beyond the ZnS:Cu-PDMS systems to achieve brighter and more durable ML composite systems.

Multimaterial 3D Printing Process for Color Blindness Correction Contact Lens Production MuhammedHisham and HaiderButt; Khalifa University, United Arab Emirates

Multimaterial 3D printing is an emerging technology that allows for the production of 3D printed objects with controlled variations in material composition and properties. However, there have been very few studies on the use of multimaterial 3D printing for optical devices. In this work, a novel multimaterial 3D printing method is presented for the production of contact lenses with color blindness correction capabilities. The method utilizes vat-photopolymerization 3D printer and employs CAD file modifications along with a pause-material change step to enable material change within the contact lens. Using this method various dyes can be deposited at different regions within the contact lens in required patterns. Atto-565 and Atto-488 dyes were utilized for red-green and blue-yellow color blindness correction respectively. A suitable combination of hydroxyethyl methacrylate (HEMA) and polyethylene glycol diacrylate (PEGDA) served as the base resin for 3D printing. Good quality hydrogel contact lenses were obtained after 3D printing. The water absorption behavior, mechanical properties and surface quality of the contact lenses were evaluated. Good mechanical and material characteristics were observed for these lenses. Both Atto-488 and Atto-565 dyes were highly stable and did not leak from the crosslinked hydrogel matrix. Multimaterial contact lenses containing both dyes were found to be suitable for simultaneously correcting two types of color blindness. The contact lenses had light absorption spectra that closely matched commercially available color blindness correction glasses. The phenomenon of interface formation due material change was studied in detail and ways to reduce its intensity were explored. Contact lenses with dyes deposited in intricate patterns were also 3D printed, demonstrating the advanced capabilities of this technique. Multimaterial 3D printing enables the production of highly efficient aesthetically pleasing contact lenses with customizable color blindness correction capabilities.

Soft Optical Fibers Made of Agar EricFujiwara[1], HiromasaOku[2] and CristianoM. Cordeiro[1]; [1]University of Campinas, Brazil; [2]Gunma University, Japan

Biodegradable optical waveguides are emerging technologies for light delivery and sensing in various in-vivo applications, such as imaging systems, optogenetics, and the surveillance of intra-body parameters. In this context, agar extracted from red algae is a promising low-cost, renewable, and edible material for developing optical devices with remarkable characteristics, such as transparency, flexibility, moldability, and thermal reversibility.
This work introduces biocompatible optical fibers fabricated by pouring melted agar solutions into cylindrical molds. The solidified waveguides assume the mold geometry, allowing the manufacture of assorted waveguides, including no-core and structured holey fibers. Furthermore, the refractive index and mechanical strength are tailorable by choosing the agar concentration or adding glycerol to the precursor. Cutback tests with a 2 wt% agar, 60 wt% glycerol fiber revealed optical losses of ~0.8 dB/cm at 633 nm, comparable to waveguides made of typical biopolymers.
Subsequently, we investigate the ability of agar optical fibers to perceive physical and chemical stimuli. A coherent light excites multiple fiber modes due to the core dimensions, creating an output speckle field whose spatiotemporal distribution transcribes the fiber state. Besides traditional bending and strain measurements, one may explore the agar's swelling and syneresis behaviors to evaluate humidity, temperature, and its degradation over time. The electrical conductivity of agar also establishes current-driven modulation of the optical response. Moreover, the holey structure of agar waveguides can transport fluids and provide refractive index detection through interaction with the core modes.
The developed agar-based optical fibers are customizable, easy to fabricate, and exhibit versatile sensing capabilities, which inspires several applications as a biocompatible and degradable probe for medical, biochemical, and environmental measurements.

Simulation of Anisotropic Thermal Expansion Coefficient of Liquid Crystal Networks using Dreiding-Force Field Wei TingHsu, Yun HsiangChang, Nien JungChiang and Yu ChiechCheng; National Taipei University of Technology, Taiwan

The study presents molecular dynamics simulations employing the Dreiding force field in the open-source LAMMPS solver to investigate the thermal expansion coefficient of liquid crystal networks (LCNs). The LCNs were intentionally aligned unidirectionally, resulting in anisotropic variations in dimensions along three orthogonal directions. The calculated coefficients were subsequently imported into a structural mechanics module in the COMSOL solver to simulate the thermal deformation of the LCNs. The outcomes of the temperature-induced deformation simulation of LCNs were found to be in agreement with the experimental data.

Conformable and Compact Multiaxis Tactile Sensor for Human and Robotic Grasping via Anisotropic Waveguides HuichanZhao and JingyiZhou; Tsinghua University, China

Rich and accurate tactile perceptive capability is important for both humans and robots. Soft materials exhibit unique characteristics to construct high performance tactile sensors such as high sensitivity and high resistance to overload. In this work, a multiaxis tactile sensor based on a soft anisotropic waveguide that can distinguish normal force and shear force, which can greatly expand its potential uses in practice, is reported. First, the anisotropy of the waveguide sensor's response to vector forces is validated numerically and experimentally, and then two of those anisotropic units are embedded into one cladding with a crossed-over layout, to form a multiaxis sensor. Then, a calibration algorithm is implemented on this sensor and the reconstruction of vector forces is achieved at an average accuracy of 28.0 mN for normal forces and 81.1 mN for shear forces, both with the sensing range of 1 N. Using this device, three demonstrations are shown to give outlooks of its potential application in human and robotic grasping tasks: a wearable tactile sensor for collecting human's haptic data during operation, a uniaxial gyroscope, and a robotic gripper's tactile sensor for assisting an unlocking task with a key. This work is a step toward more functional soft waveguide-based force sensors.

Controlling Topological Defects and Disclinations in Liquid Crystals Through Structured Polymerization Adithya PradeepNair, SteveJ. Elston, CamronNourshargh, NathanSpiller and StephenMorris; University of Oxford, United Kingdom

Line singularities in nematic Liquid Crystals (LC) known as disclinations play an important role in the understanding of topography and electro-optic phenomena in LC technologies. Manipulating these singularities and defects in a precise and controlled way can unlock new functionality and electro-optic behavior in LC devices for a range of applications including tunable lasers and beam generators for optical communications. In this presentation, we demonstrate the control of disclinations and defects using a combination of bulk photopolymerization using an optical projection system and localized polymerization using direct laser writing. We use a so-called nematic LC Pi cell to show how this control of the disclinations and defects could be used as an effective template for transferring biological matter. An extensive study has been conducted to analyze the nucleation and growth processes, highlighting the significant influence of rubbing direction on the formation of random domains. By modulating the Pi cell, distinct states with varying boundary conditions are generated. This characteristic makes the Pi cell a promising platform for the manual manipulation of nanoparticles within an electro-optical waveguide. We anticipate that our disclination movement technique can lead to tunable metamaterials, LC plasmonic devices and more efficient optical phase modulators.

Radiative Cooling and Thermoregulation in the Earth's Glow using Directional Emitters JyotirmoyMandal and MathisDeGeorges; Princeton University, United States

Buildings exchange large amounts of heat with the environment as longwave radiation. Typical building envelopes are omnidirectional emitters and absorbers of this heat. However, vertical surfaces of buildings see a thermally oriented environment – the cold sky above and a seasonally hot or cold terrestrial environment near and below the horizon. Controlling radiative heat flows to and from such environments can yield large energy savings and thermal comfort in buildings, but remains unattained because it entails avoiding seasonal terrestrial heat gains and losses, while emitting heat skywards via the radiative cooling mechanism. As a solution, we propose micropatterned, directionally emissive facades (DEFs) which, on walls and windows, can achieve a skywards net heat loss through the long-wavelength infrared (LW-IR, λ~8-13 μm) atmospheric transmission window, while blocking terrestrial heat exchange near and below the horizon. Such DEFs can radiatively cool buildings by up to 100 Wm^{-2} in the summer, and reduce overcooling by 20 Wm^{-2} or more in the winter, relative to typical envelopes. This novel passive thermoregulation may yield similar or much greater energy savings per m^2 than cool roofs, depending on the type of facade. Furthermore, DEFs may cool urban canyons by 1-2°C, reducing heat island effects, and in turn lowering building cooling loads. Our design represents a new platform for tremendous and untapped energy savings.

10:45 AM EL06.01.02
Development of Highly Thermal Conductive Composites with Large Latent Heat YapengChen; The Hong Kong University of Science and Technology, Hong Kong

Investigating innovative methods for concurrently enhancing the thermal conductivity and preserving the high latent heat of phase change materials is crucial for improving their capacity to regulate the operating temperature of electronic devices by quickly collecting thermal energy within a small temperature range. Among these strategies, compositing the organic phase change matrix with prefabricated frameworks that provide high thermal conductivity and exceptional encapsulation capability is the most promising approach for efficiently boosting heat transfer while retaining its inherent high latent heat. Despite extensive efforts, constructing these frameworks using conventional casting methods remains challenging due to solid interlayer interaction and gravity-induced densification of high thermal conductivity nanosheet frameworks. In this study, a novel approach for the controllable casting of hierarchically aligned graphene frameworks was proposed by regulating the interface tension of the solvent, which imparted the eicosane matrix with a significantly enhanced thermal conductivity of up to 71.6 $W\ m^{-1}\ K^{-1}$ at 27.8 vol% graphene loading. Moreover, the constructed graphene-based framework featured numerous capillary channels that greatly enhanced the encapsulation capacity of the eicosane matrix, which exhibited a high composite latent heat of 129.6 $J\ g^{-1}$. We conducted visual and data-based characterizations as well as finite element-based simulations to confirm that our composites simultaneously improve thermal conduction and phase change matrix encapsulation capacity. We believe that our research will advance the construction paradigm of high thermal conductivity nanosheets toward controllable structures and contribute to enhancing the mechanical, electrical, and thermal properties of composites.

11:00 AM EL06.01.03
Photomolecular Effect: Visible Light Interaction with Air-Water Interface GuangxinLv, YaodongTu, RohithMittapally, JamesH. Zhang and GangChen; Massachusetts Institute of Technology, United States

Despite that water is nearly transparent to visible light, we hypothesize that visible light can directly cleave off water molecular clusters at water-vapor interfaces via a process we call photomolecular effect. We had used this hypothesis to explain why some of the past experiments on solar-interfacial evaporation from porous materials can exceed the apparent thermodynamic limit, calculated based on the energy of the incident light and latent and sensible heat required for water evaporation. In this work, we show that this process happens at the air/water interface by measuring the dependence of photomolecular effect on the wavelength, the angle of incidence, and the polarization of the incident light. We further support the photomolecular effect by measuring the temperature response in water and the vapor phases, Raman and infrared spectroscopy, and multiple pump-probe measurements.

Mechanically Durable Camouflage Materials by Coating Polyimide Nanofilm with Controlling Radiative Energy NamkyuLee; Yonsei University, Korea (the Republic of)

Camouflage is an innate behavior observed in creatures that allows them to blend in with their surroundings, thereby increasing their chances of survival by evading predators [1]. The artificial camouflage materials is emerging from the inspiration from this natural phenomenon. These materials can be designed to exhibit specific electromagnetic properties across various domains such as acoustics, microwave, infrared (IR) waves, visible light, and ultraviolet light, depending on their intended applications. Among these domains, IR wave manipulation has gained significant attention due to its relevance in energy and military sectors [2-5].

Micro-nano structures show great promise in overcoming the limitations of conventional materials and realizing the designed properties for camouflage materials. However, these structures are susceptible to external stress such as mechanical or chemical, which can lead to a sudden degradation in material performance, making them challenging to use in practical applications. For this reason, various strategies have been explored, including chemical treatment, the implementation of hierarchical structures, and thin-film coatings for enhancing durability.

However, directly applying conventional methods to improve durability in the context of manipulating electromagnetic waves poses challenges. This is because electromagnetic properties are highly sensitive with residues on the surface, which can generate additional resonances and opaqueness in the target wave, resulting in different material performance. To meet requirements of IR camouflage materials, a polyimide nanofilm is used as a dielectric layer firstly. In the previous work, the polyimide nanofilm exhibits flexibility, anomalous dispersions, and, in particular, satisfies the IR camouflage requirements in the absorbed band based on atmospheric transmittance. Moreover, polyimide is chosen for its excellent mechanical properties and thermal stability. Based on these characteristics and optical properties, we utilize the nanofilm coating of polyimide on the structures, which can enhance mechanical durability.

In this study, we present durable camouflage materials specifically designed for IR radiative energy [6]. We coated ordinary metal-dielectric-metal (MDM) structures with a polyimide nanofilm to improve their mechanical durability. The electromagnetic performance of these durable materials was evaluated through measurements using Fourier transform infrared spectroscopy (FT-IR) and simulations using COMSOL Multiphysics. To check the mechanical durability, two methods, namely manual brushing and the root cause analysis (RCA) test, were employed for comparing conventional camouflage materials. Finally, the IR radiative energy was assessed by IR camera and calculation. We demonstrate that the mechanical stress doesn't change the IR camouflage performance.

Ultrafast and Nanoscale Photonics: From Metamaterial-Based All-Optical Switching to Plasmon-Driven Polaritonic Chemistry NicolòMaccaferri; Umeå University, Sweden

Ultrafast control of light-matter interactions is fundamental to mark new technological frontiers, for instance in light-driven information processing and nanoscale photochemistry [1]. In this context, we have explored the possibility to use metal-dielectric nanocavities to achieve all-optical modulation of light states, such as reflectance, transmittance and polarization. Without the need of driving higher order effects, our system is based on linear absorption, provides large relative modulation exceeding 100% and switching bandwidths of few hundred GHz at moderate excitation fluence [2]. This archetypical system becomes even more interesting if the dielectric inclusion is not just a "passive" insulator material but an inorganic van der Waals bonded semiconductor, like a transition metal dichalcogenide (TMD). TMDs are subject of intense research due to their electronic and optical properties which are promising for next-generation opto-electronic devices. In this context, understanding ultrafast carrier dynamics, as well as charge and energy transfer at the interface between metals and semiconductors, is crucial and yet quite unexplored. By employing a pump-push-probe scheme, we experimentally study how optically-induced thermionic charge carrier injection affects the exciton formation dynamics in bulk WS2 [3], disclosing excellent opportunities to control exciton formation and annihilation. The strong electric field associated with thermionic carriers excitation can have also important implications in polaritonic chemistry. In fact, if an electronic transition (e.g., exciton, singlet, etc.) strongly interacts with the optical modes of a resonator, we can tailor the energetics and the morphology of a molecular state. By combining quantum mechanical modelling and pump-probe spectroscopy, we recently shed new light on the ultrafast dynamics of a hybrid system composed of photo-switchable molecules coupled to optically anisotropic plasmonic nanoantennas, which allow us to selectively switch between two regimes where the light-matter interaction is either weak or strong [4]. Our synergistic approach is thus instrumental to devise new strategies for tailoring electronic states by using plasmons for applications in polaritonic chemistry on femtosecond timescales.

Artificial Intelligence Aided Rapid Design of THz Stereo-Metamaterials Based Polarization Conversion Devices for Highly Sensitive and Efficient Strain Sensors PatrickKung, M.ZekiGüngördü, M. ReefazRahman, AnirbanSwakshar, AbbySanders, CallanSpooner and SeongsinM. Kim; University of Alabama, United States

Polarization conversion devices, pivotal in the field of photonics, are crucial for manipulating the polarization state of electromagnetic waves. These devices have significantly contributed to advancements in technology, specifically in the realms of communication, imaging, and remote sensing. They have facilitated applications ranging from space exploration to the detection of hidden objects, the identification of explosives, and even cancer detection using the Terahertz (THz) spectral range, which spans from 0.1 to 10 THz. Owing to its wide bandwidth and remarkable ability to penetrate dielectric materials, the THz wave is garnering more interest for noninvasive screenings, high-resolution imaging, and improved precision in data collection. Metamaterials (MM), which are artificially synthesized materials composed of repeated subwavelength-sized meta-atoms, offer a promising avenue for the advancement of these devices. Metamaterial-based THz polarization conversion devices have an advantage over conventional devices because of their thin and compact structure. They are not only easier to integrate but also offer flexibility, marking a new era in the evolution of polarization conversion technology. Stretchable electronics have recently obtained rising interest because the mechanical deformation of elastomeric substrates has been used to induce spectral shifts in the resonance of nanophotonic structures such as nanoparticle dimer extinction and gratings. With the advancement of polymer technology and lithographic techniques, it is possible to fabricate metamaterials on thin, flexible substrates, including Kapton polyimide or polyimide (PI), polyethylene naphthalate (PEN), and polydimethylsiloxane (PDMS). Research indicates that crumpling an unbending metamaterial on a soft backing layer surface can influence the response. The ability to realize such structures on elastic substrates presents further opportunities for tuning via mechanical straining.

In light of that information, we utilized a stereo-metamaterial (SMM) structure for new-generation THz polarizers converting the polarization from linearly to circularly and elliptically polarized wave at the THz frequency range in reflection mode. In this work, we present the processes and results of the inverse design of SMM using the artificial neural network (ANN), trained by various parameters, including polarization status and ellipticity angle, to achieve highly efficient device performance. Training and testing our ANN with the created datasets by simulation for the inverse design of the device, design parameters were obtained by giving an artificial EM response or ellipticity angle spectrum or vice versa more efficiently and rapidly. This study was designed to use a tandem neural network (TNN). It is created by two deep neural networks (DNNs); an inverse neural network (INN) predicts design parameters from the target spectrum, and a forward neural network (FNN) predicts the target spectrum from design parameters, as demonstrated in this work. During the training process of TNN, FNN is trained and tested first. Then, after FNN's weight freezes, it is cascaded with INN for training and testing TNN. The training error can be derived by comparing the target and prediction spectra, solving the non-unique input problem.

The SMM devices based on the ANN-powered design were successfully fabricated on the stretchable substrate. We demonstrated efficient sensing of different polarization statuses using THz polarimetry spectroscopy under the different strains. The sensitivity reaches to 0.1% strain sensing. More details on the results will be presented.

9:00 AM EL06.03.03
Inverse Design of Functionalized Photonic Patches for On-Chip Imaging and Spectroscopy YilinZhu, TornikeShubitidze and LucaDal Negro; Boston University, United States

In this talk, we present our work on the inverse design and experimental characterization of compact functionalized photonic structures, called “photonic patches”, using adjoint optimization coupled with the rigorous two-dimensional generalized Mie theory (2D-GMT) and validated by three-dimensional finite elements simulations. In particular, we demonstrate compact (10μm×10μm) silicon and silicon nitride structures that steer four different wavelengths into four predefined far-field directions with efficiencies close to 60%. Moreover, we inverse design structures for the compact spectrometers with nanometer-level spectral resolution. In addition, we demonstrate novel photonic patch geometries for near-field focusing at multiple focal lengths, achieving focusing efficiencies that exceed 70%. We also present our results on achromatic focusing devices with optimal aperiodic geometries and enhanced local density of states (LDOS) at predefined spatial and spectral locations. We show that our devices support localized optical modes with two-orders of magnitude enhancement of the Purcell factor for both TE and TM polarizations, enabling the fabrication of active photonic devices with ultracompact footprints. The performances of the fabricated devices are characterized experimentally using light emission spectroscopy and spectroscopic ellipsometry from the visible to the infrared spectral range. Leveraging on the rigorous mesh-free solution of the multiple scattering problem of dielectric cylinders, our approach provides an efficient and accurate inverse design methodology for the realization of novel aperiodic structures with optimal functionalities for nonlinear photonics, miniaturized light sources, and on-chip imaging and spectroscopic devices.

Observation of Topological Phase Transition in Complex Momentum Space YungKim[1], SonuVerma[2], MinwookKyung[1], KyungminLee[1], Moon JipPark[2,3] and BumkiMin[1]; [1]KAIST, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of); [3]Hanyang University, Korea (the Republic of)

It is well known that topology of a periodic crystal can be characterized by calculating a topological invariant using the real Bloch wave vector. In systems governed by non-Hermitian Hamiltonians, however, this conventional knowledge is challenged due to a phenomenon known as the non-Hermitian skin effect, in which wave functions accumulate at the boundaries. To address the failure of Bloch's theorem in non-Hermitian systems, two representative approaches have been utilized: one involving complex spectral topology in the conventional Brillouin zone and the other revolving wave function topology in the generalized Brillouin zone. The complex spectral topology approach provides the topological information of a system by demonstrating the presence of point gap and line gap in the complex plane. On the other hand, the wave function topology provides a method to calculate non-Hermitian topological invariants using the complex Bloch wave vector, which hosts conventional topological boundary states. Recently, a new approach has been introduced - the intrinsic topology of the generalized Brillouin zone within the complex momentum plane. In this work, we present the first experimental demonstration of topological phase transition within the generalized Brillouin zone, occurring in complex momentum space, through a one-dimensional non-Hermitian electric circuit lattice. More specifically, we designed a one-dimensional non-Hermitian electric circuit lattice inspired by the Hatano-Nelson model with generalized boundary conditions. By adjusting the boundary conditions, specifically the onsite potentials and couplings of boundary nodes, we observed the emergence of topological boundary modes in complex momentum space. Furthermore, we identified that this topological phase transition, known as an exceptional transition, is accompanied by the manifestation of an exceptional point. To build upon and generalize our modified Hatano-Nelson model, we introduced next-nearest-neighbor hopping into the system and observed the emergence of multiple topological boundary modes within the complex momentum space. Our experimental findings hold significant promise for advancing the understanding of bulk-boundary correspondence within non-Hermitian systems, by highlighting the novel topological phase transition that occurs in complex momentum space.

10:30 AM EL06.03.06
Observation of Polaritonic Topological Nodal Line States in Natural Materials MingsongWang[1], XiangNi[1,2] and AndreaAlu[1,3,4]; [1]CUNY Advanced Science Research Center, United States; [2]Central South University, China; [3]Graduate Center of the City University of New York, United States; [4]City College of the City University of New York, United States

Photonic topological systems have displayed significant potential for various applications, including robust wave propagation, topological lasers, non-Hermitian photonics, and nonlinear topological phases. A promising direction in the field of topological photonics is the exploration of interactions between photons and a diverse range of material excitations, such as excitons, plasma, and optical phonons. These interactions can give rise to half-light-half-matter quasiparticles called polaritons. Recent studies have unveiled the formation of topological exciton/phonon polaritons resulting from the strong coupling between photonic topological modes and excitons or optical phonons. However, most investigations into topological polaritons have focused on artificial structures or a combination of artificial topological structures with natural materials. These studies often require precise fabrication of sophisticated artificial structures, thus posing challenges for their practical implementation in real-world applications.

In this study, we report the observation of polaritonic topological nodal lines supported by unpatterned natural materials and experimentally characterize the associated surface polaritonic waves using scattering-type scanning near-field optical microscopy (s-SNOM). In electronic materials, topological nodal lines are manifested as one-dimensional lines in the electronic band structure, where the energy levels are doubly degenerate in three-dimensional momentum space, exhibiting a Berry phase of π. These nodal lines are topologically protected under specific spatial symmetries, rendering them robust against perturbations when these symmetries are preserved. The discovery of topological nodal lines has opened exciting opportunities for designing and synthesizing materials with intriguing electronic and optical properties. However, due to technical limitations and the delicate nature of their topology, the exploration of topological nodal lines in condensed matter experiments has been limited. More recently, the concept of topological nodal lines has been extended to classical wave systems, leading to a surge of interest in characterizing these modes and investigating their unique properties. Notably, the study of topological nodal lines in photonics and metamaterials has emerged as a rapidly growing field within topological photonics in recent years.

Through theoretical exploration and simulations, we have discovered that calcite crystal offers an outstanding platform for demonstrating polaritonic topological nodal line states in natural materials. The topological nodal line originates from a two-fold degeneracy within the upper Reststrahlen band of calcite when the crystal surfaces are oriented along the plane (001), forming angles θ of 90° with respect to the optical axis. At the interface of calcite, this topological nodal line gives rise to a novel type of topological surface polaritons, whose dispersion in momentum-energy space can be effectively characterized using s-SNOM. Additionally, we experimentally demonstrate optical spin-momentum locking for these new surface polaritons, with their propagation direction steered effortlessly through the handedness of circularly polarized excitations.

10:45 AM *EL06.03.07
Nanoscale Directional Photocurrents with Symmetry-Broken Optoelectronic Metasurfaces Hou-TongChen; Los Alamos National Laboratory, United States

Light-driven electrical currents are of great importance in information science and microelectronics, particularly in emerging topological, magnetic, and low-dimensional materials, which introduce new speed limits and light-based control degrees of freedom. However, such photocurrents typically rely on the broken spatial or temporal symmetries, thus either intrinsic to the lattice and constrained to specific light-matter interaction geometries, or dependent upon applied static fields that are difficult to texture on small spatial scales. Artificially structured plasmonic systems can be utilized to overcome these spatial limitations and concentrate light down into deeply sub-diffractive nanometer scales. In this work, we show that hybrid plasmonic metasurface systems offer much broader capabilities for harnessing charge flows at previously inaccessible spatial scales. Nanoscale directional photocurrents in these systems are a universal manifestation of broken inversion symmetry, with patterned gold resonators on graphene serving as a testbed system. The rapidly-evolving nanoscale dynamics across the coupled photonic, electronic, and thermal responses introduces net photothermoelectric currents that are sensitive to the local symmetry of the light-matter interaction. The local (nanoscale) and global (millimeter-scale) photocurrents are highly responsive to the polarization and frequency of the ultrafast light pulses, leading to a combination of designer patterning and active control over ultrafast, nanoscale vectorial currents. As an immediate application, we exploit this scheme for efficient and versatile generation of broadband ultrafast terahertz radiation and terahertz vector beams.

Metallic Polymers as New Materials for Plasmonics and Active Metasurfaces: Video-Rate Beam Switching and Multi-Focal Metaobjectives HaraldGiessen; University of Stuttgart,

Germany

Miniaturizing optical components is key to achieve ultimate spatiotemporal control of light. Active subwavelength nanoantennas and metasurfaces are a prime candidate to achieve this goal, whose functionalities are currently limited by the proposed switching schemes.
We introduce nanoantennas and metasurfaces from *metallic polymers* which can be electrically switched in the infrared spectral range via CMOS-compatible voltages of ±1V (Fig. 1A) [1]. The concept is based on an electrically driven metal-to-insulator transition. A positive voltage turns the polymer metallic and the nanoantennas exhibit a strong plasmonic resonance (right). In contrast, a negative applied voltage (left) switches the polymer into the insulating state with no nanoantenna resonance present. The electrical switching between ON- and OFF-state occurs fast, permitting video-rate switching frequencies of up to 30 Hz.

Using such nanoantennas we demonstrate, on the one hand, an electrically switchable metallic polymer metasurface for ultra-high-contrast active beam switching (Fig. 1B). On the other hand, we realize an electro-active metaobjective comprising two metalenses-on-demand [2]. The state of metalenses can be set fully independently. Non-volatile operation is used to set the refractive power of the individual metalenses either ON or OFF. Such, four different metaobjective states become possible. By using gel electrolytes, our metadevices can even be integrated into state-of-the-art on-chip electro-optic components [3,4].

Fig. 1 (A) Concept of electrically switchable nanoantennas made from metallic polymers. Right: Nanoantenna ON-state at applied voltage +1 V, plasmonic resonance observed. Left: Antenna OFF-state at -1 V, no plasmonic resonance observed. Switching is possible with video-rate frequencies of 30 Hz. (B) Metallic polymer plasmonic metasurface for ultra-high-contrast active beam steering. Camera images and intensity profiles in the ON- (left) and OFF-state (right). (C) Multi-focal metaobjective comprising two stacked metalenses-on-demand. The state of each metalens can be set individually in a non-volatile operation.

Scalable Classical and Quantum Light Sources BoubacarKante; UC Berkeley, United States

The scaling of lasers and in-particular of surface emitting lasers is a multi-decade long question that has been investigated since the invention of lasers in 1958. It is an important question with numerous applications. In this talk, I will propose and discuss an intriguing solution to this question that we named the Berkeley Surface Emitting Laser (BerkSEL) and it is the world's first scale-invariant laser. In the second part of the talk, I will discuss our demonstration of the first deterministic quantum light source in silicon that emits single photons in the telecom band. The work opens unique perspectives for scalable quantum networks.

2:30 PM EL06.05.03
Multiplexed Immunoassays Enabled by Pixelated High-Quality Factor Metasurfaces and Acoustic Bioprinting SajjadAbdollahramezani, ParivashMoradifar, FareehaSafir, SahilDagli, VarunDolia, JackHu, HamishM. Carr Delgado, KaiChang, Butrus T.Khuri-Yakub and JenniferA. Dionne; Stanford University, United States

Nanophotonic biosensors hold the promise of early disease identification and continuous treatment monitoring due to their high sensitivity, fast response time, and possibility for label-free detection. Here, we leverage ultra-densely-pixelated high-quality factor (high-Q) metasurfaces in conjunction with acoustic bioprinting surface chemistry to enable scalable multiplexed immunoassays. Our platform capitalizes on a 2D array of finite-size all-dielectric metasurfaces supporting quasi-bound state in the continuum (qBIC) resonances to significantly enhance light-matter interaction with high spatial resolution. Unlike conventional metasurfaces, where sharp resonances are generally generated via the interference of sub- and super-radiant modes in a large 2D arrangement of metaunits, our high-Q metasurface exploits photonic mirrors to highly confine the collective qBIC mode of a 1D array of broken-symmetry resonators. Without comprising the optical performance, such small-scale (i.e., 15×3 um^2) metasurfaces provide high Q-factors (~3000) with a mode volume below $(\lambda/n_{eff})^3$. We demonstrate an ultradense array of pixelated biorecognition elements by introducing an acoustic bioprinting approach for the local functionalization of each metasurface resonator. In contrast to conventional surface functionalization approaches, which expose all sensing elements at once, our approach facilitates the realization of multiplexed biodetection by addressing individual elements at Khz rate. In combination with hyperspectral imaging, this sensitive label-free sensing platform allows for the simultaneous quantitative detection and kinetic analysis of multiple antibodies (e.g., SARS-CoV, Influenza A, and Influenza B) on a single chip. Further, we demonstrate how a single chip can also allow simultaneous detection of proteins and the associated gene fragments. Our AI-enhanced technique can capture two-dimensional spatially resolved images across contiguous spectral bands revealing subtle differentiation of spectral signatures associated with each linked bioanalyte, without relying on bulky and expensive spectrometers. The capability of our multiplexed immunoassay platform for parallel measurement of several biological targets of interest opens the door for easy-to-use and portable diagnostics.

2:45 PM EL06.05.04
A Simple Route for Generating Iridescent Retroreflective Color Filter JieunYeo, Joo HwanKo and Young MinSong; GIST, Korea (the Republic of)

Iridescent colors found in the body of various animals and insects, such as tails of birds or wings of butterflies, exhibit eye-catching visual information, enabling camouflage, predation, courtship, and communication in various environmental changes. In particular, certain living, *Papilio palinurus,* which has multilayer photonic structures on the concave structure of the wing surface, exhibits conspicuous light-matter interaction with both iridescent color reflection and retroreflection, which delivers vibrant visible information in the direction of light input[1]. Conventionally, retroreflectors employ geometric structures, such as corner-cube shapes, to redirect incident light back toward its source. However, these structures typically yield non-iridescent colors and are challenging to apply in various applications due to these limitations. Moreover, the use of organic materials such as dyes and pigment for colorization compromises the color purity and durability of retroreflective materials. Based on a lesson from natural photonic structure, specific examples have been introduced to make an iridescent retroreflector inducing gap interference within biologically inspired microsphere structures or distributed Bragg reflector (DBR)[2]. However, these methods still suffer from limitations such as intricate structures and time-consuming manufacturing processes. In this study, inspired by the structural properties of butterflies, we present a conspicuous iridescent retroreflective color filter that dynamically changes in response to the incident angle. The filter aims to overcome limitations in dynamic coloration and durability by utilizing an ultra-thin resonant layer (UTRL) on a metal film.
To implement the iridescent retroreflective filter, a metal film is deposited on a micro-concave array (MCA) designed to implement retroreflective behavior to form a UTRL. The round curvature of the MCA possesses different deposition angles at various locations, which consequently allows the UTRL to deposit with a gradual change in porosity, resulting in sequential color changes under modulated resonance conditions [4]. The fabricated UTRL converts white light into iridescent light that gradually changes with the curvature of MCA by turning the direction of light to the original light source. The resonance conditions were regulated by controlling the porosity of the absorption medium in the metal reflector, which means that when resonance occurs in the visible wavelength range, the change in porosity causes a color change[3]. The dynamic angle-sensitive color changes resulting from the difference between this porosity and the effective index are experimentally confirmed by the measurement of the reflection spectrum and its spectral color at a wide angle. Additionally, the retroreflective filter can analyze using a rotational linear polarizer. When the polarizer was located in front of the light source and the image sensor, the retroreflection can be confirmed by observing the near-field pattern. When the polarizer in front of the image sensor rotated 90°, the retroreflected light was detected in four segments of the concavity. As a result, we implemented a sustainable retroreflective structural color filter that is constructed using a self-graded porous medium comprising concave structures. The iridescent color filters can be used in various visual applications such as load signals or optical devices.

Plasmonic Metasurfaces for Taste Visualization JuhyeongLee, DoeunKim, GyurinKim, JuhwanKim, Hyun MinKim, Jang-HwanHan and Hyeon-HoJeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Discriminating taste information before food consumption is vital for mitigating health risks associated with factors such as virus infection, radioactive pollutants, and drug abuse. Plasmonic

nanosensors based on refractive index sensing have emerged as a promising platform for taste molecular sensing due to their facile and modular sensing capabilities with low detection thresholds. However, a challenge for the plasmonic nanosensors lies in the lack of qualitative analysis of multiple target species.

Here, we present a breakthrough in plasmonic nanosensors that addresses the challenge of taste-sensing through a wafer-level plasmonic metasurface. This plasmonic metasurface is constructed in a scalable manner by coating metallic nanoparticles onto a metallic mirror, which are separated with a uniform solid nanogap. This design ensures an identical plasmonic cavity resonance (i.e., color) with enhanced sensitivity (> 100 nm/RIU) and uniform surface-wetting properties across the entire wafer. Leveraging this plasmonic metasurface, we introduce the concept of 'binding-free' multiple molecular sensing by simply capturing 2D projection images of molecular droplets on the single plasmonic metasurface using a conventional optical microscope. We are then able to extract two essential physical properties: the molecular refractive index and surface tension, obtained from the droplet's color and size, respectively. The combinatorial analysis of these two properties offers a scalable and intuitive means of detecting and visualizing the five basic tastes, otherwise impossible from either physical property alone. To showcase the utility of our surface-sensitive sensing platform, we successfully identify the tastes of various commercially available liquids. This breakthrough holds significant potential in establishing an end-user-friendly potable taste-sensing platform.

In this presentation, the fabrication method of the plasmonic metasurfaces will be discussed along with their theoretical and experimental optical features and sensing performance. Furthermore, we will demonstrate how to qualitatively model and mathematically analyze the colors and sizes of molecular droplets as a function of the molecular concentrations of each taste molecule for taste visualization and discrimination.

3:45 PM EL06.05.06
Procedural Metamaterials: A Unified Procedural Graph for Metamaterial Design LianeMakatura[1], BohanWang[1], Yi-LuChen[2], BoleiDeng[1], ChrisWojtan[2], BerndBickel[2] and WojciechMatusik[1]; [1]MIT, United States; [2]IST Austria, Austria

Metamaterials have been architected to achieve a wide range of incredible material properties, from optical to acoustic, mechanical and beyond. These highly-performant metamaterials generally exhibit an equally wide range of structural “architectures”, including diverse elements such as straight trusses, curved beams, thin shells, and solid bulks. Although this breadth is powerful -- as each architectural class offers a unique set of strengths -- it also complicates the process of metamaterial design, because no existing representation is well-suited for all classes. Generic representations like voxel grids can express any structure, but the specification is cumbersome and difficult to edit. Class-specific representations are often more practical, as each structure’s description is compact and editable. However, the underlying specifications are as varied as the structures themselves, and they are generally incompatible with one another. These issues make it difficult to explore over the full space of interesting metamaterial architectures, which limits the set of structures that are easily accessible to engineers.
To alleviate these challenges, we propose a unified procedural graph representation that can succinctly represent the construction process for any structure using a simple thickness-annotated skeleton. Our high-level approach is intuitive and accessible: the designer builds a skeleton that describes a small fundamental piece of the desired structure; applies a sequence of mirror or rotation operations; and then thickens this skeleton to obtain the final volumetric object. Our low-level skeleton representation preserves this powerful simplicity, by leveraging intuitive, easy-to-specify elements like lines and surfaces. Each skeletal element is constructed from a small set of simple, high-level specifications comprised of vertices and edges, a bounding volume, and the type of skeletal element (e.g. line, surface) to be instantiated. Ultimately, the spatially-varying thickness function associated with each element determines how it should be thickened into a physically realizable volume (e.g., beam, shell, or solid bulk).
Despite its simplicity, our representation is expressive enough to capture a wide range of established structures, including those based on the complex *triply periodic minimal surfaces* (TPMS), which have traditionally been challenging to explore. Our representation can also seamlessly combine elements from various architectural classes. Moreover, our representation is compact, intuitive, and easily-editable, such that it is amenable to manual or automated design space exploration. As such, our approach streamlines the process of metamaterial design and greatly expands our capacity for exploration.
To demonstrate the expressiveness, accuracy and efficiency of our representation, we recreate a wide range of established structures with diverse architectures. We also conduct a user study to verify our representation’s intuitiveness and ease-of-use. Finally, we demonstrate the potential of our approach by showing that random searches over our representation can efficiently produce large collections of novel structures with promising material properties.

4:00 PM EL06.05.07
Development of Spiropyran Immobilization and Characterization Protocols for Reversible Photo-Patterning of SiO_2 Surfaces BokunZhou and VincentRemcho; Oregon State University, United States

Spiropyran, a type of photochromic compound, is distinguished by its reversible transformation between its colorless, hydrophobic spiropyran (SP) form and the purple, hydrophilic merocyanine (MC) form. This transformation can be triggered by UV light and reversed by either visible light or heat. Spiropyran functionalized surface, therefore, present reversible contrast in properties such as color, fluorescence, and reactivity, rendering it optimal for a range of applications in chemical sensor, biosensor, drug delivery, and heavy metal extraction.

Despite the successful application of spiropyran attachment in various substrates: non-covalently in metal organic frameworks (MOFs), poly (ethylene glycol) (PEG) lipids, polydimethylsiloxane (PDMS), and covalently in poly (methyl methacrylate) (PMMA), polystyrene microbeads, silica microbeads, cellulose nanofibers, cellulose nanocrystals - its implementation on plain surfaces has been limited due to surface area constraints and insufficient characterization.

Our research focuses on a 3-step spiropyran immobilization protocol tailored for thermally grown SiO_2 surfaces. This process involves surface activation, amination using (3-aminopropyl) triethoxysilane (APTES) and spiropyran functionalization. We have also developed a robust characterization method utilizing techniques such as ellipsometry, X-ray photoelectron spectroscopy (XPS), Fourier transform infrared spectroscopy (FTIR), and fluorometric detections.

Our main results include comparing the effectiveness of various activation methods, such as H_2SO_4 acid, oxygen plasma, and piranha solution treatments. XPS and contact angle measurements show that the surface is clean and properly activated for all cases. We then monitored the uniformity and thickness of the APTES layer. By varying the reaction temperature, time, and concentration, we achieved a uniform and thin layer immobilization of APTES, verified by ellipsometry and XPS. A 1% APTES incubation for 5 minutes at room temperature yielded the best results. The functionalization step was verified by fluorescence microscopy, showing a clear contrast between SP and MC forms. FTIR monitors the change of functional groups after each step. The developed protocol demonstrated exceptional repeatability, with photo-patterning results showing reversibility over more than ten cycles and feature sizes of less than 20 μm.

We also discussed the intrinsic limitations of immobilizing spiropyran onto a plain and rigid substrate, such as steric hindrance and effective activated surface sites, which greatly reduced the number of spiropyran immobilized. To address these challenges and expand the potential applications of our protocol, we propose several innovative directions for future research. One approach involves immobilizing spiropyran to a porous media that provides a larger surface area or finding a type of surface with more effective activated sites. Another strategy is to further modify the MC form to enhance the contrast between SP and MC forms.

In conclusion, our study highlights the potential of spiropyran in surface patterning applications and offers a comprehensive protocol for its immobilization on SiO_2 surfaces, which should also be applicable to other surfaces. These findings pave the way for the development of on-chip sensing and other applications.

SESSION EL06.07: Poster Session: Metamaterials Innovation in Photonics, Acoustics, Fluidics and Thermal Sciences

Ductile Mode Machining Process of Piezoelectric Single Crystal for the Broad-Bandwidth Ultrasonic Transudcer Applications Jun SaeHan, Dong-HyunSeo, Eun-JiGwak, Tae-JinJe and Doo-SunChoi; Korea Institute of Machinery and Materials, Korea (the Republic of)

Ductile mode machining process was investigated with piezoelectric single crystal material based on laser assisted mechanical cutting process. For the fabrication of acoustic/ultrasonic metamaterials, micro/nano patterning of functional material have been widely researched. Especially for therapeutic ultrasound transducer, focusing and enlarging of ultrasonic wave have special interest to achieve high intensity. As a promising candidates for micro/nano hybrid patterning process of function piezoelectric single crystal, ducitle mode machining process was

established and optimized. In this research, machinability of the relaxer based PMN-PT single crystal was investigated to achieve crack free cutting surface. Especially, effects of laser assisted cutting parameters were systematically investigated in the aspects of mechanical, chemical, crystallographic, and piezoelectric perspective. Based on the optimized process, crack-free high quality machined surface can be obtained with the roughness of 2.1 nm. Also, lens like curved structure was smoothly machined without showing any brittle crack defects. Fabricated structural PMN-PT single crystal was assembled as ultrasonic transducer and validated its ultrasonic transducer performance. Fabricated curved shape structure showed enhanced bandwidth properties which enable to achieve broad-bandwidth ultrasonic gas flow meter application. Based on established material processing technology, multi-scale patterning results will be presented for the advanced manipulation of ultrasonic wave.

8:00 PM EL06.07.02
High-Performance Transparent Radiative Cooling Integrated with Janus Emitter JunkyeongPark[1], DongwooChae[2], HeonLee[2] and JunsukRho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Passive daytime radiative cooling (PDRC) technology is a method that achieves cooling by reflecting incoming solar radiation and enhancing thermal radiation in the part of the atmosphere that allows radiation to pass through. Its ability to operate without consuming energy makes it a promising technology for future energy conservation, and it has gained significant interest in various research communities. In particular, the visible transparent radiative cooler offers advantages in a broad range of applications, including passive cooling for vehicles and buildings. In this study, we demonstrate the implementation of a high-performance transparent radiative cooler by attaching a broadband and selective emitter to both sides of the visible transparent film that blocks near-infrared (NIR) radiation. We conduct outdoor cooling experiments on the fabricated PDRC devices to demonstrate the cooling potential. This design not only achieves remarkable surface cooling but also provides space cooling when used as an energy-saving window. As a result, the proposed device can effectively counteract the greenhouse effect within enclosures while delivering surface cooling capabilities that are comparable to conventional radiative coolers.

8:00 PM EL06.07.03
Inverse-Designed Contact Lenses for Precise Correction of Color Vision Deficiency YeTian and JianfengZang; Huazhong University of Science and Technology, China

Color vision deficiency affects more than 300 million people on the earth. Although no radical cure for the disorder exists now, some specialized color filtering glasses/lenses have been used on color vision deficiency management. However, as color vision deficiency patients usually diversify on their classification and severity, none of current glasses/lenses provides customized correction for various color vision deficiency patients, resulting in undesirable correction effects.
Here we demonstrated the new inverse-designed contact lenses based on nanoparticles for precise correction of color vision deficiency. Firstly, due to the diverse severity of color vision deficiency patients, the wavelength shift (Δλ) of patient's abnormal photoreceptors was measured to inversely design the best blocking wavelength and blocking rate of our contact lenses. The customized contact lenses were then fabricated by adding silica-coated gold nanoparticles (Au@SiO2 nanoparticles) with appropriate sizes and concentrations to hydrogels or Polydimethylsiloxane (PDMS). Thus, contact lenses obtained a narrow optical absorption band due to the surface plasmonic resonance effect of the added Au@SiO2 nanoparticles. The effect of customized inverse-designed contact lenses was then verified by the simulated color vision and practical human tests.
In summary, inverse-designed contact lenses for color vision deficiency correction were developed and testified in this work. The proposed concept of this work may open avenues to precise color vision correction, optical metamaterials in the wearable device and medical field, thereby addressing the challenge and unmet needs for color vision deficiency management.

8:00 PM EL06.07.04
Polarimetric Study of an Embeddable, Flexible, Textile-Compatible Ferromagnetic Microfiber Platform SeokkeeMin[1], JosephPlumitallo[1], PetrMoroshkin[1], ZhengChen[2], RichardM. Osgood[3], IhsanUluturk[3] and JimmyXu[1]; [1]Brown University, United States; [2]Howletech, China; [3]U.S. Army DEVCOM SC, United States

In the information age, much effort and attention remain focused on the processing and transmission of information. Of equal importance is data acquisition and execution, which is made even greater with today's big data and AI. In this work, we present an embeddable, flexible, wearable, and scalable sensing and actuation platform for monitoring, communicating physical and chemical conditionals, as well as extracting/delivering molecular substances. The platform is based on a novel ferromagnetic microfiber and can be configured into various embedded structures such as 2D arrays and 3D stacked sheets,
It offers many degrees of freedom to exploit, such as electrical, magnetic, and optical activities. The microfiber itself consists of a 30 μm diameter conductive ferromagnetic alloy (CoFeSiB) core, encased in a 10 μm thick borosilicate glass (Schott Duran) shell. This choice of materials and feature sizes allows us to exploit magnetic and electrical degrees of freedom, and strong polarization dependent electromagnetic activity that can be embedded in coating layers, fabrics and textiles and then read-out and/or activated from remote, over a broad spectral band from RF to visible to deep infrared while maintaining flexibility, chemical stability, cost effectiveness, and manufacturing lengths up to kilometers. In addition to individual fibers or their random ensembles, we can also structure them into 2-/3-dimensional arrays of these fibers (e.g. photonic band-gap engineering) to exploit their collective optical activities or functionalities, which are therefore variable via their spacings, fillings, and externally applied electric and/or magnetic fields.
Applications of these tunable degrees of freedom include but are not limited to sensing, actuation, remote-tracking, and thermal property management. Some configurations would also allow for delivering payloads (e.g., drug) via inductive heating of the conductive ferromagnetic core combined with thermal expansion and the Laplace force.
As an example, we report on a polarimetric study of a 1-D array of parallel microfibers, embedded between two PET double-sided acrylic adhesive layers, that are invisible to human eyes and indiscernible by touch. A polarimetric reflectance spectra, however, can read out this array and determine its structure features (e.g. optical thickness, orientation, and effective spacing). The experiment was conducted over the 600~1750 nm spectral range with a polarized broadband (Halogen) light source. To isolate the optical activity of the fibers from their 'concealing cover' (PET), the normalized reflectance spectra was subtracted from a control spectra of the PET films. The resulting spectra revealed a polarization-dependent cavity effect. When the polarization was both parallel and rotated 45° counterclockwise to the longitudinal axis of the fibers, we observed a free spectral range of 7.14 THz (optical thickness ~21 μm). When the polarization was both orthogonal and rotated 45° clockwise from the longitudinal axis of the fibers, we observed a free spectral range of 7.89 THz (optical thickness ~19 μm). The measured effective optical thickness of the array is consistent to the ~200 μm periodic spacing of the array. But the polarization preference off of the principal axes is curious. One contributor is the anisotropy of the PET films, resulting from a residual strain from the rolling and pressing process during manufacturing. Since the fiber spectrum was isolated from the control, the measurements also suggest an additional and likely mesoscopic physical origin (e.g. the ferromagnetic alloy grain/domains). However, the current 1D ferromagnetic array at a layer thickness of 50 μm already shows promise for a wide range of sensing and photonic management applications.

8:00 PM EL06.07.05
Anisotropic Metamaterials for Elastic Wave Mode Conversion Over a Wide Incidence Angle Range JeseungLee, GihyunKim and Yoon YoungKim; Seoul National University, Korea (the Republic of)

The constitutive relation of an elastic medium requires a fourth-order elasticity tensor, leading to multi-modal characteristics in the elastic wave regime. As a result, elastic waves in solids carry not only longitudinal (pressure) but also transverse (shear) waves. This multi-modal characteristic complicates but enriches elastic wave phenomena, the most unique of which is the mode conversion between longitudinal and transverse waves. Early studies demonstrated that full-mode conversion between longitudinal and transverse waves could be realized by using anisotropic metamaterials with the non-zero mode coupling component in the elasticity tensor. However, the previously suggested anisotropic metamaterials for the mode conversion phenomenon operate only at normal incidence or oblique incidence with a specific incidence angle. Here, we present a novel anisotropic metamaterial with a spatially dispersive anisotropic tensor that converts longitudinal waves into transverse waves with high mode conversion efficiency over a wide range of incidence angles. The proposed anisotropic metamaterial was fabricated by drilling aperiodic holes with different sizes and angles in an isotropic base material. The mode conversion performance of the proposed anisotropic metamaterial was verified using ultrasonic-guided waves in aluminum plates.

8:00 PM EL06.07.06
Development, Fabrication and Characterization of Hyperbolic Flat Lensing in the X-Band using 3D Printing and Quasi-Conformal Transformation Optics AlexandrosCooke-Politikos, AndrewRittenberg, DanielMartin and BrianM. Wells; University of Hartford, United States

Transformation optics is a well-established technique that can be used to design many novel electromagnetic and optical devices; some include cloaking, integrated optical components, focusing devices, and antennas. The method relies on the form-invariance of Maxwell's equations under a spatial coordinate transformation. Consequently, this approach can be difficult to implement in fabrication due to the complex material properties imposed, often requiring anisotropic lossy metamaterials. In this work, we restrict the transformation to a quasi-conformal mapping, requiring only dielectric isotropic materials. This allows for flat lens designs with varying focal lengths and thicknesses to be fabricated through 3D printing, experimentally tested, and compared with FEM numerical simulations.

Various flat hyperbolic lenses with controlled thicknesses and focal lengths have been designed for fabrication and experimental characterization in the X-band microwave regime. Standard Polymaker PLA 3D-printer filament has been optically characterized, allowing the refractive index to be modeled as a function of infill percentage. Quasi-Conformal transformation optics is used to transform modeled hyperbolic canonical lenses of various focal lengths into a planar lens of controlled thickness with variable refractive index. The varying refractive index regions of the flat lens are controlled through the 3D-printed infill percentage. After FEM numerical simulations verify the desired optical properties of this transformation, the lenses are fabricated using

3D printing. Both the flat lens and hyperbolic lens are created for experimental comparison. It is verified through this process that these flat lens variants are in excellent agreement with the FEM simulations and the experimental results from their hyperbolic canonical lens counterparts.

8:00 PM EL06.07.07
High-Performance Confocal Piezoelectric Energy Harvesting using the Achromatic Elastic Lens GeonLee[1], JeonghoonPark[1], WonjaeChoi[2], BonggyuJi[2], MisoKim[3] and JunsukRho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

In this study, we present a novel and high-performance confocal piezoelectric energy harvesting system that overcomes limitations observed in previous energy harvesting platforms. These limitations include changes in coal position with operating frequencies and impedance mismatch caused by inclusions or holes. To address these challenges, we developed a Mikaelian lens-based piezoelectric energy harvesting platform with a gradually distributed refractive index profile. This platform leverages the self-focusing ability based on conformal mapping theory and the achromatic ability based on the Kirchhoff-Love thin plate theory. The proposed platform demonstrates exceptional elastic wave focusing capabilities. Through the experimental validation, we achieved highly amplified output electrical power up to 1.44 mW within the frequency range of 40 kHz to 60 kHz, originating from confined elastic wave energy. Notably, the output electrical power extracted at the confocal position was up to 3.76 times higher than that extracted at the lens's input position. This highlights the effectiveness of our broadband achromatic piezoelectric energy harvesting platform. The remarkable performance and broad applicability of our platform lay a solid foundation for potential applications in wireless sensing, structural health monitoring, and biomedical devices.

8:00 PM EL06.07.08
Near-Infrared Signal-Based Sensor Platform with Wireless Data Transmission System for Accurate Detection of Infectious Disease Virus SuyeonKim, EunyoungJeon, SunghyunPark and JoonseokLee; Hanyang University, Korea (the Republic of)

Luminescent nanomaterial-based Lateral flow immunoassay (LFA) is widely used in on-site detection of infectious virus. Foot-and-mouth disease virus (FMDV) is a highly contagious infectious disease virus that can be spread over long distanced in the air. The keys for reducing the risk of infectious disease spread and economic damage are; 1) rapid and sensitive on-site detection, and 2) real-time surveillance and remote monitoring in the field. However, on-site saliva samples from livestock are considerably opaque due to the high levels of contaminants and biological components such as food, feces, soil, and blood. These interfering agents in clinical saliva samples interfere with the detection of colorimetric signals of LFA by the naked eye. Commercial gold nanoparticle-based LFA, whose excitation and emission are located in the visible region, is limited in their low sensitivity affected by the background interference in the opaque sample. Here, we report a high sensitive detection of FMDVs in clinical samples and the wireless monitoring system of FMD's outbreak. We introduced near-infrared (NIR)-to-NIR upconversion nanoparticles (UCNPs) as a nanoprobe of the LFA platform for background-free sensitive detection of FMDV. The NIR-to-NIR UCNPs are effective in minimizing the interference noise of opaque biological samples because the interfering agents in the samples have low autofluorescence, scattering, and absorption within the NIR window. This NIR-to-NIR nanoprobe shows stable emission intensity at 800 nm without being disturbed by interfering agents under 980 nm excitation. The sensitivity of LFA assembled with NIR-to-NIR nanoprobe (denoted as NIR signal LFA) was improved in opaque clinical samples. The NIR signal LFA has 32-fold lower limit of detection (LOD) compared to a commercial gold nanoparticle-based FMDV LFA for assay using live FMDVs for all 7 serotypes. 148 clinical samples including saliva and vesicular fluid samples were used to validate the sensing performance of NIR signal LFA for FMDVs. The NIR signal LFA successfully detected FMDVs in clinical samples with a high sensitivity of 96.9%, and a specificity of 100.0%. In addition, information such as virus-detection results and infection location were successfully stored and transmitted in real-time through an online server. The developed platform is promising for establishing a quarantine linkage system that can effectively prevent and control the spread of FMDV at an early stage.

8:00 PM EL06.07.09
A Local Water Molecular-Heating Strategy for NIR Long-Lifetime Imaging-Guided Photothermal Therapy of Deep-Tissue-Bearing Tumor DongkyuKang, HyungshikKim, InaeLee, DongyunLee and JoonseokLee; Hanyang University, Korea (the Republic of)

1.0 μm near-infrared (NIR) is considered unsuitable as an imaging and analytical signal in biological environments owing to the strong absorption of water at around the regions. However, the 1.0 μm NIR can be converted to heat and used as a local water-molecular heating strategy for photothermal therapy of biological tissues. Herein, we designed a we developed Nd-sensitized 1.0 μm emissive core@shell NPs ($NaYF_4$:50%Yb@$NaYF_4$:40%Nd,20%Yb, denoted as water-heating NPs) as a local water-molecular heating material as a strong 1.0 μm emissive NP to target the absorption band of water. Especially, the strong energy absorption coefficient derived from the overtones and the stretching vibrations of O–H oscillators matches the emission spectrum of water-heating NPs. Furthermore, introducing Tm ions into the water-heating NPs enabled the NIR lifetime, and it was developed as an NIR imaging-guided water-heating probe (water-heating NIR NPs). In the glioblastoma multiforme (GBM) mouse model, tumor-targeted water-heating NIR NPs reduced the tumor volume by 78.9% in the presence of high-resolution intracranial NIR long-lifetime imaging. Hence, water-heating NIR NPs can be used as a novel nanomaterial for imaging and photothermal ablation in deep-tissue-bearing tumor therapy.

8:00 PM EL06.07.10
Enhanced Thermoelectric Properties of $Bi_{0.4}Sb_{1.6}Te_3$ Through the Decoration of SnO_2 Nanoparticles SungWookYe[1], JeongminKim[2], SehoonSeo[1], Dae-HwangYoo[1] and JongWookRoh[1]; [1]Kyungpook National University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Thermoelectric energy harvesting has emerged as a promising solution to mitigate global climate change by enabling the conversion of waste heat into electricity. The efficiency of thermoelectric devices relies heavily on the performance of thermoelectric materials, evaluated through the thermoelectric figure of merit (ZT). ZT is defined as $ZT = S^2\sigma T/\kappa$, where S, σ, T, and κ represent the Seebeck coefficient, electrical conductivity, absolute temperature, and thermal conductivity, respectively. To achieve high ZT values, thermoelectric materials must exhibit high σ and S values while minimizing κ, particularly κ_{ele} and κ_{lat}. However, independently controlling these parameters is challenging, making simultaneous optimization of these thermoelectric properties difficult.
Numerous studies over the past few decades have focused on enhancing the power factor (σS^2) by manipulating carrier density or conducting band engineering. Additionally, reducing κ_{lat} through nanostructuring or maximizing phonon scattering has been explored to achieve low thermal conductivity. Among various thermoeletric materials, $Bi_{0.4}Sb_{1.6}Te_3$ (BST) stands out as a material capable of converting temperature differences into electricity. Consequently, BST-based alloys have been investigated to improve thermoelectric performance by incorporating other materials as nanoparticles, aiming to increase the power factor and decrease thermal conductivity. However, the trade-off relationship between electrical and thermal properties presents challenges in simultaneous control.
To overcome this trade-off, we propose a novel approach called the metallization of surface reduction nanoparticle method. This method enables independent control of electrical and thermal properties, offering enhanced stability in the interface between the base material and the surface. SnO_2, a typical n-type semiconducting oxide, exhibits unconventional behavior due to disruptions in the stoichiometric ratio of tin and oxygen caused by interstitial Sn atoms or O vacancies. The reduction reaction from the surface allows the existing base material (SnO_2) to form crystals without surface amorphousness, facilitating sequential arragement (SnO_2 - SnO_x - Sn rich) from SnO_2 (in the core) to metallic Sn (on the surface).
Based on this principle, we fabricate n-type SnO_2-decorated BST alloys using a combination of microwave irradiation, ball milling, and spark plasma sintering processes. These processes prevent the synthesis of SnO_2 nanoparticles with other elements from BST, enabling the decoration of pure SnO_2 nanoparticles onto the surface of the BST matrix (BST_SnO_2). We confirm the presence of approximately 100nm-sized SnO_2 nanoparticles as a secondary phase on the BST matrix, exhibiting excellent dispersion. By decorating the surface with SnO_2 nanoparticles, the average thermoelectric figure of merit (ZT) improves from 0.78 to 1.24 at 400K. The observed enhancement in thermoelectric performance can be attributed to two primary factors. Firstly, in terms of electrical properties, the power factor improves due to a slight reduction in electrical conductivity and a significant increase in the Seebeck coefficient. Secondly, in terms of thermal properties, the total thermal conductivity experiences a slight reduction due to the reduced electrcial thermal conductivity and the suppression of bipolar thermal conductivity.

8:00 PM EL06.07.11
Photonic Surface Energy Modification for Enhanced Flexible Substrate in Printed Electronics MohamadTaherian[1], ArjunWadhwa[2], KrunalShah[2], Francois-XavierFortier[2], SylvainG. Cloutier[2] and MartinBolduc[1]; [1]Université du Québec à Trois-Rivières, Canada; [2]École de Technologie Supérieure, Canada

This paper presents a comparative study on surface energy modulation to enable new types of enhanced surfaces from flexible polyimide that is necessary in printed electronics. The survey conducted in this research work focused on the impact of the surface structure modification on the surface energy of polyimide flexible substrates, which was measured through contact angle analysis using a calibration method from different liquids. We employed three distinct methods for the surface modification : from controlled mechanical abrasion with various sandpaper grit values to finer photonic irradiation methods using Laser-induced Periodic Surface Structures (LIPSSs) and Intense Pulse Light (IPL) with a sacrificial ceramic layer. The results revealed that these surface structure modifications had significant effects on the surface energy value, leading to improved wet-ability and adhesion strength. In addition, we found that optimizing surface energy values of the substrate to the proper printing ink is crucial, especially at the early stage of the printing work. The photonic process is shown to enable the control of surface structures size and periodicity, which provide control on ink spreading and allow an adequate interfacial bonding during printing. These findings bring valuable insights into the optimization of flexible substrates for printed electronics, offering higher performance and expanding the potential applications in this rapidly evolving field.

8:00 PM EL06.07.12

Modeling Vapor Transport in Nanoporous Materials for Solar-Interfacial Evaporating Materials JamesH. Zhang, RohithMittapally, GuangxinLv and GangChen; Massachusetts Institute of Technology, United States

Fresh water scarcity is a growing challenge for many communities due to global warming. Solar desalination by direct evaporation is an attractive method to produce fresh water from brackish sources due to its simplicity and low capital costs. Many research groups have shown solar evaporation rates beyond the thermal limit by using porous materials that can efficiently utilize solar energy to evaporate water from its capillary pores. Although a lot of research has been focused on the material's development side, there is insufficient understanding on the heat and mass transport inside of the porous materials and how the internal geometry can be optimized to maximize evaporation into the ambient. In this work, a heat and mass transport model is proposed to understand the evaporation process inside of materials with microchannels surrounded by nanoporous walls. Results are compared with experimental studies on solar-interfacial evaporation from porous materials to show how this model can be used to optimize the material properties for solar desalination.

8:00 PM EL06.07.13
Highly Transmissive Scalable Colored Silica Nanoparticle Coatings for Photovoltaic Panels AkbarSyed[1], ClarkBoyd[2] and HaniElsayed-Ali[1]; [1]Old Dominion University, United States; [2]Evergreen Technologies, United States

Large area highly transmissive colored coatings were fabricated by roll coating of SiO_2 nanoparticles on glass substrates and on the photovoltaic cell glass covers. This coating is to maintain an attractive color appearance of the exterior surface for architecturally integrated photovoltaics and can be coated on fabricated photovoltaic panels. These nanoparticles form ordered layers with thickness that can be controlled from one layer of nanoparticles to several layers. The color and optical properties of the nanoparticle coating was investigated for different SiO_2 nanoparticles with diameters of 200, 300, and 400 nm, which showed blue, pink, and green colors, respectively. Multilayer coatings of the nanoparticles coated on polycrystalline silicon solar cells provided blue, pink, and green colors with solar cell power loss of 5.47 %, 15.61 %, and 10.73 % for the 200, 300, and 400 nm, respectively. Single-layers act as an antireflection coating enhancing solar cell power without a noticeable change in solar cell appearance. Power gain of 3.39 % and 3.21 % is observed for single-later of 200 and 400 nm nanoparticles, respectively.

8:00 PM EL06.07.14
Thermal Radiative Switching Interface for Energy-Efficient Temperature Control XuanjieWang[1] and ShankarNarayan[2]; [1]Massachusetts Institute of Technology, United States; [2]Rensselaer Polytechnic Institute, United States

Materials with dynamically switchable optical properties can modulate their interaction with sunlight, poten- tially saving significant energy for heating and air-conditioning if used as building exteriors. This study proposes a new technique for solar-thermal regulation using porous polytetrafluoroethylene (PTFE) layers integrated with a spectrally-selective absorber (PTFE-SS). This multilayered structure can provide tunable optical properties by wetting or dewetting the porous PTFE with a refractive index-matching liquid, allowing a highly reversible change in solar transmittance of 0.62. This variation allows the multilayered structure to switch between highly reflecting and absorbing states that is tunable using different PTFE thicknesses. With this multilayered structure as building exteriors, sunlight can be reflected or absorbed to reduce dependence on conventional heating and cooling systems driven by non-renewable primary energy sources. When exposed to 1 sun illumination under ideal conditions, this variation allows a 51 °C change in PTFE-SS steady temperatures. When applied to buildings as roofing materials, the PTFE-SS promises significant energy reduction with annual cooling and heating savings of around 77% and 27%, respectively. Hence, the proposed PTFE-SS structure presents a new paradigm for passive thermal management of buildings by controlling their interaction with sunlight and decreasing our dependence on fossil fuels.

Plasmonic Controlled Nonreciprocal Transmission of Ultrasonic Waves in an Acoustic Meta-Atom ArupNeogi[1,2], JiaxinWang[1], YuqiJin[2], TengYang[2], ZhimingWang[1] and TaeChoi[2]; [1]University of Electronic Science and Technology of China, China; [2]University of North Texas, United States

Controlling the direction of energy flow in a matter-wave or vibrational mode of oscillation is challenging compared to electrons or electromagnetic waves. Vibrational or acoustic waves are dominantly longitudinal in nature and are not directly influenced by electric, magnetic, or electromagnetic fields. Effective control of the directionality of sound wave propagation and reversing the flow of energy can yield acoustic isolators, diodes, or rectifiers. Current nonreciprocal techniques use complex metamaterial systems or require large mechanical pumps for physical actuation of the medium to break the time-symmetry or require asymmetric structures that induce dissipation. The mechanical actuation process is also slow and cannot be precisely controlled. A new class of acoustic meta-atom-based laser-driven nonreciprocal acoustic devices is demonstrated. Novel light-controlled techniques are used to control the nonreciprocal transmission of sound waves. A photoacoustic or magneto-optical pump based on nanophotonic principles has been used to control fluid flow within meta-atom in the form of a ring resonator or linear Bragg cavity. Instead of mechanical actuation and flow pumps, a non-contact laser and or magnetic force field are applied for remote control of the acoustic energy to modulate the direction of the acoustic wave propagation transmitted through the fluid medium.
In the first case, a fluid-filled acoustic meta-atom cavity in the form of a 2cm diameter ring resonator was designed using 3D printing to confine acoustic modes excited by an external transducer as a probe wave. A photo-elastic process induced by lasers resonant to the plasmon frequency of Au-implanted quart windows can induce pump ultrasonic waves within this meta-atom cavity. The plasmonic window was fabricated using metal-ion implantation or photo-thermal evaporation of metal to form plasmonic nanoparticles resonant to a 532nm laser source. The photo-elastic effect also acts as a fluid pump and induces an active motion of the fluidic medium within the cavity. The ponderomotive forces can drive the fluid within the meta-atom cavity that can either co-propagate or counter-propagate with acoustic waves in the cavity. The fluid motion within the cavity and the wave mixing between the laser-induced pump waves and the external probe waves can result in a nonreciprocal or unidirectional transmission of sound waves within the acoustic cavity. A fluid flow as fast as 6 cm/s was generated that can induce a nonlinear wave mixing and active motion for T-symmetry violation resulting in nonreciprocal wave transmission within the meta-atom resonator. A large nonreciprocity exceeding 25dB was observed. An optically controlled acoustic diode operation was realized and the transmission of the acoustic wave can be biased using the laser intensity. In the second case, a DBR cavity-like device design was used to demonstrate magneto-optically controlled acoustic nonreciprocity. In this case, a magneto-caloric force based on the temperature-dependent magnetization of the ferrofluid was used to drive the fluid in the presence of a magnetic field. Acoustic isolation due to nonreciprocity as large as 20dB was realized which can be controlled by the magnetic field strength and the laser intensity.
We used theoretical analysis, and numerical simulation for the design of additively manufactured ultrasonic devices which were then characterized using ultrasonic spectroscopy for the study of nonreciprocal acoustic wave transmission. Quantum optical effects such as Zeeman-like and Optical Stark-like effects on acoustic states have been observed. Ultrasonic spectroscopy characterized the optically driven diode and the isolator. This work is the first report on the realization of laser and magneto-optical control of ultrasonic acoustic diodes and isolators in a compact fluidic medium.

Micro-Structured Heat Exchangers for Energy-Efficient Control of Temperature and Humidity RohithMittapally, YaodongTu, JamesH. Zhang and GangChen; Massachusetts Institute of Technology, United States

As the climate extremities continue to rise, the demand for air-conditioning (AC) is expected to increase 3-fold in a few decades[1]. To reduce the carbon-footprint of AC systems, it is necessary to make them more efficient. The conventional vapor-compression systems over-cool the process air for dehumidification, resulting in a low coefficient of performance (COP). Incorporating liquid desiccants into these systems can improve the COP by 2-fold[2]. Recent efforts in this direction have resulted in efficient AC systems, but these large-scale demonstrations are not readily suitable for residential applications. Here, I will discuss the development of a heat exchanger with simultaneous heat and mass transfer characteristics, which can improve the efficiency of residential AC systems. In specific, the designed heat exchanger exhibits faster absorption-desorption kinetics with negligible carry-over of a liquid desiccant into the process air. In this talk, I will first discuss the fabrication of the heat exchanger and describe the development of a test chamber to characterize its performance. Our preliminary experiments on individual fins indicate an efficient moisture control at adsorption rates faster than state-of-the-art systems. Further, I will discuss a theoretical model that can predict the experimentally observed heat and mass transfer dynamics. Finally, I will discuss our efforts at scaling these techniques for low-cost mass production of heat exchangers for an efficient AC cycle.

Broadband Nanophotonics: From Theory to Application AaswathP. Raman; University of California, Los Angeles, United States

While many applications of nanophotonic structures are geared towards narrow bandwidth applications, over the past decade there has been significant interest in better controlling the flows of broad spectrum light. From thermal imaging to solar cells and radiative cooling, interacting with broad spectrum light imposes numerous demands on nanophotonic structures and devices. In this talk we will introduce theoretical, computational and experimental demonstrations of the exceptional control and performance possible when optimizing for broadband applications. We will introduce approaches to enhance both transmissive and reflective optical components for thermal imaging, making use of resonant metasurfaces that enable high transmission through Silicon over infrared wavelengths, and a plasmonic reflective filter using a low-cost, solution-processed approach for a reflective optic. We will next explore machine learning approaches to optimizing broad spectral responses, and highlight how a multiscale approach to controlling broad spectrum emissivity is possible even in ultralight photonic structures that might be used for aerospace applications. Finally, we will introduce a coupled mode theory framework capable of accurately modeling multi-resonant systems that can control broad spectrum thermal emission from a bottom-up perspective.

8:45 AM EL06.08.02
Ultrafast Energy Transfer from Plasmonic Hot Carriers: Disentangling Injection Mechanisms in Pulsed Photocatalysis AndreaSchirato[1,2,3], StephenK. Sanders[3], RemoProietti Zaccaria[2,4], PeterNordlander[3,3], GiuseppeDella Valle[1,5] and AlessandroAlabastri[3,1]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Rice University, United States; [4]Chinese Academy of Science, China; [5]Consiglio Nazionale delle Ricerche, Italy

Photocatalysis involves capturing energy from light to initialise and promote chemical reactions of industrial and environmental relevance. In the process, the photocatalyst absorbs and converts photons into charge carriers, driving thermodynamically favourable and non-spontaneous reactions. Since, as for natural photosynthesis, sunlight can be used, photocatalysis represents an attractive sustainable alternative to current chemical industrial processes, which often require intensive energy input, are fed by non-renewable sources and operate at high temperatures and pressures. In this framework, increasing attention has been drawn to plasmonic photothermal catalysis, offering opportunities for light-driven reactions under substantially milder conditions. At the interface between chemistry, nanophotonics and thermodynamics, this approach relies on plasmonic nanostructures and their peculiar optical properties. These nanostructured metallic materials couple strongly to light and support resonant oscillations of their free electrons, known as Localized Surface Plasmons. Their ability to concentrate electromagnetic visible radiation, excite highly energetic (hot) carriers, and locally convert their excess energy into heat via ultrafast non-radiative relaxation processes has made them crucial in various applications. In the context of catalysis, strong interaction between light and plasmonic nano- and metastructures (especially metasurfaces) provides the energy needed for photocatalytic conversion, and photoexcited nanoparticles can alter chemical reactions through both thermal and non-thermal pathways, close to the thermodynamic limit.

Among the mechanisms involved in photocatalysis, the hot carrier contribution is at the same time the most intriguing, as it leads to unique phenomena (e.g., changes in energy barriers for certain reactions) and the most challenging to control, mainly due to the carrier internal relaxation (which, on ultrafast timescales, brings them back to equilibrium). While promising advances have been reported on the carrier generation and ultrafast dynamics, a comprehensive theoretical description of their behaviour when interacting with nearby chemical species is missing. This is pivotal towards the accurate modelling of the energy harvesting from light to catalyse chemical transformations.

Here, we propose a novel approach to model the ultrafast dynamics and ensuing effects of hot carriers across extended plasmonic nanostructures in the presence of adsorbed molecules resonantly accepting energy from the photoexcited electrons. For that, we develop a numerical platform based on a rate-equation model of the excitation/relaxation of nonequilibrium carriers, where the injection of electrons to the molecule acts as an extra decay channel. Our approach combines the well-established quantum description of inelastic electron scattering with ‘hot’ adsorbate (generating transient negative ions) with a thermodynamics-like formalism (approximating the Boltzmann equation) for nonequilibrium electrons in metals. This results in a compact model enabling us to track over time and space, with a resolution of les than 1 fs and a few nm across nanostructures/meta-atoms of hundreds of nm, the evolution of the electronic energies in the metal upon pulsed illumination. The accurate modelling of the carrier spatio-temporal dynamics unlocks relevant information, e.g., reaction rates and quantum yields. Furthermore, with this model, we are able to disentangle the contributions arising from thermal effects and charge injection, and to quantify the impact of input variables such as pulse fluence and duration, photon energy, nanostructure dimension and shape. Our results are a promising step towards the design of photocatalytic platforms with enhanced electronic and thermal effects and provide a comprehensive, predictive approach suitable for directly comparing theory and experiments.

9:00 AM *EL06.08.03
Designing Chemical Reactivity in Plasmonic Nanogaps ReginaRagan; University of California, Irvine, United States

I will present data on vibrational spectroscopy alongside state-of-the-art computational methods to ‘visualize’ chemical reactions in plasmonic nanogaps in order to understand physical and chemical cues governing reactions between functional groups on molecules. An experimental platform, using electrohydrodynamic (EHD) flow, which produces flow fields in solution with components parallel to an electrode surface in the presence of a perturbation, is used to facilitate interactions between plasmonic nanoparticles (NP). Au NP from colloid are first deposited using electrophoresis to seed EHD flow on a working electrode patterned with polystyrene-*block*-poly(methyl methacrylate) (PS-b-PMMA) copolymer. Au NP with ligands having carboxylic acid functional groups attach to ethylenediamine functionalized PMMA domains using carbodiimide coupling chemistry. After, an AC potential with a bias of 10 V_{pp} is applied resulting in EHD flow around Au NP seeds. Electron microscopy analysis of clusters chemically crosslinked during assembly shows deposition with a potential having an amplitude of 5 V and frequency of 500 Hz produces surfaces with a high density of Au NP trimers with 1 nm gap spacings controlled by crosslinking chemistry.

We have monitored crosslinking reactions between Au seeds and Au NPs deposited using EHD flow using surface-enhanced Raman scattering (SERS) *in situ*. Au NP functionalized with either lipoic acid, 4-mercaptophenylacetic acid and 4-mercaptobenzoic acid ligands may form anhydride bridges using carbodiimide crosslinking chemistry and reactivity appears governed by the proximity between the reactive carbon atom in the *O*-acylisourea intermediate and the deprotonated oxygen atom from molecular dynamics simulations. Comparing experimental spectra with that simulated using density functional theory simulations indicate that chemical reactions within nanogaps are promoted by the confined geometry, i.e., entropically driven sampling of molecular conformations in nanogaps leads to reactions. Reactions do not occur in the absence of EHD flow; the long range EHD driving force allows chemical reactions with high activation energy barriers to proceed in observable time frames. The temporal evolution of an acetylation reaction between analytes and anhydride bonds in plasmonic nanogaps will also be presented. Control of nanogap spacing and surface chemistry in plasmonic hotspots has numerous applications including molecular sensors, non-linear optics, and photocatalysis.

9:30 AM EL06.08.04
3D Interconnected Nanowire Scaffoldings that Increase the Thermoelectric Efficiency in Comparison to Similar Diameter 1D Nanowires MarisolMartin-Gonzalez[1], AlejandraRuiz de Clavijo[1], NicolasPerez[2], OlgaCaballero[1], KorneliusNielsch[2], FrancescaPeiró[3] and SegiPlana[3]; [1]Inst de Micro y Nanotecnologia, Spain; [2]Ifw Dresden, Germany; [3]Universidad de Barcelona, Spain

We will present how 3D interconnected nanowire scaffoldings can increase the thermoelectric efficiency in comparison to similar diameter 1D nanowires and films grown under similar electrodeposition conditions. Bi_2Te_3 3D nanonetworks offer a reduction in thermal conductivity (κT) while preserving the high electrical conductivity of the films. The reduction in κT is modeled using the hydrodynamic heat transport equation, and it can be understood as a heat viscosity effect due to the 3D nanostructuration or to additional scattering centers. The Seebeck coefficient is twice that of nanowires and films, and up to 50% higher than in a single crystal. This increase is interpreted as a nonequilibrium effect that the geometry of the structure induces on the distribution function of the phonons, producing an enhanced phonon drag. These thermoelectric metamaterials have higher performance and are fabricated with large areas by a cost-effective method, which makes them suitable for up-scale production. Other studies have also explored the transport properties of Bi_2Te_3 nanowires, including low temperature magnetoresistance measurements and local magnetic suppression of topological surface states. The crystalline structure and composition of the 3D Bi_2Te_3 nanowire network can be finely tuned by controlling the applied voltage and the relaxation. These findings have important implications for the development of macroscopic nanostructured thermoelectric materials based on scalable fabrication processes that could be directly integrated into devices.The study of the localization and directionality of electron transport in Bi_2Te_3 ordered 3D nano-networks is a fascinating area of research. In this study, the resistance of an ordered 3D-Bi_2Te_3 nanowire nano-networks were analyzed at low temperatures, and the increase in resistance below 50 K was found to be compatible with the Anderson model for localization.
The angle-dependent magnetoresistance measurements showed a unique weak anti-localization characteristic with a double feature, which could be associated with transport along two perpendicular directions dictated by the spatial arrangement of the nanowires. The coherence length obtained from the HLN model was about 700 nm across transversal nanowires, corresponding to approximately 10 nanowire junctions. The observed localization effects could be the reason for the enhancement of the Seebeck coefficient observed in the 3D-Bi2Te3 nanowire nano-network compared to individual nanowires. This research has important implications for the development of macroscopic nanostructured thermoelectric materials based on scalable fabrication processes that could be directly integrated into devices.

Acoustic Metamaterials at the Microscale RachelSun, YunKai and CarlosM. Portela; Massachusetts Institute of Technology, United States

Micro-architected materials allow for tunability of extreme static mechanical properties such as stiffness, Poisson's ratio, or strength. However, dynamic and acoustic properties of micro-architected materials remain largely unexplored, partially because it is challenging to measure their response at these scales. Dispersion resulting from Bragg scattering occurs at wavelengths which are dictated by the characteristic dimensions of the metamaterials, while local resonance remains wavelength-independent. Therefore, micro-architected materials have the potential to allow control of mechanical waves both at high (MHz) and medium-range (kHz) frequencies.

Here, we design, fabricate, and characterize micro-architected materials with tunable mechanical and acoustic properties in the megahertz regime. Using a two-photon lithography prototyping method, we explore the response of a class of architected material morphologies with varied mass distribution, features down to ~1.5 µm, and unit cell sizes of 15 µm. We demonstrate that decoupling mass and stiffness by strategically placing micro-inertia affects the effective stiffness scaling of this class of acoustic metamaterials at the microscale. We present novel measurement techniques for wave velocity of three-dimensional architected materials that employ laser-ultrasonic principles, demonstrating a tunable range of wave velocities around 1000 m/s for different designs in a wide range of relative densities. We then validate their acoustic response numerically with Bloch wave analysis to determine their dispersion relation and rod-wave velocities. Our results provide a baseline to map the tunable acoustic metamaterial design space at the microscale and megahertz regime. These materials could have important implications in acoustic devices in microelectromechanical systems, biomedical imaging, and microscale waveguides.

10:30 AM EL06.08.06
Mechanical Metamaterials Enabling Knudsen-Pump-Based Propulsion for Novel Sensor-Based Mesosphere Exploration ThomasCelenza, AndyEskenazi, ZhipengLu, LorenzoYao-Bate and IgorBargatin; University of Pennsylvania, United States

We propose a novel flight mechanism powered solely by light, with no moving parts, capable of photophoretically levitating metamaterials with kilogram-scale payloads. The ability to study certain atmospheric regions, such as the mesosphere, is hindered by current propulsion methods. The urgency to address climate change makes learning about all layers of the atmosphere imperative. For example, carbon dioxide in the mesosphere is critical due to its cooling effect, a crucial factor in climate prediction models [1]. Unfortunately, recording atmospheric data in the mesosphere is challenging due to air pressures that are too low for aerodynamic plane or balloon flight and too high for satellites. Developing an airborne platform operating in a low-density, low-pressure atmosphere on Earth for gathering atmospheric data related to wind patterns, temperature, pressure variations, and gas concentrations would be tremendous. Our proposed solution leverages the mesosphere environment through architected metamaterials to generate a high-speed gas jet due to Knudsen pumping [2], allowing controllable lift.

Nanocardboard, the metamaterial that achieved photophoretic flight, was created for tuning material properties such as increased bending stiffness and strength, shape recovery capabilities, and weight reduction [3]. Nanocardboard is a microfabricated analog of sandwich composites (like cardboard), made of Al_2O_3. The structure consists of 0.1-micron face sheets on top and bottom, connected by several micron tall hollow rectangular channels, giving an area density of approximately 1 g/m^2. For our purposes, we coated 1-cm wide nanocardboard plates with carbon nanotubes (CNTs). Due to the Al_2O_3 being an exceptional thermal insulator, a temperature difference between the top and bottom of the plates is introduced, given that CNTs absorb light and heat up. This temperature difference drives air through the channels and creates a lift force due to the Knudsen-pumping effect. Optimal at mesosphere air pressures, this phenomenon is known as photophoretic levitation. However, with such small plates, the experimentally recorded lift force is only a few milligrams [4]. Photophoretic levitation is not new for macroscale objects, but increasing payloads becomes more interesting.

Hence, we created a MATLAB model to scale the photophoretic force, employing nanocardboard on a large scale, simulating 3D structures with dimensions of tens of meters. The geometries included spheres, rockets, and cones, made of nanocardboard, with CNTs on the inner walls. When illuminated, CNTs heat up to Knudsen-pump air into the hollow inner chamber and out of a nozzle to create jet velocities, increasing lift. The model considers flight altitudes from sea level to 80 km in the atmosphere. We analytically solved a heat transfer system to calculate the temperature inside the structure. When the CNTs heat up, they heat the surrounding air in the inner chamber, decreasing its density and creating a buoyancy force. This solar buoyancy regime loses significance as the photophoretic regime starts dominating around 40 km, where balloons can no longer fly. We calculate the overall lift force from a characteristic equation discovered in our previous work [5] combined with the solar buoyant force. The results show a several-kg payload for a 30-meter radius spherical structure, which is comfortably sufficient to carry atmospheric data sensors like GPS and thermocouples from sea level to 80 km. These structures present brand-new flight mechanisms in the mesosphere, enabled by the unique mechanical and thermal properties of the nanocardboard metamaterial.

10:45 AM EL06.08.07
Laser-Based Ultrasound Spectroscopy for Characterization of Mechanical Metamaterials YunKai, ThomasPezeril and CarlosM. Portela; Massachusetts Institute of Technology, United States

Mechanical metamaterials, possessing custom-designed 3D structures at the nano- to microscale, exhibit exceptional properties that surpass those of their constituent materials. These structures unveil a diverse mechanical property landscape. Previous studies relied primarily on contact-based methods for mechanical characterization, such as nanoindentation, extracting static properties like stiffness and strength. These techniques often necessitate laborious sample preparation or specialized sample designs. There is a need for time-resolved characterization techniques to accelerate the process of characterizing the mechanical behavior of metamaterials and broaden our understanding of their dynamic response.
We present a characterization method for metamaterials that allows us to capture their effective dynamic elastic constants and linear dynamic response in a reliable and iterative manner. We fabricate architected materials using two-photon lithography with feature sizes on the order of ~1 µm and unit cells on the order of 10 µm. We employ a laser ultrasonic scheme to determine their effective elastic properties to excite elastic waves within the materials. We utilize a common-path interferometric setup to register the sample eigenvibrations. We experimentally reconstruct partial dispersion relations and attenuation properties of the 3D micro-architected materials, present their fully experimental dynamic elastic surfaces, and demonstrate the potential to use dynamic responses to identify defects in these materials. We validate this technique using a variety of 3D architectures along various crystallographic orientations. The field of mechanical metamaterials is in need of novel characterization techniques since, at this point, the design of new metamaterials has significantly outpaced efforts to construct structure-property relations. Our work addresses this need and provides a route for the accelerated data-driven discovery of materials and microdevices for dynamic applications such as protective structures, medical ultrasound, or vibration isolation.

11:00 AM EL06.08.08
Frequency Responsive Metamaterials for Contactless Acoustic Manipulation SamKeller, MatthewStein, YujieLuo and OgnjenIlic; University of Minnesota-Twin Cities, United States

The radiation pressure of waves—such as acoustic waves or electromagnetic waves—enables mechanisms for entirely contactless actuation of objects with relevance spanning materials assembly, bioengineering and biomedicine, and imaging and sensing. However, the ability to control such motions is substantially limited by the way conventional objects scatter waves. For instance, acoustic actuation is often restricted to small (subwavelength) objects or objects with specific symmetries where actuating energy potentials are easy to create. Additionally, this form of contactless manipulation often features single-task devices that can only produce a single dynamic response. Here, we show how such wave force limitations can be overcome by embedding subwavelength metasurface patterns to alter the acoustic momentum of inaudible ultrasonic fields locally. Consequently, these metasurfaces can facilitate precise control of local acoustic forces independent of the size or shape of the object. We present the theory, modeling, and experiments to support the development of metasurfaces exhibiting novel dynamical behaviors, such as self-guiding metasurfaces and frequency-responsive metasurfaces. We survey several families of metasurface topologies and compare their advantages and limitations for contactless actuation. Additionally, we discuss the benefits and tradeoffs associated with ultralightweight acoustic metasurfaces. Our findings present a new approach to controlling radiation pressure forces and achieving dynamic behaviors that go beyond the limitations of traditional wave-matter interactions.

1:30 PM *EL06.10.01
Bound States in the Continuum in Dielectric and Plasmonic Metasurfaces: From Optofluidics to Thermal Emission Engineering JustusC. Ndukaife, SenYang, GuodongZhu and IkjunHong; Vanderbilt University, United States

Recently, the concept of bound states in the continuum (BICs) has emerged as a promising approach to achieve sharp spectral resonances and strong electromagnetic field enhancements in plasmonic and dielectric metasurfaces. BICs represent eigenmodes that exist above the light cone but remain decoupled from the radiation continuum of free space. While true BICs, are completely invisible in the radiation spectrum and inaccessible, perturbations can lead to quasi-BIC modes characterized by a sharp spectrum peak and a finite quality factor (Q). In the first part of my talk, I will discuss the utilization of quasi-BIC modes to enable optofluidic control in all-dielectric metasurfaces. By exciting BIC modes, we can significantly enhance the speed of particle transport and assembly. The high-Q nature of quasi-BICs allows for precise tuning of particle assembly by adjusting the wavelength within a narrow spectral range. This enhanced optofluidic control enabled by quasi-BICs holds great potential for lab-on-chip applications, including analyte enrichment for sensing, on-chip mixing, and reconfigurable optically-active colloidal assembly. Moving on to the second part of my talk, I will introduce the use of plasmonic quasi-BICs for engineering thermal emission. Additionally, I will present a slotted quasi-BIC metasurface design that further enhances the quality factor of thermal quasi-BIC metasurfaces. Our numerical simulations demonstrate an ultra-narrowband emission peak with a Q factor of approximately 64 and near-unity absorptance over a broad band spanning more than 10 μm. By symmetrically introducing air slots, the Q factor can be further increased to around 100. Importantly, our experimental measurements confirm the remarkable stability of the resonance frequency in the face of temperature fluctuations. This research showcases the potential of plasmonic quasi-BICs in the design of ultra-narrowband thermal emitters that remain insensitive to temperature changes in the mid-infrared range. Furthermore, this concept can be readily adapted to other frequency ranges, such as near-infrared, Terahertz, and Gigahertz.

2:00 PM EL06.10.02
Enhanced Piezoelectric Energy Harvesting Through Multiband Elastic Wave Localization using Trampoline Metamaterials GeonLee[1], JeonghoonPark[1], WonjaeChoi[2], BonggyuJi[2], MisoKim[3] and JunsukRho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

In this study, we investigate the efficient piezoelectric energy harvesting at both low and high frequency bands. Traditional energy harvesting platforms were limited to a narrow or high frequency range and showed insufficient electrical performances. To address this, we propose a novel piezoelectric energy harvesting platform based on a periodically arranged trampoline metamaterial with a defect. Our platform demonstrates exceptional electrical output at both low and high frequencies. By utilizing Bragg scattering, our platform expands the bandgap in the high frequency range, while the local resonance enables a wide bandgap in the low frequency range. Through the introduction of periodically broken structures, we create defect states that facilitate the trapping of flexural wave, capitalizing on fundamental physical phenomena. Through experimental validations, we confirm the localization of flexural waves within the defect cavity, which are efficiently converted into electrical energy using piezoelectric elements. Our measurements reveal an output voltage of 1.37 V and 4.05 V, as well as an output power of 24.4 μW and 1.28 mW at the 1st and 2nd defect modes, respectively. These values represent a significant improvement of 188% and 400% compared to the bare plate configuration. The high-power energy harvesting platform we present holds promising potential as a renewable and sustainable energy source in various applications, including structural health monitoring, signal processing, and sensors.

2:15 PM EL06.10.03
Glass Materials for Emission Stabilization Under High Temperatures JanetA. Elias[1], LuisA. Díaz-Torres[2], GemmaPerez-Cuellar[1], PabloReyes-Hernandez[1], EduardoMontes[1] and Miguel ÁngelVallejo Hernández[1]; [1]Universidad de Guanajuato, Mexico; [2]Centro de Investigaciones en Óptica, Mexico

By melt-quenching technique, sixteen samples of lithium diborate glass doped with Er^{3+}, Yb^{3+}, Dy^{+3} and containing Ag and Cu nanoparticles were synthetized. SEM micrograph is presented. X-ray diffraction patterns of all samples reveal their amorphous structure. Physical properties such as density, molar volume and boron-boron separation of amorphous materials are shown. UV–Vis-IR absorption spectra of all samples were recorded and display the characteristic bands of the used rare earths; all absorption bands present an enhancement with increasing metallic nanoparticles concentration. The estimated optical energy band gap of the samples was obtained using the Tauc plot method. Emission spectra of doped samples were collected in the temperature range from 30 to 180 °C. The results of emission under temperature indicate that the addition of metallic nanoparticles (Ag and Cu) in glass matrices are responsible for emission stabilization in samples when the temperature is increased creating a glass material for photonics and thermal sciences.

3:30 PM *EL06.10.04
High-Temperature Thermal Energy Transport and Conversion using Photonic Nanostructures and Metamaterials RenkunChen; University of California, San Diego, United States

High-temperature thermal energy transport, conversion, and management is fundamentally important for a multitude of energy processes, such as thermochemical, solar-thermal, thermophotovoltaic, thermal energy storage, and industrial heating, etc. Heat transfer physics at high temperature is also markedly different from its counterpart at room- and low-temperatures, including stronger phonon-phonon scattering leading to lower phonon thermal conductivity and the more prominent or even dominant role of radiation heat transfer. On the other hand, high temperature poses tremendous challenges on materials, especially on their thermal and chemical stability. Here we present two recent examples from our studies on photonic thermal energy transport and conversion at high temperature. First, we experimentally probed the more prominent role of surface phonon polariton (SPhP) in polar dielectric (e.g., SiO_2) nanostructures and studied their contribution to thermal radiation and conduction from room to high temperature. We show that the geometry of the polar dielectric nanostructures can be manipulated to engineer the SPhP-mediated thermal radiation and conduction. In particular, we observe photon-like heat conduction contributed by SPhP in SiO_2 nanoribbons. Second, we developed high-temperature selective emitters based on metamaterials. While metamaterial emitters have been widely explored, they are often not stable at high temperature due to the presence of nanoscale interfaces. We use novel material and structural designs to attain high temperature stability. These selective emitters could be used to more efficiently converting optical and electrical energy into thermal energy within a desirable spectrum that are useful for systems such as thermophotovoltaic and infrared heating.

Thermal Photonics with Low-Dimensional Materials GeorgiaT. Papadakis, MichaelEnders, MitradeepSarkar and MaximeGiteau; ICFO – Institute of Photonic Sciences, United States

The blackbody spectrum for room temperature peaks at mid-infrared (IR) frequencies, making this spectral range of prominent importance for both fundamental science and technology. Examples include mid-IR thermal energy harvesting and radiative cooling, spectroscopy, molecular sensing and detection, thermal camouflage, and mid-IR free-space communications. Despite the relevance of mid-IR photonics, however, phase retardation, the process of rotating light's polarization and converting linear to circularly polarized light is limited to wavelengths up to approximately ten micrometers. Beyond this wavelength, due to the lack of strongly birefringent crystals and the prominent resonances in all polar media due to lattice vibrations (phonons), there exists no commercial phase retarder. In this talk, I will discuss how, by leveraging the strong frequency dispersion of a low-dimensional van der Waals crystal, a-molybdenum trioxide (a-MoO3), we built the first deeply subwavelength phase retarders at mid-IR frequencies, achieving 90 degrees polarization rotation within a micrometer of material.

Using the strong frequency dispersion due to optical phonons in crystals, I will also discuss how once can built fully pattern-free heterostructures that can achieve directional control of thermal emission and absorption at mid-IR frequencies. By considering hexagonal boron nitride (hBN) as a thermal emitter, we theoretically predict thermal emission lobes thare are comparable to those achievable with conventional gratings, yet without any lithography.

Furthermore, I will discuss approaches to leverage the strong anisotropy of several low-dimensional crystals to achieve deep-subwavelength control of optical chirality, without any nanopatterning. Chirality up to 0.8 is estimated with a-MoO3 at mid-IR frequencies. I will discuss our current efforts to measure mid-IR chirality in the laboratory.

Furthermore, mid-IR-relevant low-dimensional materials, such as a-MoO3 or hBN, are typically exfoliated in the laboratory, rather than grown in large scale. Exfoliated flakes are typically too small for mid-IR far-field optical experiments, due to the size mismatch between an IR beam and a flake. This introduces a major challenge: rather than being directly measured experimentally, for example via spectroscopic ellipsometry, the dielectric function of most low-dimensional materials is approximated by numerical fitting in experiments performed in the near-field, via scanning microscopy. I will introduce a robust method for retrieving the mid-IR dielectric properties of exfoliated flakes using far-field optics.

Controlled Growth of Titanium Oxynitride Thin Films for Plasmonic and Photovoltaic Applications IkennaC. Chris-Okoro[1], SheilahCherono[1], CatalinMartin[2], ValentinCraciun[1,3] and

DhananjayKumar[1]; [1]North Carolina Agricultural and Technical State University, United States; [2]Ramapo College of New Jersey, United States; [3]National Institute for Laser, Plasma, and Radiation Physics, Extreme Light Infrastructure for Nuclear Physics, Romania

Single crystalline pure titanium nitride (TiN) and partially oxidized titanium nitride (TiNO) thin films have been grown in a rock-salt structure using high vacuum conditions with and without intention oxygen ambience by a pulsed laser deposition (PLD) method. The films were grown under different vacuum conditions on different single-crystal substrates such as sapphire, silicon, and doped/undoped TiO_2. X-ray photoelectron spectroscopy (XPS) and Rutherford Backscattering spectroscopy analysis have shown that the oxygen content of the titanium oxynitride (TiNO) films increases with film thickness (or deposition time) and also with an increase in oxygen pressure during film deposition. The lattice constant of the TiNO films, measured using XRD, is found to increase with the oxygen content in the film. The lattice constant increase is explained using enhanced electrostatic repulsion between O^{2-} orbitals in the absence of vacant Ti^{3+} sites; in order to maintain charge neutrality within the lattice, one Ti^{3+} cation vacancy is created for every three substitutions of N^{3-} ions by O^{2-} ions. Despite the oxygen content, all films show metallic behavior, with a resistivity around 70-100 mW×cm and a carrier concentration of the order of $n_e \approx 10^{23}$ cm^{-3}, confirmed by (determined from) electrical transport, Hall effect and infrared spectroscopy measurements.
A spectroscopic ellipsometer was used to measure TiN/TiNO's spectroscopic optical properties and structural parameters. The reflection coefficient of TiN/TiNO films was measured within the electromagnetic spectrum range of 193 nm to 1690 nm by taking the ratio of perpendicular and parallel polarized light. The optical constants (refractive index, extinction coefficient, and film thickness) of the TiN/TiNO films were determined by analyzing the amplitude and phase difference components of the reflection coefficient where a line-shape analysis a point-by-point fit, or a parametrized function model were applied. A maximum in refractive index curves appears at a wavelength in the region of ~ 300 nm and a minimum at a wavelength range of 500-650 nm. The extinction coefficient plots of the films showed a minimum in the wavelength range of 300-400 nm. This result suggests that nitrogen present in the sample contributes to the additional critical point around 400 nm when compared to a pure TiO_2 layer in the literature. A widening of the absorption spectrum was seen, which indicates a narrowing of the bandgap when compared to TiO_2. We have observed a variation in the optical bandgap of the TiNO films as a function of film thickness. The band gap values obtained are suitable for the absorption of solar light in the full spectrum range, which indicates that the TiNO thin films can be used for converting solar light into electrical energy.

Nanostructuring Plasmonic Dendron Core-Shell Nanoparticles: Energy and Charge Transfer Applications RigobertoC. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

Organic-Inorganic hybrid nanomaterials and metamaterials accommodate interesting transport behavior when properly nanostructured by self-assembly or directed assembly. These hierarchical levels of relationships enable microscopic to the macroscopic transition of properties. Au nanoparticle plasmonics phenomena are well-known however, their utilizing beyond localized and propagating plasmons is the key to their appreciation of enhanced properties. This talk will highlight the use of dendron-based ligands of organic electro-active and electrochemically active organic molecules which can be used to enable specific energy and charge transfer properties with metal and quantum dot nanoparticles. Investigating these properties makes use of lateral ATR and surface-propagating plasmons methods, SPM, Electrochemistry, and fluorescence and scattering methods. The ability to control these transfer and transport properties enables new applications in sensing, solid-state display devices, sensors, and array structures that have macroscopic properties.

Three-Dimensional Colloidal Nanocrystal Metamaterials CherieR. Kagan; University of Pennsylvania, United States

Colloidal nanocrystals (NCs) have inorganic cores and organic or inorganic ligand shells. They are prized for their size- and shape-dependent properties and serve as building blocks of artificial materials and unconventional devices. Here, we describe NC-based, three-dimensional optical metamaterials constructed using imprinting techniques from single- and multiple-types of metal and metal oxide NCs. We focus on the chemical and thermal addressability of NCs, i.e., the ability to select, exchange, strip, or add atoms, ions, and molecules during or post-deposition, that is not accessible in bulk materials, and allows the control of metamaterial structure and properties. Through ligand engineering we tailor the dielectric function of metal NC assemblies through an insulator-to-metal transition.[1] By juxtaposing NC assemblies and bulk thin films to make bilayer heterostructures, we exploit ligand exchange to trigger folding of two- into three-dimensional structures,[2] which we use to achieve broadband[3,4] and reconfigurable 3D chiral optical metamaterials. These structures can also be released from the surface to create and study active matter and its interface with microscale robotics.[5]

From Electrophononics to Photophononics—Controlling Heat Flux with External Fields ClaudioCazorla[1], SebastianBichelmaier[2], CarlosEscorihuela Sayalero[1], JorgeIniguez[3], JesúsCarrete[2] and RiccardoRurali[4]; [1]Universitat Politècnica de Catalunya, Spain; [2]Technische Universität Wien, Austria; [3]Luxembourg Institute of Science and Technology, Luxembourg; [4]Institut de Ciència de Materials de Barcelona, Spain

Dynamical tuning of the thermal conductivity in crystals, k, is critical for developing novel phononic devices able to perform logic operations with phonons, as well as for solid-state refrigeration, energy harvesting, and thermoelectrics. Such a desired k control can be achieved in functional materials that experience large structural and phonon variations as a result of field-induced phase transformations.
Current strategies to design materials with tailored thermal properties typically rely on the creation of structural inhomogeneities that scatter phonons and reduce the thermal conductivity (e.g., lattice defects, grain boundaries and nanostructure surfaces) and the engineering of periodic heterostructures (superlattices) in which wave interference induces the appearance of phonon frequency gaps. These approaches, however, yield changes in the thermal properties of materials that are static and irreversible. The design of *phononic* devices [1], capable of performing logic operations with phonons similarly to what their electronic counterparts do with charge carriers, on the other hand, relies on the possibility of dynamically tuning the thermal conductivity of materials, k.
A promising dynamical k tuning approach consists in using electric or magnetic fields to manipulate the lattice of polar and magnetic materials, respectively, ideally exploiting the effects of field-induced phase transitions on the thermal properties. The ensuing *electrophononic* [2-5] and *magnetophononic* [6-7] effects can provide fast and dynamical manipulation of the heat carriers, thus yielding *à la carte* thermal properties for on-demand applications.
Nevertheless, for these strategies to be practical, the operation conditions need to be close to zero-bias transition points, since otherwise the required driving fields may grow unfeasibly large

and the materials performances be seriously compromised owing to the presence of leakage/eddy currents and dielectric/magnetic losses. On the other hand, the possibility of manipulating k with light thus far has received very little attention. Light-driven control of the thermal conductivity could bypass some of the issues posed by the schemes described above (e.g., application of large driving fields) as well as simplify the design of logic devices (i.e., lack of electrical contacts) [8].
In this talk I will discuss our predictions, based on first-principles calculations, of each of these three effects: *electro-*, *magneto-*, and *photopononic* couplings as effective way to dynamically manipulate the thermal conductivity of materials with external fields.

Scalable 2D Material-Based Plasmonic Phototransistors Yu-JungLu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Monolayer transition metal dichalcogenides (TMDs) are promising materials for electronics and photonics at highly scaled lateral dimensions. However, their low photon absorption poses a challenge for high-performance optoelectronic devices. We present plasmonic phototransistors (photoFETs) that integrate monolayer molybdenum disulfide (MoS2) with plasmonic metasurfaces [1-2], such as Ag, Bi, HfN, and TiN. These plasmonic photoFETs exhibit a significant enhancement in photocurrent compared to pristine 2D photoFETs, enabling high-performance devices with ultrahigh photoresponsivity. The enhancement is achieved through plasmonic nanostructures that enhance light absorption [1-4], photo- carrier generation, photo-gating, and hot-carrier transfer rates. We also discuss the design of 2D material- based plasmonic photodetectors that can be extended to other 2D materials, facilitating the development of ultrathin, high-performance scalable optoelectronic devices. Lastly, we explore the prospects for next- generation ultra-compact optoelectronic devices in the trans-Moore era, where traditional silicon-based electronics face limitations. The integration of monolayer 2D materials with plasmonic metasurfaces offers an avenue for enhancing optoelectronic device performance, while the design flexibility enables the utilization of various 2D materials. These advancements hold promise for developing ultrathin, high- performance optoelectronic devices for applications in telecommunications, sensing, and data processing.

Creating Superlattices for Interlayer Excitons with Metasurface Nanoelectrodes QitongLi, Sze CheungLau, TonyF. Heinz and MarkL. Brongersma; Stanford University, United States

Atomically-thin transition metal dichalcogenide (TMDC) monolayers have attracted significant and broad interest in the last decade. They serve as a promising material platform for future low-dimensional electronics and optoelectronics because of their exceptional charge-carrier mobility and quantum yield, and provide a clean 2D system for fundamental physics study because of the enhanced quantum effects and correlations due to the reduction of the available states in the system. As compared with intralayer excitons in monolayers, interlayer excitons in TMDC heterostructures display longer lifetimes as their recombination rate is limited by the tunneling effect, resulting in a diffusion length of up to a few micrometers and creating an exciting playground for quantum many-body physics study.

Here, we propose that with state-of-the-art nanofabrication techniques, we can spatially control the energy level of interlayer excitons down to the nanometer scale via the DC Stack effect with the carefully designed metasurface nanoelectrodes. For instance, an electrode with patterned nano-holes (diameter ~ 30 nm) can trap interlayer excitons in quantum wells. The depth of the quantum wells can be scaled with the applied external vertical electric field up to ~ 100 meV. A superlattice can therefore be achieved with a periodically nanopatterned hole array (period ~ 50 nm), where its Hamiltonian can be described using a Bose-Hubbard model. By gradually tuning the depth of the quantum wells, a material phase transition (from insulating to conducting) is expected. What's more, a more complicated material phase (i.e., Hamiltonian), including but not limited to defect states, quasi-crystal, as well as general quantum metasurfaces, can all be simulated by engineering the geometry of the metasurface electrodes and associated DC electric field distribution.

10:45 AM EL06.11.06
Electromechanically Reconfigurable Optical Vortex Array SanghyeokPark, DonghaKim and Min-KyoSeo; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

An optical vortex (OV), which is a topological texture of the electromagnetic field with the intensity singularity and spiral phase rotation, has been garnering significant interest due to the supported orbital angular momentum [1]. The generation and modulation of OVs are important for applications that utilize the orbital angular momentum of light, such as multiplexing and multi-valued logic systems that aim to increase data capacity [2]. To date, active pixel arrays, including spatial light modulators or digital micromirror devices, have been typically employed to create and control a reconfigurable array of OVs [3]. However, these systems suffer from the modulation speed limited by the intrinsic response time of the materials used and the requirement to control each pixel individually. Moreover, the size of the pixel unit imposes constraints on achieving a compact OV array and increasing the number of OVs. Recently, the gradient thickness optical cavity (GTOC) has been proposed as an innovative platform for creating and controlling an array of reconfigurable OVs, capable of exhibiting quasi-particle-like behaviors [4]. The GTOC platform projects the parametrized space defined by the thicknesses of the employed dielectric spacers onto the real space through thickness gradients. The GTOC enables to spontaneously generate OVs and actively change their positions by engineering the optical thickness of the interlayer separating the dielectric spacers.
In this study, we demonstrate the creation and high-speed manipulation of a reconfigurable OV array using an electromechanical GTOC (EM-GTOC). Employing a piezo-actuator to rapidly control the thickness gradients of the dielectric spacers, the EM-GTOC can control the position and periodicity of the generated OV array with a speed exceeding tens of kHz. The EM-GTOC is a multi-layered structure that includes a glass layer combined with a piezo-actuator, an air spacer, an 8-nm-thick Ni layer, a polymer layer (Norland Optical Adhesive), and an Al bottom mirror. The thickness of the air spacer between the glass and Ni layers changes with position, and the piezo-actuator electromechanically controls the thickness gradient. Phase distributions measured by a holographic interferometer reveal that the period of the OV array varies depending on the voltage applied to the piezo-actuator. Furthermore, the OVs can actively move in one dimension over distances of approximately 1.92 times of the period of the OV array.
The high-speed piezo-actuator allows the rapid reconfiguration of the OV array at the region of interest. We assessed the reconfiguration speed of the EM-GTOC employing the orbital angular momentum dependent diffraction by a fork-grating. We observed that the EM-GTOC encodes the orbital angular momentum into the reflected light at a speed of 10 kHz, equivalent to the typical speed limit of the spatial light modulator, or potentially even faster. We also demonstrated a reconfigurable OV array of which the OVs move in two-dimensional space. Another piezo-actuator combined with a Ni-coated cover glass, which replaces the Ni/polymer/Al structure, provides the second OV driving axis. By applying voltage to the two piezo-actuators connected to the cover glass and the slide glass, we successfully maneuvered the vortex and anti-vortex within a space of 1.33 period 2.19 period. We expect that the EM-GTOC platform, which can rapidly reconfigure an array of OVs, can find applications in orbital angular momentum-based multi-level logic networks. We also anticipate that the use of Micro-Electro-Mechanical Systems (MEMS) techniques could potentially control OV arrays at sub-GHz speeds.

11:00 AM EL06.11.07
Laser Patterning of Semi-Transparent Oxide Nanotubes for Solar-Driven Processes KatarzynaGrochowska, AmeerNasih, Saiful IslamKhan and KatarzynaSiuzdak; Szewalski Institute of Fluid-Flow Machinery Polish Academy of Sciences, Poland

Novel and efficient renewable energy sources, solar cells or water splitting devices are hot topics within the society. The emphasis is put on the usage of solar energy, e.g. light-driven water splitting as well as its transformation into electrical energy by applying photovoltaic cells. Those devices require photoelectrode materials exhibiting wide absorption range overlapping solar spectrum, low recombination rate of photogenerated charges and photocorrosion resistance. Among different materials TiO_2 has been widely studied, in particular titania nanotubes (TiO_2 NTs) that provide unique set of geometrical and electrical properties as well as low production costs via anodization, chemical inertness and non-toxicity [1]. Though, it should be taken into account that it is a wide-bandgap semiconductor and some strategies should be undertaken to increase its absorption in visible range [2].
In this studies, we propose semi-transparent nanostructure fabricated via combined electrochemical and laser processing. In the first step the formation of flat metallic (pure Ti or Ti-Ni) layers onto the transparent conducting oxide substrate was realized via DC and RF magnetron sputtering. In order to obtain highly ordered metal oxide architecture anodization process was performed for applied voltage in the range of 30 – 60 V. SEM inspection confirmed the presence of nanotubes for both types of layers, i.e. Ti and Ti-Ni. Moreover, the outer NTs diameter increases with the anodization voltage, from 90 to 120 nm and 50 to 70 nm, for NTs formed out of Ti and Ti-Ni films, respectively. Interestingly, with the increase of the voltage value the length of NTs decreases from 1050 to 770 nm for the NTs obtained from Ti layers, while increases from 970 to 1100 nm for the ones obtained from Ti-Ni layers.
The optical band-gap values estimated for pure TiO_2 NTs vary in the range of 3.11-3.25 eV for different anodization voltage which is consistent with changes in geometrical features. Meanwhile, the band-gap values decrease for oxide nanotubes prepared out of Ti-Ni films confirming the correctness of undertaken strategy. Additionally, the presence of nickel in the anodizing layer led to the appearance of highly pronounced fringes in the UV-vis spectra of oxide NTs that were not observed for pure titania material. This phenomenon can be described by surface plasmon resonance, photonic behavior of the material and constructive and destructive interference of partially reflected light [3].
After calcination ensuring phase transition to anatase, the samples underwent laser processing (355 nm wavelength, 2 Hz repletion rate, 6 ns pulse duration) with varying fluence of 20-100 mJ/cm^2. Such processing resulted in the partial melting of the NTs tops with preservation of the tubular scaffold. The electrochemical measurements, such as cyclic voltammetry and linear sweep voltammetry, were performed for all the laser-treated and non-treated samples. All the samples show good electrochemical stability while the material treated with 40 mJ/cm^2 fluence exhibits 14.5 times higher photoactivity than the non-annealed one.
Overall, these findings suggest that the elaborated synthesis route can be successfully employed to form the systems exhibiting nature of the photonic crystal and plasmonic effect. Therefore, proposed material can be regarded as a promising electrode for utilization in optoelectronic devices, particularly solar cells and water photosplitting reactor.

Dynamic Digital Control of the Translational Geometric Phase in Optical Metasurfaces JunghyunPark[1], ChunghwanJung[2], Sun IlKim[1], Byung GilJung[1], MinkyungLee[1], YoungKim[1] and JunsukRho[2]; [1]Samsung Advanced Institute of Technology, Korea (the Republic of); [2]POSTECH, Korea (the Republic of)

Dynamic metasurfaces facilitate on-demand wavefront shaping upon the control signal and can provide a versatile platform for various applications including light detection and ranging (LiDAR), free space optical communication, and holographic displays. There has been considerable research on the extension of the phase sweep range, increasing degree of freedom with complex amplitude modulation, and non-volatile tuning mechanism. However, the proposed configurations suffer in common from the analog property, where the device output is nonlinearly dependent on the input signal, giving rise to limited reliability and wavefront purity. The resulting wavefront with non-negligible grating lobes and background noises prevent us from achieving practical devices for real applications. In this presentation, we present a novel concept of the dynamic digital control of the translational geometric phase in the near infrared regime. Each pixel with independent functionality is composed of various sub-gratings, and the reflectivity of each grating can be electrically turned on and off. As a result, we can invoke apparent translation of the effective grating units. We show experimental measurement of the 4-step digital phases of 0°, 90°, 180°, and 270° with a constant amplitude at the wavelength of 1400 - 1550 nm regimes. We believe our work will shed light on innovative science and engineering toward high purity beam manipulation.

8:30 AM *EL06.15.02
Extreme Dissipation in Scalable Nanoscale Absorbers and Resonant Heat Transfer for Decentralized Solar Thermal Desalination AlessandroAlabastri; Rice University, United States

Thermal desalination is a flexible choice for water treatment, given its key advantages in robustness and limited salinity dependence. Light can power thermal desalination by carrying electromagnetic energy if efficiently turned into heat [1-2]. Solar-driven photothermal desalination (SDPD) can lead to decentralized water purification, improving accessibility and reducing the environmental impact over conventional, heavy infrastructure-based desalination practices like reverse osmosis. However, today's best decentralizable SDPD technologies barely surpass 10% of the thermodynamic limit for thermal desalination. A few years ago, we introduced the concept of nanophotonics-enabled solar membrane distillation, where solar-driven localized heat drives the distillation process [1]. Moreover, the desalination efficiency was increased by redistributing the photon flux incident on the membrane, suggesting the possibility of reducing the process footprint by utilizing miniaturized optics instead of more costly and bulky optical concentrators [2]. However, energy recovery is still a challenge.

Two key ingredients are necessary for practical solar desalination: 1) Input power (e.g., from direct sunlight) and 2) energy recovery. Light-heat conversion drives evaporation in solar thermal desalination, and I will show how properly designed large-scale ultrathin (~250nm) TiN-based metasurfaces allow extremely large (~GW/m^3) and broadband (~90% of solar spectrum) dissipated power densities [3]. More recently, we have shown how thicker (~μm) nanoporous structures uniquely enhance light absorption thanks to deep subwavelength dissipative regions [4]. Such efficient absorbers allow exploiting the vast majority of sunlight as a heat source for desalination.

Heating and evaporating water is only one stage of the desalination process. Water vapor needs to be collected through condensation and latent heat recovered to make the process energy efficient. We have been developing desalination modules based on the concept of Resonant Heat Transfer (RHT), where a combination of conductive and convective heat transfer mechanisms allow the desalination process to be described as an oscillating thermal system where heat is re-utilized, thermal energy is stored, and losses are minimized [5,6]. Such an energy recovery method makes compact modules robust, performing and scalable.

We successfully demonstrated an RHT-based solar desalination module capable of delivering up to 20 L/m^2/day [7], paving the way to realizing scalable and sustainable light-driven water purification systems. I will provide a perspective on the future opportunities and challenges of modular thermal desalination systems [8].

Non-Linear and Non-Local Light-Matter Interaction in Quantum Materials GuruV. Naik and DingZhang; Rice University, United States

The optical response of quantum materials under illumination is interesting. The fine balance between many microscopic processes in quantum materials can be tipped by low-intensity light leading to a nonlinear response. Further, tipping such equilibrium also leads to an incommensuracy of the quantum order resulting in domains with different electronic properties. This coexistence of multiple quantum many-body phases or electronic inhomogeneity is fundamental to quantum materials and gives rise to a nonlocal optical response. This optical nonlocality in quantum materials captures the competition between different electronic phases and serves as a useful material parameter. Here, we present a model to describe the optical non-linearity and nonlocality in quantum materials and validate it by optical experiments carried out on a charge density wave (CDW) material, 1T-TaS2. 1T-TaS2, a quasi-2D material, supports nearly commensurate CDWs at room temperature. CDW domain walls exist in every layer of 1T-TaS2. Each CDW domain can now stack on top of the others in neighboring layers differently giving rise to a stacking order. This stacking order is sensitive to low-intensity incoherent light. Light tips the competition between center-to-corner and center-to-corner stacking types. As a result, the reflectance of TM polarized light changes with illumination intensity manifesting in an optical nonlinearity.

Apart from nonlinearity arising from the underlying competition between different orders, the optical response of quantum materials is also nonlocal. The nonlocality arises from spatial inhomogeneity. The existence of domains of different orders results in optical nonlocality. In 1T-TaS2, the CDW domains in each layer corresponding to a particular stacking type are about 50 nm wide in any layer
at room temperature. This level of spatial inhomogeneity at visible frequencies would result in appreciable nonlocality. Employing a single-shot energy-momentum microscopy, we capture the non-linear and non-local optical response of 1T-TaS2 and infer the quantum order in this material. This work not only sheds light on light-matter interaction at low illumination intensities in quantum materials, but also demonstrates a quick and non-invasive technique to design, discover, and optimize quantum materials.

9:30 AM *EL06.15.04
Explorations into the Dynamics of Maxwell Lattices NicholasBoechler; University of California, San Diego, United States

In this invited talk, I will describe our recent collaborative studies into the dynamics of a class of mechanical metamaterial referred to as Maxwell lattices. Maxwell lattices are mechanical structures on the verge of instability, and they have drawn interest due to their capacity to support topologically protected, zero-energy modes of quasi-static deformation. Within this scope, I will show new phenomena observed in Maxwell lattices including: synthetically non-Hermitian deformation fields, the time evolution of said fields; backscattering free edge wave transport; and the interplay of finite energy thresholds with topologically protected localized modes, and their implications for active, and dynamic material phase transformation.

Optical Metasurfaces Saving Energy in Optical Computing and Photovoltaics AlbertPolman; AMOLF, Netherlands

I will present our recent collaborative work on the design, fabrication and operation of silicon-based optical metasurfaces that perform mathematical operations in an analog way, using light fields as input and output signals. We show how the interplay between scattering components in silicon metasurfaces creates a mathematical derivative on an input image. We then design and fabricate a silicon metasurface that solves an integral equation by using visible light in which we use grating orders as input and output ports on a periodic metasurface with a specially tailored unit cell. The new analog optical computing concepts operate with very low energy consumption, at the speed of light, and can form the basis of more complex geometries solving multiple equations and can be applied in optical neural networks, control systems, and more.
We then apply optical metasurfaces to control and enhance the interaction of free electrons and highly-localized optical near fields in scanning electron microscopy (SEM). Using angle-resolved cathodoluminesence spectroscopy we analyse the spatial modulation of Smith-Purcell radiation that results from the coherent interplay of free-electron driven optical excitations in a chirped metagrating. We embed cylindrically-shaped metagrating patterns onto the input facet of a multi-mode optical fiber to experimentally demonstrate the coupling of free electrons and guided fiber-optic modes via the Smith-Purcell effect.
In the last part of the talk I will introduce an integrated near field/far-field multiple scattering formalism to control the absorption of light in solar cells. We design and fabricate a metallodielectric metasurface back contact for an ultra-high efficiency InGaAs/InGaAsP/Si multi-junction solar cell and enhance the light trapping inside the silicon bottom cell by multiple scattering, creating a record photovoltaic energy conversion efficiency for silicon-based tandem solar cells of 36.1%.

Tunable and Dnamic Photonics with Tailorable Conducting Oxides and Metal Nitrides AlexandraBoltasseva; Purdue University, United States

Transparent Conducting Oxides (TCOs) and Transition Metal Nitrides (TMNs) are emerging material platforms for applications in tunable and nonlinear optics such as tailorable/tunable flat optics, all-optical switches and modulators, high harmonic generation as well as novel photonic time crystal concepts and beyond. We report on various approaches to both statically tailor the materials' properties and dynamically tune the optical response at the ultrafast time scales. We demonstrate remarkable control of the epsilon-near-zero response of TCOs such as aluminum-doped zinc oxide (AZO) and yttrium doped cadmium oxide. We also investigate the strong thickness dependence of the TCOs and TMNs optical properties. Employing the Berreman modes of TiN and AZO films on the same platform, we demonstrate variable switching speeds of an optically-pumped metasurface. We also demonstrate the nonlinear capabilities of undoped ZnO for all optical switching and third harmonic generation. To explore the realization of photonic time crystals, we investigate the fastest material response to an optical pump in AZO, showing sub-10 femtosecond rise time. Our approach paves the way to novel phenomena and device design with ultrafast tunable and tailorable materials.

Active Metasurfaces in Space and Time HarryA. Atwater; California Institute of Technology, United States

Electro-optically tunable active metasurfaces that enable dynamic modulation of reflection and transmission amplitude, phase, and polarization using resonantly excited materials and phenomena are powerful design elements for meta-imaging and computation. As flat, low-profile optical elements, active metasurfaces have potential serve as cascadable, programmable components in optical meta-imaging systems, such as lens-less cameras and single-photon imaging systems. In this talk, I will discuss metasurfaces with high quality factor, local, resonant elements capable of two-dimensional phase gradient generation, in both passive and active metasurface designs. I will also describe active metasurfaces with both spatial and temporal phase gradients, and an active metasurface as a lens-less imaging system, and compare the characteristics to conventional lens-coupled image sensors.

Making Waves: Acoustic and Nanophotonic Platforms for Amplification-Free Cellular and Molecular Detection JenniferA. Dionne[1], MarkLawrence[2], FareehaSafir[1], JackHu[1], VarunDolia[1], HallehBalch[1], SajjadAbdollahramezani[1] and ParivashMoradifar[1]; [1]Stanford University, United States; [2]Washington University in St. Louis, United States

Infectious diseases are one of the leading causes of death in the 21st century, claiming the lives of over 16 million individuals each year. These staggering numbers highlight the need for rapid, sensitive, and multiplexed diagnostics to minimize the spread of infectious disease and guide appropriate treatment. Existing diagnostic methods often suffer from a need for sample culturing or molecular amplification, leading to long diagnostic times or high limits of detection when amplification is not possible. Here, we combine acoustic bioprinting with nanophotonics towards 1) culture-free detection and identification of bacteria in blood, sputum, and wastewater samples using surface enhanced Raman Spectroscopy and 2) enrichment-free detection of proteins using high-Q metasurfaces. While acoustic bioprinting allows for rapid, picoliter volume sample handling for isolation of analytes of interest from clinical samples, nanophotonics enables control of light at molecular scales and optical concentration that minimizes the need for sample enrichment or amplification.

First, I describe how acoustic bioprinting combined with surface enhanced Raman spectroscopy (SERS) can be used to rapidly detect and identify pathogens from complex multicellular samples. Acoustic droplet ejection allows for nozzle-free, kHz-rate printing of biological samples in ~2pL droplets while maintaining cell viability. We use our home-built 150 Mhz acoustic bioprinter to rapidly digitize droplets from solutions of blood, sputum, or wastewater. When the sample is infused with plasmonic gold nanorods, SERS enhancements of up to 1500x are achieved. We train a machine learning (ML) model on droplets consisting of either pure cells or mixed, multicellular species. We achieve ≥99% classification accuracy of droplets printed from cellularly-pure samples, and ≥87% accuracy in droplets printed from cellularly-mixed samples. Our combined acoustic droplet ejection, SERS and ML platform could enable clinical and industrial translation of SERS-based cellular identification for rapid pathogen detection.

Next, I describe a high quality-factor ("high-Q") dielectric metasurface assay that, when coupled with our acoustic bioprinter for site-specific surface chemistry, allows for detection of multiple gene fragments and proteins. Our high-Q resonators produce a strong concentration of the electromagnetic field intensity within sub-wavelength-scale volumes. This platform can enable simultaneous read-out of the ~5 million independent sensor elements patterned per square cm. Unlike existing assays that rely on secondary tagging, our high-Q surfaces generate resonant scattering intensities that are proportional to minute refractive index changes from target protein load. We use hyperspectral imaging to demonstrate binding of Inf. A, Inf. B, and SARS-CoV2 gene fragments, as well as the associated IgG antibodies, with sub-femtomolar sensitivity and over 96% specificity. Together, this work provides a foundation for faster, higher-throughput, and more sensitive cellular and molecular diagnostics.

Hydrogel Infusion-Based Additive Manufacturing of Nano-and Micro-Architected Materials for Photonics and Micro-Filtering JuliaR. Greer[1,2], WenyuanChen[1,2], SammyShaker[1] and AndriiSyrota[1]; [1]California Institute of Technology, United States; [2]Kavli Nanoscience Institute, United States

Creation of reconfigurable and multi-functional materials can be achieved by incorporating architecture into material design. We design and fabricate three-dimensional (3D) nano-architected materials that can exhibit superior and often tunable thermal, photonic, electrochemical, biochemical, and mechanical properties at extremely low mass densities, lighter than aerogels, which renders them useful and enabling in technological applications. Dominant properties of such meta-materials are driven by their multi-scale nature: from characteristic material microstructure (atoms) to individual constituents (nanometers) to structural components (microns) and overall architectures (millimeters and above).
Additive manufacturing (AM) represents a set of processes that fabricate complex 3D structures using a layer-by-layer approach, with some advanced methods attaining nanometer resolution and the creation of unique, multifunctional materials and shapes derived from
photoinitiation-based chemical reaction of custom-synthesized resins and thermal post-processing. A type of AM, vat polymerization, has allowed for using hydrogels as precursors, and exploiting novel material properties, especially those that arise at the nano-scale and do not occur in conventional materials. The focus of this talk is on additive manufacturing of metal ion-containing hydrogels to create 3D nano- and micro-architected metals and metal oxides via vat polymerization for applications in nanophotonics and magneto-filtering.
Rapid development of medical imaging applications calls for the miniaturization of optical systems into ultra-compact micro-optical elements to allow for non-invasive and non-destructive examination of tissues. In the first case application, I will describe additive manufacturing of 3D nano-architected titanium dioxide (TiO_2) for meta-nano-optics that would allow us to redefine optical components. We use two-photon lithography and Ti-infused hydrogel photochemistry with subsequent calcination to produce 3D-sculted TiO2 structures with ~100nm resolution and characterize them using thermal analysis, FTIR, and finite difference time domain (FDTD) solver for NIR wavelengths .
The second part of the talk will be focused on the application of 3D micro-architected Fe (iron) as magnetofilters. Using multi-physics computational analyses of thermodynamic and magnetic forces, we model candidate device configurations that slow venous blood flow enough for magnetic interactions with filters but not cause flow stagnation and thrombosis under anticoagulated conditions. Micro-architected lattices made of iron alloys are first synthesized by hydrogel swell-in method and 3D printed using a photoresin composed of polyethylene glycol diacrylate (PEGda) dissolved in N,N-dimethylformamide (DMF). After exchanging DMF with water, the printed structures are swollen with aqueous metal nitrate solutions. Calcination and reduction transforms the metal ion-polymer structures into metal structures that are subsequently magnetized and tested in flow to capture magnetic microparticles. Using this approach, we fabricated twisted honeycombs, a theoretically predicted optimal geometry for particle capture, from iron and permalloy (80% nickel-20% iron) and characterized their microstructure and particle capture efficiency using X-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS), magnetometry measurements, and flow experiments.

Plasmon-Enhanced Photocatalysis for Green Chemistry PeterNordlander; Rice University, United States

Plasmons can serve as efficient generators of hot electrons and holes that can be exploited in light harvesting applications. The physical mechanism for plasmon-induced hot carrier generation is plasmon decay. Plasmons can decay either radiatively or non-radiatively with a branching ratio that can be controlled by tuning the radiance of the plasmon mode. Non-radiative plasmon decay is a quantum mechanical process in which one plasmon quantum is transferred to the conduction electrons of the nanostructure by creating an electron-hole pair, i.e., excitation of an electron below the Fermi level of the metal into a state above the Fermi level but below the vacuum level. These hot carriers interact with all charge carriers in the system and eventually transfer their energy into phonons (heat). In my talk, I will discuss the time-dependent relaxation of plasmon-induced hot carriers including electron-electron scattering, fluorescence, and electron-phonon coupling [1] and show that the hot carrier lifetimes can exceed several picoseconds. I will also discuss recent applications of plasmon-induced hot carrier generation such as plasmon-enhanced photocatalysis, and how photocatalytic efficiencies can be enhanced and quantified by placing catalytic reactors in the nearfield of a plasmonic antenna in Antenna/Reactor geometries [2-6].

Polarity and Non-Linear Optics of Guided Nanowires ErnestoJoselevich, RegevBen-Zvi, OmriBar-Elli, YahelSoffer, TommasoSalzillo, MaorRosenberg, OmerYaffe and DanOron; Weizmann Institute, Israel

The large-scale assembly of nanowires (NWs) with controlled orientation on surfaces remains one challenge toward their integration into practical devices. During the last decade, we have reported the growth of perfectly aligned, millimeter-long, horizontal NWs of GaN, ZnO, ZnSe, ZnTe, CdSe, CdS, ZnS, $CsPbBr_3$ and other materials, with controlled crystallographic orientations on different planes of sapphire, SiC, quartz, and spinel. The growth directions and crystallographic orientation of the NWs are controlled by their epitaxial relationship with the substrate, as well as by a graphoepitaxial effect that guides their growth along surface steps and grooves. We demonstrated the massively parallel self-integration of NWs into circuits via guided growth and the production of optoelectronic nanosystems, including photodetectors, photodiodes and photovoltaic cells. This talk will present systematic studies to map the crystallographic orientations and polarity of epitaxially guided NWs based on their nonlinear optical response under external electric fields [1]. Studies about epitaxially guided ZnO NWs on sapphire by Au-catalyzed vapor-liquid-solid (VLS) growth reveal interesting details about their formation mechanism and the role of the substrate and the catalyst in determining the polarity and morphology of the guided NWs. Studies done with epitaxial $CsPbBr_3$ perovskite NWs on sapphire by non-catalytic vapor-solid (VS) growth reveal an intriguing memory effect and a strong modulation of their photoluminescence under electric field [2]. These studies reveal the important interplay between epitaxy, polarity and optoelectronic behavior of guided NWs.

11:00 AM EL07.01.02
Short-Range Atomic Ordering and Unintentional Doping of Ge/Ge-Sn Semiconductor Alloy Core/Shell Nanowires JohnLentz[1], JoeWoicik[2], MatthewBergschneider[3], RyanDavis[4], ApurvaMehta[4], KyeongjaeCho[3] and PaulMcIntyre[1,4]; [1]Stanford University, United States; [2]National Institute of Standards and Technology, United States; [3]The University of Texas at Dallas, United States; [4]SLAC National Accelerator Laboratory, United States

Ge-Sn alloys exhibit a tunable direct gap in the mid-infrared in an all-Group IV semiconductor system compatible with Si complementary metal-oxide-semiconductor (CMOS) technologies, presenting interesting possibilities for detectors and on-chip photonics. Ge-Sn films grown epitaxially around Ge nanowires result in core/shell structures with a strain-free Ge-Sn shell. In recent work, extended x-ray absorption fine structure (EXAFS) measurements detected short range order (SRO) in such structures, wherein Sn atoms are ~40% less likely to be nearest neighbors relative to a random alloy film[1]. SRO has been shown to produce interesting mechanical properties in metals, but is not well-studied in semiconductors and has been predicted to substantially alter the electronic structure of Ge-Sn[2]. EXAFS data are also consistent with a vacancy concentration in the Ge-Sn shells less than the detection limit. Vacancies produce acceptor levels in Ge and, therefore, are thought to be the origin of the high as-grown carrier concentrations in Ge-Sn films, often in the 10^{18} cm^{-3} range[3]. By lithographically patterning metal contacts onto single nanowires and performing four-point probe measurements, we have obtained electrical resistances corresponding to much lower carrier concentrations of about 10^{15} cm^{-3}. This also suggests that the Ge core/Ge-Sn shell nanowire geometry promotes atypically small vacancy incorporation, reducing the unintentional hole doping compared to conventional, planar Ge-Sn films.

11:15 AM EL07.01.03
Condensation-Driven Growth of Tellurene Nanosheets for Memristive Applications SaraGhomi[1,2], CarloGrazianetti[1], AlessioLamperti[1], ChristianMartella[1] and AlessandroMolle[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Politecnico di Milano, Italy

The increasing demand for the development of memories with low operating voltage, compatible with CMOS technologies and simple structure, has recently targeted the class of two-dimensional (2D) materials [1]. Novel 2D materials such as transition metal dichalcogenides like MoS_2 and $MoTe_2$ have inspired ultra-scaled layouts of non-volatile random-access memory (RAM) devices based on a resistive switching or phase change mechanism [2,3]. In this respect, monoelemental 2D crystals, termed Xenes [4], may lead to a structural simplification with benefits in terms of energy consumption and performance. In this work, we report on the low temperature synthesis of tellurium nanosheets, known as tellurene, by condensation-driven vapor transport growth processing inside a chemical vapour deposition reactor towards the development of a tellurene-based memristive cell layout. First, we show that the process microscale tellurium structures like hexagonal pillars and nanotubes is scaled down to the 2D level by mastering the growth of tellurene sheet on SiO_2/Si substrates with lateral coverage on the order of tens of microns with a process temperature below 100°C, namely within BEOL compatible thermal regime. On the same line, we applied the same process to (111)-terminated metal templates like Au(111) and Ag(111) epifilm on mica as metallic substrates readily enabling the manufacture of a diode. For the case of tellurene growth on Au/mica substrate we can discriminate two different regimes depending on the substrate temperature T, i.e. a kinetically driven regime where tellurium grows as tellurene nanosheets with no interaction with Au with T<350°C (condensation and nucleation) and a chemisorption regime where tellurene reacts with the Au surface to form $AuTe_2$ (tellurization) with T>350°C. We characterized the two regimes by means of several probing techniques including Raman spectroscopy and atomic force microscopy, and we define the best condition for the growth by means of finite element simulation guidance. The tellurene nanosheet on Au(111)/mica stands out as an optimal configuration where to check a memristive behavior as reported in case of other 2D compounds like MoS_2 on metal substrates [5]. With this purpose in mind, we investigated the local current-voltage (I-V) response of tellurene nanosheet with thickness from 5 to 20 nm by means of conductive atomic force microscopy (C-AFM) with a sharp conductive diamond coated tip the Au substrate as top and bottom electrodes, respectively. A resistive switch behavior of tellurene was revealed by local C-AFM probing, i.e. by applying a linearly ramped voltage and measuring the current passing from the sample to the tip. A trap assisted space charge limited current conduction (SCLC) in the tellurene nanosheets was found to be consistent with the observed I-V behavior thus paving the way to store, read, and write a non-volatile information through tellurene. As such, the configurational details of the growth are accordingly developed for tellurene to be integrated as active layer in a memristor device, and thus transferred to a neuromorphic computing architecture.
This work has been financially supported by the European Commission under the H2020 ERC-COG grant n. 772261 “XFab”.

11:30 AM +EL07.01.04
Low-Dimensional Neuromorphic Electronic Materials and Applications MarkC. Hersam; Northwestern University, United States

The exponentially improving performance of digital computers has recently slowed due to the speed and power consumption issues resulting from the von Neumann bottleneck. In contrast, neuromorphic computing aims to circumvent these limitations by spatially co-locating logic and memory in a manner analogous to biological neuronal networks [1]. Beyond reducing power consumption, neuromorphic devices provide efficient architectures for image recognition, machine learning, and artificial intelligence [2]. This talk will explore how low-dimensional nanoelectronic materials enable gate-tunable neuromorphic devices [3]. For example, by utilizing self-aligned, atomically thin heterojunctions, dual-gated Gaussian transistors have been realized, which show tunable anti-ambipolarity for artificial neurons, competitive learning, spiking circuits, and mixed-kernel support vector machines [4]. In addition, field-driven defect motion in polycrystalline monolayer MoS_2 enables gate-tunable memristive phenomena that serve as the basis of hybrid memristor/transistor devices (i.e., ‘memtransistors’) that concurrently provide logic and data storage functions [5]. The planar geometry of memtransistors further allows multiple contacts and dual gating that mimic the behavior of biological systems such as heterosynaptic responses [6]. Moreover, control over polycrystalline grain structure enhances the tunability of potentiation and depression, which enables unsupervised continuous learning in spiking neural networks [7]. Overall, this work introduces foundational circuit elements for neuromorphic computing by utilizing the unique quantum characteristics of low-dimensional nanoelectronic materials [8].

Nanoscale Heterogeneities at Transition Metal Dichalcogenide-Au Interfaces TaisukeOhta; Sandia National Laboratories, United States

Two-dimensional geometry renders unique screening properties in transition metal dichalcogenides (TMDs). Consequently, the electronic properties of TMDs are susceptible to extrinsic factors (e.g., substrate interactions, mechanical strains, and charge transfer), and display spatial nonuniformities as evidenced in recent reports. Thus, material combinations (i.e., TMD, dielectrics, and metals) and their nuanced interactions need to be considered when designing TMD-based devices. Of particular importance are the interfaces with metallic contacts. Uncovering the origin of heterogeneities at TMD-metal interfaces and establishing strategies to control TMD-metal interfaces could enable engineering pathways for future applications. In this presentation, we show that the electronic structures of mechanically exfoliated TMD-Au interfaces exhibit pronounced heterogeneity arising from the microstructure of the supporting metal. These electronic structure variations indicate spatially nonuniform doping levels and Schottky barrier height across the junction, which are pertinent for device applications. Through examination of the electronic structures of WS_2 and WSe_2 at 10s of nanometers spatial resolution via photoelectron emission microscopy (PEEM) we reveal key differences in work function and binding energies of the occupied states. Complemented with ab-initio calculation, electron backscatter diffraction, and scanning tunneling microscopy, our measurements show distinct variations in excess of 100meV due to the crystal facets of Au [namely (111), (112), and (110)]. Additionally, when multilayer WS_2 and Au(111) facets are azimuthally aligned, strong interactions induce mechanical slippage of the interfacing WS_2 layer, with respect to the rest of the WS_2 layers, resulting in local stacking variations with an occupied state energy shift of 20-50meV. Finally, we employed oxygen plasma treatment of Au to fabricate homogenous TMD-Au interfaces while also tuning the electronic properties of the TMDs. Our findings illustrate that the electronic properties of TMDs are greatly impacted by the interface interactions at energy and length scales pertinent to the operation of TMD-based electronics and optoelectronics.

2:00 PM EL07.02.02
Cryogenic Nano-Imaging of Second-Order Moire Superlattices PetrStepanov; University of Notre Dame, United States

Magic angle twisted bilayer graphene has been realized as a new platform to study strongly correlated quantum states of matter such as superconductors, correlated insulators and topological

orders hosted by its native flat bands. Recent observations of anomalous Hall effect in MATBG revealed a non-zero Berry-curvature-induced orbital ferromagnetism and has been followed by extensive experimental and theoretical studies of its origin. Initial electronic transport studies demonstrated anomalous Hall effect at ν=+3 electrons per moire unit cell in the samples aligned with the adjacent insulating hBN layer, which breaks MATBG moire inversion symmetry thus assisting in opening non-trivial insulating gaps with finite Chern numbers. Here we report on photovoltage scanning near-field imaging at cryogenic temperatures (10 K) of a MATBG device structurally aligned with hBN layer. We reveal a complex pattern of quasi-local photovotage fringes attributed to the second-order superlattice (supermoire) potential modulated through the sample bulk. We assume that predominantly the photocurrent originates from PV generation mechanisms induced by the proximity of a hot spot formed on the metallic atomic force microscopy tip radiated by mid-infrared photons. Strikingly, we find a clear change of the PTE fringes' real-space orientation when the sample doping changes between the valence and conductance flat bands which may signal a nematic ordered state in a highly doping-dependent low-energy spectrum of MATBG. Our observation sheds a new light on the microscopic mechanisms of the inversion symmetry breaking on a mesoscopic lengthscale.

Raman Spectroscopy on 1D Graphene Nanoribbons: From Structure to Electron-Phonon Interactions AngelLabordet Alvarez[1], MickaelPerrin[1,2], KlausMüllen[3], RomanFasel[1,4], MichelCalame[1,5], GabrielaBorin Barin[1] and MirjanaDimitrievska[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland; [3]Max Planck Institute for Polymer Research, Germany; [4]University of Bern, Switzerland; [5]University of Basel, Switzerland

Low-dimensional materials (1D and 2D) are promising candidates as building blocks of future electronics and optoelectronics. Controllable bandgap, strong light-matter interaction, and sub-nanometer thickness are among their favorable properties for various applications. In this regard, graphene nanoribbons (GNRs) are especially interesting, due to their remarkable physical properties that are critically determined by their width and edge structure [1]. A comprehensive characterization of these materials is a crucial learning step toward their reliable integration in devices.

In this work, we showcase the use of various types of Raman spectroscopy along with density functional theory (DFT) calculations, for the investigation of intrinsic and defect-induced structural, vibrational, and optoelectronic properties of GNRs, with special emphasis on probing the interaction in-between GNRs and with various substrates (metal and oxides). The 9-atom wide armchair GNR (9-AGNR) is chosen as an example system.

We start by using low-temperature, polarization Raman spectroscopy measured with multi-wavelength excitation (488, 532, and 785 nm) to investigate the differences in fundamental and defect-activated phonons of 9-AGNRs grown uniaxially aligned on gold (Au(788)) and transferred to oxide substrates using the process from [2]. We probe the possible interaction between the GNRs by investigating two samples with distinct surface coverages: a full monolayer (ML) and 0.3 ML assuming that the interaction between the GNRs decreases by decreasing the surface coverage. Raman measurements on these two samples show particular differences in the spectral region corresponding to C-H vibrations (1000 to 1400 cm^{-1}), suggesting possible activation of interaction-induced Raman peaks.

Next, we use temperature-dependent Raman measurements, in the range from 70 to 500 K, in order to probe phonon-electron and phonon-phonon coupling in these systems. We systematically investigate the dependence of Raman peak positions and widths of G, D and C-H related phonons with temperature. We show that, for the full monolayer GNRs on the Au (788) substrate, the electron-phonon coupling is dominating up to temperatures of 250 K. This is a surprising feature, considering that 9-AGNRs grown on Au substrates, have a semiconducting behavior with a bandgap of about 1.4 eV [3]. This should diminish electron-phonon coupling for all phonons with energies lower than 1.4 eV (11200 cm^{-1}). We explain this behavior in terms of interactions between adjacent GNRs and/or between GNRs and the substrate. Finally, we discuss how electron-phonon and phonon-phonon coupling can have a profound effect on the electronic properties of these materials, which can be especially crucial for device performances.

Intercalation of Graphene Nanoribbons in Ultra-High Vacuum Towards Optimized Dry-Transfer into Devices DominikLüthi[1,2], LinYang[3], JiMa[3], AkimitsuNarita[4,5], XinliangFeng[3], KlausMüllen[4], PascalRuffieux[1], RomanFasel[1] and GabrielaBorin Barin[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]University of Bern, Switzerland; [3]Technische Universität Dresden, Germany; [4]Max Planck Institute for Polymer Research (MPIP), Germany; [5]Okinawa Institute of Science and Technology, Japan

Atomically precise graphene nanoribbons (GNRs) show exciting properties deriving from electron confinement and related band gap tunability. The ability to tune GNRs' electronic and magnetic properties at the single atom level makes them an ideal platform for a wide range of device applications, from classical transistors to spintronics. To achieve such control, atomic precision in the fabrication of the GNRs is indispensable.
On-surface synthesis, based on covalent coupling of specific precursors on a metallic surface, allows access to various types of GNRs including armchair-GNRs (AGNRs), [1] zig-zag-GNRs (ZGNRs) [2], and GNRs with specific edge-extensions [3].
Such edge topologies can give rise to intriguing physical properties such as spin-polarized edges with a long spin lifetime and topological quantum states, making these GNRs an interesting template for quantum-based technologies. [3]
To probe such properties in a device, GNRs need to be transferred from their metallic growth substrate to insulating ones.
However, the enhanced chemical reactivity of the zigzag edge states hinders the integration of these GNRs into devices, which so far has prevented any investigation on their (magneto) transport characteristics.
In this work we explore GNR-intercalation to achieve their decoupling (and decreased interaction) with the underneath metal, as a viable path to allow GNRs' dry-transfer in ultra-high-vacuum. Such method would allow better access to GNRs electronic characterization decoupled from the metal substrate as well as their direct integration into different device architectures without any air exposure, therefore preserving GNRs intrinsic properties.

Our first approach was to explore the intercalation of GNRs with carbenes (BIM) [4], as it has been shown to strongly interact with Au(111) by forming covalent bonds. The intercalation occurs due to the formation of a dense self-assembled monolayer (SAM) on the surface, causing stochastic intercalation of GNRs. We attribute a sterical argument to the intercalation, as the high excess of carbenes on the surface leads to some GNRs migrating to the top layer. Scanning tunneling microscopy and spectroscopy characterization of intercalated GNRs will be discussed.

Another exciting approach is the intercalation to open a pathway to study the interaction of GNRs with other surfaces. A promising template in this regard is the growth of transition metal halides with tuneable electronic and magnetic properties [5]. Intercalation of GNRs with transition metal halides allows to probe their interaction with magnetic layers by scanning tunneling spectroscopy (STS), while potentially keeping the advantage of decoupling GNRs for device integration via dry-transfer.

On-Surface Synthesis of Graphene Nanoribbons and Spin Chains PascalRuffieux; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Recent advances in on-surface synthesis has allowed the selective fabrication of a number of prototypical types of graphene nanoribbons. The thereby achieved properties include width-dependent electronic band gaps in armchair graphene nanoribbons, edge-localized states in zigzag graphene nanoribbons and topological band engineering in width-modulated topological graphene nanoribbons. More recently, on-surface synthesis of magnetic nanographenes has been reported. Here, the spin originates from unpaired electrons present in nanographenes with controlled sublattice imbalance or topological frustration. The corresponding magnetic moments live in π-orbitals and are hence largely delocalized, which allows for chemical control over their exchange interaction when covalently linking several molecular building blocks. Here, I will present synthesis of various prototypical magnetic nanographenes and the possibility to covalently link them to form coupled spin systems where exchange coupling can exceed 100 meV. Using halogen-substituted precursors, we achieve the on-surface synthesis-based deterministic bottom-up fabrication of various spin chains including a triangulene spin-1 chain revealing the predicted Haldane gap and fractional excitations at the chain termini or a strictly alternating spin-½ chain with chemically engineered coupling strengths J_1 and J_2. Scanning tunneling microscopy and spectroscopy is used to determine the length- and site-dependent

magnetic excitations. Furthermore, we apply hydrogenation to achieve spin site passivation and controlled tip-based local reactivation to fabricate and characterize specific spin patterns in one-dimensional spin chains and spin clusters.

Emerging Two-Dimensional Materials for Device Applications JunLou; Rice University, United States

Two-dimensional (2D) materials, such as Graphene, h-BN and MoS_2, are promising candidates in a number of advanced device applications, owing to their exceptional electrical, optical and mechanical properties. Scalable growth of high quality 2D materials is crucial for their adoption in technological applications the same way the arrival of high-quality silicon single crystals was to the semiconductor industry. While CVD growth of wafer-scale monolayer graphene and TMDs has been demonstrated, considerable challenges still remain. In this talk, we first report a CVD method to grow fluorine rich 2D polymer (2DP-F) on varies substrates for low-k dielectrics in 2D TMDs based devices. Using precursors with low vaporize temperature, a uniform and ultra-flat 2DP-F film with controlled thickness can be deposited on silicon oxide wafer, glass, sapphire and mica substrates. Dielectric properties and relevant mechanical properties were carefully characterized. These 2DP-F films were then used as the substrate for transition metal dichalcogenides (TMDs) based devices, and significant improvements in device performances were found, possibly owing to the ultra-smooth and dangling bond free surface of 2DP-F that can significantly reduce the interfacial scattering of carriers.

Next, we show that atomically thin $Cs_3Bi_2I_9$, an all-inorganic lead-free perovskite derivative with strong optical activity can be successfully synthesized by vapor growth method. Reducing the dimensionality of such perovskites could utilize the materials' advantages for solid-state information devices like valleytronics. By breaking the inversion symmetry, 2D $Cs_3Bi_2I_9$ flakes with odd-layer number exhibited persistent, optically addressable valley polarization. This study potentially opens generalizable CVD method for growing a broad range of 2D perovskites towards cost-effective and energy-efficient integrated device applications. Finally, we report a two-step vapor phase growth process for the creation of high-quality vdW heterostructures based on perovskites and TMDCs, such as 2D $Cs_3Bi_2I_9/MoSe_2$, with a large lattice mismatch. Supported by experimental and theoretical investigations, we discover that the $Cs_3Bi_2I_9/MoSe_2$ vdW heterostructure possesses hybrid band alignments consisting of type-I and type-II heterojunctions because of the existence of defect energy levels in $Cs_3Bi_2I_9$. More importantly, we demonstrate that the type-II heterojunction in the $Cs_3Bi_2I_9/MoSe_2$ vdW heterostructure not only shows a higher interlayer exciton density, but also exhibits a longer interlayer exciton lifetime than traditional 2D TMDCs based type-II heterostructures. Such vdW heterostructures provide promising platforms for exploring novel physics and cutting-edge optoelectronics and valleytronics applications.

4:15 PM EL07.02.07
In-Plane Polarization in 3R-β'-In_2Se_3 Grown by Molecular Beam Epitaxy Derrick Shao HengLiu[1], SebastianCalderon[2], AlbertSuceava[1], ElizabethC. Dickey[2], VenkatramanGopalan[1] and JoanM. Redwing[1]; [1]The Pennsylvania State University, United States; [2]Carnegie Mellon University, United States

Two-dimensional ferroelectrics have gained increasing attention due to their promising potential in new memory device applications, such as ferroelectric field effect transistors (FeFETs) and non-volatile memory (NVM). The In_2Se_3 family represents a promising system for 2D ferroelectrics that can be deposited at temperatures compatible with back-end-of-line processing and can enable an ultra-thin body due to the 2D layer structure. However, it is a complex material system with many combinations of polymorphs (a, b, and g) and polytypes. In the current scientific literature, phase assignment and phase characterization are still controversial. The phases are determined by the crystal structure of repeating quintuple layers, and the polytypes are determined by the stacking sequences of the quintuple layers. The α-In_2Se_3 has two polytypes (2H and 3R), and β-In_2Se_3 has three polytypes (1T, 2H, and 3R). γ-In_2Se_3 is not a 2D material, but has a distorted wurtzite structure leaving room for polarization in the tetrahedra. While existing reports suggest in-plane or out-of-plane polarization in In_2Se_3, many existing publications fail to discuss the specific phase or polytype when reporting the synthesis and ferroelectric properties. A deeper understanding of the In_2Se_3 phases and polytypes is crucial as ferroelectricity is directly coupled to the crystal structure. On top of that, not all of the phases and polytypes are noncentrosymmetric. Detailed studies are therefore needed to explore the synthesis and structural properties of specific phases and polytypes of In_2Se_3 to unambiguously connect to their respective ferroelectric properties.
This talk presents our findings on the growth and characterization of 3R-β'-In_2Se_3 films grown on c-plane sapphire and Si(111) substrates by molecular beam epitaxy (MBE). Single phase b-In_2Se_3 films were obtained on sapphire at 600°C and on Si(111) at 350°C. High Se/In flux ratio was required to suppress the formation of other indium selenide phases. In and Se atomic fluxes were calibrated with a quartz crystal microbalance (QCM) at the film growth position. The tooling factors of the QCM flux calibration were previously determined from physical thickness measurements on calibration samples using X-ray reflectivity (XRR) and scanning electron microscopy (SEM). An infrared (IR) camera was installed to serve as an additional substrate temperature metric along with the system's thermocouple installed behind the substrate. *In-situ* reflective high energy electron diffraction (RHEED) was used to monitor the structural formation of the films. Phase examination of the samples was determined by *ex-situ* X-ray diffraction (XRD) and Raman spectroscopy. Scanning transmission electron microscopy (STEM) carried out on the sample cross-sections revealed the films on sapphire and Si(111) to be the 3R polytype with small polytype impurities at the film/substrate interface. Furthermore, analysis of the STEM images indicated that the central Se atoms in the Se-In-Se-In-Se quintuple layer structure were slightly displaced in the in-plane direction, resulting in in-plane polarization and the phase assignment of the β' phase. The results were further supported by second harmonic generation (SHG) polar plots which were consistent with the observation of in-plane Se atoms displacement. I-V measurements and piezoresponse force microscopy (PFM) are being applied to capture the hysteresis behavior of 3R-β'- In_2Se_3 grown by MBE.

4:30 PM EL07.02.08
Characterisation of Monolayer MoS_2-Dielectric Interfaces HanYan[1], YanWang[1], YangLi[1], SoumyaSarkar[1], DibyaPhuyal[2], JunghoKim[1] and ManishChhowalla[1]; [1]University of Cambridge, United Kingdom; [2]KTH Royal Institute of Technology, Sweden

The atomically thin nature of two-dimensional (2D) transition metal dichalcogenides (TMDs) makes them susceptible to the dielectric environment. Efforts on dielectrics for 2D semiconductors have been focussed on gaining better gate control using high *k* dielectric STO or thin HfO_2 [1, 2]. While SiO_2, HfO_2, and ZrO_2 are widely employed as dielectrics, our understanding of how they influence the electronic properties of atomically thin semiconductors remains limited [3]. In this study, we investigated interfaces between monolayer MoS_2 and various dielectrics (SiO_2, HfO_2, ZrO_2 and hBN) using photoluminescence (PL), synchrotron X-ray photoelectron spectroscopy (XPS), and electrical transport measurements. PL results show that MoS_2 on SiO_2 gives the highest exciton peak energy at 1.91 eV and MoS_2 on ZrO_2 gives the lowest at 1.89 eV. Through XPS, we find that the Mo $3d_{5/2}$ core level binding energies are 231.05 eV, 230.6eV, and 230.22 eV, when MoS_2 is in contact with SiO_2, HfO_2, and ZrO_2, respectively. The results indicate monolayer MoS_2 has the highest electron doping when in contact with SiO_2 and the lowest when in contact with ZrO_2. Furthermore, we determined the band alignments at the interfaces between monolayer MoS2 and the dielectric materials through angle-dependent XPS, elucidating the depth profile of elemental core-level binding energy and thus providing insights into the charge-transfer behaviour when atomically thin MoS_2 interacts with different dielectrics.

Replacing Hydrogen Sulfide with Di-tert-butyl Disulfide as an Atomic Layer Deposition Precursor for Synthesizing Transition Metal Dichalcogenides IanCampbell, DouglasHeine and AgeethBol; University of Michigan–Ann Arbor, United States

Sulfur-containing transition metal dichalcogenides (TMDs), like molybdenum sulfide, have proven to be promising materials for electrocatalysis, energy storage, and microelectronics applications that are demanding increasingly thinner films and smaller particles over large areas. Useful films of TMDs can be prepared via the process of exfoliating layers within TMDs, which suffers from poor scalability, or through approaches like chemical vapor deposition and atomic layer deposition (ALD). ALD is capable of depositing atomically thin layers of material by using self-limiting, surface-saturating reactions that make it uniquely capable of synthesizing subnanometer-scale layers and particles over large areas with variable topography. Currently, the dominant method for preparing sulfide TMDs via ALD is to alternately expose a substrate to a metalorganic precursor and a sulfur source, which is often hydrogen sulfide (H_2S) or a plasma containing H_2S. H_2S is a corrosive, toxic, and flammable gas that is heavier than air, which makes it hazardous and expensive to store, install, and transport. Additionally, the odor of H_2S is imperceptible at life-threatening concentrations, making it even more dangerous. Alternative sulfur precursors in the solid or liquid phase would be beneficial in terms of cost and safety and would require the installation of no additional hardware for most ALD reactors. In this contribution, the widely researched ALD process using bis(tert-butylimido)bis(dimethylamino)molybdenum(IV) ($(^tBuN)_2(NMe_2)_2Mo$) and H_2S plasma is compared to a novel ALD process using $(^tBuN)_2(NMe_2)_2Mo$, hydrogen plasma, and di-tert-butyl disulfide (TBDS), which is an inexpensive, liquid-phase sulfur precursor. The growth behavior of both ALD processes is characterized via continuous in-situ spectroscopic ellipsometry, which reveals saturating reactions for H_2S-plasma and TBDS exposures. The composition and stoichiometry of the deposited films are determined using X-ray photoelectron spectroscopy, Rutherford backscattering, and elastic recoil detection. The crystallographic structures of the films are assessed using Raman spectroscopy and selected-area electron diffraction in conjunction with transmission electron microscopy. Molybdenum sulfide films prepared using both sulfur precursors are compared for their abilities to catalyze the hydrogen evolution reaction and for their electronic resistivities and charge carrier mobilities as determined by van der Pauw measurements. Finally, it is demonstrated that the TBDS-based ALD process is transferrable to the synthesis of other TMDs like niobium sulfide.

Ag-Au-PANI Multilayered Nanowire Network Approach for Visible-To-Infrared Display and Data Encryption Kyung RokPyun[1], YeongjuJung[1], Seok HwanChoi[1], HuijaePark[1], MinjaeLee[1,2], Deog-GyuSeo[1] and Seung HwanKo[1,1]; [1]Seoul National University, Korea (the Republic of); [2]Hyundai Motor Group, Korea (the Republic of)

Polyaniline (PANI) is a conductive polymer with distinct electrochemical characteristics that facilitate the functionalization of nanomaterials, enabling the development of various smart devices. In particular, it is known that its reversible redox process allows for the modulation of optical properties in the visible and infrared regions. While previous studies have explored the electrochromic properties of PANI, they utilized conventional electrodes such as ITO and Au sputtered electrodes, which restrict their application in flexible devices. To address this limitation, we present a novel approach that leverages metal nanowire networks, known for their high electrical conductivity and mechanical flexibility, as the electrode material. Specifically, we synthesize Ag-Au core-shell nanowires and employ a laser-based plasmonic welding process to enhance adhesion between the nanowire network and substrate. This prevents delamination during the electropolymerization of PANI in an aqueous solution, enabling the successful deposition of PANI onto the core-shell nanowire-based electrode. Furthermore, the Ag-Au core-shell nanowire network electrode exhibited excellent electrochemical stability, primarily attributed to the presence of Au outer shell. This characteristic facilitated the direct electropolymerization of aniline monomer on the Ag-Au core-shell nanowire network electrode, preventing the oxidation of core silver nanowires during the electropolymerization process. Thereby, the electrode successfully serves as both a current collector and a backbone for the electro-polymerization process. By optimizing the electrodeposition conditions, we can achieve variable optical properties in the Ag-Au-PANI multilayered nanowire network not only in the visible wavelength region (reflectance) but also in the infrared wavelength region (emissivity). In essence, our proposed flexible multispectral display can alter its visible color and apparent temperature in the visible and infrared wavelengths, respectively, by applying the desired electrical input. Furthermore, we have designed pre-patterned and multi-pixel displays for data encryption and confidential data visualization. This device provides the additional functionality of data encryption, making it highly suitable for diverse applications, including military camouflage, confidential data visualization, and secure communication systems.

8:00 PM EL07.03.02
Substitutional Oxygen-Mediated Se-Vacancy Healing in WSe_2: Enabling High-Mobility p-Type Field-Effect Transistors. RiyaDutta[1], Hae WonCho[1], YounghyunJu[1], PavanPujar[1], Young-MinKim[1], SeonginHong[2], YoungkiYoon[3] and SunkookKim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Gachon University, Korea (the Republic of); [3]University of Waterloo, Canada

Transition-metal dichalcogenides (TMDs) exhibit high carrier mobility and can be scaled down to sub-nanometer dimensions, presenting themselves as viable alternatives to silicon electronics. Among TMDs, WSe_2 stands out for its ability to facilitate both hole and electron carrier transport, making it a crucial component in CMOS logic circuits. However, the p-type electrical performance of WSe_2-field effect transistors (FETs) is still limited, prompting the exploration of various approaches to overcome this challenge. In this study, we employed a heterostructural multilayer WSe_2 channel and utilized solution-processed aluminum-doped zinc oxide (AZO) to modify the composition of WSe_2, resulting in a device with outstanding electrical properties. By introducing oxygen anions from AZO to the WSe_2 channel, we successfully eliminated subgap states through Se-deficiency healing, leading to enhanced transport capacity. Se vacancies, known to cause mobility degradation through scattering, were mitigated via ionic compensation. Consequently, the hole mobility reached high values, peaking at approximately 100 cm^2/Vs. Furthermore, we systematically analyzed the transport behavior of the oxygen-doped WSe_2-FET using density functional theory simulations and photoexcited charge collection spectroscopy measurements.

8:00 PM EL07.03.03
Charge Transport Characteristics in Non-Van der Waals 2D Transition Metal Nitrides Synthesized via Atomic Substitution Approach HongzeGao[1], DaZhou[2], ZifanWang[1], LuPing[1], JunCao[1], MauricioTerrones[2] and XiLing[1]; [1]Boston University, United States; [2]The Pennsylvania State University, United States

Two-dimensional (2D) materials have been extensively explored in the past decade to advance the development of nanoelectronic devices by virtue of their exciting properties emerging at the reduced dimension. Numerous 2D crystals have been synthesized and studied, including graphene, transition metal dichalcogenides (TMDs), and h-BN, which are van der Waals (vdW) layered materials with vdW gaps between two adjacent atomic layers. Such vdW gaps result in an anisotropic bonding in the crystal and hence a weak interlayer interaction, which facilitates the separation of ultra-thin layers of these crystals. However, given the technological gaps in vdW 2D materials (e.g., absence of high-K dielectrics), exploring the non-vdW 2D crystals plays a vital role in advancing the development of 2D electronics. In contrast to vdW crystals, the isotropic strong bonding in non-vdW crystals imposes great challenges in downscaling these materials. Targeting on this technological challenge, our group developed an atomic substitution approach to prepare ultra-thin non-vdW 2D crystals, where vdW 2D crystals (e.g., MoS_2 and WSe_2) are used as precursors and converted into non-vdW materials through a chemical reaction. Non-vdW 2D metal nitrides (MN_x) (e.g., Mo_5N_6 and W_5N_6) with high crystallinity, smooth surface, and well controlled thicknesses have been successfully synthesized. Hereby, we further investigated the charge transport characteristics in these 2D MN_x prepared by the atomic substitution approach. A wide range of electrical conductivities of different MN_x were measured using four probe electrical measurements, and we also found high 2D carrier concentrations of the MN_x from Hall measurements. Temperature-dependent resistance (R-T) measurements further revealed the thermal excitation mechanisms and weak localization effect in the charge transport behaviors of the 2D MN_x. We comprehensively investigated the charge transport characteristics in MN_x and demonstrated their potential applications in nanoelectronic devices

8:00 PM EL07.03.04
Unusual Properties of TiO_2 Nanotube Arrays Formed Anodically in Alkanamide-Based Electrolytes NavneetKumar, KaziM. Alam, DaminiVrushabendrakumar, HarshithaRajashekhar, JohnGarcia and KarthikShankar; University of Alberta, Canada

The formation of highly ordered transition metal oxide nanotube arrays through electrochemical anodization of valve metals (Ti, V, Hf, Zr, Ta, Nb, etc) in fluoride-containing electrolytes is relatively well-established. Titanium dioxide nanotube arrays (TNTAs) have shown immense potential as photocatalysts, photoanodes, photodetectors and electron transport layers for photovoltaics. In the overwhelming majority of journal and conference papers on this topic, the TNTAs are grown in ethylene glycol-based organic electrolytes (eg-TNTAs) containing water and fluoride salt. Ethylene glycol is a polar protic solvent with a dense network of hydrogen bonds resulting in a high viscosity and a moderate dielectric constant of 37. On the other hand, alkanamides whilst polar protic solvents, have a polymer-like structure due to the availability of merely two hydrogen bonding sites in a *trans*-configuration. Furthermore, alkanamides exhibit large values of the dielectric constant - significantly higher than water e.g. formamide has ε_r of 111 while n-methylformamide has ε_r of 171 at room temperature. Herein, we present some unusual properties of TNTAs grown in formamide-based electrolytes (fa-TNTAs). Unlike eg-TNTAs which are self-organized into a closed honeycomb structure with a triangular lattice ordering, fa-TNTAs are non-periodic and have a more open structure with ready access to both the inner and outer nanotube walls. The fa-TNTAs absorb more visible light compared to eg-TNTAs, exhibit much lower lattice strain, differ in surface composition, possess a lower work function and demonstrate superior performance (3-fold improvement) in sunlight-driven transformation of carbon dioxide into carbon monoxide. Infrared spectroscopy indicated the dramatically different nature of adsorbates on fa-TNTAs compared to eg-TNTAs following CO_2 chemisorption. These differences in electronic properties and electronic device performance will be elaborated upon, and explained in the context of the different anodization electrolytes producing changes in morphology, composition, lattice strain and electronic band-structure.

8:00 PM EL07.03.05
Chemical Vapor Etching of Silicon Wafer for the Synthesis of Highly Dense and Aligned Sub-5 nm Silicon Nanowires Arrays JuyeonSeo[1], SenGao[1], SanghyunHong[1], JianlinLi[1], PeiyunFeng[1], Ji YoungByun[2] and Yung JoonJung[1]; [1]Northeastern University, United States; [2]Korea Institute of Science and Technology, Korea (the Republic of)

Silicon nanowires (SiNWs) have attracted great interest for applications in high-performance miniaturized devices and energy harvest and storage systems. Vapor-liquid-solid growth and metal-assisted chemical etching methods are the most commonly used approaches for synthesizing silicon nanowires. Still, using these catalyst-assisted methods, producing a large quantity of silicon nanowires with diameters less than 10 nm is elusive, and the removal of catalysts is a challenge for their practical applications. Recently, we reported the synthesis of highly dense and vertically aligned sub-5 nm silicon nanowires with a high aspect ratio of over 10,000 by a catalyst-free chemical vapor etching of silicon. In this paper, we systematically investigated the effect of key chemical vapor etching parameters that govern the morphology of silicon nanowires. We achieved highly aligned nanowire arrays with sub-5 nm diameter and a length of up to 52.1 μm by controlling the oxidant gas concentration, reaction temperature, and hydrogen concentration. The results demonstrate that ppm level of oxidant gases is crucial for silicon's steady-state etching into nanowires by passivating their surface with a silicon suboxide layer. Furthermore, the thermodynamic analysis combined with the experimental result suggests that anisotropic etching of silicon is also facilitated by increasing the reaction temperature and hydrogen concentration due to the increased ratio between two primary etchants ($HCl/SiCl_4$),

suggesting an optimum range of the etchant ratio (0.131–0.216) for the nanowire formation. Our results can help us understand the chemical vapor Si etching process and guide a scalable synthesis of ultra-narrow silicon nanowires for future scientific research and practical applications.

8:00 PM EL07.03.06
Structural Phase Transitions for Multi-Level In2Se3-Based Phase Change Memory NicholasD. Ignacio[1], YuqianGu[1], SabanHus[2] and DejiAkinwande[1]; [1]The University of Texas at Austin, United States; [2]Oak Ridge National Laboratory, United States

Layered materials such as In2Se3 and MoTe2 have multiple crystal phases with differing electrical properties and can achieve reversible phase changes between them. Compared to transitions between amorphous and crystalline phase in conventional phase change memories (PCM), changes between crystalline phases are expected to have faster and low energy write operations for PCM even compared to interfacial PCM based Sb2Te3-GeTe superlattices due to the lower entropy of the crystalline-crystalline phase change. In2Se3 PCM have been demonstrated utilizing β and γ as the low and high resistance state respectively, however multilevel switching has not been extensively explored.
We report multi--level In2Se3 based PCM with device resistance covering a range of six-orders of magnitude. Local transport measurements conducted with scanning tunneling microscopy (STM) show the resistance of the vertical devices changes exponentially with the number of switching steps. These results indicate the existence of a layer-by-layer phase change in the structure of the material, rather than a lateral enlarging of low and high resistance phases as in conventional PCM. Compared to a planar PCM structure which only shows a three-orders of magnitude resistance change, tunneling like transport through the active material occurs in the vertical structure indicated by the six-orders of magnitude resistance change. The structural changes between crystalline β-In2Se3 and crystalline γ-In2Se3 phases of In2Se3 provide a high speed and low-entropy switching mechanism in conjunction with multi-level switching can allow for high density data storage and neuromorphic applications.

Flexible Gas Sensors Based on rGO and rGO-ZnO for NO_2 Detection at Room Temperature ValmorR. Mastelaro and AmandaA. Komorizono; University of Sao Paulo, Brazil

With the progress in materials science, wearable devices have attracted great interest from the scientific community and the market. These devices can be integrated into watches, bracelets, glasses, clothes, and shoes and even adhered to the skin of the human body and monitor physiological and environmental conditions in real-time. Among the various types of wearable devices, flexible gas sensors have become an area of great importance due to the high demand for monitoring ambient air and exhaled air to identify possible environmental hazards or diseases, respectively[1]. Among toxic gases, NO_2 is one of the most harmful to health. When humans are exposed to a concentration above the safety limit, of 1 ppm for NO_2, this gas can be harmful to the human respiratory system, irritating the skin and eyes[2]. With this, the objective of this work is the manufacture of flexible gas sensors of rGO and rGO-ZnO for the detection of NO_2 at room temperature. ZnO was synthesized by the Pechini method using zinc nitrate hexahydrate as a precursor. The rGO used was the commercial one. Dispersions of rGO and rGO-ZnO with 1, 2 and 5% ZnO were prepared at a concentration of 0.2 mg/ml. For the fabrication of flexible gas sensors, the rGO and rGO-ZnO dispersions were deposited by drop-casting on the interdigitated electrode on the PET substrate. XRD analysis confirmed the formation of the wurtzite structure of ZnO. SEM images show that ZnO has quasi-spherical nanoparticles with an average diameter of 45 nm. SEM images from the rGO sensors show the rGO sheets with some folds due to the stacking of the sheets. For the rGO-ZnO sensors, the ZnO nanoparticles are anchored on the surface of the rGO sheets and surrounded by the rGO sheets. Measurements of NO_2 detection at room temperature show that the formation of composites with ZnO significantly increases the response of the sensors and reduces the response times of the sensors. Among the rGO-ZnO sensors, the rGO-5%ZnO sensor showed the best results in terms of response and response time. When exposed to 1.5 ppm of NO_2, the flexible rGO sensor showed a response and response time of 5.6% and 21 min, respectively. While the rGO-5%ZnO flexible sensor showed a response and response time of 18.5% and 14 min, respectively. Furthermore, the calculated limit of detection (LOD) of the rGO-5%ZnO sensor was 0.075 ppm, below the WHO recommended limit (1 ppm of NO_2).

Keywords: flexible gas sensor, rGO-ZnO gas sensor, PET substrate, NO_2 gas sensors

Multi-Ion Sensor Based on Carbon Nanotube Fibers for Wearable Electronic Tongue HocheolGwac and Seon JeongKim; Hanyang University, Korea (the Republic of)

Wearable electronic tongue (e-tongue) sensors have garnered significant attention for their potential in enabling taste sensing in robotic systems and monitoring aberrant conditions, such as poor water quality, food spoilage (or freshness), and microbial contamination. Despite notable advancements in wearable multi-ion sensors, challenges persist in achieving stretchability and miniaturization of ion-selective sensors capable of detecting a wide range of ions for practical applications. In this study, we present a wearable multi-ion sensor based on ion-selective coiled fiber (ISCF) integrated with Carbon nanotubes (CNTs). The ISCFs were fabricated by coating CNT fibers with ion-selective membranes that include ionophores (valinomycin, sodium ionophore X, and Hydrogen ionophore I) corresponding to the target ions. In additional, the ISCF was fabricated in a coiled configuration to achieve stretchability without employing elastomers. Furthermore, they demonstrated selectivity for each target ions. Importantly, this sensitivity and selectivity were sustained even under mechanical deformations, such as a 25% strain, bending, and knotting. Furthermore, we endeavored to downscale the sensor into a single fiber (about 250 μm) by plying three types of ISCFs and an all-solid-state reference electrode. This multi-ion potentiometric sensor was successfully woven into fabrics, such as clothing or gloves, demonstrating functional sensing performance in various solutions (sea, river, distilled waters, lemon, coconut, and grape juices) as practical applications. Collectively, these findings underscore the high potential of our potentiometric sensor as a taste sensor and monitoring device within the realm of e-tongues.

Side Gate Capacitive Coupling Reconfigurable Devices Based on BN-MoS_2 Van Der Waals Heterostructures MiaoZhang, DaobingZeng, GuanyuLiu, HuihuiLu and ZiaoTian; Shanghai Institute of Microsystem and Information Technology, Chinese Academy of Sciences, China

As the traditional silicon-based device size has been miniaturized to its physical limits, to fullfill the requirements of big data and artificial intelligence technology, the devices with new materials and work principles are urgently required. Developing two dimensional (2D) reconfigurable multifunctional devices is of great potential in further miniaturizing the chip area and simplifying circuit design. Dissimilar atomically thin 2D materials can be vertically stacked to form van der Waals (vdW) heterostructures without being limited by lattice mismatch. Many previous reports have integrated various functions in a single 2D vdW heterostructures device. However, most of reconfig-urable multifunctional devices are based on complex multilayer heterostructures (such as $MoTe_2$-MoS_2-BN-Graphene vdW heterostructures) or air-unstable ambipolar semiconductor channel materials (BP and WSe_2), inevitably limiting their application and manufacture in integrated circuits. Thus, it is urgent to develop 2D reconfigurable multifunctional devices with simple structures and stable electrical properties. MoS_2, one of the most air-stable 2D semiconductors, has shown great prospect to replace conventional silicon materials attributed to its high carrier mobility and tunable bandgap with thickness. Different from ambipolar semiconductors that polarity can be ad-justed from ambipolar type to n or p type by electrostatic doping, MoS_2 generally behaves as an n-type semiconductor due to strong Fermi level pinning near the conduction band. Therefor, few works have reported reconfig-urable multifunctional MoS_2 devices. Most of MoS_2-based reconfigurable devices are based on MoS_2 thickness engineering, potentially limiting their practicality and flexibility in reconfigurable multifunctional circuits. In this work, we propose a side gate capacitive coupling reconfigurable device based on simple Au-BN-MoS_2 heterostructures, in which Au, MoS_2 and BN serve as top semifloating gate, channel material and gate dielectric, respect-ively. Our work realize the integration of three different functions in a single device, including a diode, a double-side-gate reconfigurable logic transistor and a top floating gate memory. The side gate voltage can control the carrier concentration in the MoS_2 channel due to the capacitive coupling between the side gate and the extra extension of top semifloating gate. We demonstrate that the channel can switch between the deplete state, n^+n junction, and accumulated state as the side gate voltage changes from negative to positive. The device exhibits rectification ratios of 10^5 as a diode. The device can also be modulated by the two side gates simultaneously, in which the voltage of the two side gates and drain current serve as input signals and logic output respectively, reconfigurable logic operations (OR, AND) can be realized in a single device by switching the direction of source-drain voltage. The current on/off ratios of AND and OR logic reach about 104. Moreover, the device demonstrates a large memory window and high on/off ratio ($>10^7$) under a small back gate voltage (30V). Those results provide a way for integrating the same reconfigurable multifunctional devices to realizing complex electronic systems.

8:00 PM EL07.03.10
An Electrostatic Force Microscopy-Based Analysis for Metallic and Semiconducting Carbon Nanotubes Indra MemdiKhoris[1], YukiKuwahara[1], FahmidaNasrin[1], RyotaYuge[2] and TakeshiSaito[1]; [1]National Institute Advanced Industrial Science and Technology, Japan; [2]NEC Corporation, Japan

Carbon nanotubes (CNTs) have been known as a promising material for developing high-performance electronic devices. Depending on its chirality, CNTs can be semiconducting (s-type) and metallic (m-type). S-type CNTs have bandgaps, and high carrier mobility which is suitable as transistor, sensor, and logic nano-devices. On the other hand, m-type CNTs have near-ballistic conductance and high current density which is excellent as electrodes and interconnecting component in electrical circuits.[1,2] In general, as-grown CNTs are composed of the mixture of m-

type and s-type. So, there is a need to quantify their m/s ratio. Optical methods, such as Raman spectroscopy and absorption spectroscopy, are widely used to characterize the m/s ratio and structure of CNTs.[3] It is suitable for macroscopic analysis of multiple nanotubes in the bulk sample, but it is not easy for the optical methods to evaluate the microscopic analysis of individual CNTs. The direct observation of individual CNTs is a promising approach for visualizing and characterizing an individual CNT on the area of interest. Electrostatic Force Microscopy (EFM) has been reported to determine the metallicity of CNTs individually based on the line-shape of profile.[4] Another work demonstrated the primary use of EFM to analyze the m/s fraction based on the counted number of CNTs.[5] In this work, we demonstrated the determination of the m/s ratio of CNTs through the analysis of the topographic and EFM images, expressed as value of phase shift (ΔΦ).
The sample in this work was prepared by drop-casting as-grown CNTs on the APTES-functionalized Si wafer. Then, PtIr-coated cantilever were used to obtain the topographic images and EFM images. Then, the topographic image was analyzed to obtain the selections of all CNTs. The selection lines representing CNTs are drawn based on nearest end-to-end point selection of CNTs. Next, the selected lines were transferred to the EFM images to obtain the corresponding data of ΔΦ from each of the selected CNTs. The ratio of the m-type and s-type CNTs were determined by two methods, direct contrast observation of the EFM images and the ΔΦ average calculation. Based on the value of the phase shift, the height, and length of CNTs, we obtained the ratio of m-/s- type, the diameter and the length distribution of the as-grown CNTs.
By analyzing three data sets of topographic and EFM images, the developed EFM-based analysis showed the fraction of s-type CNTs in the as-grown sample around 67% ± 1%. The threshold of the sampling is determined to be around 600 units (line selection) to obtain 1% deviation. This result agrees to theoretical ratio of m-/s- type CNTs for as-grown samples. In addition, m-type and s-type CNTs showed asymmetric length distributions with mean length of 396.36 ± 10.93 nm and 232.85 ± 4.99 nm, respectively.
Further analysis and more experimental would be conducted to address characterization of CNTs' bundling, the non-straight CNTs analysis, and a simple quantification with precision down to 0.1% change of composition in the mixture of CNTs.

Performance Improvement of Thread Transistor using Carbon Nanotube Composite Thread with Ionic Gel HirokiKodaira and TakahideOya; Yokohama National University, Japan

We propose a unique transistor based on carbon nanotube (CNT) composite threads with ionic gel.
It is known that the CNTs have many excellent properties such as highly electrical conductivity, highly chemical stability, electrical properties that can be metallic or semiconducting depending on their structure. Because of these properties, CNTs are expected to have a wide variety of applications. However, since the CNTs exist on a nanoscale, it is difficult to handle them on their own. For this reason, many approaches such as combining with other materials have been proposed. We have succeeded in developing "CNT composite threads" (CNTCTs), which combines CNTs with threads, a familiar material of our daily life. This material had good properties based on CNTs. In addition, we have also succeeded in producing metallic CNTCTs with a metallic property and semiconducting CNTCTs with a semiconducting property. Furthermore, by combining these, we succeeded in developing the "thread transistor" in our previous work. However, several problems have remained, including low performance.

In this study, we are aiming to develop ionic-gated thread transistors using CNTCTs.
Recently, ionic-gated transistors attracted attention because of its large capacitance and low operating voltage. Ionic liquids are suitable for gate dielectrics, but liquid state is not suitable for practical devices. Therefore, ionic gels are used as dielectrics, which is produced by combining ionic liquids and polymers. Because ionic gels have high mechanical toughness, we considered flexible transistors can be fabricated by combining them with CNTCTs.

The production method of our CNTCTs is based on the traditional dyeing method for threads. It is so simple method of dipping a thread in the CNT dispersion and drying in oven. Here we chose (6,5)-chirality CNT as the semiconducting CNT and multiwalled CNT (NC7000) as the metallic CNT. The method of preparing CNT dispersions was a typical one. Ionic gels are prepared by combing ionic liquids (EMI-TFSI), polymers (PVDF-HFP), and solvents (acetone). The solution is agitated until homogeneous. By combining the semiconducting CNTCT as a channel and the metallic CNTCT as a gate electrode, the thread transistor can be easily constructed. Here, a drop of the ionic gel is inserted between both CNTCTs to construct our ionic-gated thread transistor.

As results of measurements, the current-voltage characteristics of the thread transistor were p-type, and gate voltage dependency was improved compared to previous studies. Although the problem of high off-state current due to impurities in the CNTCTs still remains, we believe this approach is effective for performance improvement of our thread transistors.

By further developing this approach, we believe that our CNT composite thread will be used as a transistor in the near future.

Rapid Free–Patterning of Monolayer Graphene HaoCheng, TaeUkLim, JieHu, SangyouKim, YeongjunLee and WonsukJung; Chungnam National University, Korea (the Republic of)

The current methods for patterning graphene–based electrodes are complex and expensive, posing challenges for the commercialization of such electrodes due to repeated damage to the transferred graphene. In this study, we have devised a simple and efficient one–step free–patterning technique for graphene electrodes. This technique involves converting the C=C bonds in graphene to C–O bonds while pseudo-annealing the electrode. We compared the macroscopic and microscopic graphene electrodes produced using our method with those created using traditional techniques. Our evaluation included Raman spectroscopy, X–ray photoelectron spectroscopy, water contact angle measurements, field−emission scanning electron microscopy, and semi–auto probe station analysis. Moreover, we performed electron transport simulations and analyzed the results for both ideal graphene nanosheets (GNs) and GNs containing C–O bonds using a semi-empirical tightly coupled DFTB+ method based on density functional theory. Our findings demonstrate the feasibility and scalability of this proposed graphene patterning approach, which we anticipate will expedite the advancement and commercial availability of graphene–based devices.

Ferroelectric Field Effect Transistor Based on Graphene/$CuInP_2S_6$ Van Der Waals Heterostructures MaheeraA. Ghani, SoumyaSarkar, YanWang and ManishChhowalla; University of Cambridge, United Kingdom

Ferroelectric field-effect transistors (FeFETs) demonstrate non-volatile hysteresis in transfer characteristics, which could be useful for logic and memory devices. FeFETs with two dimensional (2D) ferroelectric, Copper indium thiophosphate, CIPS ($CuInP_2S_6$) as the gate insulator and 2D semiconductor channels show variations (clockwise/anticlockwise hysteresis) in transfer characteristics.[1–3] It is therefore important to understand the influence of polarization, interface charge transfer and trap states on the performance of FeFETs based on CIPS van der Waals (vdW) heterostructures. Here, we investigate top gated 2D FeFET using ferroelectric CIPS and graphene channels with vdW contacts.[4] We observed clockwise hysteresis in graphene FET with SiO_2 back gate due to interface trap states. This clockwise hysteresis can be mitigated by encapsulating graphene with hexagon boron nitride (hBN). We demonstrate the effect of charge transfer from CIPS by the shift of the dirac point in graphene field effect transistor. Furthermore, we reveal anti-clockwise hysteresis in FeFET due to ferroelectricity of CIPS through minimising the influence of trap states at the interfaces.

Development of "Transpiration-Type Thermoelectric Power Generating Paper" using Carbon-Nanotube-Composite Papers Without Need for Heat Source YudaiKamekawa[1], KoyaArai[2] and TakahideOya[1]; [1]Yokohama National University, Japan; [2]Mitsubishi Materials Corporation, Japan

We propose a unique thermoelectric power generating device using carbon nanotube (CNT) composite paper, "transpiration-type thermoelectric power generating paper."
In recent years, thermoelectric power generation has been attracting attention because of its ability to effectively utilize heat that tends to be disposed of. However, the problem is that many of the thermoelectric materials currently in use are rare metals. Therefore, we focused on CNT, which has been shown to have high electrical conductivity and a high Seebeck coefficient. However, CNT is difficult to handle because they exist in powder form. For this, we have solved by developing CNT composite paper by combining paper and CNT. In this study, we are developing thermoelectric power generating devices based on the CNT composite papers.
Conventional thermoelectric power generating devices require a heat source to generate electricity. This research focuses on the capillary phenomenon of paper and aims to develop a new type of thermoelectric power generating paper that does not require a heat source and generates a temperature difference using the heat of vaporization when liquid evaporates from the CNT composite paper containing liquid.
The CNT composite paper is made using the modified Japanese washi paper making process. Specifically, a CNT dispersion consisting of single-walled CNT and SDS (sodium dodecyl sulfate) as dispersant dispersed ultrasonically in pure water is mixed with a pulp dispersion consisting of pulp, the raw material of paper, dispersed in pure water. Next, the water is removed from this mixed dispersion with a fine mesh. Finally, it is dried and molded to complete the process.
To conduct thermoelectric power generation without heat source, one end of this transpiration-type thermoelectric power generating paper is dipped in pure water filled in a container, and the other end is fixed from the top. At the top, the temperature is lower than at the bottom, which is immersed in water, due to the heat of vaporization caused by the evaporation of water lifted by capillary action. The difference in temperature causes the Seebeck effect. In the fabricated paper, a temperature difference of 0.9K was spontaneously generated, resulting in an electromotive force of 22μV.
As the next step in this research, we aim to further improve the output by changing the amount of material and the structure of the paper. Since our transpiration-type thermoelectric power generating paper obtained in this study does not require a heat source, we believe that it can be used as an environmental power generator in rivers and oceans in the near future.

8:00 PM EL07.03.15

CNFs/CNT-Prussian Blue/Chitosan Modified Thread Electrode for Non-Invasive Sensor of Glucose and Lactate NadtinanPromphet[1], ChusakThanawattano[2], ChatchaiBuekban[2], ThidarutLaochai[1], PraneeRattanawaleedirojn[1], KrisanaSiralertmukul[1], PranutPotiyaraj[1], JuanHinestroza[3] and NadnuddaRodthongkum[1]; [1]Chulalongkorn University, Thailand; [2]National Science and Technology Development Agency, Thailand; [3]Cornell University, United States

Non-invasive diagnosis is an alternative approach to monitor health status without the patient painfulness. Among the flexible substrate materials, thread textile has become a promising substrate format for non-invasive wearable sensor fabrication owing to its small size, high flexibility, non-skin irritation, low-cost, and easy-to-use as an auto-microfluidic device. Herein, thread based non-invasive electrochemical sensor for sweat glucose and lactate was engineered. The cotton thread surfaces were modified by cellulose nanofibers (CNFs)/carbon nanotube (CNT) ink-Prussian blue/chitosan to enhance liquid adsorption, increase bioreceptor immobilization and improve sensor performance. The CNFs/CNT-prussian blue/chitosan modified cotton thread was characterized by laser scanning confocal microscopy, scanning electron microscopy, and fourier transform raman spectroscopy. Amperometric measurements using a hydrogen peroxide (H_2O_2) were applied for electrochemical characterization of the modified thread electrodes. A portable potentiostat was designed as a wristwatch and integrated with the modified thread electrode to provide a real-time detection of glucose and lactate. This sensor provides a linear range of 0.1–3 mM with the detection limit of 0.1 mM for glucose and a linear range of 1–35 mM with the detection limit of 1 mM for lactate which can distinguish the cut-off level of both glucose (0.3 mM) and lactate (25 mM) between the normal and high-risk people.

Enhancing Learning Accuracy with Floating-Gate Memristors in a Multi-Terminal Spiking Neurosynaptic Network HosungChoi and WoojongYu; Sungkyunkwan University, Korea (the Republic of)

Spiking neural networks (SNNs) are regarded as a more natural representation of artificial neural networks, distinguishing them from other types of networks. While several studies have been conducted to model SNNs, incorporating multiple connections between neurons has proven challenging due to the limited number of terminals in memristors. In this research, we propose a novel spiking neurosynaptic network that utilizes a multi-terminal floating-gate memristor.
Our memristor, named TRAM (Tunneling Random Access Memory), leverages the change in the Fermi energy level (Ef) of graphene, exhibiting desirable memory characteristics such as a high on/off ratio (>10^5), excellent retention (>10,000 times), strong endurance (>100,000 times), and low energy consumption (120pJ). To emulate synapses and neurons, we adjusted the thickness of the insulating film layer (Al_2O_3). A thin layer (3nm) was used for neurons to demonstrate the Leaky Integrate-and-Fire (LIF) characteristic, while a thicker layer (7.5nm) was employed for synapses to exhibit Spike-timing-dependent Plasticity (STDP).
When voltage inputs are applied to multiple synapses, all inputs are transmitted to the neurons. If the cumulative input from the synapses fails to surpass the threshold voltage of a neuron, the neuron slowly discharges its voltage in accordance with its leaky properties. However, if the threshold voltage is exceeded, the neuron fires and generates an output signal to update the weight (conductance) of the synapse. The threshold and feedback voltage of the neuron are created using a comparator.
Through our multi-terminal spiking neurosynaptic network, we achieved a high learning accuracy of up to 83.08% on the unlabeled MNIST handwritten dataset.

8:00 PM EL07.03.17

Tuning of Ultrafast Carrier Dynamics in 2D GeS and GeSe by Cu Intercalation SepidehKhanmohammadi[1], KaterynaKushnir[1], CatherineTran[2], KristieKoski[2] and LyubovV. Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]University of California, Davis, United States

Germanium sulfide (GeS) and germanium selenide (GeSe) are 2D layered van der Waals semiconductors. These semiconductors have high carrier mobilities and moderate band gaps in the near-infrared (1.55-1.65 eV for GeS and 1.1 eV for GeSe, in the bulk)[1-4]. Previously, we demonstrated that photoexcitation with either above or below the bandgap energy results in long-lived transient conductivity. Plus, photoexcitation above the bandgap results in emission of THz pulses in both materials due to shift current generation[5]. We found that 800 nm (1.55 eV) excitation results in longer-lived free photocarriers, lasting for hundreds of picoseconds to several nanoseconds. While it was in the order of hundreds of picoseconds for 400nm (3.1 eV) excitation[6]. Here, we focus on photoexcited carrier lifetimes by intercalation of zero-valent Cu into the van der Waals gaps of GeS or GeSe nanoribbons. We find that intercalation of copper drastically decreases carrier lifetime and introduces a much faster decay time. This behavior can be observed in both GeS and GeSe which can be promising for engineering optical properties of these materials for high-speed optoelectronic devices.

8:00 PM EL07.03.18

Complementary Logic Circuit Based on Two-Dimensional Field-Effect Transistors with Ultrashort Gate Lengths GeonhoMun[1,2], CheolheeHan[1,2], Heon-SuAhn[1,2] and Moon-HoJo[1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

As silicon transistors approach the sub-10-nm technology level and encounter increasingly complex technical obstacles, it becomes crucial to explore alternative device structures and new channel materials. Two-dimensional (2D) van der Waals semiconductors, which confine charge carriers within a 2D space, show promise as channel materials for transistors with gate lengths (L_G) below 10 nm, while maintaining a small subthreshold swing and low leakage current. Previous studies have demonstrated MoS_2 transistors with L_G of approximately 1 nm, utilizing a single-walled carbon nanotube or the edge of graphene as the gate electrode. However, the handling of these materials presents challenges, preventing the realization of ultra-scaled 2D transistors compatible with complementary logic circuits. In this study, we present high-quality 2D NMOS and PMOS transistors with a subthreshold swing of about 65 meV dec^{-1} and an On/Off ratio of up to 10^7, utilizing the MoS_2 mirror twin boundary as a gate electrode. These devices have an effective L_G below 10 nm, as the mirror twin boundary embedded in a MoS_2 bi-crystals acts as a one-dimensional metal with a width of only few atoms. Additionally, we demonstrate an array of CMOS inverters by controlling the nucleation sites of the MoS_2 bi-crystals,

offering prospects for a new generation of ultrashort electronic devices and their circuits that go beyond the limitations of Moore's law.

Mechanism of Magnesium Oxides Mg_xO_x Adsorption onto Pristine Graphene: Density Functional Theory Approach MahlatseMatloga[1], MMTibane[1] and RRMaphanga[2]; [1]UNISA, South Africa; [2]CSIR, South Africa

The demand for high energy storage systems has generated interest in metal-air batteries as a promising next generation battery technology due to their high theoretical energy density which surpasses that of metal-ion batteries. In this study, we investigated the adsorption mechanism of magnesium oxides (Mg_xO_x) onto pristine graphene during oxygen reduction reaction (ORR) for metal-air batteries operation using density functional theory. We studied different adsorption configurations, comprising the O_2 and Mg as ORR reactants and the MgO_2, and Mg_2O_2 as ORR products and propose preferred pathways. Mg atom weakly adsorbed onto graphene with an adsorption energy of (-0.035 eV to -0.043 eV), whereas O_2 molecule adsorbed with an adsorption energy of (-0.101 eV to -0.134 eV) slightly stronger than Mg adsorption. Furthermore, the ORR product MgO_2 adsorbed strongly (-1.536 eV) than other reaction product Mg_2O_2 with a calculated adsorption energy of (-0.879 eV) onto graphene. Overall, the reaction product MgO_2 revealed strong stability than other configuration systems. Lastly, the electronic properties, i.e., the total and partial density of states were calculated to understand the electronic behaviour of graphene/Mg_xO_x composites.

Study of n-Type Paper Transistor Fabrication using Carbon Nanotube Composite Paper KaitoAdachihara and TakahideOya; Yokohama National University, Japan

We propose paper transistors using CNT composite papers. It is known that CNTs have many properties such as high electrical conductivity, light weight, high strength, and flexibility. Because of these properties, CNTs are expected to be applied in various fields. However, since CNTs exist in nanoscale and powder form, it is necessary to devise ways to apply them to devices. Therefore, we focus on paper, which is inexpensive, easy to process, and a familiar material. By combining CNTs and paper, we are applying CNTs to devices as the CNT composite paper, which has the properties of both CNTs and paper.
The method of making our CNT composite paper is described below. Our CNT composite paper is produced by using modified Japanese *washi* papermaking method. Specifically, CNT and Sodium Dodecyl Sulfate (SDS) are dispersed in pure water by ultrasonication to prepare CNT dispersion. Next, the pulp is placed in pure water and stirred to prepare pulp dispersion. The CNT dispersion and pulp dispersion are mixed, and then dehydrated on a fine mesh. After dehydration, the paper is formed in a heat press to complete the paper. By selecting metallic or semiconducting type CNTs when making the composite paper, it is possible to make the composite paper with each characteristic. Next, the paper transistor fabrication method is described below. Paper transistors can be made by cutting each part to the size used, moistening it with pure water, and then heat pressing it so that the paper fibers intertwine and adhere to each other. Since CNTs exhibit p-type semiconducting characteristics in air, it is known that fabricated paper transistors exhibit p-type characteristics. Therefore, n-type doping for CNTs should be used to prepare n-type semiconducting CNTs. By using the n-type doping to our paper transistors, they should show a n-type property. In previous research, our composite paper was dipped in a n-type doping solution and dried in an oven, was used. However, it failed to develop a desired n-type paper transistor because the dependence of the gate voltage could not be confirmed even after doping. One possible cause was that soaking the paper in the solution led to degradation of the paper fibers and the CNT network. Therefore, we adopted a new doping method, vapor deposition, to develop a desired n-type paper transistor. In this method, we do not immerse the paper in the solution, but instead uses the doping solution as a vapor to attach the dopant to the CNT composite paper. As a result of this deposition method, we obtained an on/off ratio of 1.82 with the deposition method compared to 1.51 with the previous doping method at a drain voltage of 2 V, confirming a significant performance improvement. We were also able to confirm the gate voltage dependence and succeeded in developing a paper transistor with desired n-type characteristics, which could not be obtained in previous studies.
In the future, we will aim to realize paper logic circuits by combining p-type and n-type paper transistors. If this technology is realized, it will be possible to make every paper product have information processing functions, we believe.

Analytical Device Physics Model for the Design and Fabrication of a Nanowire-Based Betavoltaic Device AmandaThomas and RayR. LaPierre; McMaster University, Canada

The need for robust and versatile energy sources that surpass the lifespan limitations of traditional lithium-based devices have made betavoltaic (BV) devices a solution with promising potential. BV devices employ the direct conversion of radioactive decay energy into electrical power through a process analogous to the photovoltaic effect. In a BV device, the energy of the highly energetic electrons (beta particles) emitted from a radioisotope source generates electron-hole pairs (EHPs) within a target semiconductor material through impact ionization events induced by a series of scattering interactions between the betas and the semiconductor target. The separation and collection of the EHPs into the contact regions by the semiconductor p-n junction results in the generation of electrical power.

Given the extremely low flux of beta particles, BV devices generate very small current densities on the order of μAcm-2 to nAcm-2. The half-life of the radioisotope used determines the lifetime of the device, allowing for device lifespans up to nearly 100 years. BV devices are also compact, occupying less than a cubic centimeter of volume. The temperature insensitivity of BV devices allows for continuous operation with minimal fluctuations in device performance in a variety of environmental conditions. The small footprint, long lifetimes, and operational robustness of BV devices make them highly suited for low power applications, particularly those that necessitate minimal or remote access. BV devices have found utility in a diverse range of fields, including health-care, space exploration, deep-sea operations, and military defense/intelligence industries.

Conventional BV devices employ a planar geometry, resulting in the loss of nearly half of the isotropically emitted beta flux, reducing device conversion efficiency. Planar BV devices are limited by the available surface area for source deposition. Increasing the available surface area for deposition increases the source thickness, resulting in the loss of beta flux due to self-absorption of the betas by the source material. In 2005, Sun et al. fabricated a tritium (3H) source BV device with a porous silicon (PS) diode structure, reporting improvement of the BV power-generation efficiency by a factor of 10 compared to planar devices [2]. The observed device performance improvements were attributed to the geometry increase from 2D to 3D, suggesting nearly every emitted beta entered a nearby PS BV junction as a result [2]. Many of the performance-limiting factors of planar BV devices can be mitigated by adopting a 3D interpenetrating device structure, in which the beta emitter source is embedded in the volume between the nanowires (NWs). This results in increased source deposition and overall device efficiency.

Unlike thin film BV devices, NW-based device material systems are not limited by the lattice mismatch constraint. In NWs, lattice mismatch-induced strain can be relaxed elastically at the NW free surface without the formation of dislocations [3], allowing for greater accommodation of lattice mismatch-induced strain within the NWs. As a result, NW hetero-structures can be readily grown on inexpensive silicon substrates, offering increased flexibility in materials system choice at reduced manufacturing costs. The limiting efficiency of a betavoltaic device can be approximated by the ratio of the active region bandgap and the effective ionization energy. Gallium phosphide's relatively large bandgap energy of 2.26 eV corresponds to a limiting efficiency of ~25%, exceeding that of conventional silicon-based BV devices. We introduce an analytical device physics model that simulates the current-voltage (J-V) characteristics of NW array-based betavoltaic devices for nanostructured and planar source configurations. This model serves as a roadmap to determine the ideal geometry and material properties of NW arrays, crucial for the development of a GaP "nanowire betavoltaic battery".

Ultralow-Power and Miniaturized X-Ray Sensor using the Single-Walled Carbon Nanotube Micro Network-Based Geiger Counter Design HyeheeKim[1], JianlinLi[1], AnthonyChildress[1], JuyeonSeo[1], PoornaprakashBathalavaram[2], AhmedBusnaina[1], Sung-HyunMoon[3], JihwanBoo[4], Hak SooChoi[3], GeehyunKim[4], Young LaeKim[2] and Yung JoonJung[1]; [1]Northeastern University, United States; [2]Gangneung-Wonju National University, Korea (the Republic of); [3]Massachusetts General Hospital and Harvard Medical School, United States; [4]Seoul National University, Korea (the Republic of)

We present an ultralow-power, highly sensitive, and miniaturized X-ray sensor with micropatterned single-walled carbon nanotube (SWCNT) interdigitated networks inspired by the Geiger-Mueller counter design. Due to the unique nanostructured surface and superb electronic transport nature of assembled SWCNTs, a strong electric field is formed between and within highly organized SWCNT interdigitated electrodes, which effectively separates electrons and ionized ions created by incident X-rays into electrodes, facilitating electron detection. As a result, the device can detect a low X-ray dose rate (9.97 $\mu Gy\ s^{-1}$) with an extremely low power consumption of 80–90 fW, demonstrating a sensitivity of up to 203.96 $\mu C\ Gy^{-1}\ cm^{-2}$. Furthermore, the interdigitated SWCNT electrode design produces a low noise level in the picoampere range, permitting exceptional real-time signal detection during X-ray exposure. These unique features of our SWCNT X-ray sensing device enable various low SWaP (size, weight, and power) radiation detectors in the fields of medicine, homeland security, and defense.

Quantitative Comparison of Conductivity and Piezoresistance in Networks of Graphene Nanosheets with Different Aspect Ratios EoinCaffrey, JoseMunuera, LukeDoolan, KevinSynnatschke, CianGabbett, OranCassidy, TianCarey, JosephNeilson, AdamG. Kelly and JonathanN. Coleman; Trinity College Dublin, Ireland

Solution processed 2D nanosheet networks have found applications in printed transistors, batteries, photodetectors, catalysts and strain sensors. These networks are assembled from nanosheets in a liquid phase through a range of deposition techniques, yielding notably different structures. In this work, we prepared graphene inks by liquid phase (LPE) and electrochemical (EE)

exfoliation with very different nanosheet aspect ratios (~30 vs ~1000) and processed them into networks via spray coating and liquid-liquid interfacial assembly techniques. Top-down SEM and FIB SEM 3D imaging of the networks show clear differences in morphologies due to both nanosheet aspect ratio and deposition technique. Small, rigid LPE nanosheets form highly porous networks with point-like junctions, displaying different degrees of alignment depending on the deposition technique, while large, flexible EE nanosheets yield compact networks with large conformal junctions for every deposition technique. The electrical conductivities of these networks show a similar dependance on morphology, with a tenfold increase (~10^4 to ~10^5 S/m) for spray-coated LPE and EE nanosheets. Piezoresistance measurements show a strong dependance on the network morphology on gauge factor, as predicted by the percolation based model developed in previous work. Gauge factors of nanosheet networks were found to range between 0.4 and 350 depending on the network structure. This study casts light on the key tuning parameters to modify the network structure of nanosheet networks and the effect different structures have on the conductivity and piezoresistive response of the networks. Understanding these key electronic propetries will pave pathways towards device applications using 2D materials, including strain sensors and printed flexible electronics.

Enhanced Photoelectrochemical Performance of $CuBi_2O_4$ Photocathodes by Constructing a Built-In Voltage Joon-SooYoon, Young-MinKim and Yun-MoSung; Korea University, Korea (the Republic of)

$CuBi_2O_4$ (CBO) is a p-type semiconductor showing numerous attractive features for photoelectrochemical (PEC) water splitting. Although the theoretical photocurrent density of the CBO photocathode is high enough to be practically applied to water splitting, the loss of charge carriers is considerable due to the recombination in the bulk. In this study, we designed a concentration gradient in a CBO photocathode where the Cu-rich phase is located at the top, and the Bi-rich phase is located at the bottom through the diffusion occurring during thermal annealing of CuBi thin film. The stacking order of Cu and Bi thin metal film was switched to analyze the effect of the gradient direction on PEC characteristics. UPS, UV-vis spectroscopy, and Mott-Schottky plots confirmed the resulting band structures of CBO photocathodes. The photocurrent densities of the CBO photocathode with Cu-rich top reveal -1.14 mA/cm^2 and -0.68 mA/cm^2 at 0.38 V vs. RHE in the electrolyte of 0.5 M NaOH purged with N_2 and O_2, respectively. These values are 33.8 and 49.7 % higher than the photocurrent densities obtained from the CBO photocathode with Bi-rich top. The enhancement was also verified by IPCE measurements. This is attributed to the internal electric field acting as a driving force for efficient charge separation and collection. The successful solid-state synthesis of CBO photocathodes having a built-in electric field demonstrates an effective and simple route toward band-engineered photoelectrodes for ternary oxide-based materials.

Enhanced PEC Water Oxidation of Rh-Decorated α-Hematite Through Reduced Overpotential Young-MinKim, Joon-SooYoon and Yun-MoSung; Korea University, Korea (the Republic of)

The photoelectrochemical behavior of Rh cluster-deposited hematite (α-Fe_2O_3) photoanodes (α-Fe_2O_3@Rh) was investigated and the interactions between Rh clusters and α-Fe_2O_3 nanorods were elucidated both experimentally and computationally. A facile UV-assisted solution casting deposition method allowed the deposition of 2 nm Rh clusters on α-Fe_2O_3. The deposited Rh clusters effectively enhanced the photoelectrochemical performance of the α-Fe_2O_3 photoanode, and electrochemical impedance spectroscopy (EIS) and Mott-Schottky analysis were applied to understand the working mechanism for the α-Fe_2O_3@ Rh photoanodes. The results revealed a distinctive carrier transport mechanism for α-Fe_2O_3@Rh and increased carrier density, while the absorbance spectra remained unchanged. Furthermore, density functional theory (DFT) calculations of the oxygen evolution reaction (OER) mechanism corresponded well with the experimental results, indicating a reduced overpotential of the rate-determining step. In addition, DFT calculation models based on the XRD measurements and XPS results provided precise water splitting mechanisms for the fabricated α-Fe_2O_3 and α-Fe_2O_3@Rh nanorods. Owing to enhanced carrier generation and hole transfer, the optimum α-Fe_2O_3@Rh3 sample showed 72% increased photocurrent density of 1.06 mA/cm^{-2} at 1.23 V_{RHE} compared to that of the pristine α-Fe_2O_3 nanorods electrode.

Optical Blocking Layer and Field-Induced Junction on Silicon Nanowire Multispectral Photodetectors Toward High Quantum Efficiency DeokjaeChoi, JungtaekLee and KwanyongSeo; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Crystalline silicon nanowires (c-SiNWs) have unique optical characteristics that enable tuning of their spectral response depending on their diameter. However, real-world applications of c-SiNWs multispectral photodetectors are still hampered by their low selectivity and low quantum efficiency (< 30%). The primary obstacles include the broad-spectrum light absorption of the bottom crystalline silicon (c-Si) substrate underneath the c-SiNWs. In addition, it is difficult to form appropriate p-n junctions on c-SiNWs and it leads to severe recombination which makes low external quantum efficiency (EQE). In this study, a thin metal film was applied as an optical blocking layer to block light absorption in the bottom c-Si substrate, and atomic layer deposition (ALD)-based Al_2O_3 was employed to form a dopant-free p-n junction on diameter-controlled c-SiNWs. Consequently, the maximum EQE of the fabricated photodetector was 77.4% at 620 nm with remarkable wavelength selectivity. This work removes major stumbling blocks for the use of c-SiNW as selective light spectral bandpass photodetectors.

SAW-Induced Spin Wave Excitation in Ferromagnetic Epitaxial Thin Films AlfonsG. Schuck, SebastianKölsch, SwarnasreeBanik and MichaelHuth; Institute of Physics, Goethe-University, Germany

Surface acoustic wave (SAW) excitation of spin waves in ferromagnetic thin films has recently gained significance due to the potential for the realization of novel microwave devices and applications in magnonics.
So far, SAW excitation has commonly been accomplished by use of piezoelectric substrate materials, such as $LiNbO_3$, on top of which the ferromagnetic thin film is deposited. This approach has severe limitations with regard to studying SAW-spin wave coupling effects in epitaxial magnetic thin films. For epitaxy to occur, selected substrate materials and crystal orientations have to be used; and these substrate materials tend not to be piezoelectric.
Here we show how textured piezoelectric AlN thin film transducer structures can be fabricated on different substrate materials by means of reactive RF sputtering. By proper selection of the material for the interdigital transducer electrode structures and standard UV lithography, the frequency range up to about 3 GHz becomes available for spin wave excitation.
Selected examples of SAW-induced spin wave excitation in epitaxial magnetic thin films are presented and compared to results obtained on Nickel thin films as commonly used reference material.

Aptasensors Based on 2D Transition Metal Dichalcogenides for Label-Free and Ultrasensitive Detection of Cytokine Biomarkers. MiretteFawzy, ThushaniDe Silva, HamidrezaGhanbari, KarenKavanagh and MichaelAdachi; Simon Fraser University, Canada

Cytokines are small immune-system signaling proteins found in body fluids such as blood, saliva, and sweat, that are considered as biomarkers for numerous health conditions and diseases. An abnormal variation in cytokine concentrations is an indicator of uncontrolled inflammatory reactions that has been associated with diseases such as cancer, diabetes, Alzheimer's, rheumatoid arthritis, and cardiovascular diseases. Most diseases, particularly cancers, can often be cured if they are detected at an early stage. Thus, the ability to monitor and detect a slight change in cytokine levels is of great significance for early clinical diagnosis.
In this work, we report the development of aptasensors based on 2D transition metal dichalcogenides (TMDs) for rapid, label-free, highly sensitive and specific detection of tumor nercosis factor-α (TNF-α), a representative inflammatory cytokine biomarker.
Our biosensors employ mechanically exfoliated multilayer TMD flakes (MoS_2 and WSe_2) as the sensing channel, and aptamers (short single-stranded nucleic segments) as the bioreceptors. The sensing area is passivated with a thin aluminum oxide layer (around 5 nm) using atomic layer deposition technique (ALD) to provide available sites for facile functionalization with bioreceptors. The aptamers are immobilized on the sensor surface via surface chemical functionalization with (3-aminopropyl) triethoxysilane (APTES) and glutaraldehyde. A fluorescence measurement is used to confirm that the aptamers, labeled with a fluorescent dye (FAM dye), are successfully immobilized on the sensor surface. Aptamers were chosen as cytokine biomarker receptors since they bind specifically to the target cytokine forming G-quadruplex structures, bringing charged cytokines closer to the surface of the sensor. The change in the surface charge density can be used to detect the concentration of cytokines via a chemiresistive I-V measurement. The experimental results demonstrate that the cytokine aptasensor can rapidly (incubation time is around 2 mins) respond to the change in TNF-α concentration with a sub-picomolar limit of detection (LOD). The aptasensor showed good selectivity against other biomarkers such as IL-6 and C-reactive proteins. Therefore, our sensor has great potential for the early diagnosis of various human diseases.

8:00 PM EL07.03.29
Demonstration of Controlled Doping and Complementary Inverter Operation in Transition Metal Dichalcogenide Transistors using Self-Assembled Monolayers Dong HyunLee, YoungminHan and HocheonYoo; Gachon University, Korea (the Republic of)

Transition metal dichalcogenides (TMDC) are attracting attention as next-generation semiconductor materials due to their theoretically high carrier mobility and excellent optical properties [1-3]. In addition, the TMDCs are extensively researched as an alternative that can overcome the limitations of integration in conventional silicon-based electronic devices. However, a method for controlling the electrical properties of TMDC-based electronic devices has not been established. The conventional ion implantation suitable for silicon-based electronic devices causes damage to the lattice structure of TMDC. As a countermeasure, the chemical doping method using self-assembled monolayer (SAM) minimizes damage to the lattice structure of the TMDCs and simultaneously controlling the energy band of the semiconductor. In this study, we demonstrated the p-type or n-type doping effect for ambipolar $MoTe_2$ transistors by applying the chemical doping method using SAMs. The SAM materials such as 1H,1H,2H,2H Perfluorooctyltriethoxysilane (PFOTES) and (3-Aminopropyl)triethoxysilane (APTES) doped onto $MoTe_2$ transistors accumulate holes or electrons in the channel due to their opposite electronegativity. As a result, the electron mobility and on/off ratio of n-type $MoTe_2$ transistor doped with APTES increased by 4.6 times and 79 times, respectively. On the other hand, $MoTe_2$ doped with PFOTES present p-type behavior had increased 18.4 times of the hole mobility and 159 times of on/off ratio. Finally, we demonstrated a complementary inverter using SAM-doped n-type and p-type $MoTe_2$ transistors, presenting a clearer full-swing operation compared to before SAM doping.

8:00 PM EL07.03.30
Advancements in Precise Atom Manipulation for Tailored One-Dimensional Molecular Arrays: Synthesis, Characterization and DFT calculations OrlandoJ. Silveira[1], KeweiSun[2], LauriKurki[1], JoseLado[1], OndrejKrejci[1], KeisukeSagisaka[2], ShoheiSaito[3], ShigehiroYamaguchi[4], OscarCustance[2], TakashiKubo[5], TomohikuNishiuchi[5], TakuyaKodama[5], YuanZhangyu[2], AdamFoster[1,6] and ShigekiKawai[2]; [1]Aalto University, Finland; [2]University of Tsukuba, Japan; [3]Kyoto University, Japan; [4]Nagoya University, Japan; [5]Osaka University, Japan; [6]Kanazawa University, Japan

The synthesis of one-dimensional molecular arrays with tailored stereoisomers presents a challenging yet highly promising avenue for molecular opto-, electronic-, and magnetic-devices, where the local array structure critically influences functional properties. This research showcases significant advancements in the synthesis and characterization of one-dimensional materials through precise atom manipulation. Utilising scanning tunnelling microscopy (STM) and spectroscopy (STS) with functionalized tips, coupled with density functional theory (DFT) calculations, we comprehensively characterised the materials. Firstly, we show that the magnetic states of a Boron substituted graphene nano ribbon (GNR) on an $AuSi_x$ intercalation layer are suppressed by Si atoms adsorbed into the substituted areas, but can be recovered and controlled by tip-induced removal of the embedded Si atoms, as a clear Kondo resonance peak appears [1]. The successful control of such spin polarised states in an extended π carbon system holds great potential for spintronics application. Next, we describe the sequential tip-induced removal of bromine atoms on a linear array of 3D moieties with C-Br bonds protruding from the molecular plane [2]. Subsequently, an open-shell singlet diradical is observed, which undergoes an inelastic spin transition of 91 meV to a triplet state. Furthermore, we show the synthesis and characterization of one- and two-dimensional covalent orbital frameworks whose backbones contain 1,4-disilabenzene (C_4Si_2) linkers [3]. Substituting carbon with silicon in organic molecules and materials has long been an attractive way to modify their electronic structure and properties. Silicon-doped graphene-based materials are known to exhibit exotic properties, yet conjugated organic materials with atomically precise Si substitution have remained difficult to prepare. Our results for this part demonstrate the high generality of the C–Si on-surface coupling by depositing Si atoms and subsequent polyaromatic hydrocarbons on Au(111). These remarkable advancements pave the way for novel functional materials with vast scientific and technological implications.

Selective Passivation of 2D TMD Surface Defects by Atomic Layer Deposited Al_2O_3 for Enhancement of Recovery Properties of Gas Sensor LeeRaeyoung[1], SohnInkyu[1], WiSungjoo[1], KimYoungjun[1], KimMyoungsub[1,2], YoonHwi[1], ShinDain[1], KimJaehyeok[1], SeoJeongwoo[1], SeungminChung[1] and KimHyungjun[1]; [1]Yonsei University, Korea (the Republic of); [2]SK Hynix, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDs) which possess large surface-to-volume ratio have been widely used for room temperature gas sensing applications. [1] However, due to its intrinsic defect or vacancies on TMD surface, incomplete recovery of TMD gas sensors hinder the realization of reliable and repeatable use of 2D TMD gas sensors. [2] Here, we demonstrate improvement of recovery rate of TMD gas sensors by selectively passivating TMD surfaces' defect or vacancies with Al_2O_3 using atomic layer deposition. SEM analysis confirms that nucleation and growth procedure of atomic layer deposited Al_2O_3 occurs along the grain boundaries and defects of 2D MoS_2 and WS_2, not covering inert basal plane. Also, Raman, Photoluminescence and XPS spectra shows the slight n-doping effect of Al_2O_3, which attributes to improvement of gas sensor response as well as recovery rate. Our unique and unreported defect passivated TMD gas sensors show 400 % response toward 10 ppm of NO_2, and the recovery rate rises up from 74% to 96% as the number of ALD cycle increases even at room temperature. Also, the recovery rate toward NH_3, which is the reducing gas, shows an increase of more than 30% implying that our proposed method is a promising strategy for improving the recovery rate of 2D TMD gas sensors.

Low Temperature Magneto-Transport Properties of ALD Grown TiN_xO_y Films FilippBaron; SAAZ Micro Inc., United States

We report results of the magnetoresistivityand R(T) measurements of TiN_xO_y films with different N/O-content grown by ALD in magnetic fields up to 11 Tesla. Our results indicate that the films are amorphous metals, which follow the Mooij rule, they demonstrate both positive and negative magnetoresistivity, and some of them undergo superconductive transition below 4.2K. The technology for obtaining a compact temperature sensor for wide temperature range (liquid helium to +260deg C) based on 40 nm thick $TiN_{0.87}O_{0.97}$ is presented. This technology is fully compatible with standard CMOS.

8:00 PM EL07.03.33
Development of Graphene Oxide with a Single Oxygen Functional Group and Applications for the Gas Barrier Membrane TatsukiTsugawa, KazutoHatakeyama, MichioKoinuma and ShintaroIda; Kumamoto University, Japan

Graphene oxide (GO) has a variety of oxygen functional groups on the surface, making it highly dispersible in various solvents such as water and N,N-dimethylformamide. This makes it possible to easily fabricate laminated membrane on the substrates of various shapes by using GO dispersion solution. Furthermore, GO has excellent potential for gas barrier applications due to high aspect ratio and flexiblity. Therefore, GO has been investigated as gas separation membranes that can achieve both high flow rate and high selectivity, but in general, the many defects (nanopores) located in the nanosheet causes reduction in gas barrier performance. As a result, the gas barrier performance is significantly lower than that of graphene. Because of the uncontrolled introduction of these defects during GO synthesis, its use as a barrier membrane has been limited to large molecles or ions. In particular, the barrier performance for small molecules and ions such as H^+ has only been achieved by graphitization using strong reducing agents, which was impractical given the damage and hazards to the substrate. In this report, we describe the GO with low defect density that sweep away this perception and barrier membranes based on it. The nanopores on the GO surface are formed by introducing COOH and C=O groups and breaking the C=C bonds of the graphene backbone during oxidation treatment. In other words, GO without nanopores can theoretically be obtained by introducing oxygen functional groups in-plane while maintaining the C-C bond. Oxygen functional groups that achieve these results include C-O-C (epoxy group) and C-OH (hydroxy group). It has been reported that graphite oxide treated with fuming HNO_3 and $KClO_3$ has almost only epoxy groups, and such GOs are considered to be free of nanopores. In this study, we succeeded in obtaining highly efficient monolayer nanosheets from this graphite oxide using a weakly basic solvent with the addition of ammonia, and clarified the detailed structure. It was found that the barrier performance against specific gases of GO without nanopores was found to be 10^3 times higher than that of conventional GO and superior to Kapton and PET films in terms of gas permeability coefficient considering the film thickness. Furthermore, it was found that GO without nanopores exhibits 10^6 times higher proton barrier performance than conventional GO.

8:00 PM EL07.03.34
Observation of Topological-Hubbard Phase Diagram in Twisted Homo-Bilayer $MoTe_2$ Moiré Superlattice KaifeiKang[1], YichenQiu[1,1], KenjiWatanabe[2], TakashiTaniguchi[2], JieShan[1,1,3] and Kin FaiMak[1,1,3]; [1]Cornell University, United States; [2]National Institute for Materials Science, Japan; [3]Kavli Institute at Cornell for Nanoscale Science, United States

At half-filling of a honeycomb lattice, competition between the onsite Coulomb repulsion and spin-orbit interaction leads to the Kane-Mele-Hubbard phase diagram, consisting mainly of a topological band insulating phase and an antiferromagnetic Mott insulating phase. Despite decades of theoretical efforts, experimental evidence is yet to be observed. Here we present the first

demonstration of such a phase diagram in a honeycomb moiré superlattice formed by small angle twisted $MoTe_2$ monolayers. A quantum phase transition from a quantum spin Hall insulator (QSHI) to an antiferromagnetic Mott insulator (AFMI) is realized by tuning the vertical electric field. In the QSHI state, we observe a resistance plateau of ~ $h/2e^2$ for temperatures below 10 K. In the AFMI state, we observe a zero Hall plateau and sharp magnetic transitions up to a Neel temperature of $T_N \sim 30$ K. At high magnetic fields of B > 10 T, both QSHI and AFMI are driven into Chern insulators with the quantized Hall resistance $R_{xy} = h/e^2$. A spin density wave state is further observed when the AFMI is electron doped. Our observation paves the way for realization of exotic phases of matter such as quantum spin liquid and heavy fermion superconductivities in moiré materials.

8:00 PM EL07.03.35
Charge Transport in Charge Transfer Cocrystal Nanoribbons YuriChung, SatwikR, ScottMelis and EdwardVan Keuren; Georgetown University, United States

Charge transfer cocrystals have interesting applications in the field of organic electronics due to their unique optical and electronic properties, and have potential advantages over inorganic materials, such as being flexible and biodegradable. Controlled evaporative self-assembly (CESA) is a technique that produces long, ordered ribbons of material on a substrate from an evaporating solvent, a more convenient method of fabrication than for many inorganic material devices. Charge transfer cocrystals were successfully grown using this method to form a neat arrangement of ribbons that were readily integrated with metal electrodes to create organic field-effect (OFET) transistors for electronic measurements. We show that the temperature dependence of device mobility can be described by a hopping mechanism for the charge transport in cocrystals such as phenothiazine and 7,7',8,8' tetracyanoquinodimethane (PTZ-TCNQ) and phenoxazine and TCNQ (PXZ-TCNQ). Ongoing work involves studying the semiconductor potential of other cocrystal pairs and superexchange modeling.

8:00 PM EL07.03.36
Ink-jet Printed Graphene-Silicon Schottky Diodes AlessandroGrillo[1], ZixingPeng[1], AnielloPelella[2], AntonioDi Bartolomeo[2] and CinziaCasiraghi[1]; [1]Univeristy of Manchester, United Kingdom; [2]University of Salerno, Italy

Integration of graphene (Gr) in silicon-based technology is of crucial importance for enabling the next generation electronics, photonics and sensors [1]. Although numerous works have reported devices based on Gr-Si junctions, the integration process relies on the use of high quality Gr produced by Chemical Vapour Deposition (CVD), making the fabrication steps expensive, time consuming and by limiting the large scale devices' reproducibility.
In this work we show that inkjet-printing enables simple and scalable integration of Gr into Si-technology [2]. We developed a simple fabrication procedure, based on the mechanical or chemical etching of the SiO_2 layer from a standard Si wafer, followed by the inkjet printing of water-based printable Gr inks [3] on the exposed area, leading to Schottky diodes with excellent rectifying behaviour and figures of merit, comparable to those produced with CVD graphene. We fully characterized the devices and applied several theoretical models achieving deep understanding of the underlying physics of the devices. We also investigated the optical response of the diodes by demonstrating a spatially selective photodetector.
Our results demonstrate that inkjet printing is a cost-effective and scalable method, which is also compatible with back-end-of-line fabrication processes for the integration of graphene in the modern Si-technology.

On-Chip Electrocatalytic Microdevices: A New Platform for Electrochemical Interfacical and Micro-Kinetic Studies MengningDing; Nanjing University, China

Electrocatalysis has broad application prospects in the energy conversion and sustainable chemical synthesis, and thus has attracted considerable research attentions. For most electrocatalytic systems, the optimization and improvement of their electrocatalytic performances are usually generated from the reasonable construction of active sites and accurate descriptions of the catalytic mechanism. The continuous enrichment of measurement methodologies can greatly promote the in-depth studies and applications of electrocatalysis. In recent years, the continuous maturity and cross-disciplinary developments of micro-nano (device) processing technologies have provided a new and more sophisticated on-chip platforms for: 1) the *in situ* measurement/investigation of electrocatalytic materials and electrochemical interfacial processes; 2) the on-chip modulation of catalytic and sensing properties; and 3) the on-chip electrochemical fabrication of the novel functional devices. Here, we show some of the examples from our recent studies.

Visualizing the Electrochemical Microenvironment in Engineered Electrode Structures YimingWang, MingxuanZhu, ZhifeiYan, SamVeroneau and DanielNocera; Harvard University, United States

The activity and selectivity of an electrocatalyst are intricately tied to the micro-environment at the electrochemical interface. While several factors influence the micro-environment, the impact of mesoscale electrode geometry remains relatively underexplored. Most electrocatalysts employ three dimensional structures to increase the electrochemical surface area. However, due to mass transport, local diffusional gradient emerges inside the pores or trenches of the catalyst layer, which creates the micro-environment distinct from that of the bulk. To fully understand the effect of electrode geometry, operando study is essential. Experimentally probing micro-environment in operating condition is challenging not only because it requires high spatial and temporal resolution but also because of the difficulty in systematically varying the mesoscale electrode geometry. Researchers have been using a variety of methods to elucidate the interplay between electrode structures and its micro-environment. However, most of the studies only provided qualitative insights, lacking the quantitative descriptors vital for the rational design of electrode architectures and the corresponding local environment. To address the above-mentioned challenges, we use fabricated micro-wire arrays to systematically study the effect of electrode architecture on local pH near the electrocatalyst. By varying the shape, size and spacing of the micro-wires we aim to attain a quantitative understanding of the influence of diverse geometric descriptors. We use confocal fluorescence microscopy to map pH near the micro-wire arrays in operando conditions. Our findings hold potential applications across numerous proton-coupled electron transfer reactions. The experimental design could also be easily adapted to study other elements within the microenvironment.

8:00 PM EL07.03.39
WS_2 & MoS_2 from 3D to 1D Structures: curvature and Chirality Induced Properties of NanotubesS.Ghosh[1], C.Pallellappa[1], YijinZhang[2], Y.Iwasa[2], AntonioDi Bartolomeo[3], IfatKaplan-Ashiri[4], V.Bruser[5], Y.Gao[6] and AllaZak[1]; [1]Holon Institue of Technology, Israel; [2]The University of Tokyo, Japan; [3]University of Salerno, Italy; [4]Weizmann Institute of Science, Israel; [5]Leibnitz Institute of Plasma, Germany; [6]Beijing Institute of Technology, China

Study of the multiwall WS_2 nanotubes (NTs) behaviour for numerous applications has been demonstrated that rolling of the WS_2 molecular layers into co-nanocylinders promotes modifications in their structure. This results in unusual mechanical, chemical and electrical properties, which appear not only due to size reduction and quantum confinement, but mainly due to strain in the lattice, curvature and chirality of the layers, inherent to the tubular structure.Thus, rare bulk photovoltaic effect (BPVE) was recently discovered in WS_2 NTs and exhibited the photocurrent in the nanotube-based devices orders of magnitude larger than in other BPVE materials. BPVE appears due to the intrinsic properties of NTs: the small band gap (1.4-2.1 eV), broken inversion symmetry and polar structure [1]. An exponential increase of the NTs' resistivity with tensile strain up to a recorded elastic elongation of 12 % was revealed, thereby making WS_2 NTs suitable for piezoresistive sensor applications [2]. Bandgap engineering via size and number of layers control was recently demonstrated via cathodoluminescence measurements of these NTs [3]. Moreover, a fully operated artificial vision system was built based on the memory ability, produced by discovered programable photoeffect and sliding ferroelectricity in

multiwalled WS_2 NTs [4]. Such a wide investigation of this nanomaterial, became possible due to the breakthrough in their vapor-gas-solid (VGS) synthesis, which result in a pure phase and macroscopic amounts [5]. Special efforts were applied to complete extremely complicated synthesis of MoS_2 NTs from molybdenum trioxide (MoO_3) nanowhiskers in three-step high-temperature reaction with H_2/H_2S gases [6]. The availability of MoS_2 semiconductor NTs will enable their wide investigation in the future.

SESSION EL07.04: 1D and 2D Materials—Ab Initio Simulation
Session Chairs: Xi Ling and Zafer Mutlu
Tuesday Morning, November28, 2023
Hynes, Level 3, Ballroom B

8:00 AM *EL07.04.01
Emerging Functionalities of Carbon-Based 1D and 2D Nanoarchitectures AranGarcia-Lekue[1,2]; [1]Donostia International Physics Center (DIPC), Ikerbasque, Basque Foundation for Science, Spain; [2]Ikerbasque, Basque Foundation for Science, Spain

Nanostructuring graphene at the atomic scale is now possible by on-surface synthesis methods, which unite the sturdiness of covalently bonded networks with the easy tunability of molecular materials.[1,2] These experimental advances have boosted the research attempts to create novel 1D and 2D carbon-based structures aimed at the development of new nanoelectronic, spintronic or optoelectronic devices. However, before graphene nanostructures can be used in practical applications, an atomic level understanding and control of their properties is required. As such, *ab-initio* simulation has developed as an essential partner in the search of optimal carbon-based low dimensional materials.

In this talk, I will present some studies of prototype graphene nanostructures, such as graphene nanoribbons (GNRs) and nanoporous graphene (NPG), that we have recently performed in our group. Using mainly density functional theory (DFT), and in collaboration with our experimental colleagues, we have investigated their structural, electronic, magnetic and transport properties. On the one hand, we have explored the emergence of localized spins in metallic GNRs realized by substitutionally doping a narrow band gap GNR with boron atoms in its interior.[3] We have also reported on a novel NPG structure, which can be envisioned as GNRs laterally fused by phenylene bridges. Interestingly, electron transport simulations demonstrate the capability of modulating the interribon coupling by different degrees of freedom provided by the phenylene bridges.[4] Our results thus show that chemical doping offers the perspective of electronically controlling spins in 1D carbon nanoarchitectures, while molecular bridges emerge as an efficient tool to engineer quantum transport in 2D networks.

From a purely theoretical perspective, we have investigated prototypical hybrid GNRs formed using two existing carbon-based precursor molecules and a porphyrin center.[5] Our results reveal that narrow band gap hybrid GNRs might be achieved, and that embedding an iron atom in the porphyrin center gives rise to a spin-polarized ground state. Besides, our electron transmission calculations demonstrate how strain or chemical adsorption on the Fe atom gives rise to spin-crossover. This work highlights the potential of porphyrin-based hybrid GNRs as a highly tunable and flexible platform for spintronics and sensing applications.

Topological Radical Pairs Produce Ultrahigh Conductance in Long Molecular Wires LiangLi, ShayanLouie, AustinEvans, ElenaMeirzadeh, ColinNuckolls and LathaVenkataraman; Columbia University, United States

In the field of molecular electronics, it has been a challenge to make highly conductive long molecular wires. Typically, the conductive wires made to date are mostly designed and built from conjugated units, which conduct through a coherent and off-resonant mechanism. Within this mechanism, the conductance decays exponentially with increasing length. Therefore the conductance becomes low when more units are added to lengthen the wires. To overcome this problem, a new class of molecular wires with topological radical states at the edge sites (so-called edge states) can be created following the Su-Schrieffer-Heeger (SSH) model. These wires are one-dimensional topological insulators (1D TIs) and conduct through the energetically low-lying edge states that are localized to the wire ends. As a result, such 1D TI wires feature a reversed conductance decay, that is, the conductance increases exponentially with increasing wire length (*Nat. Chem.* **2022**, *14*, 1061-1067.). However, the reversed conductance decay only appears for short wires, as when the wire length increases beyond a threshold, the localized edge states become decoupled and no longer support electron transport. To extend the wire length at which these properties can be observed, we designed topological oligo[*n*]emeraldine wires, using short 1D TIs as building blocks (*J. Am. Chem. Soc*. **2023**, *145*, 2492-2498.). As the wire length increases, so does the number of topological states, resulting in an enhanced electronic transmission along the wire with increasing length. In our experiments, we successfully drove a current of over a microampere through a single ~5 nm molecular wire, significantly surpassing the performance of previously reported long wires. With DFT calculations, we demonstrated that the longest topological oligo[7]emeraldine exhibits over 10^6 enhancements in the transmission compared to its isostructural non-topological molecular wire. Furthermore, there is no theoretical limit to the number of 1D SSH TI repeat units that can be incorporated with a single chain. Therefore, it is reasonable to expect that longer analogues of topological oligo[*n*]emeraldine ($n > 7$) will achieve higher currents and conductances. This discovery represents a significant breakthrough in implementing molecules into complex, nanoscale circuitry, as it overcomes a fundamental hurdle that their structures become too insulating at practical lengths for designing nanoscale circuits.

8:45 AM EL07.04.03
Leveraging Density Functional Theory in the Design of Novel Metal Organic Chalcogenide Assemblies (MOChAs) AdrianaLadera, AriaMansouri Tehrani and TessSmidt; Massachusetts Institute of Technology, United States

In this work, we use density functional theory (DFT) and geometric algorithms to propose hypothetical low-energy metal organic chalcogenide assemblies (MOChAs) to aid synthesis efforts. MOChAs are hybrid organic-inorganic, self-assembled Van der Waals crystals where low-dimensional transition-metal chalcogenide (TMC) inorganic structures are scaffolded by organic ligands, which insulate the TMC structures from one another.
Despite being bulk crystals, MOChAs, like other low-dimensional TMC materials, host excitonic properties relevant to optoelectronic applications. The choice of organic ligand can control the geometry of the inorganic structure which drives the optoelectronic properties of the MOChAs. This tunability and ease of synthesizability makes MOChAs a compelling material class for exploring structure-property relationships.
We propose hypothetical MOChA structures by systematically generating hypothetical combinations of inorganic structures, organic ligands, and corresponding stacking patterns and evaluating their energetics with DFT. We benchmark our methods on experimentally synthesized MOChAs. In this talk we (i) discuss the efficacy of using DFT as a computational aid to evaluate MOChA structure feasibility, (ii) relate changes in MOChA geometry to electronic properties, and (iii) present a library of energetically favorable hypothetical MOChAs.

Quantum Theory of Sputtering Rates in 2D Materials by Transmission Electron Microscopy VincentMeunier; Penn State University, United States

Many computational models have been developed to predict the rates of atomic displacements in two-dimensional (2D) materials under electron beam irradiation. However, these models often drastically underestimate the displacement rates in 2D insulators, in which beam-induced electronic excitations can reduce the binding energies of the irradiated atoms. This bond softening leads to a qualitative disagreement between theory and experiment, in that substantial sputtering is experimentally observed at beam energies deemed far too small to drive atomic dislocation by many current models. To address these theoretical shortcomings, this paper develops a first-principles method to calculate the probability of beam-induced electronic excitations by

coupling quantum electrodynamics (QED) scattering amplitudes to density functional theory (DFT) single-particle orbitals. The presented theory then explicitly considers the effect of these electronic excitations on the sputtering cross section. Applying this method to 2D hexagonal BN and MoS_2 significantly increases their calculated sputtering cross sections and correctly yields appreciable sputtering rates at beam energies previously predicted to leave the crystals intact. The proposed QED-DFT approach can be easily extended to describe a rich variety of beam-driven phenomena in any crystalline material.

Nonlinear Probing of Structural and Electronic Phase Transition in 2D Quantum Materials XiaofengQian; Texas A&M University, United States

2D quantum materials have demonstrated a plethora of novel physical properties with complex structural and electronic phase transition and potential applications. It is thus highly desirable to understand the underlying mechanism associated with those phase transitions. In this talk, I will report our recent theoretical effort on predicting nonlinear responses in 2D quantum materials, demonstrating nonlinear probe for structural and electronic phase transition, and showing the promise for quantum nonlinear electronics. Specifically, I will present microscopic theory of ferroelectric nonlinear Hall effect in time-reversal invariant layered topological materials and discuss the complex interplay of symmetry, electronic structure, and Berry curvature, and briefly report the experimental demonstration of Berry curvature memory effect as a high-order multiferroicity. Second, I will also present our recent theoretical work on magnetic shift photocurrent and magnetic injection photocurrent as the counterparts of normal shift current and normal injection current in time-reversal symmetry and inversion symmetry broken systems, and demonstrate how these nonlinear photocurrent responses can help decipher magnetic structures and interactions which could be particularly fruitful for probing and understanding magnetic topological quantum materials and phase transition.

10:30 AM EL07.04.06
Giant Rectification in Strongly-Interacting Driven Tilted Systems JuanJ. Mendoza-Arenas[1,2] and StephenClark[2]; [1]University of Pittsburgh, United States; [2]University of Bristol, United Kingdom

Correlated quantum systems feature a wide range of nontrivial effects emerging from interactions between their constituting particles. In nonequilibrium scenarios, these manifest in phenomena such as many-body insulating states and anomalous scaling laws of currents of conserved quantities, crucial for applications in quantum circuit technologies. In this work [1] we propose a giant rectification scheme in one-dimensional systems based on the asymmetric interplay between strong particle interactions and a tilted potential, each of which induces an insulating state on their own. While for reverse bias both cooperate and induce a strengthened insulator with an exponentially suppressed current, for forward bias they compete generating conduction resonances; this leads to a rectification coefficient of many orders of magnitude. Based on numerical and analytical calculations, we uncover the mechanism underlying these resonances as enhanced coherences between energy eigenstates occurring at avoided crossings in the system's bulk energy spectrum. Furthermore, we demonstrate the complexity of the many-body nonequilibrium conducting state through the emergence of enhanced density matrix impurity and operator space entanglement entropy close to the resonances. Our proposal paves the way for implementing a perfect diode in currently-available electronic and quantum simulation platforms.

10:45 AM EL07.04.07
A Many-Body Diffusion Monte Carlo and DFT+U Study of Monolayer VSe_2DanielWines[1], KayahanSaritas[2], JaronT. Krogel[2], NishwanthGudibandla[3,1], KamalChoudhary[1], FrancescaTavazza[1] and CanAtaca[3]; [1]National Institute of Standards and Technology, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Maryland Baltimore County, United States

Previous works have controversially claimed near-room temperature ferromagnetism in two-dimensional (2D) VSe_2, with conflicting results throughout the literature. For T-phase VSe_2, competing magnetic and non-magnetic states are predicted to exist, which can drive charge density wave (CDW) formation. Although density functional theory (DFT) calculations can capture the differences in chemical composition and polymorphism, strong coupling between the magnetic and structural properties in this material makes it difficult to trust the results from approximate density functionals. For example, T and H-VSe_2 have a close lattice match and similar total energies, which makes it difficult to determine which phase is being observed experimentally. In this study, we used a combination of density functional theory (DFT), highly accurate diffusion Monte Carlo (DMC) and a surrogate Hessian line-search optimization technique to resolve the previously reported discrepancy in structural parameters and relative phase stability. With DMC accuracy, we determined the freestanding geometry of both phases and constructed a phase diagram. In addition, we studied the energy differences between the ferromagnetic, antiferromagnetic and CDW phases through a many-body lens to resolve these discrepancies for T-VSe_2. Going one step further, we also studied the effect of strain and Se vacancies on the electronic and magnetic properties of these competing magnetic states. Our findings demonstrate the successes of the DMC method when applied to a correlated 2D magnetic system such as VSe_2.

A New Strategy to Develop p-Type Semiconductivity in Transition Metal Dichalcogenides: A First-Principles Study NikhilSivadas, MahdiAmachraa and YongwooShin; Advanced Materials Lab, United States

Over the years, silicon has been the preferred choice of channel material in transistors due to its simplicity and scalability. However, the performance of Si-based transistors degrades significantly as the channel thickness is reduced below 4 nm [1]. TMDs with group formula MX_2, where M = Mo, W and X = S, Se are a class of two-dimensional (2D) semiconductors that can replace Si in the next-generation transistors. Recently, it was shown that the mobility of monolayer TMDs are comparable with 4 nm thick Si channels [1]. Therefore, integrating TMDs into existing hyper-scaler geometries has the potential to leapfrogging decades on Moore's law time scale [2]. However, strategies to p-dope TMDs have been largely unsuccessful. Conventional approaches like substitution doping creates inhomogeneity such as charged defects within the channel layer that limits the transistor mobility [3].

In this talk, we propose a new strategy to p-dope TMDs via a surface charge transfer mechanism (SCTM) using inorganic oxides. Using physics based HT screening we identify 11 element that when doped into the high-k dielectric oxide layer (e.g. HfO_2) can p-dope TMDs without creating channel defects. To validate these finding, we demonstrate p-doping of WSe_2 using Ni-doped HfO_2 using first-principles density functional theory (DFT) calculation. We also discuss practical device geometries for implementing this SCTM induced doping and strategies to control the concentration of dopants. Thus our holistic approach proves the feasibility of p-dope TMDs while retaining the advantages of having a high-k gate-dielectric layer. Demonstrating p-doping in atomically-thin TMDs can allow us to save decades in Moore’s law scaling, and can usher in the post-Si era for transistors. This approach can be easily generalized to tackle a broad array of materials design challenges. Our results provide a new strategy for p-doping TMDs.

Tunability of Doping in 2D Material Heterostructures using High Work Function $RuCl_3$: A First Principles Study DakotahM. Kirk and MarceloKuroda; Auburn University, United States

The facile formation of heterostructures based on two-dimensional (2D) materials permits controling the electronic properties of the resulting systems [1,2,3,4]. In particular, charge transfer between adjacent layers may be exploited to dope layers that improve charge carrier injection and engineer band alignments [3,4,5,6,7]. Here we quantify how large work function $RuCl_3$ alters the electronic properties of heterostructures formed with various 2D materials: semiconducting transition metal dichalcogenides (TMDs), and few layer graphene structures. To this end we produce first principles calculations within the density functional theory (DFT) accounting for the on-site Coulomb interaction and spin-orbit. In the proximity of $RuCl_3$, TMD and graphene layer(s) become heavily p-doped with carrier densities of ~ $5 \times 10^{13} cm^{-2}$, in agreement with prior experiments on $RuCl_3$ on graphene and WSe_2 [7]. We successfully rationalize our first principles results employing an analytical model based on properties of individual constituents. Study of the structural and electronic properties of the heterostructure upon application of vertical strain on these systems reveals that strain barely alters charge transfer but yields a stronger hybridization between layers. Additionally, accounting for the magnetic order in the $RuCl_3$ also results in similar doping when adjacent to semiconducting TMDs or graphene layers. The results of this work show that 2D material heterostructures may improve charge injection efficiency and band engineering in these systems.

First Principles Study of Nernst Effect in 2D Materials EmadS. Rezaei and PeterSchindler; Northeastern University, United States

The rapidly growing demand for replacing fossil fuels with clean energy harvesting methods necessitates research in renewable energy generation and management. Two-dimensional materials have attracted much attention in energy conversion applications due to their unique transport properties, more enticingly, when a thermoelectric power factor greater than 5 was reported in $Fe_2V_{0.8}W_{0.2}Al$ thin films[1]. Similar to the Seebeck effect, the ratio of the developed voltage to the temperature gradient in the presence of a magnetic field is called the Nernst effect[2] which has been utilized in cryogenic cooling[3], thermopile systems[4], and radiation detector applications[5]. The Nernst effect was observed in Bismuth for the first time and then further studied in semiconductors such as silicon, germanium, and indium antimonide. The Nernst effect in topological semimetals has been of focused interest, more recently. However, data of the Nernst coefficient of 2D materials has been very limited. Here, we present on large-scale screening of 2D structures using high-throughput density functional theory (DFT) calculations to discover promising new materials candidates with high Nernst coefficients. Our preliminary theoretical results show that some 2D materials could exhibit relatively considerable Nernst coefficients. The discovery of new ultra-high Nernst coefficient 2D materials (larger than Bismuth) could pave the way towards more efficient radiation detectors and more productive cryogenic cooling designs.

Graphene Nanoribbon-Based Field-Effect Transistors for High-Performance Logic Technology ZaferMutlu; University of Arizona, United States

Silicon has powered computing for decades through miniaturization, facilitated by innovations such as strained silicon, high-k dielectrics, fin field-effect transistor (FinFET), and the latest industry trend: gate-all-around FET (GAAFET) architectures. However, silicon is reaching its limits as miniaturization yields diminishing benefits. This necessitates a new 'wonder' material that can potentially take some pressure off silicon’s shoulders and meet the increasing demands of computationally intensive technologies such as AI. Bottom-up synthesized, atomically precise graphene nanoribbons (GNRs) feature extremely high theoretical charge carrier mobility and on-state drive current capability at the atomic scale, making them highly promising transistor channel materials over silicon for high-performance logic applications. In this invited talk, I will begin with an introduction to GNRs, explaining the features that make them promising for FETs, detailing the bottom-up synthesis, discussing techniques used for their characterization and device fabrication, presenting the current state of the art with transistors made from them, and addressing the remaining key issues. In the next part, I will detail our recent studies, involving enhancing electrostatic control of the GNR channel through the deposition of an ultrathin high-k top HfO_2 dielectric layer, ultimately scaling transistors with GNRs, and optimizing the channel-contact interface through contact engineering to reduce contact resistance. Finally, I will address the remaining challenges and potential enhancements in materials, processes, device integration, and related areas that could enable GNRs to approach outstanding theoretical predictions and explore future opportunities in the field.

Self-Assembly of Dense, Aligned, Semiconducting Carbon Nanotube Arrays for High Performance Transistors MichaelS. Arnold; University of Wisconsin--Madison, United States

Carbon nanotubes conduct more electricity per width than silicon and more rapidly switch between on and off states with less voltage, making them ideal for next-generation fast, low-energy logic and high-speed, linear RF devices. However, despite carbon nanotubes’ promise, no one has yet been able create a process for employing nanotubes in high-performance electronics commercially. Since their discovery more than 25 years ago, nanotubes’ commercialization has been delayed by manufacturing challenges in purifying, aligning, and uniformly assembling them with precision over large areas. For nanotubes to be most useful, they must be purified by their electronic type (semiconducting versus metallic) and then lined up in the same direction in a dense layer with the thickness of a single nanotube, so that electricity can rapidly and efficiently travel through them.

This talk will present recent discoveries on (1) purifying and aligning semiconducting nanotubes into massively parallel arrays and (2) the research and development of semiconducting carbon nanotubes for logic and radio frequency devices. We have pioneered nanotube array fabrication technologies that enable the (a) partial alignment of nanotubes (±30º) via shear (demonstrated 100 mm wafer-scale); (b) finer alignment (±6º) at liquid-liquid interfaces (demonstrated 100 mm size-scale); and, (c) the selected-area deposition of nanotube arrays (±7º) in lithographically-defined patterns combining topographical and chemical features (demonstrated 25 mm size-scale). Most recently, we have discovered a powerful new mechanism for driving the self-assembly of nanotubes into aligned arrays, by coaxing them to form two-dimensional liquid-crystals. We have uncovered that when nanotubes are segregated to liquid-liquid interfaces, mesogenic interactions cause them to self-align (within +/-5.7 degrees so far) and self-assemble into dense arrays (> 100 per micron) like those needed for microelectronics. The assembled nanotubes are easily integrated on silicon substrates at room-temperature and integrated into high-performance devices. Work on the development of novel multifunctional polymer wrappers and the removal of these wrappers will also be presented.

Anchoring to Prevent Bundling in Dense CNT Array Device Process ShengmanLi; Stanford University, United States

Carbon nanotubes (CNTs) are highly promising candidates for replacing silicon (Si) in digital devices due to their remarkable characteristics, including a 1-nm thin body, high mobility/velocity, and low capacitance. To achieve high-performance devices, there is a demand for high-density aligned CNT arrays with a pitch size of 2~4 nm. Significant progress has been made recently in CNT array assembly through the dimension-limited self-alignment method, along with the use of small molecule additives to suppress CNT bundling.

However, the various processing steps involved in fabricating CNT field-effect transistors (CNTFETs) introduce extrinsic defects, such as lateral aggregation and vertical stacking, into the as-prepared CNT arrays. The presence of such CNT bundles can severely impact the ability of the transistor gate to effectively control the flow of charge carriers in the CNT channel, leading to considerable device-to-device variability.
In response to these challenges, this study proposes the incorporation of dielectric anchors to prevent CNT bundling. Through the use of Atomic Force Microscopy (AFM) and Transmission Electron Microscopy (TEM), we investigate the CNT bundling conditions after essential processing steps, including post-evaporation, post-Atomic Layer Deposition (ALD), post-resist spin-coating, post-developing with the anchor layer, and without the anchor layer.
By implementing the anchoring-first approach, we demonstrate reduced subthreshold slope variation (SS) and higher drain current (Ion) in CNTFETs. These findings present a promising process flow to construct high-performance CNTFETs, thereby advancing CNTFET fabrication towards practical applications in digital devices. The elimination of CNT bundling and improved device characteristics achieved through this study are crucial steps towards the realization of high-performance CNT-based electronics.

One-Dimensional Graphene Devices HerreS. van der Zant; TU Delft, Netherlands

One-dimensional devices made of graphene are of great interest to study mesoscopic quantum transport phenomena. On one hand, one can define one dimensional channels by electrostatic gating with the advantage that the edges do not play a significant role in the transport characteristics. On the other hand, atomically precise graphene nanoribbons (GNRs) are predicted to exhibit exceptional edge-related properties, such as localized edge states, spin polarization, and half-metallicity. However, creating a good contact between electrodes and GNRs has been a longstanding challenge as it requires the controlled fabrication of sub-20 nm metallic gaps, a clean GNR transfer minimizing damage and organic contamination during the device fabrication, as well as work function matching to minimize the contact resistance. Here, I will discuss examples of both approaches: electron focusing and collimation experiments in bi-layer graphene channels defined by electrostatic gating and our progress in contacting 9-atom-wide armchair-edged GNRs with Pt, MoRe and Pd contacts. The two latter metals are known to provide low-contact resistance to carbon nanotubes. Density functional theory (DFT) calculations combined with the non-equilibrium Green's function method (NEGF) explain the observed p-type electrical characteristics using Pt electrodes and demonstrate that Pt gives a strong coupling and higher transmission in comparison to other materials such as graphene. Detailed electrical characterizations of the MoRe and Pd nanogaps, at various bias/gate voltages and temperatures allow us to investigate the formation of Schottky barriers at metal-GNR interface and extract the activation energies.

Non-Volatile Doping of Graphene Transistors using a Solid Polymer Electrolyte Crosslinked by Field Effect for Polymorphic Electronics DnyaneshDeepakSarawate[1], PriscillaPrem[1], KeXu[2,2], EricBeckman[1] and SusanFullerton[1,1]; [1]University of Pittsburgh, United States; [2]Rochester Institute of Technology, United States

Hardware security comes at a high price in the U.S. at $200 billion annually. Polymorphic electronics provide a potential solution to hardware security threats by preventing unauthorized parties from accessing circuitry information through reverse engineering. The goal of this work is to obscure a device's function by taking advantage of electric double layer (EDL) gating to reconfigure NAND gates to/from NOR gates on-demand. The key innovation is a custom-synthesized polymer electrolyte that reacts under an electric field created by the EDL (~V/nm), retaining charges in the channel by crosslinking the polymer electrolyte. Ion mobility is confirmed in a lateral, parallel-plate capacitor geometry, and graphene field effect transistors (GFETs) are used to test non-volatile doping. Preliminary evidence of non-volatile doping is observed by programming GFETs at positive gate voltages (V_G > +2 V), and then sensing the Dirac point shift and ON/OFF ratio change. Positive programming voltages less than +2 V showed no effect on the doping; however, the device becomes more n-type, and ON/OFF increases as V_G increases from +2 to +5 V. Note that in the absence of a non-volatile doping mechanism, grounding the gate would dissipate the EDL and reverse the doping effect; however, in the case of our custom synthesized electrolyte, the doping effect persists even after the gate bias is grounded, confirming non-volatile doping at the graphene channel. Applying a negative V_G demonstrates a semi-permanent - but reversible - doping effect. Specifically, as V_G increases from -1 to -5 V, the Dirac point shifts less n-type and ON/OFF decreases, implying that the doping effect is reversible but non-volatile. We will also report on the sheet carrier densities measured by Hall effect to quantify the doping, along with chemical characterization of the polymer electrolyte. The work is supported by the National Science Foundation (NSF, U.S.) under Grant No. ECCS-EPMD-2132006

4:15 PM EL07.05.06
Electronic Transport in Twisted Nanoporous Graphene/Graphene Van Der Waals Heterostructures XabierDiaz de Cerio[1], AleksanderBach Lorentzen[2], MadsBrandbyge[2] and AranGarcia-Lekue[1,3]; [1]Donostia International Physics Center (DIPC), Spain; [2]Technical University of Denmark, Denmark; [3]Ikerbasque, Basque Foundation for Science, Spain

Nanoporous graphene (NPG) is a promising candidate for the development of next generation electronic devices [1]. Recent advances in bottom-up on-surface chemistry have allowed the fabrication of increasingly large atomically precise samples of various NPG geometries, which can be thought as lateral arrays of weakly coupled semiconducting graphene nanoribbons [1,2]. Besides, the highly anisotropic electronic structure of NPG causes injected currents to flow according to the so-called Talbot effect interference pattern [3]. Such phase coherent phenomenon can be tuned by the introduction of structural and chemical modifications, making this 2D material appealing to control currents at the nanoscale [2,4]. On the other hand, van der Waals heterostructures have attracted great interest in the last decade due to their unconventional electronic properties and the high level of control achieved in the stacking of 2D materials. In this regard, the stacking of NPG over graphene has emerged as a noteworthy strategy to tune the electronic and transport properties of the latter [5,6]. However, the potential control of nanoscale currents in such heterostructure remains largely unexplored.

In this work, we theoretically study the electronic anisotropy and transport properties of twisted NPG/graphene van der Waals heterostructures. Combining Non-Equilibrium Green's Functions with a tight-binding approach, we model devices comprising ~200,000 atoms and lengths over 50nm. In particular, we simulate the current flow in various commensurate and incommensurate geometries corresponding to different interlayer twist angles. The response of currents to the twist angle parameter is rationalize by means of the evolving interlayer coupling. Our findings showcase the versatility of NPG/graphene heterostructures for electronic applications and open new prospects for the realization of carbon nanocircuitry.

4:30 PM *EL07.05.07
Atomic Substitution Approach for Electronic Non-vdW 2D Materials XiLing; Boston University, United States

Atomically thin materials often exhibit extraordinary chemical, optical, electronic, and magnetic properties compared with their bulk 3D counterparts, enabling a variety of applications for next generation electronics and quantum information technologies. While extensive research has been conducted on 2D van der Waals (vdW) materials such as graphene, transition metal dichalcogenides (TMDs), and hexagonal boron nitride (hBN), little attention has been given to non-vdW materials, which make up the majority of materials in nature. One significant challenge is the lack of an effective synthesis method to access them. In this talk, I will introduce an atomic substitution approach that we have developed to convert vdW layered materials to ultrathin non-vdW materials. This approach is universal, enabling the synthesis of diverse unconventional 2D materials with tunable thicknesses, desired dimensions, and properties for fundamental physics investigations and nanodevices. As a model system, we will investigate the conversion process from TMDs (e.g. MoS_2 and WS2) to corresponding metal nitrides (e.g. MoN_x and WN_x), characterize the electronic properties of the obtained metal nitrides, and highlight the advantages of this approach in creating new 2D heterostructures as desired building blocks for 2D electronics.

Montmorillonite/Graphene Composite Based Resistive Humidity Sensor JuhyoengYu, Jin WooAn and Seoung-KiLee; Pusan National University, Korea (the Republic of)

The needs about precise humidity sensor are getting higher gradually in numerous major industries for insuring optimal performance of electrical devices and safety in diverse environments. Graphene, the two-dimensional material, has extraordinary electrical properties due to its π-bonding of sp^3 hybrid orbital. Recent study has shown possibility of graphene-based material as the humidity sensing material because of its ultrahigh surface area. However, the results reported thus far are limited in recovery time and long-term stability due to irreversible adsorption of water molecules on graphene's surface during humidity sensing. Its high price also can be challenge for the practical application. Although doping other sensitive material to graphene is one of the possible ways that can improve recovery property, but it not that effective way to improve sensor's sensitivity.
In this study, we propose a stable humidity sensor based on a montmorillonite/graphene composite to overcome these recovery, stability, and price problem. As a natural clay mineral, montmorillonite has attracted interest because of its abundance and unique ability to absorb large amounts of water by an increase in the c-axis of the layer lattice structure.
The incorporation of graphene into montmorillonite, at the point where graphene's concetration exceeds electrical percolation threshold, forms a cost-effective composite material compared to carbon materials like GO or rGO that exhibits enhanced electrical resistance changes for humidity sensing. Additionally, the hydrophilic nature of montmorillonite facilitates the absorption of water molecules into the composite, whereas the hydrophobic nature of pristine graphene facilitates the desorption of water molecules. This combination of properties can contribute to the reduction of both response and recovery time in the composite.
The montmorillonite/graphene composite was fabricated using a simple solution-based method. The composite was then coated on an electrode deposited substrate. The best ratio of montmorillonite/graphene of composite sensor was confirmed through observation of distinct electrical resistance change in variation of ratio. And then, the sensor was characterized by measuring its resistance in response to different humidity levels ranging from 20% to 80%. The results showed that the sensor had a linear response to humidity, with a sensitivity of 10% per RH. Moreover, we find out the sensor was reversible and stable over time.
Overall, the montmorillonite/graphene composite is a promising candidate for highly efficient humidity sensor with plenty of advantages over traditional humidity sensors. The sensor is highly sensitive, reversible, and inexpensive. It is also easy to fabricate and can be scaled up for mass production. The sensor has potential applications in a wide range of fields, including civil engineering, agriculture, and industrial processes.

8:00 PM EL07.06.02
Blue-Emitting Core/Crown Nanoplatelets of CdSe/CdS for LED Application MatildeCirignano[1,2], HosseinRoshan[1], AlessioDi Giacomo[3], DavidePiccinotti[1], IwanMoreels[3] and FrancescoDi Stasio[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Genova, Italy; [3]Ghent University, Belgium

Colloidal inorganic nanocrystals are an attractive class of nanomaterials for both fundamental research and technical applications thanks to their size- and shape-dependent properties, but also because of their excellent chemical processability.[1] In particular, colloidal CdSe nanoplatelets (NPLs) are fascinating nanocrystals to explore the potential of two-dimensional (2D) materials for next generation optoelectronic devices.[2] The strong quantum confinement in the vertical direction leads to peculiar optical properties that depend on their thickness,[3] such as, narrow emission, large exciton binding energy, relatively small dielectric constant, giant oscillator strength, large linear/nonlinear absorption cross sections and short radiative fluorescence lifetime.[4] In addition, the large volume of NPLs makes Auger recombination less efficient.[5] All of these advantages make NPLs promising for application in Light-Emitting Diodes (LEDs). However, application of CdSe NPLs in the ultraviolet/ blue region remains an open challenge due to charge trapping leading to limited photoluminescence quantum yield (PLQY) and sub-bandgap emission in core-only NPLs.[6]
Furthermore, for LEDs based on II-VI semiconductor quantum dots (QDs), the efficiency and stability of red and green QD based devices is close to standards for commercial applications, while blue QLEDs (Quantum dots-LEDs) lag behind in terms of device efficiency and stability.[7]
The specific problems of blue QLEDs are as follows: surface defects and lattice mismatch of blue QDs, carrier injection imbalances, high absorption coefficient of charge injection layers, fluorescence quenching caused by exciton dissociation induced by an electric field, instability of the organic transport layer, and the loss of light caused by plane-laminated structures.[8]
We recently focused on the synthesis of 3,5 ML CdSe/CdS core/crown blue emitting nanoplatelets developed in 2023.[9] After a significant improvement in core-only synthesis[10] with a precise control over the aspect ratio (length/width), we raised the PLQY of core/crown NPLs up to 60% with complete elimination of trap state band and undesirable second phases. More specifically, our crowning procedure increases the quantum efficiency of 4 times with respect to the core-only using much less material than a core/shell structure.
Using CdSe/CdS core/crown NPLs emitting in the pure blue region of electromagnetic spectrum (2.7 eV = Eg, λ = 460 nm), we then obtained the highest EQE (2.8%) existing for blue core/crown structured CdSe-based material in Light-Emitting Diodes fabrication.
We take advantage of some important strategies to improve EQE in our proposed LED. In contrast to the majority of works present in the literature, we avoid using ZnO film as ETL due to its absorption in the same region of NPLs emission and in order to reduce self-absorption in NPLs, we use a very low thickness of NPLs as emissive layer. The electroluminescence measurement shows a 460 nm peak with a turn-on voltage of 3.3 V.
Our results show an effective way for the PLQY improvement of core-crown CdSe/CdS NPLs and good performances in hybrid organic-inorganic Light Emitting Diodes application.

Various Frequency Band Electromagnetic Shielding Film by Internal Multi-Reflection Between ITO Nano-Branches YounghoKim[1] and HakkiYu[2,2]; [1]Korea University, Korea (the Republic of); [2]Ajou University, Korea (the Republic of)

Electromagnetic wave interference (EMI) means that electromagnetic waves generated from the outside interfere with the operation of some device. As various industries develop, the contamination by electromagnetic waves increases and the risk also increases day by day. In particular, such interference in communication equipment or the space industry can lead to failure of huge capital projects from causing inconvenience in daily life. Shielding this interference is called electromagnetic wave interference shielding (EMI shielding), and various materials or processes are being studied. Representative materials studied so far include carbon, ferrite, perovskite, silicon carbide, and conducting polymer series. It is usually in the form of a composite composed of two or more materials without using a single material. What these composites have in common is that they basically use reflection by electron conductivity or absorption by dielectric or magnetic property. In addition, the effect of dielectric properties occurring at interfaces or internal scattering occurring between surface can be expected. For application to various fields, the thickness of the EMI shielding film should be thin, but considering only absorption by dielectric properties, it cannot be thinner than the skin depth, so the aforementioned additional effects are inevitable. In this study, ITO nano branches were used, and a film capable of EMI shielding on various regions was produced by increasing the density of the rods constituting the nano branches. Consequently, 22.31 dB (X band), 21.88 dB (K_u band), 21.09 dB (K band), and 17.81 dB (K_a band) shielding effect were shown for each region at a thickness of about 3um. It has a very high shielding efficiency compared to a very low thickness. Therefore, it is expected that it can be used in various fields.

8:00 PM EL07.06.04
2D Materials-Based Ink to Develop Meta-Structures for Electromagnetic Interference (EMI) Shielding SuwarnaDatar; Defence Institute of Advanced Technology, India

2-D transition metal-chalcogenides which are semiconductor materials of the type MX_2, where M is a transition metal atom (like Ni, Fe, or Co) and X is a chalcogen atom (such as S or Se) are emerging class of materials which have excellent properties like atomic scale thickness, strong spin-orbit coupling, ability to form 2D nanosheets, direct band gap which 2D carbon based materials lack and many other mechanical and electronic properties. They are actively used in the fields like flexible electronics, opto-electronics, energy harvesting spintronics, personalised medicines etc. These properties make 2D materials lucrative for EMI shielding applications because of strong electronic polarization and enhanced dielectric loss. Research on hybrid materials like magnetic metal oxides with transition metal-chalcogenides like magnetic core-shell nanomaterials, Fe doped MoS_2, doped MoS_2-rGO composite, $MoS_2/CoSe_2$ hybrids, among several others suggests, these materials have high reflection loss. Further, magnetic transition metal dichalcogenides such as $NiSe_2$, $CoSe_2$ and their heterostructures, expediate multiple reflections and scattering of the incident wave, thereby elongating the course of transmission of the incident microwave, and thereby increasing dissipation efficiency, along with large specific surface area, which caters to EM absorption. In the present work inks have been developed base on these materials to make them versatile for several applications where it can be coated or screen printed.

The second part of this work involves development of meta structures using these paints as Radar absorbing materials. The tunability of material properties like permeability and permittivity

by changing meta structure thickness and dimension allows the user to manipulate the electric and magnetic resonance at different frequencies independently, therefore, frequency selective structures can be made. In the present work we screen printed different geometries of structures using 2D material paints and tested for its capability as EMI shielding paint in X Band.

8:00 PM EL07.06.05
Morphological Characterisation of Printed Networks of Nanomaterials using FIB-SEM Nanotomography LukeDoolan, CianGabbett, KevinSynnatschke, EmmetColeman, AdamG. Kelly, ShixinLiu, EoinCaffrey, JoseMunuera, CatrionaMurphy, LewysJones and JonathanN. Coleman; Trinity College Dublin, Ireland

Networks of nanomaterials find applications in a wide variety of fields such as printed electronics, sensors, and energy storage[1]. While it is known that the morphology of the network plays a dominant role in determining their physical properties, quantitative measurements of morphology have proven difficult[2]. It has been demonstrated that changing nanomaterial size changes the network's electronic properties, however, its effect on network morphology is not well understood[3]. Utilizing FIB-SEM nanotomography we characterize the morphology of networks of nanomaterials. 3D-images with a voxel size of 5 x 5 x 15 nm were obtained from printed networks of graphene with different nanosheet length. Using machine learning, 3D images were segmented into nanosheet and pore components and a wide range of morphological properties of the networks, including porosity, pore shape, nanosheet alignment, nanosheet aggregation and pore and nanosheet tortuosity were calculated. These properties were used to distinguish between the effect of network morphology and nanosheet size on the electrical properties of the networks, allowing calculation of the resistance of the junctions between the nanosheets. The same methodology was applied to printed networks composed of silver nanoplatelets, silver nanowires and tungsten disulphide with varying nanomaterial length. The technique was then extended to investigate the interfaces within vertical printed hetrostacks, allowing measurement of the interfacial roughness and material penetration into subsequent layers, demonstrating the ability of this technique to characterize printed hetrostacks devices[4].

Oxidative Chemical Vapor Deposition of Highly Conductive and Transparent Polymer Layers for Contact Fabrication in 2D-MoS_2-Based FET Structures JinmeiZhu, FlorianMeierhofer and TobiasVoss; Braunschweig University of Technology, Germany

For 2D MoS_2 field-effect transistors (FETs), contact fabrication easily results in damaging the MoS_2 channel due to the fragility of the atomically thin structure, making it difficult to reliably achieve high-performance devices. To overcome this challenge, the deposition of highly conductive and transparent polymer layers from the gas phase (oxidative chemical vapor deposition (oCVD) [1]), is a promising approach that can lead to low-resistivity Ohmic contacts. In this work, we demonstrate a method for fabricating 2D MoS_2 bottom-gated FETs with poly (3, 4-ethylenedioxythiophene) (PEDOT) electrodes. PEDOT is a conductive polymer widely used as transparent electrode material. We used lithography to pattern oCVD-grown PEDOT layers and transferred them onto MoS_2 channels without aggressive chemical and physical treatments. This method allowed us to achieve a damage-free MoS_2 channel with a clean and smooth interface of the PEDOT electrodes, significantly decreasing the charged impurity and interface-roughness scattering processes. This universal approach could be applied to different 2D materials, thus enabling the fabrication low-resistivity Ohmic contacts in high-performance FETs without damaging the atomically thin crystals.

Designing Natural Hyperbolic Materials: Expanding the Possibilities of Two-Dimensional Systems MingwenZhao; Shandong University, China

Hyperbolic materials (HMs) have garnered significant interest for their unique electromagnetic response characteristics, including optical nanoscale cavities, spontaneous emission enhancement, nanoscale imaging, and full-angle negative refraction. While initially achieved in metamaterials, the development of meta hyperbolic surfaces through intricate substrate patterning has enabled the support of highly-directional hyperbolic surface plasmons, crucial for optoelectronic devices. In this study, we introduce the concept of hyperbolicity into natural two-dimensional (2D) materials exhibiting highly-anisotropic electronic band structures. We demonstrate that these materials present intriguing scenarios similar to those observed in meta hyperbolic surfaces. Notably, natural hyperbolic 2D materials possess advantages over meta-surfaces, leveraging their small atomic-scale periodicity to yield large wavevectors and easy predictability without the need for complicated surface patterning. Based on orbital anisotropy, we propose a design principle for 2D hyperbolic materials and predict a family of candidate materials using first-principles calculations. Our computational results showcase the broadband hyperbolic regimes exhibited by these natural 2D-HMs across the near-infrared to ultraviolet spectrum, enabling the propagation of highly directional hyperbolic surface plasmons. By simulating the directional propagation of surface waves with hyperbolic dispersion relations through the solution of Maxwell's equations, we establish a correlation between the fascinating plasmonic properties and the unique electronic structures of these highly-anisotropic 2D materials. The findings presented in this study offer a promising strategy for the design of 2D hyperbolic materials, paving the way for advancements in optoelectronic devices and expanding the possibilities of utilizing natural materials with remarkable electromagnetic characteristics.

The Effect of 2D Nanosheet Size on the Performance of Printed Devices AnthonyDawson, JoseMunuera, KevinSynnatschke, JosephNeilson and JonathanN. Coleman; Trinity College Dublin, Ireland

Printed networks of materials such as few layer MoS2 enable the production of low-cost but poorer performance devices. This poor performance is due to low nanosheet network mobility of about 0.1 cm2/Vs, this is in part due to inter-nanosheet junctions. To improve network mobility of printed networks, we must better understand these junctions. To achieve this, this project sees the development of size-controlled networks by separating nanosheets into discrete size selected samples.
Recently developed Electrochemical Pellet Intercalation (ECPI) methods enable the scalable exfoliation of nanosheets from cheap, widely available powders. The development of size-controlled networks from commercially available powders via ECPI could transform access to the development of 2D material-based device development. [1,2]
The electrical performance of these networks is characterised, and these measurements are used to refine printing parameters to optimise network morphology, toward reducing junction resistance and thus improving mobility. Applying this knowledge, transistors are developed using these optimised networks and their performance assessed. [3]

8:00 PM EL07.06.09
Borophene and Silicene-Based Humidity Sensors using Quartz Crystal Microbalance AhmetGulsaran[1,1], BersuBastug Azer[1,1], NevinTasaltin[2,2,3], CihatTasaltin[4] and MustafaYavuz[1,1]; [1]University of Waterloo, Canada; [2]Maltepe University, Turkey; [3]Consens Inc., Turkey; [4]Tubitak Marmara Research Center, Turkey

Humidity sensors, fundamental to a wide array of applications ranging from environmental monitoring to healthcare, have seen innovative advancements with the advent of two-dimensional (2D) materials. This study explores the promising potentials of borophene and silicene, two emergent 2D materials, as effective elements in humidity sensing when integrated into a Quartz Crystal Microbalance (QCM) platform.

These sensors, fabricated by transposing atomically thin layers onto a QCM surface, operate based on the detection of mass variations as a consequence of water molecule adsorption or desorption, thereby causing a resonant frequency shift in the quartz crystal. Leveraging the exceptional surface-to-volume ratio and ultrathin attributes of borophene and silicene, these sensors exhibit a marked sensitivity to ambient humidity levels.

Our rigorous examination of the borophene and silicene sensors' humidity sensing performance showed significant shifts in the QCM's resonant frequency in relation to humidity changes, demonstrating their high moisture sensitivity.

We have also analyzed the borophene and silicene's surface structure and morphology for their applications in humidity sensing. We employed Scanning Electron Microscopy (SEM) and Brunauer-Emmett-Teller (BET) analysis to determine atomic arrangements, topographical features, specific surface areas, and pore size distributions. The integrative use of SEM and BET has provided an in-depth characterization of these 2D materials, expanding our understanding of their potential applicability.

In conclusion, our research emphasises borophene and silicene as potent candidates for humidity sensing applications, with their great sensitivity and atomically thin composition demonstrating a new era in sensor development. This study's insights could guide the design and optimization of advanced 2D material-based humidity sensors.

8:00 PM EL07.06.10
First Demonstration of VGA Format Microbolometer FPAs using Semi-Conducting SWCNT Networks for Uncooled LWIR Image Sensor TomoTanaka[1,2], MasahikoSano[1], MasatakaNoguchi[1,2], TakashiMiyazaki[1,2], MegumiKanaori[2], ToshieMiyamoto[1,2], NaokiOda[1] and RyotaYuge[1,2]; [1]NEC Corporation, Japan; [2]AIST, Japan

Uncooled infrared sensors of bolometer type have a wide range of applications such as security, military, food inspection, health care, and automotive night vision system. Currently, the highly sensitive device development is the key issue for further expansion of demand. The bolometer is an infrared detector of long wave infrared (LWIR) region for radiant heat by means of an infrared absorber having a temperature sensitive electrical resistance material. Infrared radiation strikes the absorber material heating it and thus changing resistor material resistance. Therefore, bolometer's performance is strongly limited by temperature coefficient of resistance (TCR) of the resistor. The conventional resistor is generally based on vanadium oxide (VO_x) with TCR of about -2%/K [1] and an outstanding resistor is essential to achieve highly sensitive infrared detectors. Recently, single-walled carbon nanotubes (SWCNTs) have been expected as promising materials with high TCR and high chemical stability. We have reported that semi-conducting SWCNT networks extracted by the "Electric-field inducing Layer Formation (ELF)" method [2] show high TCR which is close to -6%/K [3]. The pristine SWCNTs are fundamentally a mixture of both semi-conducting and metallic SWCNTs. The ELF method is the remarkable promising technique to extract semi-conducting SWCNTs with high purity, which show stable device performance and excellent electrical transportation property.

In this study, we fabricated the Video Graphics Array (VGA) format focal plane allays (FPAs) with semiconducting SWCNTs for the first time and characterized them. Previously, we have developed a VO_x microbolometer with a suspended structure for thermally separation between the infrared absorber and the substrate by micro electro mechanical system (MEMS) process [4]. By utilizing this technology and constructing a new MEMS structure suitable for the CNT networks, we have successfully developed a SWCNT microbolometer FPAs. Device chip which was mounted on the ceramic carrier was installed in a vacuum dewar. For responsivity measurement, infrared radiation from cavity type blackbody was irradiated onto the microbolometer through the ZnSe optical window. This radiation was chopped by an optical chopper and the response signal of microbolometer was measured by lock-in amplifier.

The responsivity of LWIR region was estimated to be around 10^5 V/W in our FPAs with semi-conducting SWCNTs. This is about three times higher than that in FPAs with VO_x. TCR of our semi-conducting SWCNT networks was above -6 %/K, which is approximately three times higher than that of VO_x. Therefore, it means high TCR of semi-conducting SWCNT network was responsible for the increased sensitivity.

In conclusion, we showed the high-purity semi-conducting SWCNT networks extracted by ELF method effectively work for higher responsivity of microbolometer FPAs. In the future, we will evaluate the performance in more detail and obtain infrared images by combining a microbolometer and a readout circuit.

Spatially Heterogeneous Optical Emission from $MoSe_2$ Nanoribbons OnaAmbrozaite[1], ZheZhang[1], SarahHiestand[2], LeoSun[3], AtacImamoglu[2], AdamFriedman[3], AubreyHanbicki[3] and ThomasJ. Kempa[1,1]; [1]Johns Hopkins University, United States; [2]ETH Zürich, Switzerland; [3]Laboratory for Physical Sciences, United States

In order to fully exploit the unique physical properties of 2D materials, one must precisely control their dimensionality, composition, strain state, and edge structure. Achieving these goals through a rational chemical synthesis strategy is a compelling but challenging prospect. Here we present detailed optoelectronic characterization of atomically-thin $MoSe_2$ nanoribbons synthesized through a directed growth strategy on phosphine treated Si surfaces. Temperature-dependent photoluminescence studies reveal both systematic shifts in the emission energy of the $MoSe_2$ nanoribbons relative to their 2D monolayer counterparts, and previously unobserved regular spatial variations in the photoluminescence intensity across the nanoribbon crystals. Transport measurements on a $MoSe_2$ nanoribbon field-effect transistor device are used to examine how edge effects manifest in changes of the channel and Hall conductance. This study pushes the boundaries of 2D materials synthesis by revealing that precise control over the structural attributes (dimensionality and edge states) of these crystals gives rise to unprecedented physical properties, and thereby paves the way for harnessing their novel phenomena to advance optics, electronics, and quantum sensing.

Transition-Metal Doped Ceria Nanoparticles Loaded Metal Oxide Nanofibers: Heightened Surface Activity for Chemiresistors Jong WonBaek and Il-DooKim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Oxide semiconductor chemiresistors have shown promise as powerful gas sensors. However, their low surface reactivity limits sensitivity and selectivity. To address this issue, the functionalization of noble metal catalysts on oxide supports has been proposed, but challenges such as scarcity, agglomeration, and poisoning effects hinder practical application. In this study, we present a solution by introducing the highly promising physical and chemical properties of transition metal-doped cerium oxide (Co-CeO_2) as an alternative catalyst. To achieve uniform functionalization, we propose an elaborate design principle that employs an electrospinning technique to integrate Co-CeO_2 catalysts onto nanostructured metal oxide nanofibers. Through a single-step liquid-phase reaction involving organic solvents, we have developed sub-2 nm-sized Co-doped CeO_2 nanoparticle colloids, which can be conveniently and efficiently used for functionalizing the SnO_2 surface through solution-based electrospinning. The synthesized particles possess distinct physicochemical properties and exhibit active catalytic behavior, characterized by high purity and crystallinity. The resulting composite exhibits superior gas sensing characteristics, specifically for isoprene (C_5H_8), with low detection limit and excellent long-cycling stability. Notably, the high catalytic activities of Co-CeO_2 facilitate the spillover process of chemisorbed oxygen species, resulting in a 27.4-fold higher response towards the target analyte with exceptional selectivity. Furthermore, to gain further insights into the mechanisms behind the chemisorption of oxygen species and selective gas adsorption facilitated by the Co-CeO_2 sensitizers, we employed density functional theory (DFT) calculations and X-ray photoelectron spectroscopy (XPS) analyses. Altogether, our findings demonstrate the potential of transition metal-doped CeO_2 functionalization for highly sensitive chemiresistive gas sensors.

Imprinted 2D/3D Perovskite Film with Gradient Phase Distribution Toward High-Performance Polarization-Sensitive Photodetector DustinLiu, QiWei, LyuchaoZhuang and Shu PingLau; The Hong Kong Polytechnic University, Hong Kong

Polarization-sensitive perovskite photodetectors (PSPPDs) are attracting wide attention due to their potential application in remote sensing, optical radar, astronomy detection, and military. The current mainstream of PSPPDs is forming perovskites into anisotropy structures, especially nanowires (NWs). However, synthesizing high-quality perovskite NWs can be a challenging process. Two-dimensional (2D) Ruddlesden–Popper perovskites with the multilayered structure have emerged as promising candidates in optoelectronic devices for their higher oxygen and moist resistance than their three-dimensional (3D) counterparts. Previous research suggested that the spontaneously formed multiple phases of 2D perovskite films are always inhomogeneously distributed, hindering radiative recombination. It is an effective method to modulate perovskite phase distribution to facilitate the separation of charge carriers and improve carrier lifetime. This work reports a PSPPD with high optoelectronic performance based on a 2D/3D perovskite heterojunction with a facile preparation process. The vertical gradient phase distribution of synthesized $(PEA)_2(MA)_{n-1}Pb_nI_{3n+1}$ film was determined by transient absorption (TA). This ordered phase distribution causes a progressive band energy alignment, which promotes the separation of photogenerated carriers, thereby enhancing the photodetector responsivity. Furthermore, the imprinting method was adopted to form NW-like nanoscale linear patterns on the film surface, realizing polarized light detection. The responsivity of the PSPPD reaches almost 90 A/W, and the detectivity reaches the order of 10^{12} Jones. The photoluminescence intensity of the perovskite film with nanoscale linear patterns presents an anisotropy ratio of 2.2, and the photocurrent of the PSPPD exhibits an anisotropy ratio of 1.6.

8:00 PM EL07.06.14
Investigation of Structural Regularity of Graphene Oxide by Experimental and Computational Methods KazutoHatakeyama[1], TakashiTaniguchi[2], TatsukiTsugawa[1] and ShintaroIda[1]; [1]Kumamoto University, Japan; [2]National Institute for Materials Science, Japan

Graphene oxide (GO) is a well-known multifunctional 2D material. Owing to its highly useful properties, GO and reduced GO (rGO) are applied to a wide range of applications such as batteries, catalysts, and functional membranes. Furthermore, GO is easily produced via a liquid process from inexpensive natural graphite, and normally obtained as monolayer nanosheet well-dispersed in many kinds of solvents; thus, it is recognized that GO is a 2D material that is closest to practical use. However, the complex structure, which contains many types of functional groups and defects (nano-pores), has become a major impediment to studying GO. For example, its complex structure has prevented the elucidation of GO's useful properties and research using theoretical calculations. In addition, lack of repeatability, accuracy, and controllability is induced by its complex structure, which causes differences in results and discussions between papers. Moreover, rGO with the same characteristics as graphene has not been achieved because graphene structure cannot be restored perfectly using any reduction process. Recently, we developed an monolayer GO with low defect density and one type of oxygen functional group prepared by effective exfoliation of graphite oxide oxidized using Brodie's method. The high structural regularity of developed GO allows for detailed discussions in theoretical calculations and other methods that were not possible in the past. Herein, combining experimental results from FT-IR and UV-vis absorption measurements with DFT calculations, the structure of the developed GO is discussed in more depth. The experimental FT-IR and UV-vis absorption spectra were best explained by modelling a graphene backbone with regularly arranged epoxy groups. When slight structural defects were introduced in the model structure, inconsistencies

arise in the experimentally obtained spectra. The high structural regularity of the developed GO was also discussed from the experimental results of carrier mobility and electrical properties.

Hall Scattering Factors for Surface Termination Group Detection in Semiconducting MXenes: Unraveling Transport Behavior in 2D Materials SatadeepBhattacharjee[1], Namitha AnnaKoshi[1], Anup KumarMandia[1], BhaskaranMuralidharan[2] and Seung-CheolLee[1]; [1]Indo Korea Science and Technology Center, India; [2]Indian Institute of Technology Bombay, India

Magnetotransport phenomena, especially in two-dimensional (2D) materials, have attracted a lot of attention due to their unique electronic properties and potential applications in various fields [1,2,3,4]. Understanding the transport behavior in these materials is crucial to elucidating their underlying physics and developing advanced electronic devices. In this study, we focus on developing a method to calculate the Hall scattering factor, a key parameter in magnetotransport studies, using Rodes' iterative approach. Our goal is to enable the calculation of this factor as part of ab initio calculations, thus providing a valuable tool for studying the transport properties of 2D materials. We formulate the Hall scattering factor in the context of the *ab initio* method [5] and present it in the calculation of Hall scattering factors of semiconducting Mxenes such as Sc_2CF_2, Sc_2CO_2 and $Sc_2C(OH)_2$. By including elastic (acoustic and piezoelectric) and inelastic (polar optical phonon) scattering mechanisms, we model the electrical transport in these MXenes [6]. In particular, we find that polar optical phonon scattering is the most important mechanism in these materials. Interestingly, we observe a clear behavior of the Hall factor over a range of carrier concentrations. Specifically, Sc2CF2 exhibits an exceptionally high Hall factor of 2.49, while Sc_2CO_2 displays a relatively small value of approximately 0.5. In contrast, $Sc_2C(OH)_2$ achieves the ideal value of 1. This fascinating behavior of the Hall factor holds significant promise for surface group identification in MXenes, addressing a longstanding challenge that has perplexed researchers in the field. Furthermore, our findings shed light on the role of various scattering mechanisms and highlight the intriguing behavior of the Hall factor in different materials. This work contributes to the understanding of magnetotransport phenomena in 2D materials and offers a pathway towards harnessing their unique properties for future electronic applications.

Effects of Vanadium Substitution on the Structure and Humidity Sensing Behavior of Microporous Titanosilicate ETS-10 RamonaDavoudnezhad, DuyguKuzyaka and BurcuAkata Kurc; Middle East Technical University, Turkey

Humidity sensors hold an imperative role due to increased demand to control the indoor ambient environment, food and medicine storage, agriculture, health, industry, textile, and even space environments. There has been a rapid increase in developing humidity sensors with enhanced sensitivity at low and high relative humidity (*RH*) ranges for monitoring moisture, temperature, and chemical gases in various application fields.
Zeo-type Titanosilicate ETS-10 is microporous material that shows competitive sensitivity to TiO_2. However similar to TiO_2 at low humidity range it needs some modifications. To achieve this, vanadium (V)-incorporated titanosilicate microporous thin films were successfully fabricated to investigate their performances as humidity sensors. A structure with both vanadium and titanium atoms of differing coordinations in the quantum wire of ETS-10 was used to better understand the sensing mechanism. The results indicated that vanadium incorporation led to structural changes in ETS-10, resulting in the formation of Ti^{3+} centers along with Ti^{4+} states with a more significant amount of V^{5+} as the incorporated vanadium level increased. Vanadium incorporation also resulted in the decreased bandgap, suggesting the introduction of disorders created along the -Ti-O-Ti- chains. The developed sensors showed full range sensitivity at an optimized amount of vanadium into the -Ti-O-Ti- quantum wires in ETS-10. It was observed that V-incorporated samples with an optimized amount of V/Ti+V ratio of 0.2 showed enhanced sensitivity at particularly low relative humidity (*RH*) levels for the first time. These results demonstrated that titanosilicate ETS-10 has potential application in fabricating humidity sensors, and the sensing performance is enhanced, particularly at an optimized vanadium amount.

Band Tunable Saturable Absorber Built from MoS_2-Printed D-Shaped Fiber MingfeiXiao[1], Amar NathGhosh[2], JinruiChen[1], GuolinYun[1], NoelHealy[3], Anna ClairePeacock[2] and TawfiqueHasan[1]; [1]University of Cambridge, United Kingdom; [2]Optoelectronics Research Centre, University of Southampton, United Kingdom; [3]Emerging Technologies and Materials Group, School of Mathematics, Statistics and Physics, United Kingdom

Low-temperature additive fabrication techniques, such as inkjet printing, provide the ability to precisely deposit functional materials onto designated locations, helping to reduce costs in large-scale manufacturing. This research outlines a highly controllable materials deposition method for micro precision jetting a wide range of 2D nanocrystal inks onto nearly any surface, including plastic, glass, ceramics, silicon, and flexible substrates. Researchers can utilize interchangeable cartridges to fabricate thin films for applications such as flexible circuits, sensors, and photonics.

We use liquid phase exfoliation and solvent exchange processes to prepare the MOS_2 ink for inkjet printing. This ink contains few-layer MoS_2 flakes with ~50 nm lateral size and ~3 nm thickness, in a binary solvent combination of IPA and 2-butanol. This binary solvent ink suppresses coffee ring formation after inkjet printing.

To demonstrate the versatility of the process, we deposit the ink onto the side polished regions of D-shaped fibers. By printing the inks with different numbers of printing paths, the material thickness can be tuned, before sealing with a 1 µm thick parylene-C passivation layer. The devices demonstrate the transmittance covering the near-infrared region, with the position of absorption peak position tuned by the different number of printing paths, indicating their applicability as a band-tunable saturable absorber for the creation of ultrafast fiber lasers.

Enhancement of Electrochromic Performance of $W_{18}O_{49}$ NWs Through Instantaneous Acceleration of Ion and Electron Transport via Ti_3C_2Tx (MXene) Addition MuhammadHassan and KemalCelebi; Zhejiang University, China

The field of flexible electrochromic materials has garnered considerable attention due to their potential applications in emerging technologies like smart windows, wearable displays, and electronic paper. Transition metal oxides (TMOs) show promise as electrochromic materials for smart windows and displays. However, the challenge remains to achieve simultaneous improvements in flexibility, coloration efficiency, and response time. Effective strategy to simultaneously boost the transport kinetics of electrons and ions in TMOs thin films is critical. One effective approach is the utilization of nanostructured materials in the form of 2D nanosheets, which significantly enhance electrical and ionic transport due to their increased surface-to-volume ratio. The high contact area between adjacent nanosheets facilitates even redistribution of induced strain, leading to improved mechanical strength and film flexibility.
In this regard, we present advancements in the development of a promising material, the Mxene-$W_{18}O_{49}$ nanowires (NWs) composite, and its interfacial assembly for flexible electrochromic applications. These assembled nanometer-thick heterostructures exhibit well-balanced alignment and connectivity, enabling fast and efficient transport of ions and electrons, as well as superior mechanical and electrochemical stability. Furthermore, we demonstrate the feasibility of large-area flexible devices that can be seamlessly integrated onto curved and flexible surfaces, paving the way for future global electronics.

The ID and 2D conductive nanomaterials have contributed to an increase in interest in the advancing development of flexible and wearable electronics over the past decade [1]. The current and next generational span presents wide opportunity for the advancement of printable flexible sensors for use in human healthcare assessment [2]. The existing metal-based sensors for medical diagnostics lack human comfort because of low flexibility, and poor conformity with the skin, and offer significantly less stretchability [3]. The carbon nanotubes (CNTs) are unique electrical properties, high intrinsic current mobility, and high performance and combination with elastomer provides wide benefits. In our work, the stencil printable elastomeric nanocomposite adhesive-based formulations were used to create multifunctional printed sensors [4]. The Liquid isoprene rubber (LIR) with methyl ester of succinic acid functionality and carboxylated (c-CNT) was selected as the material to develop adhesive-based multifunctional sensors. The formulation is designed to bond with various substrates including plastics, metals, glass, and wood. We picked the highest sensitivity formulation associated with the volume fraction of CNT using the rheological and electrical percolation model. The selected formulation could respond to a wide range of stimuli, such as changes in temperature, pressure, and strain. The developed sensors show a temperature sensitivity of 0.347%/°C and strain sensitivity of 62.4 up to 40%. As a result of these benefits, these sensors are being used in a variety of human health monitoring applications at the point of care. The developed sensors are capable of detecting low- to high-strain movements associated with monitoring human motion, such as twitching, frowning, eye blinking, and finger and elbow bending. In addition, the sensors were able to accurately track vital signs like pulse rate and respiration rate as well as track vocal patterns for use in diagnostics of human health.

Thermal Conductivity and Dielectric Behavior of Nanobrick Wall Thin Films: A New Generation of High-Performance Insulation

EthanT. Iverson[1], HudsonLegendre[1], Shubham VasantChavan[2], AnilAryal[1], ManinderjeetSingh[2], SouravChakravarty[1], KendraSchmieg[1], Hsu-ChengChiang[1], PatrickShamberger[1], AlamgirKarim[2] and JaimeGrunlan[1]; [1]Texas A&M University, United States; [2]University of Houston, United States

Various high voltage electronics for aerospace, defense, and energy storage and conversion have experienced a significant increase in their miniaturization, complexity, power draw, and heat generation. Current insulation systems are inadequate to meet the demands of these rapidly evolving electronics due to subpar thermal conductivities, dielectric properties, and conformability to complex part geometries. Little research has focused on creating novel insulation systems that excel at both dissipating heat and withstanding high voltages (i.e., have both high thermal conductivity and superior dielectric breakdown strength) due to the inverse relationship between the material’s thermal conductivity and insulating dielectric properties. Electronics often require specific combinations of thermal and dielectric properties that are difficult to obtain with one material. Layer-by-layer (LbL) deposition of polyelectrolytes and inorganic nanoplatelets, yields nanocomposite coatings with a high degree of conformality and ordered structures, with unique properties which rival Kapton. Properties can be controlled by adjusting solution concentration, chemistry, and pH, which directly alters the system’s nanostructure. Thermal conductivity as high as 1.87 W/m*K and impressive dielectric constant, losses, and breakdown strength (3, 0.05, and 140 kV/mm, respectively) have been achieved. These novel insulation systems also demonstrate impressive dielectric properties at elevated temperatures, with breakdown strengths ranging from 180-270 kV/mm and low dielectric losses (<<0.1). This unique application of LbL assembly provides a practical route for the precise production of high performance, thermally conductive insulation systems for high voltage electronics.

Structural and Electronic Properties of α-Borophene Scrolls

GuilhermeFabris[1], DouglasS. Galvao[2] and RicardoPaupitz[3]; [1]Federal University of Pelotas, Brazil; [2]State University of Campinas, Brazil; [3]University of São Paulo State–UNESP, Brazil

Since the advent of graphene, there is a renewed interest in low-dimensional materials. Among the structures related to graphene, it is worth mentioning the carbon nanoscrolls (CNS). CNS can be topologically described as graphene sheets rolled up into a spiral shape (papyrus-like) [1]. CNS and scrolls of other elements have already been obtained. Recently, borophenes (single-layer boron structures) were predicted and experimentally realized [2,3]. A natural question is whether stable borophene scrolls can exist.
In the present work [4], we proposed and investigated the structural and electronic properties of boron-based nanoscrolls (armchair and zigzag) using the DFTB+ method. The electroactuation process (injecting and removing charges) was also investigated. Our results showed a giant electroactuation, similar to what was reported for carbon nanoscrolls [5]. Our results also show that the borophene scrolls are thermally and structurally stable for a large range of temperatures (up to 600K), and the electroactuation process can be easily tuned and can be entirely reversible for some configurations.

New Paradigm of Label-Free Biosensor Enabled by Two-Dimensional Hexagonal Titanium Oxide

YangeLuan, Bao YueZhang and JianzhenOu; RMIT University, Australia

Biosensors with high sensitivity and selectivity are increasingly in demand, especially in the fields of medical devices, health monitoring, and treatment, etc. Two-dimensional (2D) materials-enabled nanotechnology has brought promising pathways in rapid, highly sensitive, and selective cancer biomarker sensors. The recently developed 2D planar hexagonal titanium oxide (h-TiO_2) monolayer derived from the metal-gas interface exhibited a unique narrowed bandgap and extraordinary carrier transport performance up to 950 $cm^2 V^{-1}s^{-1}$ at room temperature, compared to that of conventional bulk phased ones. The findings show exciting opportunities in realizing high-performance electronic biosensors.
Herein, we demonstrated the sensing capability of 2D h-TiO_2 by FET-based biosensor for carcinoembryonic antigen (CEA) detection-a representative broad-spectrum tumor marker. The h-TiO_2 nanosheets FET devices were functionalized with monoclonal CEA antibody using the probe linker of 3-aminopropyltriethoxysilane. The dissociation constant between anti-CEA and CEA protein was estimated to be approximately 1.03×10^{-10} M by hill model, showing high affinity between CEA protein and anti-CEA. Multiple techniques including XPS, and KPFM were carried out to investigate the surface condition at each of the functionalization stages. The real-time measurement of 2D h-TiO_2 FET biosensor showed a high specificity of and an ultralow limit of detection (LOD) down to 0.23 pg ml^{-1}, exceeding the performance enabled by conventional 2D systems including graphene, black phosphorus (BP), transition metal dichalcogenides (TMDs), etc. The outcome of this work demonstrates the significant potential of 2D hexagonal metal oxide in biological sensing applications.

Significantly Improving CNT-Fiber Thermal Conductivity via Ultra-Fast Pulsed Laser Annealing

RachelMartin[1], ZacharyPiontkowski[1], MitchellTrafford[2], WyattHodges[1], AnthonyMcDonald[1], LyleBrunke[3], MatteoPasquali[2] and MichaelSiegal[1]; [1]Sandia National Laboratories, United States; [2]Rice University, United States; [3]Oak Ridge National Laboratory, United States

We studied pulsed laser annealing (PLA) via an ultraviolet excimer laser with a 248 nm wavelength to perform ultra-rapid thermal annealing to coalesce or merge adjacent carbon nanotubes (CNTs) within graphitic CNT-fibers; this results in > 30% improvements to the overall fiber thermal conductivity. CNT-fibers are comprised of aligned, high aspect ratio (length/diameter >3,000) CNT bundles held together with weak Van der Waals interactions. While individual CNTs have thermal conductivities > 3000 W/m*K, CNT-fiber thermal conductivities are only ~350 W/m*K. The lower conductivity is attributed to poor thermal contact between adjacent CNTs that act as phonon scattering sites. We hypothesized that coalescing adjacent CNTs in the contact regions to form larger diameter CNTs would reduce phonon scattering sites and improve the overall fiber thermal conductivity, although the CNTs would become somewhat more defective. CNT coalescence was recently demonstrated by furnace annealing to temperatures > 1700°C. Instead, we perform PLA, with ~ 20 ns pulse durations, to achieve rapid, targeted heating of fibers to induce CNT coalescence at a greatly reduced thermal budget. We operated the laser at a 20 Hz pulse frequency; hence 5 seconds of laser operation results in 2 microseconds of total annealing time.
PLA uses modest energy to anneal at high temperatures due to strong UV absorbance by opaque CNTs. Radial breathing modes (RBMs), found in Raman Spectroscopy data at low wavenumber, identify the various CNT diameters within the fiber. The degree of CNT coalescence within a fiber is assessed via increases in CNT diameters as a function of PLA conditions

(whereby laser energy density and total pulses are analogous to temperature and time respectively). We measure fiber thermal conductivities using the 3ω method, where AC current induces Joule heating of the sample, resulting in a 3ω output voltage correlating to the sample thermal conductivity. We find that the CNT-fiber thermal conductivity indeed increases with optimized PLA exposure, reaching values > 500 W/m*K, surpassing that of even the best metals. This work was supported by the Laboratory Directed Research and Development program at Sandia National Laboratories (SNL). SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Role of Carbon-Based Nanocomposites for Energy Storage JakeIrvin, DuyPham, MasonCox and AshishAphale; Kennesaw State University, United States

Certain allotropes of carbon have unique properties that have the potential for clean energy storage systems, healthcare, aerospace, and energy conversion applications. In this work, graphene-based nanocomposites (GNCs) were synthesized and investigated for their use in an ultracapacitor device. GNCs were selected for use as an electrode material for the supercapacitor due to their superior electrochemical properties and high surface area which is promising to provide superior energy storage performance. GNCs will be were synthesized using an electrochemical deposition technique and the performance will be was evaluated using various electrochemical studies in the presence of various three different aqueous electrolytes. Distinct Faradaic and non-Faradaic charge transfer mechanisms will be were investigated using cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS), and galvanostatic charge-discharge (GCD) studies. Results of different percentages of dopants in the nanocomposite during synthesis and their effect on ultracapacitor performance will be presented. Lifecycle testing of the ultracapacitor device will be discussed and its post-test analysis were be presented. The role of different substrates, electrolytes, and their effect on the device performance will be discussed. Mechanisms of charge storage and transfer between the electrolyte and GNC surface will be presented.

Mist CVD Modulated High-κ a-$Al_{1-x}Ti_xO_y$ Films for p-$WS_{0.3}Se_{1.7}$-Channel Metal Oxide Field Effect Transistors (MOSFETs) AbdulKuddus[1], KojunYokoyama[2], ShinichiroMouri[1,1], KeijiUeno[2] and HajimeShirai[2]; [1]Ritsumeikan University, Japan; [2]Saitama University, Japan

Introduction: High-κ amorphous (a)-AlO_x, and a-TiO_2 thin films from $Al(acac)_3$ and $Ti(acac)_2OiPr_2$ precursors dissolved in alcohol solvent investigated by mist CVD method in our previous reports [1,2]. In addition, the AlO_x, and TiO_2 alloy of a-$Al_{1-x}Ti_xO_y$ (ATO) films revealed an adjustable dielectric constant of 6.23-25.12 and band gap of 4.25-6.38 eV studied. Further, an exfoliated $MoSe_2$-channel MOSFET on $Al_{0.74}Ti_{0.26}O_y$ thin film as gate insulator with Au as the source and drain electrodes showed a mobility of 85 cm^2/Vs, the threshold voltage of 0.92 V, and an on/off current ratio of 10^8 [3]. However, a consistent fabrication of TMDCs such as MoS_2, $MoSe_2$, and WS_2, WSe_2, or their alloys such as $WS_{2-x}Se_x$ film and the high-κ dielectric is highly promising toward large-scale device fabrication. To date, the synthesis of high-quality defect-free large-area TMDCs films and transfer-free device fabrication are major hindrances to further advancing in TMDCs-based devices technology. In this study, we investigated a consistent fabrication technique of metal oxide and TMDCs films as high-κ dielectric and channel layers in MOSFETs toward transfer-free large-scale TMDCs device fabrications.
Experiment: A 0.015 M $Al(acac)_3$ and $Ti(acac)_2OiPr_2$ solution with CH_3OH dilution was placed directly above a 3 MHz atomizer, N_2 was used as a generator, and dilution gas (500 and 2400 sccm) was used to transport the mist. A cleaned Si substrate was placed 16 cm inside the tube furnace in the open air. On the other hand, ammonium tetrathiotungstate $(NH_4)_2WS_4$ dissolved in N-methyl-2-pyrrolidone (NMP) solvent was used as a precursor of $WS_{2-x}Se_x$. The $WS_{2-x}Se_x$ films were synthesized by mist CVD with Ar gas containing H_2 (25%) at a T_f of 400-600 °C at atmospheric pressure. Subsequent selenization of mist CVD WS_x was executed to further improve the flake's quality at T_f of 600 °C for 20 min. The p-$WS_{2-x}Se_x$ channel MOSFETs on ATO dielectric were fabricated with Pt source and drain electrodes [4].
Results and Discussion: The deposition rates were found of 11 nm/min for $Al_{0.74}Ti_{0.26}O_y$ with an adjustable dielectric constant of 6.23-25.12 and band gap of 4.25-6.38 eV. While, an average flake size of over 700-800 µm on ATO substrate. the mobility over 40 cm^2/Vs, the threshold voltage around 0.30 V, and an on/off current ratio in the range of 10^6 were obtained in p-$WS_{0.3}Se_{1.7}$-channel MOSFETs on ATO dielectric retaining reduced leakage current. Thus, a strong potential is revealed by the mist CVD to be used as a consistent manufacturing process for the fabrication of metal oxides and TMDCs films as high-κ dielectric and channel layers in MOSFETs toward transfer-free, large-scale TMDCs device technology.

Atomic Layer Etch of Tungsten Disulfide Semiconductor using Downstream Plasma Treatment and Wet Etch Removal Young-HyunYou, JoonyupBae and JihyunKim; Seoul National University, Korea (the Republic of)

Silicon has been used as a channel material for field-effect transistor (FET), driving the growth of the semiconductor industry. However, in modern technology where the channel size has been reduced to several nanometers, silicon has shown limitations such as short channel effects. Since numerous defects such as dangling bonds exist on the surface of silicon, the movement of carriers is hindered by the defects in channel with atomic-scale thickness. High-performance transistors with smaller form factor require the next-generation semiconductors to replace silicon. Recently, two-dimensional (2D) materials have drawn considerable attention due to their unique layered structure. Since layer-to-layer bonding is achieved through van der Waals (vdW) interaction, layer-to-layer separation can be easily achieved with relatively weak force. The separated monolayer has a complete structure and no defects on surface compared to silicon. Several semiconductor chip manufacturers have reported results of applying 2D materials as channels in various structures of next-generation transistors.
Transition-metal dichalcogenides (TMDCs) are one of the most actively studied 2D materials. Among them, WS_2 has a very high electron mobility of ~234 $cm^2V^{-1}s^{-1}$ and generally exhibits n-type behavior due to its sulfur vacancy. WS_2 can also be used as a p-channel through p-doping and it is possible to implement a single semiconductor-based complementary metal–oxide–semiconductor (CMOS). Thickness-dependent energy band gap and excellent mechanical properties of WS_2 enable multiple device applications such as photo detectors and wearable devices. However, various problems exist in the fabrication process of electrical devices using TMDCs. In general, the mechanical exfoliation is used for interlayer separation of TMDCs and it is difficult to obtain the materials with accurate thickness due to its randomness. Photoresists or contaminants may also remain on the surface of TMDCs, which can cause interface defects and reduce device reliability. WS_2 can be oxidized in atmosphere and the oxide layer gives an unwanted doping effect. The fabricated devices exhibit different electrical properties from those originally designed because of the above problems.
In this study, we propose a method to accurately control the thickness and restore the contaminated surface to the pristine state through atomic layer etching of WS_2. Only the outermost layer of WS_2 can be oxidized by self-limiting reaction using downstream O_2 plasma. Subsequent KOH solution treatment selectively removes only the oxide layer (WO_X) for layer-by-layer control of thickness. A back-gate FET using WS_2 as a channel material was fabricated to confirm the changes of physical and electrical properties by atomic layer etching. The etch rate of WS_2 channel measured with atomic force microscope (AFM) was approximately 0.65 nm/cycle, equivalent to the thickness of WS_2 monolayer. Micro-Raman spectroscopy and high-resolution transmission electron microscopy (HR-TEM) showed that atomic layer etching had a minor effect on the crystallinity of WS_2. Finally, the n-type behavior was recovered through the surface cleaning effect and the recessed-channel WS_2 FET with improved output current on/off ratio higher than 10^6 was realized. This method, which provides a facile approach to thickness control and surface cleaning, allows TMDCs to be precisely engineered, increasing their potential as channel materials for next-generation transistors.

Electrochemical Sculpting of Phosphorene Nanoribbons: Unleashing the Anisotropy of Black Phosphorous JacekB. Jasinski, UsmanAbu, SharminAkter, BimalNepal, GaminiSumanasekera, BadriNarayanan and HuiWang; University of Louisville, United States

In recent years, phosphorene, a two-dimensional (2D) form of black phosphorus (BP), has garnered significant research attention due to its exceptional properties, including high carrier mobility (2,000 $cm^2 V^{-1}s^{-1}$), thickness-dependent bandgap (0.3 – 2.0 eV), and strong in-plane anisotropy. Moreover, phosphorene nanoribbons (PNRs) exhibit even more impressive characteristics owing to their one-dimensional (1D) nanostructure, which gives rise to additional quantum confinement effects, density of states redesign, and a high density of active edge sites. While several methods for producing PNRs have been explored, scalable synthesis with narrow widths remains challenging.

Here, we present our recently developed method termed "electrochemical sculpting" to synthesize PNRs through an electrochemical process utilizing the highly anisotropic ion diffusion in BP along the [001] (zigzag) direction. In this method, BP flakes are nanostructured via an electrochemical process into bundles of parallel PNRs separated by narrow amorphous phosphorus channels running along the zigzag direction, as confirmed by transmission electron microscopy (TEM) and in-situ Raman spectroscopy. A subsequent ultrasonic treatment in a solvent can be used to separate the PNR bundles into individual, well-defined PNRs. Using this low-cost and scalable electrochemical method, we were able to fabricate PNRs with confined widths (< 10 nm) that are significantly narrower than those produced by most previous methods. Our fabricated PNRs exhibit a highly confined structure with a suppressed B2g vibrational mode. Notably, when employed in field-effect transistors (FETs), the PNR bundles demonstrate n-type behavior, which differs from that of BP flakes.

In our ongoing study, we focus on understanding this process and extending it to other anisotropic 2D layered materials. So far, the obtained results indicate that electrochemical sculpting and the fabrication of nanoribbons can also be achieved in black arsenic-phosphorus (b-AsP) alloys, i.e., 2D layered materials where some of the phosphorus atoms in the BP structure are

substituted by arsenic atoms. This is significant because b-AsP alloys are promising 2D materials, exhibiting unique electronic and optical properties. However, the fabrication of their nanoribbons using chemical approaches is particularly challenging due to the low solubility of arsenic in many solvents and the difficulties in controlling the crystal structure of the resulting material. While the overall mechanism responsible for electrochemical sculpting in BP and b-AsP alloys is similar, our study indicates several significant differences between these materials. These differences can be attributed to the variation in in-plane anisotropy as well as the disparity in defect formation energy between these systems.

Our study provides valuable insights into this novel synthesis approach for PNRs, opening up new possibilities for the development of nanoribbons using BP and other anisotropic 2D layered materials. The demonstrated electrochemical sculpting method offers improved scalability and holds promise for advancing the applications of PNRs in various fields.

Preparation of 2D MoS_2 Atomic Layers from Precursor Solution Formulation and Simple Thermal Annealing for Patterned MoS_2 TFT Thi Thu ThuyCan and Woon-SeopChoi; Hoseo University, Korea (the Republic of)

Due to unique properties such as high carrier mobility and innate band gap, two-dimensional (2D) transition metal dichalcogenides (TMDs) have attracted great attention in optoelectronic and nanoelectronic fields as well. Among those atomically thin materials, molybdenum disulfide (MoS_2) has become an emerge candidate because of the indirect to direct band gap transition in monolayer limit. Chemical vapor deposition (CVD) with sulfur gas is the most popular method for synthesizing large- scale 2D materials with high quality. Various MoS_2 can be obtained from this meth[od using various precursors with different properties, process temperatures, and substrate materials. Solution process methods show advantages for preparing films with large size, high throughput, low cost, thickness control, and an environmentally friendly process.
We developed a Mo-based solution formualtion for solution-processed synthesis of MoS_2 with large-scale and uniformity. The precursor solution can be converted to atomic layer films using simple thrmal annealing without using chemical vapour process. A MoS_2 thin film was prepared by a simple jet printing and one-step annealing method. Three atomic layers of MoS_2 were obtained with 0.0125 M of precursor solution, which was confirmed by STEM. he atomic layers of the synthesized MoS_2 were identified as 2 layers for 0.0070 M, 3 layers for 0.0125 M, and 5 layers for 0.0250 M of MoS_2 solution by STEM-FIB. A printed MoS_2 TFT shows a high current ratio of approximately 10^6, a good mobility of 27.5 $cm^2V^{-1}s^{-1}$, a threshold voltage of 1.76 V, and a subthreshold slope of 1.32 $Vdec^{-1}$.

8:00 PM EL07.06.29
Observation of Intrinsic Seebeck Coefficient of 2D $PtSe_2$ Semiconducting Films Through Two-Step Annealing Process MinjeongKim, YunhoKim, Jae WonChoi, JungminCho, HyeokjunKwon, Gil-SungKim, SangkwonLee and No-WonPark; Chung-Ang University, Korea (the Republic of)

The Seebeck coefficient is an important indicator of the thermoelectric (TE) properties of a material, so accurately measuring the Seebeck coefficient is essential. However, it is challenging to evaluate the Seebeck coefficient of a 2D film having extremely high resistance. Here, we propose a simple method to measure the intrinsic Seebeck coefficient of a 2D $PtSe_2$ thin films with high electrical resistance over 2 MΩ by two-step thermal annealing process. After two-step annealing process, the electrical resistance was decreased from ~2 MΩ to ~400 kΩ and the intrinsic Seebeck coefficient could be measured, and the value is exceeding 159 μVK^{-1}, which is approximately 400% higher than that of single crystalline $PtSe_2$ bulk. Furthermore, the power factor of the sample was calculated up to 44 $\mu Wm^{-1}K^{-2}$. Additionally, it was observed that the measured intrinsic Seebeck coefficient was independent of the top metal electrode. We discuss the role of thermal annealing process in high resistance 2D semiconducting films based on the atomic crystallographic characteristics and contact resistance between the film and electrode. Our findings demonstrate significant achievements in measuring and understanding the Seebeck effect of 2D transition metal dichalcogenide (TMDC) materials.

SESSION EL07.07: 1D and 2D Materials—Logic Devices and Interconnects II

1D Topological Systems for Next-Generation Electronics JudyCha; Cornell University, United States

Topological nanowires, topological materials confined in one dimension (1D) at the nanoscale, hold great promise for robust and scalable quantum computing and low-dissipation interconnect applications, which will transform current computing technologies. To do so, research in topological nanowires must continue to improve their synthesis and properties.

In this talk, I will discuss my group's efforts to develop a synthesis method that is high throughput, scalable, and well controlled to fabricate 1D topological systems with precision in crystalline phase, morphology, and dimensions [1]. I will highlight our results on topological semimetal nanowires that can rival current state-of-the-art Cu interconnects for low-resistance interconnect applications. Specifically, we experimentally demonstrate that the resistivity scaling of MoP nanowires is superior to those of the latest Cu interconnect technologies and Cu alternative metals [2], presenting MoP as a breakthrough metal for the low-resistance interconnect applications.

Unconventional Resistivity Scaling in Nanocrystalline NbP and TaP sub-5 nm Thin Film Asir IntisarKhan[1], EmilyLindgren[1], XiangjinWu[1], Hyun-MiKim[2], AkashRamdas[1], ByoungjunWon[3], FelipeJornada[1], Il-KwonOh[3], H.S. PhilipWong[1], YuriSuzuki[1] and EricPop[1]; [1]Stanford University, United States; [2]Korea Electronics Technology Institute (KETI), Korea (the Republic of); [3]Ajou University, Korea (the Republic of)

The electrical resistivity of ultrathin metal films typically increases with decreasing film thickness due to electron scattering from the film surfaces. This behavior limits the performance of metal-based interconnects in all modern nanoelectronics [1]. To overcome this bottleneck, novel quantum materials like topological semimetals with disorder-tolerant conductive surface states have been suggested in the ultrathin film limit [2, 3].

Here we uncover the reduction of electrical resistivity with decreasing film thickness of ultrathin nanocrystalline NbP and TaP films, probed by detailed transport measurements, material characterization, and modeling. These materials have been demonstrated to be topological Weyl semimetals in the bulk [2], a class of materials wherein surface conduction is predicted to dominate thin-film transport even in the presence of disorder [3].

NbP and TaP thin films are sputtered on both r-plane sapphire and MgO substrates at 400 °C, a process compatible with back-end-of-the-line (BEOL) semiconductor fabrication. A thin seed layer of Nb (or Ta) is used to reduce lattice mismatch between the substrate and sputtered NbP (or TaP) thin films. High-angle annular dark-field (HAADF) scanning transmission electron microscope (STEM) imaging reveals nano-crystallinity of the ultrathin NbP films with short-range ordering at the NbP surface, irrespective of the film thickness. The compositional homogeneity of the NbP thin films is further confirmed by energy-dispersive X-ray analysis.

Our measured resistivity of NbP at room temperature decreases from 207 to 149 μΩ-cm (from ~18 nm down to ~2.3 nm film thickness), unlike conventional metals. We further confirm the decreasing resistivity trend with decreasing thicknesses of NbP film irrespective of the thickness of the seed layer. For example, with a 4 nm Nb (Ta) seed layer, we find that the resistivity of NbP thin films decreases from 135 μΩ-cm (18 nm thick film) to ~34 μΩ-cm (~1.5 nm thin film). On the other hand, the measured resistivity for ~1 nm thin TaP film is ~12 μΩ-cm. For both cases, the resistivity is significantly lower than the bulk single-crystal resistivity. We also note that the resistivity of NbP (TaP) thin films with a 4 nm seed layer is lower compared to their thinner seed layer counterparts due to possible charge transfers from the thicker metal seed layer to the NbP (TaP) thin films.

Temperature-dependent electrical resistivity measurements of NbP show a significantly weaker temperature dependence of resistivity in the thin NbP compared to control metal Nb. This behavior suggests a disorder-driven localization of conduction instead of phonon-dominated transport. To understand our measurements, we present a transport model in terms of a surface channel and bulk conduction in all films with surface-dominated conduction in the thinner NbP films leading to a decrease in effective electrical resistivity. Our measured Hall resistance is nearly linear with the magnetic field. This is a signature of transport dominated by single carriers (holes for NbP).

In summary, we demonstrated an unconventional resistivity scaling trend with the film thickness in sub-5 nm NbP and TaP thin films. Our transport measurements suggest surface-dominated conduction in such materials even at room temperature, which is promising for next-generation nanoelectronics. This work was supported in part by the Stanford Graduate Fellowship (A.I.K.) and the Stanford SystemX Alliance.

8:45 AM EL07.07.03
Synthesis of Thin Film Weyl Semimetal TaP ArkaChatterjee and ShengxiHuang; Rice University, United States

Topological Weyl semimetals (WSMs) have opened up a new horizon in physics and materials science due to their unique electronic, optical, and thermal properties. So far, experimental studies of WSMs have mainly focused on bulk samples. However, it has been predicted that thin films of WSMs could generate unique phenomena unachievable by bulk crystals, such as the unusual twisting of the Fermi surface, a metal-insulator transition upon thickness confinement, and the emergence of Floquet topological insulator phase modes. Furthermore, the synthesis of WSM thin films could potentially open up opportunities for creating heterostructures and functional interfaces with other materials, such as superconductors, ferromagnetic or antiferromagnetic materials, and ferroelectric materials. These interfacial interactions have been found to be promising for applications in spintronics and superconducting devices. Thus, the synthesis of thin film WSMs would be impactful from both fundamental and practical standpoints.
TaP, a type of WSM, has attracted significant attention due to its cleanest carrier pockets close to the Weyl fermions dominated Fermi energy and unsaturated negative magnetoresistance (MR), highlighting its potential for electronic applications. Here, we report the successful synthesis of thin films of TaP using a fast thermal process. State-of-the-art characterization techniques were employed to confirm the high quality of the synthesized TaP thin films. The electronic and optical properties were also obtained. Our synthesis method also offers the potential for wafer-scale manufacturing of thin film TaP. In summary, our synthesized TaP thin films hold great promise in both fundamental topological physics and novel electronic applications.

Electronic Transport in 2D Semiconductors and Interconnect Metals ChenmuZhang, ZhongcanXiao, RongjingGuo and YuanyueLiu; The University of Texas at Austin, United States

The performance of many electronic devices heavily relies on how fast the electrons can transport. Thus there is a critical need to understand and improve electronic transport. Here I will present our recent progress in developing and apply first-principles methods to accurately calculate and understand the electronic transport in 2D semiconductors as well as interconnect metals. I will also present new materials with improved transport properties.

10:00 AM *EL07.07.05
MoS2 Transistors with Sub-10nm Channel Length XuZhang; Carnegie Mellon University, United States

As the lateral dimensions of silicon based transistors scale down, their vertical dimensions, i.e. semiconductor body thickness and dielectric thickness, have to be simultaneously shrunk to maintain a tight electrostatic control over the channel and avoid short channel effects (SCE). However, as silicon thickness is scaled down to sub-3 nm, its unavoidable surface dangling bonds will strongly scatter with charge carriers and dramatically degrade its carrier mobility. The atomically thin body thickness of two-dimensional (2D) semiconductors, especially 2D transition metal dichalcogenides (TMDCs), makes it ideal to scale while maintaining a tight gate electrostatic control over channel. In this talk, we will share our recent results on the scalable fabrication of MoS2 electronics devices with sub-10-nm channel length. A combined experimental and theoretical investigation was done to systematically study their short channel effects and performance limits.

10:30 AM EL07.07.06
Transport and Electron-Phonon Coupling of 2D Electrons in Layered Electrides VahidAskarpour and JesseMaassen; Dalhousie University, Canada

Layered electrides are ionic solids comprised of weakly-interacting atomic layers in which the conducting 2D electrons are confined to the interstitial region between the atomic planes, or on their surfaces when exfoliated to form 2D electrides. Because the conducting electrons are physically separated from the lattice, layered electrides display high conductivity, low electron-phonon (el-ph) coupling, and low work function. As a result, they are promising material candidates for applications in transparent conductors, electron emitters, ohmic contacts to 2D semiconductors, and interconnects.

In this talk, we present our first-principles study exploring the transport and electron-phonon scattering characteristics of seven layered electrides of the form M_2X, where M is an alkaline earth metal (M = Ca, Sr, Ba) and X is a pnictogen (X = N, P, As, Sb). Our density functional theory calculations reveal that Sr_2N and Ca_2N have the lowest electrical resistivity and el-ph scattering rates among this group of electrides. To better understand what controls these properties, we analyze and compare their scattering phase space, average el-ph coupling, distribution of modes, average velocity, and mean-free-path for backscattering. Interestingly, while Ca_2N shows some of the lowest el-ph collision rates, resulting from its small scattering phase space, it has the largest el-ph interaction strength. Repeating these calculations for the metals Al, Au, and Cu reveals that their el-ph coupling can be an order of magnitude greater than the electrides. The decoupling of the conducting 2D electrons from the lattice in layered electrides, leading to weak el-ph interaction, suggests that these materials may be promising interconnects in nanoelectronic circuits.

10:45 AM EL07.07.07
Monte Carlo Simulation of Joule Heating in Monolayer MoS_2 Devices MarithaA. Wang and EricPop; Stanford University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) like monolayer MoS_2 have emerged as promising semiconductors for nanoscale transistors and electronics due to their good charge mobilities at small thicknesses compared to ultrathin silicon [1]. However, to engineer high-performance 2D transistors, a detailed understanding of charge scattering and heat generation in TMDs is needed. When electrical current passes through a transistor, heat is generated due to electron-phonon scattering, an effect known as Joule heating. This effect occurs even in nanoscale transistors, where charge transport is partially ballistic [2]. Joule heating leads to increased phonon occupation, causing additional electron-phonon scattering, and thus a degradation of electrical transport; it also causes reliability concerns [2].

Here, we employ Monte Carlo simulations to investigate charge transport in monolayer MoS_2 transistors with Joule heating, inspired by earlier approaches with silicon [3]. We consider intravalley and intervalley electron-phonon scattering using the deformation potentials from [4]. To incorporate Joule heating, we consider the back-gated transistors frequently used in experimental transport studies on 2D semiconductors. The thermal resistance R_{th} of such a device is estimated as the sum of 1) the thermal boundary resistance of the MoS_2-SiO_2 interface, 2) the thermal resistance of the underlying oxide (SiO_2), and 3) the thermal resistance of the back-gate (Si) [5]. Such a thermal model can be easily modified to include heat loss through a top-gate or gate-all-around geometry for more general device structures [6].

The Monte Carlo approach is advantageous because it provides rich details on the contributions of different phonon modes to heating. With this approach, we simulate electron drift along the MoS_2 channel as the transistor heats up due to Joule heating. At steady-state, the average temperature rise is $\Delta T = PR_{th}$, where P is the power generated in the MoS_2 channel. This P is computed by summing the heat generated from electron-phonon scattering events and agrees with the expected $P = IV$, where I is the current and V is the potential across the channel. At 300 K ambient temperature, carrier density of 10^{13} cm^{-2}, and lateral electric fields in the velocity saturation regime (~4-5 V/μm), our simulations show that Joule heating leads to a transistor temperature rise of $\Delta T \approx$ 200-250 K during steady-state operation. This heating decreases the electron saturation velocity by >50% compared to when heating is not considered, indicating that high-field measurements of transistor operation must consider self-heating during analysis [7].

Overall, this work highlights the important consequences of Joule heating on charge transport in monolayer MoS_2 transistors. These simulations can further be extended to other TMDs and transient (i.e. digital) operation to identify design parameters for high-performance TMD devices that minimize Joule heating. This work was in part supported by the NSF Graduate Research Fellowship and Shoucheng Zhang Fellowship (M.A.W.) and by the SRC ASCENT JUMP Center (E.P.).

Intact Electrical Contact to Air-Sensitive Atomically Thin Semiconductors and Their Optoelectronic Applications HaeYeonLee, ZhiyingWang, YangLiu and JamesHone; Columbia University, United States

Two-dimensional semiconductors have been extensively explored with remarkable potential for applications in electronics and optoelectronics, however, high contact resistance and disorders in the monolayer still constrain harnessing their novel optoelectronic properties. There have been a lot of efforts to overcome these challenges such as using semimetal or low temperature metal deposition. Unfortunately, these approaches are not applicable for air-sensitive materials such as MoTe2 or NbSe2, as they require exposing the materials to deposit metal on top. Therefore, degradation is unavoidable unless the materials are completely encapsulated throughout the entire fabrication process. In the monolayer limit, this degradation issue becomes more critical. While the introduction of a protection layer between metal and the monolayer can prevent exposure of the monolayer to the air, it can inadvertently impede charge transfer, resulting in deteriorated performance.
Here, we present a novel technique that enables intact electrical contact to air-sensitive monolayer semiconductors while simultaneously achieving high performance by tackling both two issues. Our approach involves the perfect sealing of the air-sensitive monolayer MoTe2 throughout the process by fluorinated graphene layer. At the same time, fluorine atoms improve the charge transmission between metal and MoTe2 by reducing the interatomic spacing. As a result, monolayer MoTe2 field effect transistor exhibits more than two orders of magnitude improvement in contact performance with excellent ambipolar behavior. By taking advantage of low contact resistance, intrinsic electrical properties of monolayer MoTe2 are comprehensively elucidated. Furthermore, efficient charge transfer of both electrons and holes enables fabricating lateral p-n homojunction. The small band gap (1 .1 eV) of monolayer MoTe2 coupled with its compatibility with silicon holds promising potential for optoelectronic application including photodetector. Moreover, the electrical contact technique introduced in this study can be extended to other air sensitive materials, broadening its applicability.

11:15 AM EL07.07.09
Heat Dissipation in 2D Material Transistors: The Role of Interfaces and Contacts CagilKoroglu, Alexander J.Gabourie and EricPop; Stanford University, United States

While promising candidates for next-generation transistors, two-dimensional (2D) semiconductors like MoS_2 suffer from unique challenges due to the van der Waals gaps at their interfaces. These have made it difficult to achieve good electrical contacts, and they also result in relatively high thermal boundary resistances (TBR) to adjacent materials [1, 2]. In much the same way the electrical contact resistance is a key limiter of performance for nanoscale 2D transistors, the TBR is a major bottleneck for the cooling of these devices [2]. Coupled with their atomically thin channel which has limited capability of in-plane heat transport, this results in elevated temperatures during operation, reducing mobility [3] and posing thermal degradation and reliability concerns [4].

Here, we present fast analytical thermal models for common 2D transistors, carefully taking into account their thermally-resistive interfaces, contact geometry and other non-idealities. We first develop a steady-state thermal model for simple back-gated transistors, which quantifies the device temperature for a given power input. This model elucidates the cooling mechanisms for a wide range of device geometries and material combinations, highlighting in particular the crucial role of the contacts. Notably, scaling down the channel length does not necessarily lead to improved cooling performance as commonly assumed, because metal contacts are not ideal heat sinks for typical 2D material TBR and thermal conductivity values. Next, we extend this work into frequency-dependent models that can estimate the complex-valued device thermal impedance, which characterizes the amplitude and phase of temperature oscillations for sinusoidally-varying power. These models can be used to predict device thermal time constants, as well as to compute the temperature response to arbitrary power pulses, through an inverse Fourier transform. Finally, we generalize our models to top-gate and dual-gate FETs by accounting for the heat transferred to the contacts via the top gate. We validate our models against finite-element method simulations, with a worst-case temperature error of < 18% across typical device geometries and material/interface properties.

Key insights gained from this work include: (1) the thermal resistance of 2D transistors is relatively insensitive to channel length for sub-100 nm devices, which are dominated by their contact thermal resistance, (2) the short-channel transistor thermal resistance is influenced equally by the 2D material TBRs and the in-plane thermal conductivity, while also depending on contact geometry, (3) due to their ultrathin channel, thermal time constants of 2D transistors are often sub-nanosecond, making it difficult to probe intrinsic device performance (i.e. not limited by self-heating) with pulsed electrical measurements, and (4) top gates can lower temperatures by as much as 30% and 50% for wide and narrow (~50 nm width) devices, respectively.

In addition to their utility in guiding transistor design and optimization, predicting temperatures, estimating transient heating and cooling rates, and detailing pathways for heat flow, our fast analytical thermal models for 2D transistors can also be packaged into direct-current (DC), alternating-current (AC) and transient electrical compact models which incorporate self-heating.
This work was supported in part by the Stanford SystemX Alliance, by the Semiconductor Research Corporation (SRC) and DARPA JUMP Centers, and by the National Science Foundation (NSF) Engineering Research Center for Power Optimization for Electro-Thermal Systems (POETS).

11:30 AM EL07.07.10
Observing Aharonov-Bohm Oscillations in CVD-Grown, Parallel Graphene Nanoribbons at 4K ZitaoTang[1], SiweiChen[1], CynthiaI. Osuala[1], Abdus SalamSarkar[1], AronCummings[2], GrezgorzHader[1], StefanStrauf[1], ChunleiQu[1] and Eui-HyeokYang[1,1]; [1]Stevens Institute of Technology, United States; [2]Catalan Institute of Nanoscience and Nanotechnology, Spain

The Aharonov-Bohm (AB) effect demonstrates that the orbital wave function of a charged particle picks up a different phase when it moves along two different paths in the presence of an external magnetic field, which is proportional to the magnetic flux of the enclosed area divided by Planck's constant. While the AB effect has been studied in various semiconductors, including GaAs, InP, InAs, AlGaSb, phosphorene, and Bi_2Se_3 [1–3], graphene is an ideal material for studying the AB effect owing to its long coherence length of electrons: The electron coherence length in graphene is stated as 3-5 μm at 260 mK, and 765 nm-1.25 μm at 4 K [4] For this reason, several studies have been conducted on the AB effect in mechanically exfoliated graphene rings at temperatures ranging from 36 mK to 3.5 [5–10]. To date, only ring geometries have been studied to demonstrate the AB effect.
Here, we present the magnetoconductance measurements in parallel graphene nanoribbons (GNRs) for observing AB oscillations. We fabricated chemical vapor deposition (CVD)-grown GNRs and characterized their two-terminal magnetoconductance oscillations at 4 K under out-of-plane external magnetic fields up to +/-5.6T. Incorporating a baseline subtraction of the original conductance data enabled the observation of two-terminal conductance oscillations with a spacing of ΔB_{AB} from 4.14 mT to 6.46 mT, as expected for two GNRs conjoined at the start and the end, with the spacing between the GNRs of 800 nm and the arm width of 200 nm. The fast-Fourier transform (FFT) data showed a broad band of AB oscillation frequencies that constitute the interval of the *h/e* fundamental mode given by the sample geometry ranging from 155 to 242 1/T, and the interval of the *h/2e* fundamental mode is from 310 to 484 1/T. This work shows the AB oscillations in the lower mobility, non-suspended monolayer GNRs at a significantly high temperature (4K). We are currently working on modifying and improving the GNR design based on modeling inputs, including fabricating cascaded-parallel GNRs to seek amplifying oscillation signals.

2D Materials Design for Angstrom-Scale Multi-Stack Devices Hyeon JinShin; Samsung Advanced Institute of Technology, Korea (the Republic of)

Due to our life style changes, data created exponentially and continuously increases. To respond to the huge Data created, conventional Si device scaling down for angstrom era, and 3D stacking device and introduction of disruptive device should be considered [1]. However, the process technology and material performance of Si devices are gradually reaching their limits, and the development of new materials, processes and device architectures is required to overcome these limitations. Graphene and 2D Materials have an ultra-thin crystal structure with a stable surface state. For example, among diverse 2D materials, MoS_2 has a great potential in logic transistor because of its high mobility, and no short channel effect [2].
In this talk, we will introduce 2D material and integration designs via interface property control to realize the Angstrom-scale multi-stack device: (i) adhesion/pattern [3], and (ii) Interconnect with a low resistance metal barrier [4] and ultralow dielectric material [5].

Significant Device Performance Enhancement of 1L MoS_2 nMOSFETs by Van Der Waals Contact Formation with Sb_2Te_3Wen HsinChang[1], ShogoHatayama[1], YutaSaito[1], NaoyaOkada[1], TakahikoEndo[2], YasumitsuMiyata[2] and ToshifumiIrisawa[1]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Tokyo Metropolitan University, Japan

Recently, Bi semimetal contacts were found to be effective for the suppression of metal-induced gap states (MIGS), the origin of Fermi-level pinning, leading to extremely low contact resistance and enhanced device performance for MoS_2 nMOSFETs.[1] However, Bi contacts suffer from thermal stability issues owing to its low melting point (~270 °C).[2] To satisfy the VLSI back-end-of-line (BEOL) thermal compatibility requirement, the survey of a thermal stable contact up to 400 °C, while maintaining semimetal properties is still needed for MoS_2 devices. Therefore, we focused on Sb_2Te_3 as a possible contact candidate for MoS_2 devices, which melting point is higher than 600 °C[3] and can maintain layered structure at least at 450 °C.[4,5] Besides, Sb_2Te_3 is a degenerate semiconductor, and the Fermi-level of Sb_2Te_3 usually resides around its valence band maximum, resulting in a semimetallic behavior like that of Bi. Therefore, Sb_2Te_3 has great potential for reducing contact resistance of MoS_2 devices, while maintaining good thermal stability. In this work, ideal van der Waals (vdW) Sb_2Te_3/MoS_2 contacts are achieved by sputtering with low thermal budget annealing at 200 °C. The thermal-induced crystallization of Sb_2Te_3 helps to align Sb_2Te_3 with monolayer (1L) MoS_2 atomically. Significant device performance enhancement of 1L MoS_2 nMOSFETs is found owing to the vdW contact formation. Sb_2Te_3 is a very promising contact candidate for MoS_2 devices for future VLSI electronics and optoelectronics applications.

2:15 PM EL07.08.03
Demonstration of Ambipolar Transport in WS_2 via a Heterojunction-Based Charge Transfer Doping JoonyupBae[1], JihyunKim[1], Young-HyunYou[1] and DongryulLee[2]; [1]Seoul National University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Although higher device integration density is required, Si-based electronics reached the physical limits of their electrical property. The down-scaling of Si-based devices is restrained by several problems: punch-through, drain-induced barrier lowering, etc. Increment of the surface area-to-volume ratio of semiconductor devices and maintaining robust mechanical and electrical properties are prerequisites for next-generation materials.
To overcome the limitation of Si, atomically thin 2D transition-metal dichalcogenides (TMDs) have gained significant attraction due to their unique mechanical, optical, and electrical properties. TMDs layers are held by the weak van der Waals interaction and can be mechanically exfoliated into thin layers without surface dangling bonds. WS_2 belongs to the group of TMDs, which feature bandgaps that vary depending on the number of layers present (bulk: 1.44 eV, monolayer: 2.13 eV). WS_2 undergoes indirect-to-direct bandgap transitions as its thickness decreases from bulk to monolayer, which is appropriate for optoelectronic device applications. WS_2 possesses electron mobility of ~234 cm^2/Vs and hole mobility of ~39 cm^2/Vs. Ambipolar transport in WS_2 allows the modulation of both n-type and p-type channel operation under gate voltage. However, the n-dominant property exerted in intrinsic WS_2 results from the sulfur vacancy-induced trap states near the conduction band level.
In this study, a p-doping method for WS_2 is proposed using WSe_2 as a charge transfer layer. Back-gated WS_2 FETs with Ti/Au source and drain electrodes were fabricated, and WSe_2 flakes were dry-transferred onto the WS_2 FET channel. The surface of the WS_2/WSe_2 FET was oxidized by UV-ozone treatment. Previous studies have reported degenerate p-doping of WSe_2 through UV-ozone exposure. The tungsten oxide (WO_X) layer with high electron affinity effectively induces p-type doping in the underlying WS_2/WSe_2 upon oxidation. Ambipolar transport was observed with an on/off ratio of ~10^8 for the p-branch and ~10^7 for the n-branch and the hole mobility of 143 cm^2/Vs after oxidation. WS_2/WSe_2 FETs with varying WS_2/WSe_2 channel coverage ratios were fabricated to examine the behavior of the formed WO_X on the WSe_2 surface. Electrical characteristics were measured using 3-terminal measurements with back gate modulation. Crystallinity and lattice structures of the oxidized channel layers were analyzed using micro-Raman spectroscopy and high-resolution transmission electron microscopy (HR-TEM), respectively. The current fabrication of Si-based CMOS devices involves multiple processes of thermal annealing and diffusion doping. Ambipolar materials such as WS_2 can be expected to reduce process complexity with a single-channel CMOS device structure. Therefore, the proposed p-doping methods in this study enable the fabrication of complementary metal-oxide semiconductor (CMOS) devices with down-scaled architectures.

What Are 2D Materials Good For?EricPop; Stanford University, United States

This talk will present my (biased!) perspective of what two-dimensional (2D) materials could be good for. For example, they could be good for applications where their ultrathin nature gives them distinct advantages, such as flexible electronics [1] or light-weight solar cells [2]. They may not be good where conventional materials work sufficiently well, like transistors thicker than a few nanometers. I will focus on 2D materials for 3D heterogeneous integration of electronics, which presents major advantages for energy-efficient computing [3]. Here, 2D materials could be monolayer transistors with ultralow leakage [4] (due to larger band gaps than silicon), used to access high-density memory [5]. Recent results from our group [6,7] and others [8] have shown monolayer transistors with good performance, which cannot be achieved with sub-nanometer thin conventional semiconductors, and the 2D performance could be further boosted by strain [9]. I will also describe some unconventional applications, using 2D materials as thermal insulators [10], heat spreaders [11], and thermal transistors [12]. These could enable control of heat in "thermal circuits" analogous with electrical circuits. Combined, these studies reveal fundamental limits and some unusual applications of 2D materials, which take advantage of their unique properties.

High-Mobility Flexible Transistors with Low-Temperature Solution-Processed Tungsten Dichalcogenides TianCarey, OranCassidy, KevinSynnatschke, EoinCaffrey, JamesGarcia, ShixinLiu, HarneetKaur, AdamG. Kelly, JoseMunuera, CianGabbett, DomhnallO'Suilleabhain and JonathanN. Coleman; Trinity College Dublin, Ireland

Solution-processed electronic inks with two-dimensional (2D) materials have the potential to enable the next generation of low-cost printed digital electronics. [1] Here we will present the advances in fabricating printed complementary inverters achieving a voltage gain $|A_v| \approx 0.1$ with liquid phase exfoliated (LPE) flakes and discuss the limitations of the technology. [2] The electrochemical exfoliation of large-aspect-ratio (>100) semiconducting flakes of tungsten diselenide (WSe_2) and tungsten disulfide (WS_2) as well as molybdenum disulfide (MoS_2) will be necessary to create a library of high-mobility solution-processed networks that conform to substrates, remain functional over thousands of bending cycles and can be utilised in complementary solution-processed circuits.

We will present the use of Langmuir–Schaefer coating to achieve highly aligned and conformal flake networks of flakes, with minimal mesoporosity (~2–5%), at low processing temperatures (120 °C) and without acid treatments. [3] Our processing enables the fabrication of state-of-the-art flexible transistors in ambient air, achieving average mobilities $\mu > 10$ $cm^2 V^{-1} s^{-1}$, with a current on/off ratio of $I_{on}/I_{off} \approx 10^3$ - 10^4. [3] We will also demonstrate subthreshold slopes as low as 182 mV/dec, essential for maintaining power efficiency and examine the performance of our WSe_2 transistors after 1000 bending cycles at 1% strain.[3] Additionally, we will demonstrate air-stable, low voltage (<5 V) operation of inkjet-printed CMOS with MoS_2, with a voltage gain above unity $|A_v| \approx 1.4$. [4] The results represent a critical enabling step towards ubiquitous long-term stable, low-cost solution-processed digital integrated circuits.[4]

Bi-$MoSe_2$ Contacts in the Ultraclean Limit: Closing the Theory Experiment Loop ZhiyingWang[1], YangLiu[1], SongLiu[1], AmiraliZangiabadi[2] and JamesHone[1]; [1]Columbia University, United States; [2]University at Buffalo, The State University of New York, United States

Achieving robust electrical contacts has emerged as a key challenge to realizing the promise of monolayer two-dimensional (2D) semiconductors, such as semiconducting transition metal dichalcogenides (s-TMDs) in next-generation electronic technologies. While recent work has reported breakthroughs in achieving low contact resistance using defective s-TMDs, there still exists a lack of fundamental understanding of the contact interfaces, especially, the role of defects within the s-TMD and external disorder in achieving the reported low contact resistance is not well understood.

In this work, we study bismuth (Bi) semimetal contacts to monolayer molybdenum diselenide ($MoSe_2$), utilizing a device platform that combines ultrahigh-purity $MoSe_2$, damage-and strain-free interfaces, and encapsulation of the channel within hexagonal boron nitride (hBN). The ultrahigh-purity $MoSe_2$ crystal is characterized through dedicated STM imaging. Gaps etched in the hBN define the contact regions and stabilize the structure. We characterize the damage-free and strain-free metal-semiconductor junction with atomically sharp interface by cross-sectional STEM imaging. We quantify the contact characteristics using contact-front and contact-end measurements that go beyond the basic transfer length method. These measurements reveal large differences between sheet resistance inside the channel (R_{sh}) and underneath the contacts (R_{sk}), which are assumed to be equal in the standard transfer length method. We employ a charge transfer model to gain further insight into the microscopic mechanism of vertical transport across the van der Waals metal-s-TMDs interface. In deeply scaled contacts, we directly observed a steep increase in end resistance when the contact length downscaled to around 40 nm, in agreement with the experimental and theoretical model derived characteristic length. This integrated approach can be readily expanded to other clean semiconductors to allow better comparison between theory and experiment.

8:00 PM EL07.09.01
Large-Area, Pulsed Laser Deposition of MoS_2/a-BN Heterostructures for Back-Gate Field Effect Transistors Applications AndresA. Forero Pico, JyotiYadav, JunsenGao and ManishaGupta; University of Alberta, Canada

Transition metal dichalcogenides (TMDCs) have emerged as alternative 2D materials for field effect transistor fabrication. Molybdenum disulfide (MoS_2) is a TMDC with semiconducting properties with monolayer (1ML) MoS_2 having a 1.8 eV direct bandgap and multilayer (>2ML) MoS_2 a 1.2 eV indirect bandgap [1]. Sulphur vacancies tend to form on the top sulphur layer which gives MoS_2 a natural n-type doping. However, exposure to ambient oxygen and humidity oxidizes the surface of MoS_2 and, along with increased number of defects from the sulphur vacancies, MoS_2-based devices can lose performance. Therefore, encapsulation with different materials has been suggested as a solution for improving the device performance [2]. Hexagonal boron nitride (h-BN) is a 2D material with a 6.1 eV band gap [3] which can be utilised as an encapsulation material and also an insulator. The weak basal plane van der Waals forces of h-BN will not modify the surface of MoS_2 and hence improve the device performance.

One of challenges of 2D materials is the lack of scalable and reproducible large area 2D material growth. We propose to utilise pulsed laser deposition (PLD) as an alternative to high-quality, large-area growth of 2D materials capable of depositing uniform, large-area, thin-films with good control of the deposition parameters. High quality MoS_2 thin films can be grown with PLD [4], on the other hand, h-BN is difficult to grow with PLD because it needs temperatures above 1000°C. Therefore, amorphous boron nitride (a-BN) is grown as encapsulation, featuring large dielectric strength and low refractive index [5].

In this work, PLD was used to deposit a-BN thin-films on SiO_2/Si substrates. Subsequently, PLD was used to deposit the MoS_2/a-BN heterostructure on SiO_2/n++ Si substrates with optimized deposition parameters for MoS_2 [4] and a-BN, varying the thickness of MoS_2 (1ML, 2ML, 4ML, 10ML, 15 ML). Back-gated field effect transistors (FETs) were fabricated on the MoS_2/a-BN heterostructure samples using standard lithography techniques, followed by e-beam evaporation of Ti/Au contacts and rapid thermal annealing to reduce the contact resistance. The MoS_2/a-BN back-gated FETs were electrically characterized, resulting in mobilities increasing one order of magnitude when compared to back-gated MoS_2 FETs without encapsulation. The devices can turn on and off, although their leakage current is still significant (~10^2 - 10^3 nA), which can be attributed to the large voltages needed to control the gate (>50 V). Density functional theory (DFT) studies to understand the material interface will also be conducted and the results will be presented. DFT simulations of MoS_2-based back-to-back Schottky devices will be shown to compare the measured output characteristics with the calculated ones. The effect of h-BN encapsulation on the back-to-back Schottky devices was also calculated.

A Study of Transport and Optical Properties of Liquid Nitrogen-Assisted Deposition of Titanium Oxynitride Thin Films AbiodunOdusanya, DhananjayKumar and ValentinCraciun; North Carolina A&T State University, United States

This study presents a method to prevent an undesirable oxygenation process that occurs during the deposition of Ti-N thin films using the pulsed laser deposition technique. Nitrogen gas at various pressures from 0 mTorr to 50 mTorr was utilized during deposition and the oxygenation process occured because of the presence of residual oxygen in the deposition chamber or oxygen impurities in the N_2 gas used during the film deposition. The method involves using a metal trap kept at liquid nitrogen temperature to condense the residual/impurity oxygen, which helps control the oxygenation process and results in desired transport and optical properties of the Ti-N-O thin films. The optical, electrical, and stoichiometric properties of the films depend on their N/O ratio. Direct band gap transition was observed in the material, and we also take note of other important properties like stacking faults, texture coefficient, Urbach energy,

dielectric constants, optical conductivity, refractive index, extinction coefficient, and skin depth. The x-ray diffraction measurements show a reduction in the intensity and shift of the (111) and (222) TiNO peaks to higher angles with increasing nitrogen pressure during growth. The study also found that increasing the deposition N_2 pressure of the TiNO thin films resulted in increased metallicity of the films as indicated by the reduction in bandgap from 2.64 eV to 1.70 eV, however, an increase in resistivity from 133 μΩcm to 3177 μΩcm was observed due to increase in surface scattering induced by increase in dislocation density.

This work was supported by the National Science Foundation, NSF-PREM through MRSEC [grant No. DMR-2122067].

8:00 PM EL07.09.03
High-Performance Electromechanical Power Generation of Lithography-Free Large-Scale MoS_2 Monolayer Film Harvesters Ye SeulJung, Ji YeonKim and Yong SooCho; Department of Materials Science and Engineering, Yonsei University, Korea (the Republic of)

Recently, two-dimensional (2D) transition metal dichalcogenide (TMD) materials have been recognized to possess high piezoelectricity due to the lack of inversion symmetry. Because of the limited availability of large-area MoS_2 monolayer, however, the energy-harvesting performance of 2D TMD materials has not been fully understood. Only single-crystalline TMD with dimensions on the order of a few micrometers has been investigated as an electromechanical energy harvesting device so far. Here, we introduce a defect-controlled synthesis of centimeter-scale polycrystalline MoS_2 monolayers with the assistance of a Na_2S film. Beyond the known effect of Na as a growth promoter, extra sulfur supplied by the Na_2S critically passivates sulfur vacancies, enabling the preparation of a high-quality monolayer film. As a result, a millimeter-scale energy harvester with nonconventional interdigitated electrodes, which was fabricated without e-beam lithography, exhibited the unexpectedly high piezoelectric energy harvesting performance of ~402.9 mV output voltage and ~41.2 nA output current under a bending strain of ~0.47 %. These values are ~20 and ~1,370 times greater, respectively, than the reported best values for single-crystal 2D TMD materials.

8:00 PM EL07.09.04
Carrier Transport Comparison Between Inkjet Printed and Filtrated Ti3C2Tx-Ti3AlC2 Nanosheet Thin Films Mi-JinJin; Institute for Basic Science, Korea (the Republic of)

Magnetoconductance studies of thin-film MXenes are important to understanding their electronic transport properties and charge carrier dynamics, and also to appraise their potential for spintronics applications. Also, it is desirable to develop deposition strategies such as inkjet-printing, filtration that would enable direct patterning with complex structures/networks. Here, we investigate the extrinsic negative magnetoconductance of inkjet printed and simply filtrated Ti3C2Tx-Ti3AlC2 nanosheet thin film. Functional process such as inkjet-printing and filtration have strong advantage of direct patterning for thin film devices. Importantly, we report a crossover from weak anti-localization (WAL) to weak localization (WL) near 3 K for both thin-film systems. Comparably, they show strong scale dependence depends on process. The crossover from WAL to WL is consistent with strong, extrinsic, spin-orbit coupling. From the magnetoconductance analysis, we estimate that the printed MXene thin-film has a strong spin orbit coupling field. Our results and analyses offer detailed understanding into microscopic charge carrier transport in Ti3C2Tx dominant, and Ti3C2Tx-Ti3AlC2 thin films and shows strong importance of process engineering.

Macroporous Nb2O5 as a Binder-Free Anode for Hybrid Supercapacitor SeungUkCheon, JaewooLee and SungOhCho; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The Li-ion hybrid capacitor (LHC) is an electrochemical energy-storage device that bridges the gap between lithium-ion batteries (LIBs) and supercapacitors (SC). It combines a battery-like anode and a capacitive cathode to achieve substantial energy and power densities. The anode provides high specific capacity, while the cathode delivers high power density, making the LHC suitable for high-performance electrochemical energy storage applications that require both high energy and power densities.
However, the sluggish reaction kinetics of the battery-like anode during the Li-ion intercalation/deintercalation process, compared to the non-faradaic adsorption/desorption process of the cathode, necessitates a Li-insertion type electrode with fast ion diffusion to minimize the kinetic gap between the two electrodes in LHCs. Among the investigated anode materials like TiO2, Li4Ti5O12, MnO2, and Nb2O5, Nb2O5 shows particular promise due to its favorable kinetics of intercalation reaction, unaffected by Li-ion solid-state diffusion limitations. Consequently, Nb2O5 exhibits rapid Li-ion intercalation, pseudocapacitive behavior, and fast reversible electrochemical kinetics.
Previous approaches to create Nb2O5-based electrodes involved blending active Nb2O5 materials with a binder and conductive carbon black, applied to a current collector. However, the use of an insulating binder led to decreased energy/power densities due to the larger proportion of binder and carbon black. To construct a superior Li-ion hybrid supercapacitor (Li-HSC) with higher volumetric energy and power densities, researchers prefer a binder-free and freestanding Nb2O5-based film electrode, where all materials contribute to charge storage. In this study, an anodization technique was employed to fabricate a binder-free Nb2O5 electrode by directly generating a Nb2O5 oxide layer on a niobium metal substrate, controlling its nanostructure and thickness through adjustments in electrolyte, duration, voltage, and temperature.
The resulting oxide produced by anodization exhibits an amorphous state, offering superior characteristics compared to crystalline structures. The amorphous oxide demonstrates enhanced lithium ion mobility and higher capacity due to defects and vacancies. The primary objective of this research was to enhance electrochemical performance by creating a binder-free electrode utilizing amorphous Nb2O5 with a controlled nanostructure achieved through anodization.
The anodized samples were examined using Scanning Electron Microscope (SEM) and Focused Ion Beam (FIB) techniques to verify the formation of a macro-porous structure and measure the oxide layer's thickness. Electrochemical analysis, specifically cyclic voltammetry (CV) measurements, revealed a pore size of 87.1 nm and an oxide layer thickness of 11.0 μm, indicating rapid reaction kinetics. The sample exhibited the highest specific capacitance value of 469.9 F/g, confirming its superior performance compared to other electrode configurations.
Additionally, annealing was performed to compare the amorphous and crystalline states. X-ray Diffractometer (XRD) analysis confirmed the formation of Orthorhombic-Nb2O5 (T-Nb2O5) after annealing. CV measurements and rate capability tests were conducted, revealing that amorphous Nb2O5 displayed faster reaction kinetics compared to T-Nb2O5. At a C-rate of 0.5 C, amorphous Nb2O5 demonstrated a capacity of approximately 310 mAh/g, while at a C-rate of 20 C, it maintained a capacity of 260 mAh/g, exhibiting better capacity retention than T-Nb2O5. Moreover, compared to previously developed Nb2O5. the amorphous Nb2O5 electrode exhibited higher capacity and improved capacity retention.

8:00 PM EL07.09.06
An Investigation of Lithium and Cobalt Intercalation Method in 2D Transition Metal Dichalcogenides YonghaShin and WoojongYu; Sungkyunkwan University, United States

In recent studies, it has been confirmed that 2D van der Waals (vdW) materials, including magnetic elements such as CrI_3, Fe_3GeTe_2, $Cr_2Ge_2Te_6$, VS_2, and VSe_2, exhibit long-range ferromagnetic order. In addition, the previous studies have explored improving electrical properties by injecting magnetic dopants into 2D transition metal dichalcogenide (TMD) materials with semiconductor properties or chalcogen defects. However, the intercalation method of inserting a magnetic element between the van der Waals planes of 2D TMDs has rarely been explored.
This study proposes implementing ferromagnetism by inserting Cobalt (Co) between layers of Molybdenum ditelluride ($MoTe_2$) using a wet chemical method that sequentially proceeds with Li intercalation and Co intercalation. n-Butyllithium diluted in hexane is widely used as a reagent for Li intercalated complexes because Li has a small atomic radius, high reactivity, and can react at room temperature. 2D TMD materials can exist in a 2H (semiconducting) or 1T' (metallic) phase. $MoTe_2$ typically exists in a 2H phase under atmospheric conditions and has the lowest equilibrium energy difference between 2H-1T' among TMD materials. Pristine 2H-$MoTe_2$ undergoes a phase transition to 1T'-$MoTe_2$ by Li intercalation for 48 hours. This phase transition is confirmed by the 1T' peak observed in the Raman spectrum and the change in gap distance from 6.97 to 6.95 Å measured by X-ray diffraction (XRD) analysis.
Li-intercalated 1T'-$MoTe_2$ induces ionic exchange during secondary Co intercalation due to its strong reducing ability, effectively allowing zero-valent Co to settle within the vdW gap instead of Li ion. Dicobalt octacarbonyl, $Co_2(CO)_8$, is used as a precursor to provide Co.

8:00 PM EL07.09.07
Effect of Hot-Wire Oxidization and Sulfur Annealing on Layered p-MoS2 for TFT Application KousakuShimizu; Nihon University, Japan

High-quality p-type Thin Film Transistors have drawn considerable attention for switching elements in active matrix displays such as OLEDs and LCDs. We are investigating sputtered amorphous p-MoS_2 thin films for one of the good candidates. Hot-wire oxidization and sulfur annealing have been done to improve TFT performances. Raman spectroscopy and XPS were employed to characterize the film structure and compared with Id-Vg characteristics.
The sputtered amorphous MoS_2 is generally p-type[1], and the film consists of a stack of small two-dimensional MoS_2 pieces. To reduce the valence mismatch between metals and MoS_2, Cr/Cu double-layered electrode was employed. According to the TFT simulations, ATLAS, the mobility of TFT with Cr/Cu source-drain electrodes was the highest performance, around 9.95 cm2/Vs. After annealing at 200°C for one hour in air, it increased by 51.42 cm^2/Vs. It has found that the sputtered film had many sulfur defects according to the TFT simulation and XPS study. To compensate for the defects, we have tried oxidization by the How-Wire method. As a result, the mobility increased to 62.73 cm^2/Vs. The effect of oxygen introduction has been investigated by first-principles calculations [2]. Furthermore, it was found that the sulfur defects exist between the layers must be reduced in order to reduce the off-current. It was annealed at 200°C for 1 hour in a metal-sealed container containing S powder. We have succeeded in suppressing the off-current less than 10^{-10} A.

Photoelectrochemical Polymerization (PEP) of EDOT for Formation of Pattered PEDOT at Specific Arbitrary Regions on Hematite (α-Fe_2O_3) MisolHwang, TaeyoonKim and JoohoonKim; Kyung Hee University, Korea (the Republic of)

We performed photoelectrochemical polymerization (PEP) on hematite (α-Fe_2O_3) to synthesize PEDOT (poly(3,4-ethylenedioxythiophene)) in specific arbitrary regions with a high 2D flexibility. PEDOT is a conductive polymer that is highly attractive due to its ability to enhance conductivity and stability of electrical activity when used as crosslinkers or fillers. Hematite, as a semiconductor material with a bandgap of 1.9-2.2 eV, generates minority charge carriers (holes) with a short diffusion length when exposed to visible light. we confirmed the synthesis of PEDOT on hematite using cyclic voltammetry, which exhibited similar characteristics to PEDOT synthesized on Pt and ITO electrodes. Furthermore, we demonstrated the synthesis of PEDOT at lower voltages via PEP compared to voltages in the absence of light illumination. Additionally, by applying the appropriate voltage and utilizing a digital mirror device (DMD) to expose patterned light at specific arbitrary regions, we generated patterned PEDOT at the regions with a high 2D flexibility. We expect that these results can be utilized to enhance sensitivity and improve the fine-tuned functionalities of various semiconductor-based devices, including solar cells, supercapacitors, and biosensors.

8:00 PM EL07.09.09
Spatially Resolved and *In Situ* Electrochemical Imaging on Two-Dimensional Materials using Scanning ElectroChemical Cell Microscopy (SECCM)LuYang-Sheng[1], YuChun-Hung[2], ChengYu-Chieh[3], ChenChun-Wei[2] and LiShao-Sian[1]; [1]Institute of Materials Science and Engineering, National Taipei University of Technology, Taiwan, Taiwan; [2]Department of Materials Science and Engineering, National Taiwan University, Taiwan, Taiwan; [3]Department of Electro-Optical Engineering, Taipei Tech, Taiwan

In recent years scientists have used microelectrode technology to probe the electrochemical properties of a surface of interest through position feedback, allowing direct topographic and electrochemical imaging. It is especially important to determine the topological information correlated to the electrochemical activity of atomically thin 2D materials. Many researches have revealed that two-dimensional materials possess a promising potential for electrochemical catalytic reactions, such as Hydrogen Evolution Reaction (HER), Oxygen Evolution Reaction (OER), Carbon Dioxide Reduction (CO_2RR), Nitrogen Reduction Reaction (NRR),Iodide oxidation reaction (IOR).However, the topological correlation with electrochemical reactivity is relatively less reported due to a lack of high spatial resolution electrochemical measurement techniques. In this work, an advanced scanning electrochemical cell microscope (SECCM) is used to probe the microscale electrochemical reactivity of 2D materials for HER. With minuscule electrolyte droplets and surface feedback signals to adjust the surface-to-probe height, a highly spatial resolved topological correlation with electrochemical reactivity for 2D materials is revealed.
We have previously used SECCM to evaluate the activity of MoS_2, identifying the HER activity differences between edge areas and basal areas. Besides the defect related active sites, some processes were also applied to manipulate the surface properties of 2D materials for enhanced reactivity, such as light modulation, strain, or surface polarization. The morphological and topological properties that correlated to the water splitting performance of 2D materials were visually revealed through the measurements of Kelvin probe (KPFM), piezo response force microscopy (PFM), and SECCM. This work fills the gap between electrocatalytic HER and topological properties of 2D materials, and provides a microscopic understanding to further improve water splitting performance for clean energy.

8:00 PM EL07.09.10
Nanowire-Based Sensor Platform for Breath Analysis MariosConstantinou, SotiriosChristodoulou, AgapiosAgapiou and ChrysafisAndreou; University of Cyprus, Cyprus

Nanomaterials, such as nanowires (NWs), are enabling new directions in nanotechnology with significant applications in the biomedical sector. With the use of Surface-Enhanced Raman Spectroscopy (SERS) as an analytical technique for rapid biomarker identification, nanomaterials can play a pivotal role in shaping the next generation of non-invasive, rapid, and pain-free diagnostic devices. Potential applications include breath analysis for cancer screening.
SERS is an ultrasensitive vibrational spectroscopic technique used as a tool to detect volatile organic compounds (VOCs) near the surface of plasmonic metal nanoparticles with sharp features (‘hot spots’). Conventional bottom-up approaches for sensing applications are based on the self-assembly of nanoparticles, which offers a simplistic, quick, and low-cost SERS substrate preparation. However, this approach demonstrates low reproducibility, hampering the sensor’s performance. Top-down approaches use micro- and nanofabrication techniques with better uniformity and reproducibility, but with higher manufacturing costs.
We present a hybrid approach using NWs as the backbone of the SERS sensor – decorated with nanoparticles (NPs) – acting as 3D ‘hot-spot’ network for maximizing the available SERS-active surface of the device while achieving signal reliability and reproducibility.
We employed this new architecture for SERS-based gas sensing. The NWs are derived from fast and cost-effective solution processing, and form higher-order structures via dielectrophoresis (DEP)-based self-assembly. DEP offers unique features, including NW alignment on predefined locations, preferential orientation, and most importantly, controllable deposition and NW densities for precise ‘hot-spot’ distribution. The self-assembly technique will be discussed and compared to conventional SERS-sensor approaches. Our solution-based technique for the rapid gold (Au) nanoparticle decoration of the 1D titanium oxide (TiO_2) NWs will be described. This novel architecture further increases the overall ‘hot-spot’ availability, and combines strong SERS signal amplification with increased sample capture, allowing the detection of analytes at low concentrations.
The performance of the developed sensor was assessed by investigating the SERS signal of 4-aminothiophenol (4-ATP) in gas phase, at concentrations as low as 10 parts-per-billion (ppbv), and in liquid phase down to 24 picomolar (pM). Additionally, the SERS signals successfully separated - using the principal components analysis (PCA) – samples of exhaled breath from healthy volunteers. These findings demonstrate the applicability and potential of 1D nanomaterials in conjunction with state-of-the-art solution-processed techniques for the development of breath analysis platforms for cancer screening.
The developed non-invasive NW-based breath sensor platform can provide mobile, low-cost, miniaturized, and rapid breath analysis, making it suitable for clinical deployment. The sensor is suitable for real-time point-of-care (PoC) diagnosis and can significantly improve the understanding of the complex relationship between the exhaled VOC profile and disease, and lead the way to a new clinical breath-based diagnostic tests.

Sensitive Microwave Spectroscopy of Van der Waals Materials with Coplanar Waveguides VincentStrenzke, ChristianElsässer, IsabellGrandt-Ionita, JanStelzner, LarsTiemann and RobertBlick; Universität Hamburg, Germany

Strongly correlated states in graphene and transition metal dichalcogenides give rise to electrically tunable insulating, metallic and superconducting phases, making them of great interest for fundamental research and potential applications. Probing the electronic structure of such correlated systems is essential to understand their phase transitions and isospin order. Microwave spectroscopy has proven to be a powerful technique for resolving low energy gaps and studying spin interactions in large area graphene. However, implementing exfoliated van der Waals (vdW) materials into sensitive microwave measurements presents several technological challenges, including optimizing contact resistances, impedance matching, and the small area of exfoliated flakes. Microstructured transmission lines called coplanar waveguides (CPW) allow to efficiently couple microwaves to a two-dimensional material that rests nearby. Graphene Josephson junctions embedded in such a planar microwave circuit are commonly used as microwave bolometer devices, enabling detection of microwaves at the single-photon level due to graphene's broadband absorption and low heat capacity.
Generally, CPWs have to be designed and optimized for a specific purpose to minimize the attenuation (losses) in the desired frequency range. Here, we discuss design choices of CPWs that are optimized for sensitive microwave spectroscopy in two-dimensional vdW materials. We highlight different approaches and their associated technological challenges in coupling microwaves to vdW materials via CPWs. Simulations and fabrication approaches are presented along with the characterization of the finalized CPW. Our designs can be applied in various applications ranging from the investigation of strongly correlated phases and isospin physics in vdW materials using microwave spectroscopy to bolometric applications.

Ultratrace PFAS Detection using Amplifying Fluorescent Polymers AlbertoConcellón, JesusCastro Esteban and TimothyM. Swager; MIT, Department of Chemistry, United States

Per- and poly(fluoroalkyl) substances (PFAS) are environmentally persistent pollutants that are of growing concern due to their detrimental effects at ultratrace concentrations (ng/L) in human and environmental health. Suitable technologies for on-site ultratrace detection of PFAS do not exist and current methods require complex and specialized equipment, making the monitoring of PFAS in distributed water infrastructures extremely challenging.
Herein, we describe amplifying fluorescent polymers (AFPs) that can selectively detect perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS) at concentrations of ng/L. The AFPs are highly fluorinated and have poly(*p*-phenylene ethynylene) and polyfluorene backbones bearing pyridine-based selectors that react with acidic PFAS via a proton-transfer reaction. The fluorinated regions within the polymers partition PFAS into polymers, whereas the protonated pyridine units create lower-energy traps for the excitons, and emission from these pyridinium sites results in red-shifting of the fluorescence spectra. The AFPs are evaluated in thin-film and nanoparticle forms and can selectively detect PFAS concentrations of ~1 ppb and ~100 ppt, respectively. Both polymer films and nanoparticles are not affected by the type of water, and similar responses to PFAS were found in milliQ water, DI water, and well water. These results demonstrate a promising sensing approach for on-site detection of aqueous PFAS in the ng/L range.

8:00 PM EL07.09.13
Radiation Synthesis of Multimetallic Nanoparticles on 1-D Metal Oxide Nanotubes via Carbothermal Shock of Carbon Nanofibers for Highly Sensitive Acetone Gas Sensors JaehyunKo and Il-DooKim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Multi-metallic nanoparticles (MMNPs) have generated significant interest in various fields such as catalysis, bioimaging, and gas sensors due to their improved catalytic performance. Therefore, it is crucial to develop an efficient, cost-effective, and straightforward synthesis method for MMNPs, as the synthetic approach directly affects their applicability, stability, and performance. Traditional methods often involve intricate and expensive experimental procedures. Among the various approaches to synthesizing MMNPs, the carbothermal shock (CTS) synthesis has gained attention for its simple yet sophisticated mechanism. However, the CTS synthesis has a limitation, as it requires oxygenated, conductive carbon as a supporting material. To broaden the range of suitable substrates, we propose a novel and uncomplicated method that utilizes carbon support solely as a heat generator for the direct synthesis of MMNPs on SnO_2 nanotubes. The experimental procedure involves synthesizing SnO_2 nanotubes using the conventional electrospinning method, followed by loading Pt, Pd, and Ni precursors onto the synthesized SnO_2 nanotubes through immersion of SnO_2 powders in Pt, Pd, and Ni precursor solutions. The precursor-loaded SnO_2 nanotubes are then covered with a carbon nanofiber (CNF) film, and electrically-triggered Joule heating of the CNF film in a vacuum induces carbothermal shock. The successful deposition of Pt, Pd mono-metallic, PdPt, PtNi bi-metallic, and PdPtNi tri-metallic nanoparticles on SnO_2 nanotubes has been demonstrated using double cs-corrected transmission electron microscopy and energy dispersive X-ray analysis. The nanoparticle synthesis mechanism has been investigated using various analytical techniques. The MMNP-decorated SnO_2 nanotubes exhibit highly sensitive gas sensing performance, indicating the feasibility and potential of this research. This work expands the applicability of the conventional CTS synthesis method and enables the straightforward decoration of different combinations of MMNPs onto various non-carbon supports, including semiconducting metal oxide substrates.

Direct Writing of Nanowires: New Opportunities to Study Shape- and Morphology-Dependent Effects SvenBarth, FabrizioPorrati, FelixJungwirth and MichaelHuth; Goethe University Frankfurt, Germany

The fabrication of free-shaped 3D objects with very high accuracy using focused electron beam-and focused ion beam-induced deposition (FEBID and FIBID) has been demonstrated in recent years.[1] For instcnce, we demonstrate the formation of free-form ferromagnetic 3D nanostructures and nanowires that can be used as functional devices and at the same time can emulate different morphologies in terms of magnetic properties.[2]
Moreover, the direct writing also enables the growth of core-shell heterostructures by combination of 3D-nanowire FEBID scaffolds and the successive site-selective chemical vapor deposition (CVD). In particular, conductive 3D nanowire-based bridges are printed by FEBID and used as resistors allowing deposition induced by Joule heating. This hybrid-approach allows tailoring the cross section, shape and material combination for specific purposes. The applicability of the nano-CVD onto FEBID-nanowires has been demonstrated for two material systems of specific physical properties.[3] The fabrication of complex 3D core-shell heterostructures promises to add new functionalities by combining free-shaped 3D nanostructure writing with thin film deposition of different functional materials.

Tuning Electromigration Forces on Adsorbates on Low-Dimensional Materials AnshulSaxena[1,2] and NarayanaAluru[1,2]; [1]University of Texas at Austin, United States; [2]The University of Texas at Austin, United States

Electromigration, the movement of atoms induced by electrical currents, is a phenomenon of significant importance in various nanoscale applications. This study focuses on analyzing and optimizing electromigration forces on adsorbates, by considering the direct force resulting from the electric field and the electron wind force due to interactions with current-carrying electrons. Recent research has highlighted the influence of energy level alignment of adsorbates with the fermi level of the current carrying system on the nature of electromigration forces. By altering the electronic structure of current carrying membranes, fine-tuning and optimization of electromigration forces becomes possible, facilitating migration of adsorbates on membrane surfaces. This property finds diverse applications in nanofluidic systems, including mass transport and ionic current generation. Using Density Functional Theory and Non-equilibrium Green's function calculations, we investigate the nature of electromigration forces on adsorbates across a range of low-dimensional systems such as Graphene, MoS2, MXenes, etc. This study explores the impact of membrane characteristics, including semiconducting, metallic, or insulating properties, on electromigration forces. The results provide valuable insights into the underlying mechanisms and offer guidelines for designing and optimizing nanofluidic systems with tailored electromigration properties.

Reveal Atomic Phase Transition via Nanomechanical Resonator YuluMao, FanFei, MojueZhang, DajunZhang, YangchenHe, DanielA. Rhodes, ChuMa, JiamianHu, JunXiao and YingWang; University of Wisconsin Madison, United States

The diverse interactions between lattice symmetry and layer stacking orders make transition metal dichalcogenides (TMDs) especially potentially effective to detect for investigating novel topological states and quantum phase transitions. A case in point is transition metal dichalcogenides, notable for its diverse phases: hexagonal (2H, α-phase), monoclinic (1T′, β-phase), and orthorhombic (Td, γ-phase). The 2H phase exhibits semiconductors behavior while the 1T' phase and Td phase is semimetal. Current approaches to reveal the phase transition between those phases are limited to electrical and optical approaches, in which the contrast is low [1]. For example, the 1T′ and Td phases are structurally commensurate[2]-[4], in which the structural difference refers to layer-to-layer stacking orders. In this experimental study, the phase transitions in transition metal dichalcogenides is studied by nanomechanical resonators. Phase transition is clearly revealed by the frequency shift of the resonators. Modeling has been established to qualitatively correlate the frequency of the nanomechanical resonator with the phase change. Accompanied by a high-quality factor exceeding 1000, the high sensitivity of the resonator shows small sliding transition,providing the possibility of the new application degree for 2D resonators combining with materials' phase diagram investigation and the potentiality to extract the thermodynamics information during the phase transition.

Investigations of WSe_2/Graphene Heterostructures with Raman Spectroscopy ArianeMarchese[1], YangLiu[2], ThiagoSeniuk[3], ArieteRighi[3], JamesHone[1] and MarcosPimenta[3]; [1]Columbia University, United States; [2]Peking University, China; [3]Universidade Federal de Minas Gerais, Brazil

Recent work has highlighted the potential for using tungsten diselenide (WSe_2) to modify the properties of graphene, including spin-orbit coupling (Island et al., 2019), superconductivity (Su et al., 2022), and electron-phonon scattering (Banszerus et al., 2019). Here we study interaction between WSe_2 and graphene using Raman spectroscopy. We observe blue-shifting of the 2D mode of 1.6 cm^{-1} for heterostructures of graphene and few-layer WSe_2. The shift doubles with top and bottom WSe_2 coverage. The G mode for these measurements remains consistent at 1588 cm^{-1}, indicating the shifts were not due to strain. Further investigations will study the renormalization of the Fermi velocity in these heterostructures.

8:00 PM EL07.09.18
Electrical Behavior of Thin Film Devices Exposed to a Magnetic Field GuinevereStrack[1], Jin HoKim[2], AlkimAkyurtlu[1,1] and RichardM. Osgood[2]; [1]University of Massachusetts Lowell, United States; [2]US Army Combat Capabilities Development Command Soldier Center, United States

The exploration of novel, magnetically controlled thin film devices can enable a range of technologies. For example, we demonstrated that the incorporation of ferromagnetic materials into a diode-type device can enable changes in electrical behavior in the presence of a weak, permanent magnet.[1] The diode, when combined with an antenna array, could serve as a rectification device. Magnetic control of the rectenna was referred to as mem(ory)rectification, which would not increase the electrical burden given that the permanent magnet did not require an external power source. Another application is the generation or storage of code in a series of magnetic thin film devices. An applied magnetic field could write or erase an electrical message that is

stored in the thin film devices. The materials properties of an array of devices could be varied to store a code that could be decrypted or erased via the application of a magnetic field.

Moving forward, the study of the device behavior in a stronger magnetic field in different configurations with respect to the direction of the applied field (in-plane vs. out-of-plane) would enable a better understanding of how the magnetic field influences the average electronic motion through the device. We will use a dipole electromagnet with adjustable pole gap and coil spacing to apply the field, which can be at least 1T, depending on the pole gap spacing. This builds upon our previous work in which the relatively weak magnetic field (~690 Oe) was roughly perpendicular to the film stack and therefore roughly parallel to the electronic transport across the layers. For this MRS presentation, we will measure and understand the transport when the magnetic field lies roughly in the plane of the sample, roughly perpendicular to the electronic flow between layers in the Metal-Insulator-Metal (MIM) diode stack. We will also report the impact of the fabrication techniques on device quality and performance. Dielectric layer (niobium oxide (NbOx)) deposition using atomic layer deposition (ALD) can enable single layer deposition and the deposition of a few layers. Preliminary characterization of the ALD-deposited NbOx using x-ray photon spectroscopy (XPS) revealed that the deposited layer was in the Nb_2O_5 oxidation state, with peaks found at 208.4 eV and atomic percentages of 29% niobium and 71% oxygen.

[1] Strack, G., Kim, J.H., Giardini, S. Akyurtlu, A, and Osgood, R. III Application of a magnetic field to ferromagnetic diodes. *MRS Advances* (2023). https://doi.org/10.1557/s43580-023-00520-6

One-Dimensional WO_3 Nanorods Loaded by Lead Halide Perovskites Nanocrystals for Ammonia Sensors Stimulated by Visible Light LuísF. da Silva[1], FrankGüell[2], AriadneC. Catto[1], PedroAtienzar[3], RocioGarcia-Aboal[3] and EduardLlobet[4]; [1]Universidade Federal de São Carlos, Brazil; [2]Universitat de Barcelona, Spain; [3]Universitat Politècnica de València, Spain; [4]Universitat Rovira i Virgili, Spain

The development in industrial and agricultural activities, mainly in emerging economies, has increased the toxic gases dumped into the atmosphere, such as CO, NO_2, NH_3, etc. Regarding ammonia (NH_3), it is considered a health hazard because it is highly corrosive. The Occupational Safety and Health Administration recommends avoiding exposure to NH_3 levels above 100 ppm (parts per million). Semiconducting metal oxides (SMOx) have been successfully used as a sensing layer to detect toxic gases. Among the SMOx, the WO_3 compound has exhibited excellent sensing performance, however, at operating temperatures above 200ºC, which enhances the power consumption of such devices. An alternative way to get sensors working favorably at room temperature has been the photo-stimulation of the sensing element. The presence of photocarriers generated by the irradiation of the SMOx favors the chemisorption processes. The WO_3 pure has been widely used as a sensing layer under photoactivation, however, the fast recombination of charge carriers reduces its sensing activity. Thus, the loading of WO_3 by lead halide perovskites may contribute to improving the sensing performance. Note that these perovskites exhibit interesting properties, mainly the long charge carriers' lifetime. Based on these considerations, we report herein an investigation of the blue-light-assisted gas-sensing properties of 1D-WO_3 nanorods decorated with $APbBr_3$ (A= MA, FA, and Cs) towards NH_3 gas. The 1D nanorods were synthesized by aerosol chemical vapor deposition while the perovskite nanocrystals were synthesized through the hot injection method. The WO_3/$APbBr_3$ nanocomposites were prepared via spray coating. HRTEM images revealed that the APbBr3 nanocrystals had an average size of less than 10 nm, and they were successfully loaded onto the WO_3 nanorods. Regarding the gas-sensing performance, it was found a significant enhancement of the NH_3 sensing response for nanorods loaded by perovskites, especially by $FAPbBr_3$ nanocrystals. This nanocomposite was sensitive towards different NH_3 levels, i.e., from 10 to 100 ppm under blue-light irradiation and at room temperature. Also, the experiments revealed that loaded nanorods presented total reversibility, good repeatability, and stability after consecutive exposure cycles. These findings demonstrate the potential of 1D WO_3 nanorods loaded by perovskites nanocrystals as sensing material to manufacture NH_3 gas sensor devices operating at room temperature.

8:00 PM EL07.09.20

Unravelling Spin-Manipulated Magneto-Photo-Electrochemical Water Splitting in Janus 2D-Material's Heterostructures PraveenKumar[1,2] and KrishnenduRoy[1]; [1]Indian Association for the Cultivation of Science, India; [2]Drexel University, United States

Manipulation of photogenerated electron-hole pairs towards low recombination and efficient transport is one of the key strategies to achieve high efficiency in photoelectrochemical water splitting. External magnetic fields have been reported for spin-to-charge conversion using either chiral molecules or magnetic elements-assisted photoelectrodes in spin-dependent electrochemistry (SDE). Herein we demonstrate a proof-of-concept for spin-manipulated charge transport in Janus MoSSe heterostructured with *p*-GaN as a photocathode under the influence of an external magnetic field. It is worth mentioning that we have neither used chiral molecules nor magnetic elements in the proposed photocathode. Our approach provides a new, effective, and affordable path-way to improve the catalytic performance of asymmetric 2D materials in PEC water splitting. Further, this proposed approach can be utilized for other asymmetric/disordered alloys for a wide range of applications.
Among two-dimensional (2D) materials, asymmetric Janus structure (MoSSe, WSSe) has exhibited many exciting properties, such as a significant Rashba effect, out-of-plane piezoelectricity, and spatial isolation of charge carriers. However, the critical gap that remains to be addressed yet is whether the spin properties of these asymmetric 2D materials can be combined with their optical and catalytic properties to establish more efficient photoelectrochemical (PEC) water splitting along with exploring some more fascinating science. Herein, we demonstrate a proof-of-concept for spin-manipulated PEC water splitting using Janus MoSSe. Magneto-photoelectrochemical properties have been critically investigated through lifting spin degeneracy by combined Rashba-Dresselhaus spin-orbit coupling and energy band splitting in Janus MoSSe/GaN heterostructure. Delaminated 2D-MXene ($Ti_3C_2T_x$) was decorated on top of MoSSe/GaN for efficient electron channelling. The optimized $Ti_3C_2T_x$/MoSSe/GaN device showed ~35% photocurrent enhancement as well as ~40% enhancement in the product (H_2/O_2) formation in PEC water splitting under a low applied magnetic field (0.4T). The external applied magnetic field helps spin manipulation even under unpolarized light by combining Zeeman and Rashba-Dresselhaus splitting by spin-to-charge conversion in Janus MoSSe/GaN heterostructure. Density functional theory (DFT) simulations were carried out to understand the role of the Rashba-Dresselhaus effect for efficient charge transport. This proposed concept of "spin manipulated charge transport" can be extended for various other asymmetric alloys for a wide range of applications, including selective CO_2 reduction, photodetection, photovoltaics, etc. Therefore opens new research domains like "Spin Manipulated Electrochemistry (SMPE)" using asymmetric materials.

Polyvinylpyrrolidone/CNTs Electrospun Composites for Advanced Applications Fatima TuzZahra[1], AdeoluAjayi[2], QuincyQuick[1] and RichardMu[1]; [1]Tennessee State University, United States; [2]Columbia University in the City of New York, United States

Electrospinning has attracted the attention of the scientific community since it is a simple yet effective technique to prepare fibers and their composites for various applications. Moreover, it provides a variety of choices in materials as compared to other methods that are used for fiber fabrication. The composites of interest in this study are CNT-based composites, as they hold a great significance in various applications due to their superior physical properties. There are various studies that confirm the potential of carbon nanotube (CNT)-based composites for advanced applications such as superconductors, microwave absorbers, and biomedical field. In the presented study, polyvinylpyrrolidone (PVP) and CNTs have been utilized to prepare composites using electrospinning technique. The purpose of this study is to prepare wire-like fibers which have good thermal and electrical conductivity and for that, the alignment of CNTs encapsulated in the fibers is one of the main features that was aimed. PVP and CNTs composites are believed to have high thermal and electrical conductivity along with good mechanical strength. Moreover, PVP has proven to be a good source of dispersion for CNTs. Generally, the PAN based CNTs are utilized during electrospinning, however, in the presented study we propose the simplified way to encapsulate CNTs directly in PVP nanofibers by using electrospinning technique. PVP with lower molecular weight (10,000mol/gm) is utilized to attain fine nanofibers by optimizing the molarity, flow rate, voltage and needle to collector distance. The CNTs of length range 5-20µm and diameters 15±5nm, 30±10nm were dispersed ultrasonically in the PVP and ethanol solution. The optimized process parameters were used for electrospinning. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were utilized to study the morphology and structural properties of the prepared composites. The thermal and electrical conductivities of the samples were also analyzed. The CNTs tend to align along the length of the fibers, which led to enhanced thermal and electrical conductivities. Furthermore, considering the good dielectric properties of PVP, increasing the PVP content can lead to high potential of the study in microwave absorption applications.

Graphene-Enabled Selective Wetting of Liquid Metal on Polyamide Substrate for the Fabrication of Soft Wearable Electronics WedyanBabatain, OzgunKillic Afsar and HiroshiIshii; Massachusetts Institute of Technology, United States

The development of soft wearable electronics has gained significant attention due to their potential for seamless integration with the human body. This study presents a novel approach for fabricating soft wearable electronics using a graphene-enabled selective wetting of liquid metal on a polyimide substrate. Specifically, we leverage the growth of laser-induced graphene (LIG) on polyimide substrate as a surface modification functional material to allow precise patterning of liquid metal, offering control over the deposition process. The patterned liquid metal devices can be subsequently transferred from polyamide to various flexible and stretchable substrates, making them suitable for wearable applications. In order to study the interfacial behavior of LM

on top of the LIG substrate, scanning electron microscopy images of the patterned traces were reported, Raman spectrum of the grown LIG layer was obtained and scrolling angles of the LIG/LM interfaces was measured. Through a series of experiments and characterization, we demonstrate the successful fabrication of soft wearable electronics, including sensors using the proposed method. The selective wetting behavior of liquid metal on the polyimide substrate allows for the creation of intricate and functional patterns with excellent resolution producing LM traces up to 200 μm. The resulting devices exhibit remarkable mechanical robustness, enabling them to withstand bending, stretching, and other mechanical deformations for 1000 cycles without compromising their performance, allowing them to stretch up to 40% and bend with radii as small as 5 mm. The combination of graphene-enabled selective wetting and soft polymeric substrates offers several advantages for fabricating soft wearable electronics such as pressure sensors and touchpads. It provides a versatile and accessible approach that can be scaled up for mass production. The resulting devices exhibit excellent electrical conductivity, mechanical flexibility, and conformability, making them highly suitable for applications in healthcare monitoring, sports tracking, and soft human-machine interfaces.

Synthesis and Electronic Transport of Superconducting Molybdenum Nitride Ultrathin Crystalline Platelets DaZhou[1], DavidSanchez[1], AlexanderJ. Sredenschek[1], JiayangWang[1], LingruiMei[2], YuxinGao[1], LuisBalicas[2], SusanB. Sinnott[1] and MauricioTerrones[1]; [1]The Pennsylvania State University, United States; [2]Florida State University, United States

Transition metal carbides (TMCs) and transition metal nitrides (TMNs) have been intensively studied in their bulk form due to their outstanding properties such as superior hardness, high melting point, high metallic conductivity with superconductivity at low temperatures in certain phases, and chemical resistance.[1] Xu et al.[2] established a liquid-metal-assisted chemical vapor deposition (LMCVD) method to grow large-area ultrathin Mo_2C and studied their robust superconducting properties down to a few nanometers in thickness. Wang et al.[3] implemented a similar LMCVD approach to grow ultrathin MoN_x and studied their catalytic properties. However, to the best of our knowledge, the electronic properties such as the superconductivity of ultrathin MoN_x crystalline platelets have not been studied to date.

In our study, ultrathin MoN_x nanoplatelets were grown by LMCVD, and the morphology was characterized by optical microscopy, scanning electron microscope (SEM), atomic force microscopy (AFM), and scanning/transmission electron microscope (s/TEM). Using a semi-dry deterministic transfer method, we stamped nanometer-thick MoN_x flakes onto pre-patterned Hall bar/4-probe electrodes and conducted electronic transport measurements. For 120 nm thick platelets, the onset superconducting transition temperature was 12.11K which is comparable to the bulk Tc values, showing a sharp transition width smaller than 0.1K, indicating a high degree of crystallinity. A magnetic field in the out-of-plane direction was applied and series of R-T measurements were performed under different fields and the corresponding Tc values were extracted. The critical field exhibited a linear temperature dependence which is consistent with the 2D Ginzburg–Landau formalism for fields perpendicular to the planes, which supports the 2D nature of the superconducting state. By linear fitting the Hc with Tc, we extrapolated the zero-temperature critical field to be around 3.79T and the Ginzburg-Landau coherence length at zero temperature to be around 9.3 nm. By analyzing the results from Hall measurements and the longitudinal resistance measurements, the mean free path was estimated to be > 500nm, orders of magnitude higher than the Ginzburg-Landau coherence length, exceeding the superconducting clean limit.

In summary, we have successfully synthesized ultrathin MoN_x nanoplatelets through a LMCVD method and conducted electronic transport measurements. The thickness dependence of superconducting transitions was also probed. We will also show how the superconducting transitions in chromium doped/alloyed MoN_x platelets get modulated by the introduction of magnetic impurities.

Changes in Crystals of Two-Dimensional Materials According to Growth Conditions in the CVD Process and Consequent Changes in Their Properties DokyoengYun and WoojongYu; Sungkyunkwan University, Korea (the Republic of)

In this paper, we saw the change of crystal structure according to the change of the growth conditions of the 2D material. For the growth of the 2D material we used, a large-scale array resistive memristor device in which the crystallinity of the thin film was controlled by adjusting the growth conditions of hBN was used. produced.
The structure of the device we used is a MIM (Metal/Insulator/Metal) vertical 2-terminal resistive switching device composed of Au/hBN/Au. Here, the growth conditions such as growth temperature, growth time, distance and amount of amoniaborrane were adjusted to analyze the change in the state, thickness, and crystal structure of the thin film. It can be seen that they have slightly different characteristics. When a voltage is applied to the RRAM's non-conductive material, filaments are created and ions can clump together, allowing current to flow. RRAM with high electrical characteristics was realized by controlling the growth conditions.

2D $InGaO_x$ Transistors Printed by Cabrera-Mott Oxidation of Liquid In-Ga Alloys SimonA. Agnew, AnandP. Tiwari and WilliamJ. Scheideler; Dartmouth College, United States

Next-generation flexible electronics will require low-temperature fabrication of high-mobility 2D semiconductors. Continuous liquid metal printing (CLMP) powered by Cabrera-Mott oxidation can support this goal by offering rapid (< 3 s) processing of large-area (> 20 cm^2) 3 nm thick '2D' layers of semiconducting oxides with high mobility. However, their high intrinsic carrier density demands new mechanisms of electrostatic control. We present a strategy for controlling transport in 2D In_2O_3 via doping with trace Ga inclusions (0.1–0.001 wt.%) in precursor metal alloys. We use these alloys to print indium gallium oxide (IGO) transistors at < 200 °C with enhanced subthreshold slope and near 0 V turn on by reducing the electron concentrations 10-1000X with Ga-doping in the resultant channels (5–70 at.%). Printed 2D IGO transistors exhibit exceptional field effect mobility, with champion devices achieving up to 17 cm^2/Vs and I_{on}/I_{off} up to 10^6, with enhanced bias-stress stability over pure In_2O_3. Moreover, through a combination of experiments and finite element simulation, we demonstrate the synergy between 2D IGO and ultrathin high-k Al_2O_3 dielectrics for achieving low-voltage transistors with steep switching.
We apply detailed materials characterization including XPS to quantify Ga doping and oxygen stoichiometry in the 2D IGO channels and EDS to analyze the Ga-rich surface oxide of the liquid precursor alloys. IGO films were investigated by XRD to evaluate the doping threshold for amorphization and by UV-Vis to analyze modulation of the optical bandgap and effects of quantum confinement. Collectively, these results illustrate the power of liquid metal alloy printing to control 2D semiconductor electrostatics and crystallinity for developing high performance flexible electronics and next-generation display technologies.

Van der Waals SbSeI Quasi-1D Nano-Columns for Advanced Photonic Applications IvanCaño Prades, AlejandroNavarro Güell, EdoardoMaggi, JoaquimPuigdollers, SergioGiraldo, ZacharieJehl, MarcelPlacidi and EdgardoSaucedo; Universitat Politècnica de Catalunya, Spain

There is an increasing interest in novel van der Waals materials such as $Sb_2(S,Se)_3$ and (Sb,Bi)(S,Se)(Br,I) systems, thanks to their natural ability to form low dimensional structures with exotic properties. This is strongly related to their highly anisotropic crystal structure, which results in unique electrical and optical properties when the materials are correctly oriented. In addition, these semiconductors can cover a plethora of different possible technological applications including sensors, supercapacitors, piezoelectric generators, and solar cells. Amongst this family of largely overlooked materials, (Sb,Bi)(S,Se)(Br,I) pnictogen chalco-halides are highly attractive due to their wide range of possible bandgaps between 1.2 eV up to 2.2 eV, customizable optical properties by using different halides or chalcogenides while retaining their quasi-1D structure, defect-tolerance, and ferroelectric properties. Nevertheless, the progresses in the development of these pnictogen chalco-halide semiconductors are being limited by the complexity to synthesize compounds containing halogens and chalcogens in the same structure, due to the very different elemental vapor pressure.

The first attempts to synthesize these materials have been essentially focused on low temperature (<300 C) and atmospheric pressure solution-based chemical routes, resulting in columnar films with poor crystalline quality and very limited morphology tunability. Aiming towards a more controlled, reproducible and versatile system, in this work SbSeI, one of the most relevant materials amongst this family, has been synthesized by a novel procedure based on the selective iodination of co-evaporated Sb_2Se_3 films at high pressures (between 2 atm up to 20 atm), developing extremely uniform, single-crystal nano-columnar structures. We will show how the thickness, height, and density of these 1D nano-columns can be tuned by finely varying annealing temperature and pressure. The resulting nano-columns were characterized using microscopy imaging techniques, Raman spectroscopy and X-ray diffraction, demonstrating the formation of SbSeI single phase with orthorhombic structure (space group Pnma), and with excellent crystalline quality and compositional homogeneity. To study the potential of this material for different photonic applications, electrical and optoelectronic measurements have been performed on micro-scale devices, connecting nano-columnar crystals to Pt and Au contacts on a SiO_2/Si wafer. Interestingly, a clear diode response has been observed with Au-Au and Au-Pt, which is greatly enhanced under illumination. Memory effect, capacitance-voltage and ferroelectric measurements have also been performed. Kelvin probe microscope analysis has been used to determine its work function, observing that different facets of the crystals yield distinct surface potential, supporting our hypothesis that the quasi-1D growth of the material gives rise to anisotropic transport properties.

Overall, this work presents to the best of our knowledge, the first study of the physical vapor deposition synthesis and characterization of novel SbSeI chalco-halide compound, demonstrating the tunability of the SbSeI nano-columns morphology by varying synthesis pressure and temperature, as well as the potential of low dimensional chalcohalides to be implemented into innovative architectures and advanced functionalities (such as for enhanced carrier collection and light trapping), pointing the way to develop defect-tolerant and ferroelectric absorbers with anisotropic electrical properties for advanced photonic applications.

An *Ab Initio* Study of Vertical Heterostructures Formed by CdO and SnC MonolayersBilalTanatar, MahsaSeyedmohammadzadeh, ArashMobaraki and OguzGulseren; Bilkent University, Turkey

Assembling two-dimensional (2D) materials in vertical heterostructures is one of the main techniques for tuning electronic and optical properties. In most cases, known as van der Waals heterostructures (vdWHs), the interlayer distances are larger than typical covalent bond lengths resulting in weak interlayer interactions. It has been shown that reducing the distance between the layers can significantly alter the properties of separated layers, which is not so noticeable in vdWHs and thus creates a new platform for controlling the physical properties of 2D materials. Motivated by enhanced properties of 2D vertical heterostructures, employing ab-initio calculations based on density functional theory we examined CdO/SnC systems in four different configurations. Our results reveal that in spite of the thermodynamic and mechanical stabilities of all considered structures, according to the calculated phonon frequencies, only the structure formed by placing the Sn atom on the O atom and the C atom on the Cd atom is dynamically stable at zero temperature. This structure has an interlayer distance of 2.52 A which is smaller than the interlayer distance in typical vdWHs. We investigated the electronic and optical properties of this dynamically stable structure utilizing GW approximation and solving the Bethe-Salpeter equation. Unlike the monolayer CdO which possesses a single optical absorption peak close to the red light energy, the considered CdO/SnC structure has an optical band gap of 1.14 eV, and it can absorb 13% of incident light in the blue light region.

The study of the intense pulsed light sintering process of $BaTiO_3$ nanoparticles added with graphene oxide for the realization of a high-k dielectric layers. Seok-hoonJeong[1], Jong-WhiPark[1] and Hak-SungKim[1,2]; [1]Hanyang University, Korea (the Republic of); [2]Institute of Nano Science and Technology, Korea (the Republic of)

Abstract

Conventional photolithography technology is a technology for manufacturing existing devices, and has disadvantages such as complicated process problems, material loss, and expensive equipment. On the other hand, printed electronics technology is attracting attention because it can easily implement patterns through printing and coating processes using ink and solution materials. The material loss could be reduced through exposure and etching processes for patterning. However, high-temperature and long-term annealing and sintering process were required to realize high quality electrode and semiconductor layer. Accordingly, various annealing/sintering methods have been developed. Among the various methods, the thermal annealing process has disadvantages of complicated facilities for maintain the high temperature and long process time. In the case of laser annealing method, the process time could be shortened, but the disadvantage of the expensive equipment and the small annealing area. In addition, the deep-ultraviolet (UV) irradiation method can also reduce damage to the substrate material, but the process time is long and additional facilities such as inert gas was required. On the other hand, the IPL sintering method can sinter the material of a large area in millisecond units at room temperature and normal pressure using a visible ray xenon lamp. The $BaTiO_3$ has a high dielectric constant but a relatively low band gap. The low band gap has the disadvantage of a large leakage current, so the other materials, which has the adequate band gap, was used for recent industry. In this study, the disadvantages of $BaTiO_3$ was compensated by adding the graphene oxide. In addition, the hybrid layer composed of $BaTiO_3$ and graphene oxide was sintered by using IPL irradiation process. Through various analysis, the sintering characteristics, dielectric properties, and crystallinity of this hybrid layer were investigated.

Enhancement of p-type Behavior of Inkjet-Printed Single-Walled Carbon Nanotube Transistors from Phenylphosphonic acid Coating Dong HyunLee[1], SiwonHwang[2], BongjunKim[2] and HocheonYoo[1]; [1]Gachon University, Korea (the Republic of); [2]Sookmyung Women's University, Korea (the Republic of)

Single-walled carbon nanotube (SWCNT) had interest over the past decade as a high potential material due to their thermal stability and high conductivity [1-2]. In particular, SWCNTs had high carrier mobility and advantages of solution processing lead to their development for applications in electronic devices such as transistors and logic circuits [3-4]. However, the doping technology for controlling the charge carrier transport of SWCNT is still immature. The chemical doping method is a process that modulates the Schottky barrier without damaging SWCNT. In this paper, we present p-type behavior enhanced SWCNT transistor by patterning semiconductors and electrodes using inkjet printing technology and doping them with the self-assembled monolayer (SAM) material phenylphosphonic acid (PPA). The benzene rings of PPA coated on the SWCNTs without annealing process fill the voids in the channels by π-stacking interaction. As a result, SWCNTs connected through PPA form additional pathway for charge carrier transport. The p-type current of the SWCNT transistor is enhanced 4.3 times due to the improved hole injection resulting from PPA doping effect. In addition, the 10 PPA-doped SWCNT transistors increased the hole mobility by an average of 8.25 $cm^2 V^{-1} s^{-1}$. Finally, the positive-shifted threshold voltage of 0.55 V indicates the potential for application in depletion mode of PPA-doped SWCNT transistor.

Anti-cancer Drug Delivery by Janus WSSe Monolayer: A First-Principles Study Md TahmidKabir and AhmedZubair; Bangladesh University of Engineering and Technology, Bangladesh

Two-dimensional Janus transition metal dichalcogenide (TMD) have a large surface-to-volume ratio that provides a variety of suitable anchoring points for active drug loading and incorporates distinct physicochemical properties for efficient, controlled, and selective drug delivery. Carmustine, an alkylating agent, treats several types of brain cancer. In this work, we investigated the compatibility of 1H-WSSe, a Janus TMD with hexagonal lattice, as a smart delivery vehicle in the human body. The first-principles calculations based on density functional theory were performed using periodic boundary conditions to calculate the electronic and optical properties of carmustine/WSSe drug complex. After investigating the spatial interaction between it and WSSe Janus sheet, four plausible configurations of carmustine emerged. These configurations are carmustine horizontally adsorbed on S (C-I) and Se (C-II) sides and vertically adsorbed on S (C-III) and Se (C-IV) sides. Drug complexes were relaxed until appropriate total energy and force convergence thresholds were attained. C-I and C-II had similar adsorption distance resulting in comparable adsorption energies of –0.93735 eV and –0.94177 eV, respectively, which were notably higher compared to previous reports. However, the S sheet for C-III has a closer adsorption interaction with the carmustine than Se sheet for C-IV resulting in better adsorption for C-III. We calculated E-k band diagrams, orbital projection of the bands and density of states for all configurations. As the bands near the band gap were primarily contributed by W, S, and Se of Janus WSSe, the band gap (E_g~1.7 eV) remained unchanged compared to pristine Janus WSSe except for C-II. Both valance and conduction band edges were largely contributed by the d orbitals of W. In C-I, orbital projection revealed 32.23% $d_{x^2-y^2}$ and 34.3% d_{xy} contribution at valance band maxima (K-point), and the conduction band edge had ~90.7% d_{z^2} contribution. However, the emergence of a highly localized state near the conduction band edge in C-II resulted in band gap reduction to 1.642 eV. This state originated from the p orbitals of O and N atoms of carmustine. Mulliken charge analysis revealed that C, N, and O atoms of carmustine experienced an accumulation of electronic charge, and the electronic charge was depleted from H and Cl after interaction with the WSSe monolayer. The electron-dense region in the carmustine above has influenced the electron deficit region in the Janus sheet below and vice versa. Moderate to low charge transfer levels implied that carmustine was physiosorbed on WSSe monolayer. Moreover, electron localization function calculation demonstrated no bonding between carmustine and Janus sheet. All drug complex configurations had a non-zero anisotropic absorption coefficient near the band gap. Finite absorption in the IR range and drug-independent absorption of the 2D Janus WSSe made it appropriate for drug delivery. Phonon dispersion and quasi-harmonic vibrational free energy were investigated to gain insight into the practical drug release under exogenous stimuli (i.e., temperature increase). We estimated the temperature effect on adsorption energy by incorporating quasi-harmonic vibrational free energy correction. Increasing temperature from 0 to 350 K produced an ~0.2954 eV upward shift for adsorption energy which indicated enhancement of the anti-cancer drug release rate. The adsorption energy was reduced by ~31.51% which was significantly higher than those of literature for 2D nanomaterials. The high adsorption energy of the drug complex enables the effective anchoring of carmustine avoiding accidental release and the capability to make a steep adsorption energy reduction by thermal radiation allows selective release. Therefore, the 2D Janus WSSe is a perfect candidate for controlled drug release into the cancer cell by photothermal therapy.

8:00 PM EL07.09.31

The Influence of ZnO Thin Film Thickness on Anion Exchange Membrane Fuel Cell Performance RohanSuri[1], SamuelChen[2], KristeAn[3], HaoyanFang[4], Md FarabiRahman[4] and MiriamRafailovich[4]; [1]Ladue Horton Watkins High School, United States; [2]Ed W. Clark High School, United States; [3]Harvard-Westlake School, United States; [4]Stony Brook University, The State University of New York, United States

In response to the global challenge to find a clean and sustainable power source, scientists have turned their attention to anion exchange membrane fuel cells (AEMFCs). Though significant progress has been made in the development of AEMFCs, several obstacles impede their application[1]. Poor water management in AEMFCs, for example, leads to anode flooding and cathode dehydration, causing cell deterioration to occur over time. Additionally, platinum will ionize and migrate during operation, causing the AEM to degrade, leading to eventual cell failure[2]. Left unmitigated, these problems could easily render a possible solution to the energy crisis useless. Herein, we report that depositing ZnO thin films on an AEM using Atomic Layer Deposition (ALD) can lead to increased maximum power outputs for AEMFC's. For testing, ALD was used to deposit 5, 10, 15, 20, and 30 layers of ZnO onto anion exchange membranes (Sustainion grade T). Atomic Force Microscopy (AFM) was used to verify that a uniform layer formed a flat tomography, proving that ZnO was successfully coated on the surface. Our results demonstrated that there appears to be an optimal thickness of the ZnO thin film layer, with 10 cycles yielding the highest observed maximum power density of 0.430 W/cm^2 (a 28.7% increase from the control cell). Further addition of ZnO began to reduce maximum power densities, with 30 layers of ZnO causing a maximum power density of 0.274 W/cm^2 (an 18.0% decrease). Afterward, XRD measurements were performed, demonstrating the amorphous nature of the ZnO deposited, giving further insights into how the nanostructure could affect possible results. A possible explanation for our observations could be that ZnO improves the electrochemical durability of the AEM, allowing it to function for longer periods of time and become more resistant to the osmotic gradient created within the cell during operation. Future research should include further spectroscopic and microscopic characterization of the membrane and electrodes before and after the performance tests to gain a deeper understanding of our results. Regardless, the scientific community must continue to work with ZnO as a possible solution to many of the problems that plague AEMFC's, furthering humanity's goal to find sustainable energy sources.

Study of Silver Nanoparticles Deposition on Proton Exchange Membrane Fuel Cell PrishaJain[1], AnnaHeimowitz[2], JonathanSacolick[3], HaichuanWang[4], Md FarabiRahman[5], HaoyanFang[5] and MiriamRafailovich[5]; [1]Irvington High School, United States; [2]Stella K. Abraham High School for Girls, United States; [3]Hebrew Academy of Five Towns and Rockaway High School, United States; [4]Shanghai Jianping High School, China; [5]Stony Brook University, United States

Hydrogen fuel cells are an innovative technology capable of producing electricity from hydrogen gas and air. The fuel cell's electrolytic reaction emits only water, making hydrogen fuel cells a more sustainable energy technology[1]. Proton exchange membrane fuel cells (PEMFCs) are known for their low operating temperature, high power density and longer durability[2]. Existing PEMFCs utilize a platinum (Pt) catalyst for better efficiency while the performance of PEMFCs can be enhanced by adding comparatively low-cost non-Pt group nanocatalysts.

This study aims to research the impact of silver nanoparticles on the power density of PEMFCs. Silver nanoparticles, synthesized using the Brust-Schiffrin method, were capped with octanethiol or dodecanethiol. The thiol caps prevent nanoparticle interactions, reducing agglomeration, one of the main challenges with silver nanoparticles[3]. The synthesized particles were examined employing Transmission Electron Microscopy (TEM); they were spherical nanoparticles with an average diameter of about 4 nm for both octanethiol-capped (AgC_8) and dodecanethiol-capped (AgC_{12}) nanoparticles. The Langmuir-Blodgett Trough (LBT) produced isothermal curves for the AgC_8 and AgC_{12} nanoparticles respectively and exploiting the data from there we deposited the silver nanoparticles on the Nafion-117 membrane at surface pressures of 2, 5, and 10 mN/m using LBT. The PEMFC was assembled employing a 0.1mg/cm^2 Pt loading on both the electrodes (anode and cathode) and the Nafion-117 membrane was placed in between the electrodes.

Data from the PEMFC demonstrated that octanethiol-capped silver nanoparticles at surface pressures of 2 mN/m achieved slight improvement in performance; however, at 5 mN/m and 10 mN/m, a 16% and 33% increase in power density was observed respectively. For dodecanethiol-capped silver particles a similar trend was observed. There was no significant power density increase at surface pressures of 2 mN/m but there was about a 16% increase in power density at 5 mN/m and a 33% increase at a pressure of 10 mN/m. The performance of the fuel cell increased at higher surface pressure deposition as it likely increased the quantity of silver nanoparticles deposited, increasing catalytic activity. TEM data demonstrated that AgC_8 nanoparticles were more uniform than AgC_{12} nanoparticles which tended to be more agglomerated. However, both thiol-capped nanoparticles resulted in an equivalent increase in power, suggesting that the evenness of the monolayer did not impact the ability of the silver nanoparticles to catalyze the reaction. In the future, carbon monoxide test will be conducted to determine if the deposition of silver nanoparticles prevents the poisoning of the Pt catalyst.

Support from the Office of Naval Research [N00014-29-1-2858] is gratefully acknowledged by us.

Schiff Base Ligand-Based Mononuclear Co(II) / Ni(II) Complexes as Electrocatalysts for Hydrogen Production FatimahA. Hussein; University of Delhi, Iraq

Solar energy harnessing is a promising way to meet the increasing global energy needs.1-7 An important approach in this context is artificial photosynthesis (AP) wherein water is split into hydrogen and oxygen using electrocatalysts incorporating different chromophores.8-9 For the reductive side of AP (H2 generation), a highly active catalyst, stable in the presence of water and designed using earth abundant materials is preferable. Identifying a robust, active, and efficient electrocatalyst is hence, a crucial first step in this direction. Though Pt is active for proton reduction, the widespread application of Pt is limited due to its rare nature. Keeping this in mind, efforts have focused on using abundant elements such as Fe, Co, Ni, Mo and different combinations of ligands for designing the proton reduction catalysts. For the ligand platforms in developing the catalysts with inexpensive components, Schiff base ligands have received special attention in the past few years.
Based on the above-mentioned facts, tetradentate Schiff base ligands N, N'- Bis (salicyldiene)ethylenediamine(L1),2,2'-((1E-1'E)-(ethane1,2diylbis(azanylyidene))bis(ethane- 1-yl-1-ylidene))diphenol(L2) and 3-(2-(E)-(hydroxynaphthyl)methyl)imido)propylamine) (L3) were reacted with MCl2.6H2O (M = Co, Ni). The synthesized Schiff base complexes [CoII(L1/L2/L3)] 1-3 and [NiII(L1/L2/L3)] 4-6 were characterized by FTIR, NMR and UV-Vis spectroscopic techniques, mass spectrometry, elemental, and thermal analysis. The reported complexes10 1, 2, 4-6 and the new complex 3 were investigated for electrocatalytic proton reduction to dihydrogen in the presence of weak acid (acetic acid) in homogenous media (CH3CN)

Boosting the Electrochemical Reduction of CO2 to Acetylene via Ultrathin 2D Conjugated Copper-Nickel Phthalocyanine-Por COF AbebeB. Workie; National Taiwan University of Science and Technology, Taiwan

Current research efforts are focused on developing a feasible strategy to mitigate global warming while enhancing C-C coupling and multi-carbon production from the electrochemical conversion of carbon dioxide (CO2). Metallomacrocyclic materials are among those that have shown potential for catalyzing the conversion of CO2 into high-value chemicals. But thus far, it has been constrained by low current density, weak activity, product selectivity, and stability. Herein, we report a stable and conductive ultrathin 2D conjugated Copper-Nickel Phthalocyanine-Por Based COF via nitrogen-rich linker-assisted strategy. The distance of adjacent metal atoms can be tuned by adjusting the functionality and size of ligands to promote the formation of ultrathin 2D conjugated tandem Copper-Nickel Phthalocyanine-Based COF, leading to improved atom utilization efficiency, tailored catalytic activities, and high catalytic selectivity, which surpassing C-C coupling and multi-carbon products. The synthesized COF electrocatalysts could exhibit outstanding selectivity for acetylene production demonstrated in an H-type cell. A conductive ultrathin 2D conjugated Copper-Nickel Phthalocyanine-Por Based COF delivers Faradaic efficiencies (FEs) for the CO2 reduction at 0.57 V (vs. RHE) to acetylene of over 91%, with a current density exceeding 80 mA cm^{-2} in a 0.5 M KHCO3 solution, outstripping the performances of the majority of the reported CO2 electrocatalysts. This study offers a practical strategy for developing future designs of novel, inexpensive dimeric electrocatalysts with exceptional efficiency and C2+ selectivity for electrocatalytic reduction of carbon dioxide processes.

The Turbine Blades-Embedded Electrolyzer for Boosting CO2RR Performances Ta-ChungLiu[1], Jing RueiLin[2], You SyunLyu[2] and Yung ChiChang[2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Industrial Technology Research Institute, Taiwan

Aqueous CO_2 electrolysis is a promising technology for closing the carbon cycle and de-fossilizing industrial processes. In addition to vigorously developing advanced materials for electrocatalysts and ion-exchange membranes, challenges such as media flow management, module stability, and force distribution are highly associated with improving the process performance and developing a stackable cell concept to meet industrially relevant levels. The design of the “zero-gap” membrane electrolyzer assembly achieved a prevailing position in laboratory and primary industrialization. However, the utilization of CO_2 is less than 50% despite using a cationic ion-exchange membrane or bipolar membrane to reduce the CO_2 crossover between anode and cathode, making it economically less attractive. This could be attributed to the gas path architectures in the gas chamber, which touches the gas diffusion electrode (GDE) from both sides of the electrode. Herein, we reported a promising modified electrolyzer architecture concept with hierarchically continuous flow channels and GDEs. The meticulous turbine blades were introduced in the cylindrical-shaped gas path architecture to increase the CO_2 media vortex for compulsive reaction with electrocatalysts, thereby enhancing CO_2 utilization, reduction of applied cell voltage, and selectivity. The structure was built by powder bed fusion-based 3D printing and embedded with electrochemically restructured zinc oxide nanoparticles as cathode electrocatalysts. The effect of these modifications on the cell voltage, selectivity, and overall conversion was investigated at 100 mA/cm^2 with varying CO_2 feed gas flow, concentration, and humidity. This as-fabricated electrolyzer was designed to be modular and provide the cell with mechanical integrity and allowed an ionic and electric contact over the entire active cell area, which is required for both stacking and upscaling of the cell. This concept-proof configuration promises ~70% CO_2 utilization and displayed 95% CO_2 to CO conversion at 3V with 180 mA/cm^2, showing efficient and scalable CO_2 electrolysis without a notable increase in operation cost, and has high potential for practical application.

Interlayer and Spin Coupling in Magnetic Topological Insulator $MnBi_2Te_4$WenjingWu, JunichiroKono and ShengxiHuang; Rice University, United States

The emergence of magnetism in topological insulators introduces fascinating spin-related characteristics. This magnetism disrupts time-reversal symmetry, consequently fostering unique quantum states that can lead to extraordinary phenomena such as the quantum anomalous Hall effect. We will highlight our research on $MnBi_2Te_4$(MBT), a two-dimensional van der Waals antiferromagnetic material demonstrating layer-dependent magnetism. Using magneto-Raman spectroscopy, we have studied the interlayer coupling and spin collective motion in MBT flakes, ranging from 1 to 5 septuple layers thick. Notably, we have detected strong interlayer phonon peaks between MBT thin layer and substrates. We also observed the spin-phonon interaction in flakes with different thicknesses and a distinct peak featuring magnons below the Néel temperature with external magnetic fields. Our work facilitates a deeper understanding of the spin and phonon characteristics in this emerging topological magnetic material, promising for quantum computing and spintronics applications.

8:30 AM EL07.10.02
Quantum-Coherent Electron Transport in Carbon Nanotube Fibers and Bundles with Ultrahigh Conductivity ShengjieYu, NatsumiKomatsu, LiyangChen, NicolasM. Peraca, XinweiLi, RenjieLuo, OliverDewey, LaurenTaylor, AliMojibpour, GeoffreyWehmeyer, MatteoPasquali, MatthewFoster, DouglasNatelson and JunichiroKono; Rice University, United States

Macroscopic fibers of aligned carbon nanotubes (CNTs) with exceptional electrical conductivity (>10 MS/m) have emerged as potential alternatives to conventional metal-based electrical cables. However, to optimize their conductivity, a comprehensive understanding of the microscopic electronic transport processes within these CNT fibers is important, encompassing considerations of disorder, doping, and electron-electron interactions. This study presents the outcomes of temperature- and magnetic field-dependent conductivity measurements performed on solution-spun aligned CNT fibers and bundles. At high temperatures, all examined fiber and bundle samples exhibited metallic behavior, with conductivity increasing monotonically as the temperature was reduced from room temperature to a sample-specific temperature between 30 and 100 K. Below this characteristic temperature, the conductivity exhibited a gradual decrease with further decreases in temperature. Additionally, pronounced negative magnetoresistance manifested at low temperatures, signifying the presence of weak localization—a hallmark of quantum coherence in electron transport. Furthermore, investigations on individual bundles exfoliated from the fibers revealed fluctuations in conductivity as a function of magnetic field at temperatures below 50 K. These fluctuations, recognized as universal conductance fluctuations, provide further substantiation of the quantum-coherent nature of electron transport in the examined CNT bundles. By unraveling the interdependencies between temperature, magnetic field, and conductivity in CNT fibers and bundles, this study enhances our understanding of quantum-coherent electron transport phenomena, thereby contributing to the advancement of ultrahighly conductive materials for prospective applications.

Controlling Quantum Interference in Molecular Materials HatefSadeghi; University of Warwick, United Kingdom

Thanks to their sub-10 nanometre size, molecules offer a fantastic platform for exploiting quantum effects at room temperature. Recently, it was shown that molecular wires can mediate long-range, phase-coherent tunnelling with remarkably low attenuation beyond a few nanometres, even at room temperature [1]. This opens up the possibility of using quantum interference (QI) to control the transport of electrons, spins and phonons through molecular junctions consisting of a single or a few molecules between electrodes.

In this talk I will present evidence for room-temperature QI in molecular junctions and discuss the agreement and disagreement between experiments and predictions based on phase-coherent quantum transport theory [2]. Then, I will discuss strategies to control QI in molecular junctions [3] and their applications for quantum switching, quantum sensing and quantum energy conversion.

Abnormal Nonlinear Hall Effect in Thin-Film Weyl Semimetals HaotianJiang, YangchenHe, DanielA. Rhodes, JunXiao and YingWang; University of Wisconsin--Madison, United States

Type II Weyl semimetal possess exotic electronic properties arising from its unique topological structure near the Weyl nodes. Nonlinear Hall effect (NLH) is one of the most intriguing phenomenon is these materials which originated from the crystal inversion symmetry breaking. In NLH, the transverse Hall-like double-frequency voltage can be generated without the presence of any magnetic filed and this unique electronic property is determined by quantum geometry, which is known as Berry curvature. In this presentation, we will show an abnormal nonlinear Hall behavior in a layered Type II Weyl semimetal $TaIrTe_4$. From the temperature dependent NLH measurement, we find that the nonlinear response is greatly enhanced up to 2 orders below a critical temperature. We will also show angle-dependent and layer-dependent NLH measurements to reveal the mechanism of enhancing the NLH effect and how it is related to quantum geometry. A theoretical model is also established to explain the abnormal NLH effect.

Novel Atomically Materials formed via Confinement Heteroepitaxy JoshuaA. Robinson; The Pennsylvania State University, United States

The last decade has seen an exponential growth in the science and technology of two-dimensional materials. Beyond graphene, there is a huge variety of layered materials that range in properties from insulating to superconducting. Furthermore, heterogeneous stacking of 2D materials also allows for additional “dimensionality” for band structure engineering. In this talk, I will discuss recent breakthroughs in two-dimensional atomic layer synthesis and properties, including novel 2D heterostructures and realization of unique 2D allotropes of 3D materials (e.g. 2D metals, nitride, oxides). I will introduce a novel synthesis method, dubbed confinement heteroepitaxy (CHet), that utilizes graphene to enable the creation of atomically thin metals, enabling a new platform for creating artificial quantum lattices with atomically sharp interfaces and designed properties. By shrinking these traditional metals to atomically thin structures, we find that their properties are completely different than their bulk counterparts, lending themselves to unique quantum and optical applications not possible before.

10:30 AM EL07.10.06
A Novel Approach for Achieving Highly Clean Interfaces in 2D Material Spin Valves Ting-ChunHuang and MarioHofmann; National Taiwan University, Taiwan

Spintronics is expected to revolutionize traditional electronics by harnessing the intrinsic spin property of electrons, but the spin manipulation requires high quality junctions between materials with different magnetic properties. 2D materials hold great promise for such junctions due to their atomically sharp interfaces. However, the current experimental results still fall short of meeting the theoretical expectations. This observed difference is primarily attributed to undesirable oxidation of the interfaces during the fabrication process. We here demonstrate a novel approach, called the asymmetrical deposition, to fabricate FM/graphene/FM spin valves (as-GSV) with unprecedented quality. This method achieves all necessary fabrication steps in-vacuo and thus eliminates any possibility for oxidation at the interface. The resulting spin-valve structure exhibits excellent layer conformity and low contamination. This advance yields a current density of the as-GSV that is four orders of magnitude higher than conventional spin valves. Parallel and antiparallel magnetic measurements confirm the high quality of the interface and highlight the importance of lattice-induced effects on spin transport. Furthermore, nearly identical amplitudes of magnetoresistance along two mutually perpendicular magnetic fields demonstrate a novel transport regime. Our results open up new routes for the integration of 2D materials in spintronics and provide inspiration for unprecedented device functionality.

Two-dimensional (2D) magnets provoke a surge of interest in large anisotropy and long-range magnetic ordering, and are promising for next-generation information technology where dynamic magnetic tuning is essential. Here, the controllable transformation of low-temperature magnetic order into room-temperature hard magnetism and pressure-controlled magnetism in LCPC is reported. The chemical tuning via electrochemical lithiation and solvation/desolvation exhibits continuously variable magnetic features from cryogenic magnetism to the room-temperature optimum performance of coercivity (Hc) of 8500 Oe and energy product of 0.6 MGOe. Due to the interlayer coupling of these two-dimensional magnets, interlayer magnetic coupling of molecular layered compounds also can be tuned by applied pressure via chromium-pyrazine coordination. Room-temperature long-range magnetic ordering exhibits pressure tuning coercivity coefficient, while pressure-controlled interlayer magnetism also presents a strong dependence on alkali metal stoichiometry and composition. Chemical tuning and pressure-controlled magnetism pave a pathway toward the understanding of room-temperature 2D magnetism in molecule-based systems.

Long-Lived Electronic Spin Qubits in Single-Walled Carbon Nanotubes Jia-ShiangChen[1,2], Kasidet JingTrerayapiwat[3], LeiSun[1], MatthewD. Krzyaniak[2], MichaelR. Wasielewski[2], TijanaRajh[4] and XuedanMa[1,2,5]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States; [3]Boston University, United States; [4]Arizona State University, United States; [5]The University of Chicago, United States

Electron spins in solid-state systems offer the promise of spin-based information processing devices for quantum communication and computing. The key to preserving the encoding information is realized by the robust coherent spin state which acts against decoherence from losing the phase information. Single-walled carbon nanotubes (SWCNTs), an all-carbon one-dimensional material whose spin-free environment and weak spin-orbit coupling promise long spin coherence times, offer diverse freedom for extended functionality not available to bulk systems. Here, we report the creation of highly confined electron spins in SWCNTs by chemical functionalization through a bottom-up approach. The record long coherence time of 8.2 µs and spin-lattice relaxation time of 13 ms of these electronic spin qubits allow demonstration of quantum control operation manifested as Rabi oscillation. Investigation of the decoherence mechanism reveals an intrinsic coherence time of tens of milliseconds. These findings show that combining molecular approaches with one-dimensional crystalline systems provides a powerful route for reproducible and scalable quantum materials suitable for qubit applications.

11:15 AM EL07.10.09
Single-Photon Detection using a Graphene-Josephson Junction Calorimeter Part I EthanArnault[1], BevinHuang[1], WoochanJung[2], CalebFried[3], KenjiWatanabe[4], TakashiTaniguchi[4], LeonardoRanzani[5], Gil-HoLee[2], DirkEnglund[1] and Kin-ChungFong[5]; [1]Massachusetts Institute of Technology, United States; [2]Postech, Korea (the Republic of); [3]Harvard University, United States; [4]National Institute for Materials Science, Japan; [5]Raytheon BBN, United States

Single photon detectors (SPDs) are an enabling technology for quantum networks and quantum state readout. However, current implementations of SPDs often operate in narrow bandwidths, are limited in the tradeoff between the quantum efficiency and dark count, and many lack the ability to resolve photon number. The orthogonal approach of single-photon calorimetry based on graphene material properties can serve as an interesting option because it has 1) no band gap allowing for light absorption from optical down to microwave frequencies, 2) a vanishing density of states providing a low electronic heat capacity and 3) short electron-electron interactions (~100 fs). This makes graphene an ideal candidate for single photon calorimetry, where an incident photon is absorbed by the graphene and sensed through the temperature rise of the electrons.

In this two part talk, we will discuss our graphene-Josephson junction single-photon detector, which operates by measuring the heat deposited by a single photon. We are able to resolve single infrared (1550 nm) photons with a maximum quantum efficiency of ~90% and a dark count rate on the order of an hour. We can detect single-photons up to 1.2 K, paving the way to operate at liquid Helium-4 temperatures after further optimization. We further explore the heat propagation in our graphene. Using a milliKelvin optical scanner, we spatially resolve the heat propagation due to an incident single photon and find no substantial variation in switching rate over ~25 um, indicating that the thermal length scale is substantially larger. Further, by varying backgate, the efficiency of the detector wanes as the device is tuned away from the Dirac peak, confirming that we are measuring the electronic temperature rise due to a single photon.

Part one of this talk highlights the mechanisms and verification of single photon detection.

11:30 AM EL07.10.10

Atomic Layer Smoothing for Quantum Materials: An Initial Investigation HaozheWang; Duke University, United States

In the realm of quantum devices such as qubits and microwave kinetic inductance detectors, surface imperfections in metallic and dielectric films have been identified as a root cause of non-ideal behaviors. Despite significant investigations into surface-induced decoherence and low-frequency fluctuations, current nanofabrication techniques remain inadequate in addressing these issues. We introduce a novel surface smoothing technique utilizing a 'reversal' mechanism in atomic layer deposition (ALD), specifically isotropic plasma atomic layer etching (ALE), to mitigate Angstrom-level defects in quantum materials. Our approach focuses on minimizing surface roughness and native oxides, thereby enhancing device performance. This talk provides insights into the application of atomic layer smoothing in the processing of aluminum nitride, with observed smoothing effects at the Angstrom scale, offering potential improvements to AlN-based quantum optical devices. Further discussion will cover advancements in ALE for metallic aluminum, a material frequently used in superconducting circuits. We propose an integrated ALE-ALD approach to achieve smoother and oxygen-free surfaces.

2:15 PM EL07.11.02
Charge and Magnetotransport in Hybrid Molecule/Quantum Material Van der Waals Heterostructures EmanueleOrgiu; Université du Québec/Institut National de la Recherche Scientifique, Canada

2D Quantum Materials are held together by weak interplanar van der Waals (vdW) interactions. The incorporation of molecules in such materials holds an immense potential to understand and modify the fundamental physical properties of the pristine materials while creating new artificial materials. Whilst nature offers a finite number of 2D materials, an almost unlimited variety of molecules can be designed and synthesized with predictable functionalities. The possibilities offered by systems in which continuous molecular layers are interfaced with inorganic 2D materials to form hybrid organic/inorganic van der Waals heterostructures (H-vdWH) are emphasized. Similar to their inorganic counterpart, the hybrid structures have been exploited to suggest novel device architectures. Moreover, specific molecular groups can be employed to modify intrinsic properties and confer new capabilities to 2D materials. In particular, I will highlight how molecular self-assembly at the surface of 2D materials can be mastered to achieve precise control over position and density of (molecular) functional groups, paving the way for a new class of hybrid functional materials.
In particular, I will show how the presence of ordered supramolecular assemblies bearing different functional groups can modify the pristine Shubnikov-De Haas oscillations [1] occurring in graphene or tune the magnetoresistance in a given transition metal dichalcogenide [2].

Monolayer Electrolyte for an All-Solid-State Non-Volatile Memory: Local Switching and Speed SusanFullerton, HuiranWang and ShubhamS. Awate; University of Pittsburgh, United States

Using an electrolyte that is a single molecule thick, our group previously demonstrated a non-volatile, solid-state, one-transistor (1T) memory by electric double layer (EDL) gating of WSe_2 field-effect transistors (FETs), Nano Letters 19, 8911 (2019). The “monolayer electrolyte” consists of cobalt crown ether phthalocyanine (CoCrPc) molecules and $LiClO_4$ wherein each crown ether solvates a cation. The cations are positioned by field-effect at either the surface of the WSe_2 channel or a h-BN capping layer to achieve a low resistance or high-resistance state, respectively. Our prior work focused on the combination of $LiClO_4$ and 15-crown-5 CoCrPc, giving rise to non-volatile threshold voltage shifts corresponding to a change in charge density of ~ 2.5×10^{12} cm^{-2}. Here, we report the impact of salt and solvent identity on the monolayer electrolyte deposition quality and electrical characteristics. First, we demonstrate that bistability is not limited to $LiClO_4$ – it is also detected for $NaClO_4$, $Ca(ClO_4)_2$ and LiCl in 15-crown-5. However, the change in charge density varies by more than one order of magnitude depending on the identity of the salt. Specifically, the top performers are the perchlorate-based salts with charge densities in the range of $1 – 2.5 \times 10^{12}$ cm^{-2}. In contrast, LiCl only induced a charge density modulation of 1×10^{11} cm^{-2}, suggesting that the perchlorate anions may play an important, but unknown, role in the switching mechanism. Second, we demonstrate local ion switching with sheet densities on the order of 1×10^{13} cm^{-2} using electric force microscopy (EFM). Specifically, the EFM tip is used as a mobile top electrode to read, write, and erase the monolayer electrolyte on a heterostack of graphene/monolayer electrolyte/h-BN. This new approach to modulating the charge density provides insight on the lateral extent of switching which is critical for scaling the area of channel, and the energy barrier to switching. Lastly, we report on the switching speed having replicated prior results showing switching on the order of tens of nanoseconds. The interplay between device geometry and speed will be discussed. The work is supported by the National Science Foundation (NSF, U.S.) under Grant No. DMR-CAREER-1847808.

3:30 PM EL07.12.02
Role of Mobile Point Defects, Trap States and Joule Heating in Lateral Memristive Devices Based on Two-Dimensional TMDCs BenjaminSpetzler[1], DilaraAbdel[2], ZhansongGeng[1], FrankSchwierz[1], PatricioFarrell[2] and MartinZiegler[1,1]; [1]Ilmenau University of Technology, Germany; [2]Weierstrass Institute, Germany

Two-dimensional (2D) layered transition metal dichalcogenides (TMDCs) are promising materials for memristive devices and have gained significant attention because of their potential use in neuromorphic computing systems. However, despite extensive experimental work (e.g., [1,2]), the underlying resistive switching mechanisms in 2D TMDCs are still not understood, impeding progress in material and device functionality. This study discusses the contributions of various mechanisms to the current-voltage hysteresis and switching dynamics in 2D TMDC materials in detail and reveals the dominant role of mobile point defects [3]. Here, the switching process is governed by the formation and annihilation dynamics of a local vacancy depletion zone. Moreover, minor changes in the interface potential barriers cause fundamentally different device behavior previously thought to originate from multiple mechanisms. The key mechanisms are identified with a numerical charge transport model for electrons, holes, and ionic point defects, including image-charge-induced Schottky barrier lowering, Joule heating, and charge trapping dynamics. The model is validated by comparing simulations with measurements for various 2D MoS_2-based and HfS_2-based lateral devices, which also allows us to identify the characteristic dynamic behavior as a fingerprint of the underlying physical mechanism. Our results strongly corroborate the relevance of vacancies in lateral TMDC devices and offer a new perspective on the switching mechanisms and the influence of Joule heating. The insights gained from this work can be used to extend the functional behavior of 2D TMDC memristive devices in future neuromorphic computing applications.

Nanoscale Devices Based on Van der Walls Ferroelectric Materials ZijingZhao[1], KaiXu[1], WeiJiang[2], HojoonRyu[1], JunzheKang[1], TonyLow[2], ShalooRakheja[1] and WenjuanZhu[1]; [1]The University of Illinois at Urbana-Champaign, United States; [2]University of Minnesota, United States

Van der Waals (vdW) ferroelectrics have emerged in recent years as a new class of ferroelectric materials, which have many intriguing properties, such as excellent size scaling, tunable

bandgap, negative piezoelectric coefficient, and high mechanical flexibility. Many vdW ferroelectrics can retain ferroelectricity down to 1 unit-cell thickness and can be grown or transferred on any material, which makes them promising building blocks for designing functional heterostructures. These new materials and heterostructures enable a wide range of emerging applications, including nonvolatile memories, steep slope transistors, programmable junctions, photodetectors, and pressure sensors. In this talk, we will discuss our recent work in developing reconfigurable and multifunction devices based on vdW ferroelectric materials [1-6].

Non-volatile reconfigurable logic transistors can be used to address the memory bottleneck in data-intensive applications because circuits based on these devices can realize various functions without changing the layout. We developed non-volatile reconfigurable transistors based on 2D $CuInP_2S_6/MoTe_2$ heterostructures [1]. The polarity (n-type or p-type) of these logic transistors can be dynamically programmed, while the configuration is non-volatile in nature. Utilizing these ferroelectric devices, we demonstrate reconfigurable logic gates with NAND/NOR dual functions, whose input-output mapping can be transformed in real-time without changing the layout. These reconfigurable circuits will serve as important building blocks for high-density data-stream processors and reconfigurable Application-Specific Integrated Circuits.

Content addressable memory (CAM) is one of the promising in-memory computing circuits widely used in high-speed search applications. However, traditional SRAM-based CAM needs ten transistors (10T) per bit, which imposes severe limits on the area and energy efficiency. We developed a novel 1-transistor-per-bit CAM based on the ferroelectric reconfigurable transistor. By exploiting the switchable polarity of the ferroelectric reconfigurable transistor, XOR/XNOR-like matching operation in CAM can be realized in a single transistor. By eliminating the need for the complementary circuit, these non-volatile CAMs based on reconfigurable transistors can offer a significant improvement in area and energy efficiency compared to conventional CAMs.

Furthermore, we developed multifunctional devices based on semiconducting ferroelectrics (In_2Se_3), which can concurrently serve as an electronic memory, photonic memory, logic gate, and photodetector [2]. This dual electrical and optical operation of the memories can simplify the device architecture and offer additional functionalities, such as ultrafast optical erasing of large memory arrays. We also demonstrated reconfigurable Schottky diodes based on In2Se3/graphene heterostructures, where the diode polarity is reversible via switching the In_2Se_3 polarization. The current ratio between ON and OFF states at a given read voltage can be as high as 100. These results indicate that ferroelectric In_2Se_3 and other semiconducting ferroelectric materials have great potential for multifunctional devices.

Application of Van der Waals $CuInP_2S_6$ in Multifunctional Devices YiqunLiu, YonghuangWu, HaojieHan, RuixuanPeng, HetianChen, DiYi, KaiLiu, Ce-WenNan and JingMa; Tsinghua University, China

$CuInP_2S_6$ (CIPS) has gained widespread attention as an emerging room-temperature two-dimensional ferroelectric material due to its novel physical properties. There is a growing demand for achieving diverse and complex functional features in simpler device structures, aiming to simplify peripheral circuit design and reduce overall production costs. Memristors play a crucial role in realizing the in-memory computing. Versatile memristors, which can achieve non-volatile and volatile performances in a single device, holds the potential for achieving selector and memory functions simultaneously, also opening up possibilities for emulating artificial neural networks (ANN) and spiking neural networks (SNN) in a single cell. In CIPS-based versatile memristor, electrochemically active Ag is utilized as the top electrode, and resistive switching is achieved by the formation and rupture of conductive filaments under the electric field. By controlling the compliance currents (CCs) during the test, both volatile and non-volatile resistive switching can be realized in the single device. Stable diode-like volatile behaviors with notable rectification ratio of 10^3 are exhibited with CCs = 10 μA. In the same device, non-volatile memory performances with on/off ratio of 10^3 and remarkable retention time up to 10^4 s are acquired under CC = 5 mA. A 3×3 crossbar memory array is also fabricated, demonstrating the potential pattern learning in actual application. What's more, optoelectronic synapses are receiving a burgeoning amount of interest due to their ability to mimic the functionality of the human visual system. Integrating electronic and optoelectronic synapses into a single device enables their applications in more complex scenarios while maintaining low power consumption. In simple graphene/CIPS/Au device configuration, the migration of Cu^+ ions under electrical stimuli and persistent photoconductivity under optical stimuli were leveraged to demonstrate the simultaneous realization of electronic and optoelectronic synapse functionalities. Taking advantage of optical-electrical cooperative effect, information perception, processing, memorizing and light adaption behavior were efficiently demonstrated in such simple-structure electronic/optoelectronic synapse, paving a prospective way towards achieving artificial visual system. The findings presented contribute to the advancement of CIPS-based devices and their potential for various applications in the field of multifunctional electronic devices.

Monolayer Electrolytes for Nonvolatile Memory: Impact of Salt Identity on Electrical Characteristics HuiranWang, ShubhamS. Awate and SusanFullerton; University of Pittsburgh, United States

A solid-state, non-volatile memory based on electric-double-layer (EDL) gating using a monolayer electrolyte (ME) has been developed in our lab. This ME comprises cobalt crown ether phthalocyanine (CoCrPc), with four, 15-crown-5 ethers (15C5) attached, and a lithium salt that forms an ordered array on the two-dimensional (2D) semiconductor surface. The monolayer electrolyte is capped with h-BN. Each crown solvates one metal cation that is stable in two distinct states in the crown: one near the 2D semiconductor, creating a low-resistance state, and the other near h-BN, creating a high-resistance state. The switching mechanism is triggered by an electric field via a back-gated field-effect transistor (FET). Prior work focused exclusively on $LiClO_4$ deposited with ethanol. Here, we report on additional salt/solvent systems and their impact on switching, including LiCl, LiI, $NaClO_4$,and $Ca(ClO_4)_2$. The surface roughness (R_q) of bare WSe_2 flakes before electrolyte deposition is typically 0.2 ± 0.01 nm, and after 15C5-CoCrPc/$LiClO_4$ deposition, the R_q increases by a factor of 2 to 3. Therefore, for electrical characterization, we select salts for which the R_q remains within this range: LiCl, $NaClO_4$, $Ca(ClO_4)_2$ in ethanol. Non-volatile subthreshold voltage shifts (ΔV_S) in the range of 9 − 15 V are observed for all three salts measured, indicating that all three are bistable in 15C5-CoCrPc. Specifically, ΔV_S of 9.1 ± 1.4, 14 ± 2.1, and 9.2 ± 0.3 V for LiCl, $NaClO_4$,and $Ca(ClO_4)_2$, respectively, correspond sheet carrier densities (Δn_S) of 1.4×10^{11}, 1.2×10^{12}, 1.0×10^{12} cm^{-2}. Thus, the best performing salts are those containing perchlorate anions with doping densities on the order of 10^{12} cm^{-2}, suggesting that the anion may play an important role in the switching mechanism. ON/OFF ratios of < 10^3, ~ 10^3, and ~ 10^3 are measured for LiCl, $NaClO_4$,and $Ca(ClO_4)_2$, respectively. These ratios are similar to what we observe in $LiClO_4$, indicating two distinguishable resistance states in MERAM. Retention measurements will be reported. These findings advance our goal of developing a high-speed, non-volatile memory at the limit of scaling. This work is supported by the NSF under Grant # NSF-DMR-EPM CAREER: 1847808.

Highly Nonlinear Memory Selectors with Ultrathin $MoS_2/WSe_2/MoS_2$ Heterojunction HongyeChen[1], TianqingWan[1], YueZhou[1], JianminYan[1], HongyuYu[2] and YangChai[1]; [1]The Hong Kong Polytechnic University, Hong Kong; [2]Southern University of Science and Technology, China

Two-terminal (2D) resistive random access memory (RRAM) crossbar arrays require the highly nonlinear selector with high current density to address a specific memory cell and suppress leakage current through the unselected cell. Three-dimensional (3D) monolithic integration of RRAM array requires selector devices with a small footprint and low-temperature processing for ultrahigh-density data storage. Here, we design an ultrathin two-terminal n-p-n selector below 10 nm with 2D transition metal dichalcogenides (TMDs) by a low-temperature transfer method. The van der Waals (vdW) contact between transferred Au electrodes and 2D TMDs reduces the Fermi level pinning and retains the intrinsic transport behavior of TMD. The selector with single type of TMD exhibits a trade-off between the current density and nonlinearity depending on the barrier height. By controlling the thickness of p-type WSe_2 in $MoS_2/WSe_2/MoS_2$ n-p-n selector and tuning the Schottky barrier height for a punch-through transport, the selector shows high nonlinearity (~ 230) and high current density (2×10^3 A/cm^2) simultaneously. We further integrate the n-p-n selectors with a bipolar hexagonal boron nitride (h-BN) resistive switching memory and calculate the maximum crossbar size of the 2D material-based 1S1R according to a 10% read margin, which offers the possible realization of future 3D monolithic integration.

Electrical Transport in Carbon Nanotubes and Junction Conductance VasiliPerebeinos[1], DavoudAdinehloo[1], WeiluGao[2], AliMojibpour[3] and JunichiroKono[3]; [1]University at Buffalo, United States; [2]The University of Utah, United States; [3]Rice University, United States

In the study of carbon nanotubes (CNTs), we simulate the junction conductance within a tight-binding model approach. The interplay of intertube and intratube conductance as a function of temperature and CNT chirality explains the experimental measurements in CNT films of separated CNT chirality [1]. By using Anderson model, we were able to calculate the conductance in different types of CNTs. Our findings showed that intratube conductance dominates conductance in CNTs with small localization lengths. In the case of armchair CNTs, we find that at room temperature, phonon-assisted intertube junction conductance dominates the transport properties of the films. We performed a comprehensive study of the dependence of junction conductance on different factors, such as the angle between the CNTs, the twist angle, the sliding shift of the CNTs, the Fermi energy, and the applied bias voltage between CNTs [2]. Using a single geometrical fitting parameter, our calculations perfectly matched the temperature-dependent conductance measurements.

Low-Thermal-Budget Synthesis of MoS2 on 8” Wafers for BEOL and FEOL Transistors JiadiZhu, Ji-HoonPark, JingKong and TomasPalacios; MIT, United States

The development of low-thermal-budget (<300C) synthesis technologies for two-dimensional materials such as Molybdenum Disulfide (MoS2) enables both new architectures for front end of the line (FEOL) transistors, but also the integration of these devices on new substrates as well as at the back end of the line (BEOL) of Silicon chips. This paper describes our recent work on the synthesis of MoS2 below 300C and its applications to electronic devices. The trade-offs between growth temperature, precursor partial pressures and flows, substrate diameter, mobility and grain size will be discussed. Several device applications of the low temperature MoS2 material will be presented, including FEOL single and multi-channel MoS2 transistors, BEOL memory circuits, and high performance RF harvesting devices.

Chip-Less Wireless Electronic Skin Sensors Enabled by Epitaxial Freestanding Compound Semiconductors YeonginKim[1,2], JunminSuh[1], JihoShin[1], YunpengLiu[1], JiyeonHan[3] and JeehwanKim[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Cincinnati, United States; [3]Amorepacific R&D Center, Korea (the Republic of)

Electronic skin (e-skin) has been developed with a goal to obtain a non-invasive human health monitoring electronic system with its imperceptibility. So far, one of the major shortcomings in this field is the bulky wireless communication system that severely affects its wearability. In this work, we introduce a single-crystalline non-Si-based e-skin system where fully conformable, ultrathin, piezoelectric, compound semiconductor membranes are incorporated as power-efficient wireless communication modules and extremely high sensitivity sensors without needing for bulky chips and batteries. The developed GaN surface acoustic wave-based device successfully measured wirelessly three different inputs including strain, ultraviolet light, and ion concentrations. The consistency and accuracy of the measured heart rate and pulse waveforms over a 7-day period, during which the e-skin was re-attached 7 times, strongly demonstrate the reusability and long-term wearability of our device. This study will change the paradigm of e-skins by providing versatile wireless platforms for fully imperceptible e-skins with very high sensitivity and low power consumption.

Large-Scale Integrated Vector-Matrix Multiplication Processor Based on Monolayer MoS_2GuilhermeMigliato Marega, Hyun GooJi, ZhenyuWang, MukeshTripathi, AleksandraRadenovic and AndrasKis; Ecole Polytechnique Federale de Lausanne, Switzerland

In recent years, data-driven algorithms took the spotlight promising new and efficient ways for processing and extracting meaningful information from ever-growing amounts of generated data. Although the von-Neuman architecture was the backbone of the data revolution, the separation of the memory and processing units makes the current processors spend a significant amount of energy moving data compared to the energy spent in computing [1]. This motivated the research in emerging computer architectures which could provide energy benefits while performing data-driven algorithms, such as artificial neural networks or signal and image processing. Among the different proposals, in-memory computing has been systematically shown to be beneficial for the previously mentioned applications [2]. Despite the intense research efforts put into the types of memory devices used in this architecture, no technology has been able to satisfy all the requirements [3]. The lack of a universal memory platform for performing computation has led to the investigation using two-dimensional materials as a promising material system for this emerging architecture [4]. In this light, here, we fabricated a 32x32 vector-matrix multiplier with 1024 floating-gate field-effect transistors (FGFET) that use atomically thin MoS_2 as the semiconducting channel material. This large-scale integration device is developed in a wafer-scale fabrication process, achieving high yield and low device-to-device variation. Due to the low device variability, an open-loop programming scheme can be employed while obtaining multi-level memory behavior. Finally, our in-memory processor is used to demonstrate discrete signal processing based on vector-matrix multiplications. Our findings lay the foundations for creating complex in-memory processors that can harvest all the advantages of 2D materials.

Van der Waals Integration beyond the Limits of Van der Waals Forces FarnazNiroui; Massachusetts Institute of Technology, United States

Heterostructures of dissimilar materials are core building blocks of nanoscale devices. Their growth through common chemical epitaxy or physical vapor deposition often poses strict chemical and physical compatibility constraints, limiting accessible heterostructures due to potential disorder and damage. Physical stacking provides an alternative approach to hetero-integration. This has been the foundation of the growing discipline of van der Waals (vdW) integration for 2D materials and materials of varying other dimensionalities. However, vdW integration faces a fundamental limit due to vdW forces being dependent on the intrinsic materials' optical and electrical properties and thus not readily tailorable to allow direct integration of arbitrary layers. Here, we introduce the adhesive matrix transfer approach to overcome this fundamental limit to enable direct fabrication of conventionally-forbidden vdW heterostructures and single-step 2D material-to-device integration. As no solvents, high-temperatures or sacrificial layers are involved, our platform yields pristine surfaces and interfaces uniquely suited for studying the intrinsic properties of 2D materials and leveraging them in device applications which will be discussed.

NIL, Nanopatterning and Etching of Nanopillars for GaN-Based microLEDs NabilLabchir[1], SaberHammami[2], KilianBaril[3], MayaWehbe[3], SébastienLabau[1], CamillePetit-Etienne[1], BlandineAlloing[3], MatthewCharles[2], JesusZuniga Perez[3] and CécileGourgon[1]; [1]LTM/CEA, France; [2]CEA Leti, France; [3]CRHEA_CNRS, France

At present, GaN-based µLED optoelectronic devices are progressing beyond solid-state lighting, inspiring a fascinating new category of applications. Indeed, the µdisplay sector has reached a highly dynamic expansion phase. Unlike conventional displays, µdisplays require image magnification to be seen by the human eye. However, they must be able to display an image of similar quality to that of standard in terms of definition, i.e. number of pixels. To display as many pixels on a smaller surface, we need to reduce the pixel pitch, i.e. the distance between two pixels, from a few hundred micrometers to only a few micrometers. At present, controlling the internal crystal quality of the GaN substrate permits the development of smaller, more efficient µLEDs. However, the µLED lifetime is highly dependent on the density of dislocations inside GaN which behave as non-emissive zones on the µLED surface. In this context, nanoimprint lithography (NIL) will be deployed to nanotexture silicon-on-insulator (SOI) substrates in order to achieve a high density of GaN growth sites. The regrowth on these SiO_2-based sites enhances the GaN quality and therefore the µLEDs performance. The innovation in our strategy is based on the nanopatterning of deposited GaN/AlN layers on 3 cm^2 SOI surface for fabricating 200 nm nanopillar arrays with zero defect and that possess SiO_2 at the bottom, using both NIL and plasma etching techniques. Here, I have developed a process without lift-off that is compatible with industrial transfer by using metal hard mask etching. In this process, I have controlled pillar arrays with 150 nm in diameter at the bottom, and I have carefully optimized the plasma etching of materials at all the different steps, especially at the NIL and hard mask sections. For transferring our zero-defect protocol to large-scale production, we are working on extending our strategy to fabricate µLEDs on 200-300 mm wafers. This research will provide a breakthrough for the future optoelectronics industry of displays.

10:45 AM EL07.14.02
Polarity-Reversible 2D $MoTe_2$ Field-Effect Transistors and Their Logic Applications Byoung-SooYu[1,2], JongtaeAhn[1], WonsikKim[1], SoohyungPark[1] and Do KyungHwang[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]University of Science and Technology, Korea (the Republic of)

2H-type molybdenum ditelluride ($MoTe_2$) has been greatly spotlighted as a semiconducting TMDC material which facilitates polarity transition between high performance n- and p-type characteristics due to its small bandgap of ~ 1.0 eV. However, the reversible polarity control between unipolar n- and p-type conductions in $MoTe_2$ is still challenging, which causes difficulties for device strategies which require unlimited manipulation of carrier transport properties of $MoTe_2$ devices. Here, we demonstrate reversible polarity transition between unipolar n- and p-type characteristics in $MoTe_2$ FETs by controlling annealing environment. Fermi level shift and formation/removal of oxygen relevant phases in the $MoTe_2$ layer are repetitively occurred with the change of annealing atmospheres. Also, the polarity modulations in well-designed $MoTe_2$ devices are compatible with the phenomena presented in $MoTe_2$ material. This precise polarity control in $MoTe_2$ FETs eventually permits to realize functional logic application such as an inverter circuit.

Micro-Heater Integrated Nanotube Array Gas Sensor for Parts-Per-Trillion Level Gas Detection and Single Sensor-Based Gas Discrimination WenyingTang and ZhiyongFan; The Hong Kong University of Science and Technology, Hong Kong

Ensuring chemical safety and safeguarding human health require real-time monitoring and discrimination of trace gases using appropriate gas sensors. Typically, these tasks involve expensive, bulky, and power-hungry devices such as optical and electrochemical gas sensors. Metal oxide (MOX) semiconductor gas sensors possess several attractive features, such as low cost, small size and long lifespan, making them promising candidates for highly integrated sensor systems. Unfortunately, the mainstream MOX sensors suffer from poor selectivity and sensitivity, which have limited their application.

Researchers have made great efforts to address the limitations of MOX-based gas sensors. Various strategies have been explored to improve the poor sensitivity and LOD of MOX-based gas sensors, such as adding a porous overlayer on top of the sensing films as a molecular sieve or functionalizing the surface with noble metals or oxides as catalytic sites. For selectivity issue, gas sensor array with various sensing pixels has been broadly applied to discriminate multiple gases. However, the construction of complicated gas sensor arrays and the processing of high-dimensional sensing data pose significant challenges, which highlights the urgent need for gas discrimination based on a single sensor. Temperature modulation, which can provide temperature-dependent kinetic information, has been widely utilized to trigger single-sensor based gas discrimination. Nonetheless, most of the related studies discriminated gas species with the sensor responses under different operation temperatures using the continuous heating (CH) mode, which is difficult to realize real-time gas recognition due to the long operation periods. In contrast, pulse heating, featuring periodic transient thermal cycle, has great potential for real-time gas discrimination since it provides the transient characteristics emerging from gas diffusion and gas-solid surface reactions between gas molecules and sensing materials. However, most of the proposed pulse-driven MOX sensors focused on reducing power consumption and improving gas sensing performance. The gas discrimination capability of pulse-driven MOX sensors through extracting transient features has been rarely explored in the past.

In this study, we demonstrated a novel gas sensor called micro-heater integrated nanotube array gas sensor (MINA sensor), which can operate in dual modes. The sensor can detect multiple gases at parts-per-trillion (ppt) level under the CH mode and distinguish multiple gases under the PH mode. We constructed the MINA sensor on the nano-porous anodic aluminum oxide (AAO) templates with a top-bottom electrode structure, which significantly increases the sensor's surface area for molecular access. To create the sensing material layer, we used atomic layer deposition (ALD) to deposit an ultrathin and conformal SnO_2 thin film and decorated it with Pd nanoparticles (NPs). When operating under the CH mode, the MINA sensor could detect hydrogen, acetone, toluene and formaldehyde with measured LODs as low as 100 ppt, 100 ppt, 100 ppt, 4 ppb, with the corresponding theoretical LODs as 6.96 ppt, 11.88 ppt, 16.52 ppt, 70.06 ppt, respectively. Under PH mode, the MINA sensor provided varying transient responses to different gases due to the variations of gas diffusion and surface reaction activation energy of the gases. By analyzing the conductance amplitude and slope features of a single pulse, different concentrations of hydrogen, acetone, toluene, and formaldehyde can be distinguished. Furthermore, the PH mode saved 66.7% energy compared to the traditional CH mode. The remarkable capabilities of the MINA sensor make it highly appealing for various applications, including distributed low-power sensor networks and battery-powered mobile sensing systems for chemical safety, environmental monitoring, and healthcare.

11:45 AM EL07.14.05
High-Performance Infrared Light-Emitting Diodes Based on Chirality-Sorted Carbon Nanotube Films BingHan and ShengWang; Peking University, China

An important goal in the carbon nanotube (CNT) optoelectronics is to achieve a high-performance near-infrared (NIR) light source. But there are still many challenges such as CNT chirality purity, defects, thin film quality and device structure design. Here, we realized high-performance infrared light-emitting diodes (LEDs) based on the high chirality purity (10, 5) single-walled carbon nanotubes (SWCNTs) network film. Asymmetric palladium (Pd) and hafnium (Hf) contacts were used as the holes and electrons injection electrodes of the LEDs, respectively. However, the large Schottky barrier between the Hf electrode and CNTs, resulting from the polymer wrapped on the CNT surface during the sorting process, leads to difficult electron injection and low efficiency of electroluminescence (EL). We found that the electron injection efficiency could be improved by the local doping of the CNT channel with dielectric layers of YOX-HfO2, which reduced the Schottky barrier for electron injection from Hf electrodes. At last, our CNT LED device exhibits a high external quantum efficiency (EQE) of about 5×10-4 without any optical coupling structure. It shows an EL peak at the optical communication O band of 1290 nm with a simple structure and low work voltage. It’s believed that the chiral CNT infrared light source has great application potential in the field of the CNT monolithic optoelectronic integrated system and on-chip optical interconnection.

Enhancing Electrochemical Sensing via Hybridization of 2-D Mxene and Transition Metal Dichalcogenides LiaStanciu, WinstonY. Chen and DimitriosStanciu; Purdue University, United States

The exceptional conductive properties, flexibility, and surface functionality of two-dimensional (2D) transition-metal carbides/nitrides (MXenes) position them as prospective electronic materials for electronic devices and electrochemical sensors specifically. Nonetheless, strategies to amplify MXene's sensitivity to volatile organic compounds (VOCs) in particular remain relatively uncharted. In this study, we elucidate a novel methodology involving surface treatment and exfoliation to fabricate a hybrid material of 2D WSe2 and Ti3C2Tx.
By employing scanning electron microscopy, transmission electron microscopy, X-ray diffractometry, and dynamic light scattering, we characterised the microstructure, size, and surface charge states (zeta potential) of WSe2 and Ti3C2Tx nanosheets. This extensive analysis facilitated the optimal processing of the WSe2 and Ti3C2Tx hybrid, enabling its use as ink for ink-jet printing of flexible Ti3C2Tx/WSe2 electrochemical sensors, which are integrated into wireless systems.
VOCs were selected as the test subject to elucidate the functional properties of these 2D nanohybrids for electrochemical sensing. Within this configuration, the Ti3C2Tx scaffold contributes high electrical conductivity while the WSe2 nanoflakes impart remarkable sensitivity and enhanced selectivity to VOCs.
Contrasted with other Ti3C2Tx reference sensors and 2D materials-based sensors, the Ti3C2Tx/WSe2 sensors exhibit superior resilience after numerous bending cycles. They also demonstrate exceptional electrochemical durability and sustained response, with distinct selectivity for detecting model VOCs (ethanol, methanol, acetone, hexane, benzene and toluene) across a broad concentration range (1–40 ppm) at room temperature.
This work is expected to illuminate a path for future exploration into the hybridization of 2D MXenes, paving the way for the creation of high-performance electrochemical sensing devices.

1:45 PM EL07.15.02
Meniscus-Guided Control of Highly Wrinkled Reduced Graphene Oxide-Based Electrodes for Sensing ER Stress-Related Antibodies Su YeongKim, Jeong ChanLee and SteveePark; KAIST, Korea (the Republic of)

As the aging society emerges, the market for point-of-care (POC) biosensing platforms that can quickly and efficiently diagnose diseases like cancer and diabetes is rapidly expanding. Implantable electrochemical biosensors within the body enable rapid and continuous detection and facilitate prompt personalized medical treatments. Recent research has focused on flexible fiber or wire-based implantable biosensors coated with nanostructured conductive materials. This innovation addresses the degradation of the signal-to-noise ratio caused by the mechanical mismatch between the biosensor and the surrounding tissues. By overcoming this challenge, these biosensors enable accurate and continuous monitoring of biomarkers and drug delivery over extended periods. However, wire-based electrochemical biosensors face several obstacles in detecting target biomarkers within tissues. These include (1) degradation of sensing performances (i.e., sensitivity, specificity) and shelf-life of the biosensor due to non-specific binding and biofouling of various biomolecules, (2) false positive and negative increment during diagnosis, and (3) potential inflammation caused by the low biocompatible nanomaterials. Addressing these challenges is crucial for the successful development of effective wire-based electrochemical biosensors for clinical applications.

Here, we designed the wire-based electrochemical biosensor by coating the highly porous antifouling matrix composed of cross-linked bovine serum albumin (BSA) and pentaamine-functionalized reduced graphene oxide (prGOx). The conventional antifouling coating still has an issue of high electrochemical impedance because the coating is thick to improve the antifouling properties, such as the blocking layer with the BSA solution and PEG hydrogel-based coating. Unlike these coatings, we optimized the composition of cross-linker, or glutaraldehyde (GA), to contain high porosity and durability while maintaining the biocompatibility of the antifouling matrix. Coated through a solution process on gold wires, this coating showed a BET surface area two-folds higher than conventional BSA structure and provided the micro-level electrochemical signal and high antifouling property of 95 % under serum conditions. This wire-based biosensor was used to confirm the real-time glucose detection with a dynamic concentration range of 0.4 mM to 0.9 mM. In addition, we demonstrated the in-vitro stability of this sensor by detecting glucose with constant sensitivity in the presence of various nonspecific substances from the serum. As a result, this highly durable wire-based electrochemical biosensor enables various applications of implantable biosensing and customized diagnosis and treatment with high accuracy.

Rational Design of Graphene Quantum Dots for Light-Activation in Organic-Inorganic Hybrid Nanostructure: Toward Room Temperature Gas Sensing JinhoLee, MinhyunKim, SeyeonPark and Il-DooKim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The demand for power-efficient, high-performance gas sensors operating at room temperature has promoted research into light-activated gas sensors for Internet of Things (IoT) applications. While semiconducting metal oxides have been extensively employed due to their suitable electronic band structure for light absorption, their low gas response with light-activation mechanism still requires improvement with effective strategies such as catalyst decoration for enlarging light absorption. Recently, graphene quantum dots (GQDs) have newly proven their catalytic ability for room temperature gas sensing with their tunable electronic band structure and surface functional groups. Herein, we decorated high-quality GQDs on In_2O_3 nanofibers with varying the size of GQDs (2 nm to 20 nm) for enhancing light-absorption of In_2O_3 nanofiber. The electronic band gap of GQDs was tuned from ~ 2 eV to 3.5 eV to facilitate optimized light absorption and electronic transfer. The gas sensing performance of GQDs decorated In_2O_3 nanofiber was investigated with NO_2 gas under different light illumination (UV, violet, blue, green) at room temperature. Regardless of the GQD size, the GQD decoration improves NO_2 gas responses compared to bare In_2O_3. Notably, pristine In_2O_3 nanofibers exhibited their highest gas response under violet light. However, upon decoration with graphene quantum dots (GQDs), a notable shift in the activation wavelength toward a longer wavelength, specifically blue light. The most significant enhancement was observed with 5 nm-sized GQD under blue light, resulting in a remarkable 5-fold improvement in NO_2 gas response. This improvement can be attributed to the modulation of GQD electronic band gaps, enabling enhanced light absorption and suitable band alignment. In addition, the oxygen functional groups in GQDs can lower the adsorption energy of NO_2 gases, realizing selective gas responses to NO_2 gas. Our findings offer fundamental insights into the potential of graphene quantum dots as catalysts for high-performance light-activated gas sensors, paving the way for advancements in IoT applications with their low-power consumption and room-temperature operation.

Thermoelectric Structure-Property Relationship Establishment in $TlGaSe_2$TigranSimonian[1], AhinRoy[1], ZdenekSofer[2] and ValeriaNicolosi[1]; [1]Trinity College Dublin, Ireland; [2]University of Chemistry and Technology Prague, Czechia

Layered 2D materials are increasingly investigated for their often highly anisotropic properties, such as thermoelectricity. Such a property is useful in electronics, such as transistors and sensors, where wasted heat is not only economically and environmentally unsustainable, but can also be detrimental to device performance. It is repeatedly assumed that planar defects, such as stacking faults, affect the thermoelectric properties of these materials [1-2]. However, to date, no comprehensive study into establishing this relationship has been performed.
In this work, the ternary chalcogenide $TlGaSe_2$ serves as a prototypical example of this type of analysis. $TlGaSe_2$ is characterised via (scanning) transmission electron microscopy (STEM) and density functional theory (DFT) simulations. Streaking in selected area diffraction patterns are correlated to simulations which indicate the presence of stacking faults in the growth direction [3]. High resolution STEM confirms these stacking faults and indicates a lack of long-range order to the stacking. DFT calculations reveals a high preference for the system to include these faults. This is then coupled with phonon dispersion and electron transmission simulations to confirm their relationship to the thermoelectric properties of the material.

Extra Polarization-Engineered Power Generation of CNT/Halide Composite Nanofibers JuHan[1], Da BinKim[1,2] and Yong SooCho[1]; [1]Yonsei University, Korea (the Republic of); [2]University of Toronto, Canada

Diverse nanostructures have been widely applied for efficient energy generation in low-power consuming and self-powering devices. Herein, we explore the origin of bending-driven power generation in carbon nanotube (CNT)/halide/poly(vinylidene fluoride-trifluoroethylene) (P(VDF-TrFE)) nanofiber and their versatile applications in piezoelectric energy harvester, tactile sensor, and pressure sensor. Two effective fillers of inorganic halide perovskite $CsPbBr_3$ nanocrystals and CNT were incorporated in P(VDF-TrFE) matrix to demonstrate bending-driven energy harvesting performances and their ability to sense physiological signals from the human motions. Owing to the synergistic piezoelectric coupling between the fillers and the matrix, impressive harvesting outputs of ~15.9 V and 1,128 nA were achieved for the 0.3 wt.% CNT and 5 wt.% halide-incorporated samples, which are ~17.6 and 10.5 times better than the results achieved for the pure P(VDF-TrFE) nanofiber harvester. The values are also the best values reported using bending-driven operations. The origin of substantial enhancements in electromechanical energy generation under the bending motions is attributed to the extra dipolar polarization by embedded $CsPbBr_3$ and space-charge polarization by dispersed CNTs in contact with the piezoelectric polymer matrix. Wearable physiological and pressure sensors were successfully demonstrated to effectively sense the motions and convert them into electric signals. The optimal nanofiber sensors demonstrated a wide force detection range from 0.002N to 600 N, and superior reliability and repeatability for 20,000 cycles under the periodic mechanical deformation. Nanofiber composites-based pressure sensor was further applied in the pressure signal-mapping system, demonstrating its promising possibility in the self-powered

health monitoring system.

Conductive 2D Metal-Organic Frameworks for Chemical Sensor Applications Seon-JinChoi; Hanyang University, Korea (the Republic of)

Metal-organic frameworks (MOFs) are materials formed by the combination of metal nodes and organic linkers. They possess a large surface area and high porosity, making them promising materials for chemical sensing applications. Several MOFs have been synthesized and utilized as chemical sensing layers in combination with other sensing materials such as metal oxides, as demonstrated in our previous studies [1-4] However, intrinsic 3D MOFs typically exhibit insulating properties, which limits their application in electrochemical sensing materials. In contrast, electrically conductive 2D MOFs have recently gained attention for chemiresistive-type gas sensor applications. These materials possess intrinsic electrical conductivity and show redox-reactive properties with gaseous analytes.
The presentation will highlight recent progress in the development of conductive 2D MOFs and their application in chemiresistive-type gas sensors. Various electrically conductive 2D MOFs were prepared by combining metal nodes (Cu^{2+}, Ni^{2+}, and Co^{2+}) with an organic linker (hexahydroxytriphenylene, HHTP). The result showed that the 2D $Cu_3(HHTP)_2$ MOF film exhibited high sensitivity toward hydrogen sulfide and toluene at room temperature. To gain insights into the fundamental sensing mechanism, an in-situ spectroscopy analysis technique was established. This technique involved monitoring surface adsorbed species and by-products after chemical reactions using Raman spectroscopy and gas chromatography-mass spectroscopy (GC-MS), respectively. Through these investigations, a better understanding of the fundamental sensing mechanisms of 2D MOFs was obtained, paving the way for the development of high-performance chemical sensors for environmental monitoring and healthcare applications.

Hierarchical MoS_2@Au/N, S-Graphene Quantum Dots Tubular Nanostructure for Impedimetric Detection of C-Reactive Protein NareshK. Dega[1], AkhileshB. Ganganboina[2] and Ruey-AnDoong[1]; [1]National Tsing Hua University, Taiwan; [2]National Institute for Materials Science, Japan

Molybdenum disulfide (MoS_2), one of the most often used transitional metal dichalcogenides (TMDs), has gained increasing attention in various fields including sensors, lithium batteries, catalysts, and cancer therapy because of its high surface area, notable mechanical strength, efficient electron transport capabilities, and satisfactory chemical stability. However, the low conductivity of MoS_2 has limited its electrochemical applications. To address this limitation, the incorporation of metal nanoparticles or graphene-based nanomaterials has been commonly employed as a strategy to enhance the conductivity of MoS_2. Herein, a novel 1D hierarchical MoS_2 tubular structures (MoS_2 HT) doped with Au nanoparticles and N, S-coped graphene quantum dots (NSGQDs) was successfully fabricated as the sensing probe of immunosensor for impedimetric detection of C-reactive protein (CRP), a widely recognized serum biomarker used to evaluate the presence of acute inflammatory response in patients. Initially, MoS_2 HTs were synthesized by hydrothermal method, and then Au nanoparticles were formed homogeneously on MoS_2 HT in the presence of $HAuCl_4$ solution. After the deposition of 3-9 nm NSGQDs by Au-thiol linkage and drop-casting on the screen-printed electrode (Es), the Es||MoS_2@Au/NSGQDs served as a bifunctional probe to enhance the electrochemical performance by facilitating rapid electron transfer as well as to anchor the CRP-Ab for specific detection of CRP protein. The Es||MoS_2@Au/S, N-GQD immunosensor exhibits a wide linear range of 7 orders of magnitude for CRP detection, and the limit of detection can be lower to 0.04 pg/mL. Moreover, the immunosensor shows remarkable selectivity towards CRP detection over other biomarkers and biomolecules and superior reproducibility after long-term storage. The obtained results have demonstrated the superiority of the proposed Es||MoS_2@Au/NSGQDs impedimetric immunosensor for highly sensitive and selective detection of CRP. These findings highlight the potential fabrication of MoS_2 HT-based nanocomposites for high-performance electrochemical applications including electrochemical sensor and energy storage.

Magnetic Phase Transition and Magneto-Mechanical Coupling in Layered CrSBr Probed by Nano-Optomechanical Resonators FanFei[1], YuluMao[1], WenhaoLiu[2], BingLv[2], YingWang[1] and JunXiao[1]; [1]University of Wisconsin–Madison, United States; [2]The University of Texas at Dallas, United States

Recent progress in 2D magnetic materials represents an emerging research frontier. For example, various types of novel magnetic orderings at 2D limit have been discovered, including collinear ferromagnets/antiferromagnets, noncollinear spin textures, quantum spin liquid and magnetic topological insulators [1]. In addition, their spin excitations and the coupling with other quasiparticles are expected to be substantially enhanced due to the weak dielectric screening at the 2D limit [2,3]. In contrast to the abundant optical and electrical studies, the thermodynamic and mechanical properties for these rich quantum phases and unique coupling physics are important yet missing.
In this talk, I will present our study of the thermodynamic and mechanical properties in van der Waals magnets using nano-optomechanical resonators. In particular we have successfully developed nanoscale resonators based on target ultrathin magnetic membranes CrSBr, in which mechanical properties of the membrane can be electrically driven and sensed by precise optical interferometry. The nanomechanical response contains critical thermodynamic and information in magnetostriction in different spin orderings. Our work advances the understanding of magneto-mechanical coupling in 2D magnetic materials and enables new opportunities for coupling light, magnetism, and mechanics at the nanoscale.

Impact of Precursor Material on the Structural, Chemical and Gas Chemoresistive Properties of β-Ga_2O_3 Nanowires MarinaRojano-Mateos[1,1], AnnaEstany-Macià[1,1,2], GuillemDomènech-Gil[3], ElenaLopez-Aymerich[2], PaoloPellegrino[1], ChristopheSerre[1,1], MauricioMoreno-Sereno[1,1], JanRomano-deGea[4], IsabelGracia[5], CarlesCané[5] and AlbertRomano-Rodriguez[1,1]; [1]Universitat de Barcelona, Spain; [2]Danmark Technical University, Denmark; [3]Linköping University, Sweden; [4]Ecole Polytechnique Federale de Lausanne, Switzerland; [5]Consejo Superior de Investigaciones Científicas (CSIC), Spain

Gallium oxide (β-Ga_2O_3) is a wide band gap semiconductor material used in the fabrication of high power, high temperature and gas sensing devices. For its use as gas sensor, Ga_2O_3 in form of thin films has been demonstrated to be sensitive towards oxygen and reducing gases at temperatures above 600°C. To decrease the working temperature to bring sensors based on this material towards their compatibility with the Internet of Things (IoT), different innovations have been proposed, mainly based on surface functionalization, material doping or the increase of the surface-to-volume ratio using the nanowire (NW) morphology.
In this work we report the synthesis, characterisation and gas sensing behaviour of β-Ga_2O_3 NWs. These nanowires are fabricated via a metal-assisted vapour liquid solid (VLS) mechanism using either gallium metal evaporation or carbothermal reduction of Ga_2O_3 nanopowders and employing Au as seed for the growth. The NWs have been grown on oxidised silicon or on fused silica substrates. For their use as gas sensors, the NWs have been removed from the substrates where they grew and were transferred to substrates containing microelectrodes. In some cases, these are on placed on suspended microhotplates containing a buried heater. In this way, individual NWs have been contacted using Focused Electron (FEB) and Focused Ion Beam (FIB) Induced Deposition techniques, giving rise to resistors whose value changes in the presence of different gases, i.e., they are chemiresistors.
The grown NWs are monocrystalline and almost defect free, with a diameter of few tens of nm and lengths in the range of several tens of micrometre, which increases with evaporation time. The NWs grown by carbothermal reduction present, in addition, a carbon-containing shell, which is the result of the use of graphite. From the electrical point of view, this shell gives raise to an important reduction of the resistance of the resistor. The electrical properties of these chemoresistive gas sensors have been measured in the presence of different gases, which will be described.
The structural and chemical properties grown materials, their sensing behaviour and the differences among them will be discussed as a function of the fabrication routes employed.

4:15 PM EL07.15.10
Interfacial Engineering of Reduced Graphene Oxide Sensing Layer for Remote Floating-Gate FET Sensors WenZhuang[1,2], Hyun JuneJang[1,2], XiaoyuSui[1,2], ByunghoonRyu[2], YuqinWang[1,2], HaihuiPu[1,2] and JunhongChen[1,2]; [1]University of Chicago, United States; [2]Argonne National Laboratory, United States

With the increasing demand for field-deployable, sensitive, and low-cost sensors, nanomaterial-based field-effect transistor (FET) sensors have been widely studied over the past decades, due to the advantages in rapid response, lower detection limit, miniaturized sensor chip and direct digital readout. Two-dimensional (2D) materials such as reduced graphene oxide have gained the attention for FET sensors due to excellent mechanical, electrical and physiochemical properties, which enables extremely higher sensitivity and stronger selectivity to analytes compared to

bulk counterparts. Despite numerous demonstrations of high sensitivity given by 2D reduced graphene oxide (rGO) FET sensors, there is a lack of fundamental understanding of rGO interfaces, especially to improve sensing performance by engineering the rGO interfaces.
In rGO-based sensors, it has been challenging to characterize the intrinsic properties of solution interfaces due to a lack of reliable analytical tool. In our previous work, a remote floating-gate (RFG) structure proposed for a 2D rGO layer eliminates non-reliable behaviours of solution interfacial properties while remaining in a high surface-to-volume ratio at the sensing zone. To be specific, the RFG structure enables to avoid any undesirable effects from interface traps, defects, and redox reactions of 2D rGO sensing membrane, which produces a high yield of signal reproducibility and could serve as a potential analytical platform to study the rGO interfaces.
In this work, we investigated properties of rGO-based sensors that are prepared with self-assembled layers such as (3-Aminopropyl) trimethoxysilane (APTMS) and hexamethyldisilazane (HMDS) through measurements of pH sensitivity of such APTMS- and HMDS-treated rGO layers. For this analysis, we adopted the remote floating-gate FET (RFGFET) configuration which enables the characterization of intrinsic properties of solution-rGO interfaces only. The HMDS-treated surface induces more hydrophobicity on the interface and lowers pH sensitivity of rGO layers by reducing the number of oxygen functional groups. On the other hand, the APTMS-treated surface contains more rGO layers with enriched oxygen functional groups, which leads to higher pH sensitivity and hydrophilicity. Finally, we also characterized interfacial potentials of rGO layers modified by 1-pyrenebutyric acid N-hydroxysuccinimide ester (PBASE) linker molecules during functionalization process and monitored the surface charge density of the solution-rGO interface brought by PBASE functionalization. These results suggest useful interface-engineering strategies to tailor the sensing performance and functionalities of FET-based sensing devices, which holds great promise for developing advanced chemical and biological sensors.

Two-Terminal Floating-Gate Memristor Arrays for Neuromorphic Computing HongwoonYun and WoojongYu; Sungkyunkwan University, Korea (the Republic of)

As deep learning has rapidly advanced, it required significant amounts of computational load. Computers which designed based on von Neumann architecture are not suitable for deep learning, because they have limitations in computational speed due to bottlenecks and waste a large amount of energy. To address the energy and speed issue, in-memory computing based on memristor arrays is emerging as a new alternative.
In this study, we present two-terminal (Drain, Source) floating-gate memristor array using van der Waals layered materials. To significantly reduce the set, reset voltage compared to previous works [1,2], we formed a layer of gold nanoparticles between the tunneling insulator (Al_2O_3) and the floating-gate (graphene).
Using the change of the Fermi energy level (Ef) of graphene, our memristor, Au-nanoparticle TRAM (Tunneling Random Access Memory), exhibits memory characteristic. Our device shows high on/off ratio over than 10^6, retention more than 9 hours, multi-level retention of 2,500 seconds and robust endurance more than 80,000 times. Notably, our TRAM shows low cycle to cycle variability of C_v = 3.6% (n = 90, C_v = , = standard deviation, = mean value). Furthermore, non-linearity factor for long-term potentiation (LTP) ranges from 0.1 to 0.6 while for long-term depression (LTD), it ranges from 2.3 to 4.6 (n = 15), achieved through 100 potentiation (+4V, 0.5s) followed by 100 depression (-3V, 0.2s). A similar trend was shown even when the number of input pulses was changed (25, 50, 100, 150, 200 inputs for LTP, LTD).
With 400 input layers, 100 hidden layers, and 10 output layers of neural network, considering the non-linearity parameter, we were able to achieve an accuracy up to 89.56% in classifying handwritten digits of the MNIST database.

Tunable Electronic Structure in Carbon-Based Shwarzites under Mechanical Strain Paulo RodrigoE. Raulino and CristianoF. Woellner; Federal University of Parana, Brazil

The Schwarzites were proposed by Mackay and Terrones in the 90s, and are obtained by adding rings of carbon with more than eight atoms between hexagonal regions, producing structures with negative curvatures [1]. Since their proposal, several studies have been demonstrate its electronic, thermal, mechanic, and optical properties [2]. In this work, we explored the variation of the electronic behavior of some members of the P-family Schwarzites under mechanical stress/strain. We used Density Functional Theory (DFT) and Density Functional based on Tight-binding (DFTB) computationally implemented via CASTEP and DFTB+ softwares. The P8-0 Schwarzite has semimetal behavior with two Dirac cones on the first Brillouin zone [2]. After applying the mechanical stress/strain, the Dirac cones merge into a single cone with parabolic dispersion. Under approximately 18% of stress/strain, the bands separate, forming a finite bandgap between the bands, which causes the structure to behave like a semiconductor. The P8-1 structure presenting a semiconductor behavior, we notice a significant reduction of the bandgap energy between conduct and valence bands [2]. We demonstrate that it is possible to change the electronic behavior of these structures under mechanical stress and strain. Breaking the crystal symmetry allow the production of the piezoelectricity effect from a centrosymmetric structure. This effect implies a separation of the positive and negative charges in the crystal, creating polarized charges or dipole [3]. Piezoelectricity has many applications in medical and microelectronic devices, resonators and sensors [3].

Acknowledgments: We thank the Physics Department at Federal University of Parana for computational and financial support. We also thank CNPq for the financial support.

High Thermal-Conductive Packaging Composites Based on Uniform Dispersion of 2D Materials Chia-LienChao[1], Yu-ChiaoChang[1], Rong-TengLin[1], Yun-HongYang[1], Bi-XianWu[1], Kuan-YunChi[2] and Tzu-HsuanChang[1,2]; [1]Graduate Institute of Electronics Engineering, National Taiwan University, Taipei, Taiwan, R. O. C., Taiwan; [2]Graduate School of Advanced Technology, National Taiwan University, Taipei, Taiwan, R. O. C., Taiwan

The scaling of integrated circuits (IC) has posed significant challenges, particularly when aiming for nanometer-level scales capable of accommodating billions of transistors. To keep up with Moore's Law, IC industry has shifted towards developing three-dimensional integration (3DICs). The use of 3D packaging technology has allowed chips to incorporate numerous additional functionalities. While the calculation capability increased substantially by dielet stacking, power density per area increased as well. In this way, the design of 3DIC has intensified the research focus on thermal management. While heat dissipation is managed through metals in the TSV design of 3DIC, the additional supporting approaches of thermal dissipation capability by IC packaging remain unsolved. Conventional packaging materials have shown poor thermal conductivity, typically ranging from only 1 to 2 W/mK for decades, despite having maximum contact area with the stacked dielets. Consequently, it is crucial to develop innovative strategies to tackle these problems, potentially utilizing packaging materials with high thermal conductivity. While commercially available packaging materials like polymer and epoxy are lightweight, inexpensive, and easy to process, they suffer from low thermal conductivity properties. This is primarily because conventional techniques are unable to address the issue of percolation, where the stuffed and isolated ceramic particles blended that were used to enhance the thermal conductivity can not form the continuous phonon conductive path. In this study, we have successfully tackled this issue by dispensing 2D materials as the filler of packaging materials to develop novel composites with high thermal conductivity. The filler incorporates graphene, which exhibits excellent thermal conductivity, weaves continuous networks inside the epoxy, and forms thermal conductive network. To maintain the structural integrity and successful dispersion of the graphene, cellulose nanofibers (CNF) with 1D structures were used. The resulting graphene/CNF structures can form continuous heat dissipation network. Through the blending of the graphene/CNF filler, the thermal conductivity of the polymer, polypropylene, can be increased by 270 times, rising from 0.2 W/mK to 54 W/mK, and epoxy can be increased by 66 times, rising from 0.14 W/mK to 9.35 W/mK. While keeping the superior high thermal conductivity, our composite still maintains low leakage that shows a promising candidate for the next generation packaging materials.

8:15 AM EL07.16.04
Insights from Ab-Initio Simulations on the Working Mechanism of Single-Layer MoS_2 Memristors GabrieleBoschetto[1], StefaniaCarapezzi[1,2] and AidaTodri-Sanial[3,1]; [1]LIRMM, France; [2]Silvaco Europe, France; [3]Eindhoven University of Technology, Netherlands

Memristors are promising building blocks for important technological applications such as high-density memory, data encryption and neuromorphic computing. In this context, 2D memristors based on atomically thin single-layer molybdenum disulfide (MoS_2) are particularly interesting due to their extremely compact size and low-power operation [1,2].
Although few notable examples of working devices based on monolayer MoS_2 have been already reported in the literature, their working mechanism is still far from being understood, the main challenge being the great variability in terms of device architecture and quality of MoS_2 film. Nevertheless, regardless of the device architecture, intrinsic defects in MoS_2 are thought to be crucial for the functionality of memristors: for instance, S vacancies are highly abundant in CVD-MoS_2 and may impact non-trivially the properties at the interface with the metal contact, such as the contact resistance [3]. Moreover, in vertical Au/MoS_2/Au memristors it has been argued that the resistive switching mechanism may be due to the migration of metal atoms from the electrode to fill such S vacancies in MoS_2 [4].
Here, we focus on such a device architecture and we carry out atomistic computer simulations in the framework of density functional theory (DFT). We employ surface calculations based on the Green's function formalism [5] to construct realistic interfaces and to compute relevant properties at the interface between MoS_2 and Au electrode. To elucidate the working mechanism of MoS_2 memristors, we consider defective MoS_2 either with S vacancies or with Au substitution (adatoms). Then, we investigate the effect of defect concentration and defect clustering on the physics and chemistry of MoS_2 interfaces. By exploring several possible case scenarios, we were able not only to better understand the pivotal role of the extra Au atoms for the resistive switch mechanism of MoS_2 memristors, but also to provide the theoretical justification on experimental findings.

A Preliminary Study on Implementation of Five-Qubit Quantum Information Processing in Silicon Devices JungheeRyu and HoonRyu; Korea Institute of Science and Technology Information, Korea (the Republic of)

INTRODUCTION
An electrode-driven Silicon (Si) quantum dot (QD) system can be adopted to design scalable quantum processors with well-established industrial fabrication technologies [*Nat. Electron.* **5**, 184 (2022)]. Recently, there have been experimental efforts to understand the physics of electron-spin qubits in Si QD systems whose confinement is manipulated with human controls, including a successful implementation of entangling logic operations up to six qubits [*Nature* **609**, 919 (2022)]. Device designs & control engineering of physical systems consisting of many QDs, however, are still critical issues that must be uncovered with computational modeling to secure the scalability of quantum processors. Here we study the control engineering needed to initialize the linear five QD (FQD) system in Si and show the initialized spin states can be controlled to produce the magic state, one of quantum resource for realization of fault-tolerant quantum computing [*Nature* **510**, 351 (2014)].

METHODS
Device simulations are conducted for the realistically sized Si FQD system with our multi-scale modeling approach integrating the bulk physics & the parabolic effective mass approximation. Qubits are encoded to electron spins that are created with quantum confinement driven by gate biases imposed on top electrodes. A static magnetic field is applied with a lateral gradient to make the Zeeman-splitting energies of electron ground states distinguishable. Once a set of five Zeeman-splitting energies and exchange interactions between nearest QDs is obtained from device simulations, the time-response of spin qubits is obtained from solutions of a time-dependent Schrödinger equation that is described with the Heisenberg spin Hamiltonian.

RESULTS AND DISCUSSION
We rigorously explored appropriate sets of biases imposed on the top electrodes, with which the FQD can be stably created satisfying the symmetric-biasing condition. Figuring out the bias condition that fills a single electron to each QD (qubit initialization), we engineered the sizes of nine electrodes to calibrate the distance between nearest electron spins to ~100nm. When the system is initialized, the five Zeeman-splitting energies come clearly distinguishable, and the four exchange interactions between nearest electron spins turn out to be weak enough to guarantee the individual address of five qubits. Then, as an application example, we show how a specific type of 5-qubit magic states can be prepared in the Si FQD platform, where we also present the detailed guideline of controls required to implement the non-Clifford *T*-gate and the Hadamard gate that are essential to generate the magic state. Robustness of the secured 5-qubit circuit (and so the magic state) to charge noise is also confirmed by simulation results that are obtained with unintentional random fluctuations in exchange energies.

Theoretical Exploration of Two-Dimensional Electrenes for Low-Resistance Metal-2D Semiconductor Contacts MohammadRafiee Diznab, ErinR. Johnson and JesseMaassen; Dalhousie University, Canada

Transition-metal dichalcogenides (TMDCs), including MoS_2, have great potential in electronic applications. However, achieving low-resistance metal contacts is a challenge that impacts their performance in nanodevices, due to strong Fermi level pinning and the presence of a tunnelling barrier. As a solution, we explore a strategy utilizing two-dimensional (2D) alkaline-earth subpnictide electrenes with a general formula of M_2X (M = Ca, Sr, Ba; X = N, P, As, Sb) as an intermediate material between the 2D TMDC and metal. Electrenes possess one excess electron per formula unit resulting in the formation of 2D sheets of charge on their surfaces. This charge can be readily donated when interfaced with a TMDC semiconductor, thereby lowering its conduction band below the Fermi level and eliminating Schottky and tunnelling barriers. Density-functional theory calculations were performed on metal-electrene-MoS_2 heterojunctions for all stable M_2X electrenes, and both Cu and Au metals. To identify the material combinations that provide the most effective Ohmic contact the charge transfer, band structure and electrostatic potential, among other quantities, were analyzed. In all cases, a linear correlation was found between the charge donated to the MoS_2 and the electrene surface charge. The electride Ca_2N is found to be most promising for achieving an Ohmic metal-MoS_2 contact, due to its high surface charge density.

This research was supported by SRC.

Doping-Controlled WSe_2/MoS_2 Lateral Heterostructure for High-Performance Photodetection Sung HyunKim and WoojongYu; Sungkyunkwan University, Korea (the Republic of)

A two-dimensional material having an atomic thickness has an advantage in miniaturization of next-generation sensors. Some transition metal dichalgogenide (TMD) materials with semiconducting properties exhibit high light absorption in addition to their thin thickness. However, the optical properties of the current 2D heterostructure are dependent on the inherent properties of the material, and as a way to solve this, it is possible to improve it by forming an ideal PN diode by using the doping control of the 2D heterostructure. To confirm this, we fabricated a WSe_2(Nb-doped)/MoS_2 PN heterostructure photodetector and confirmed its characteristics.
In our experiment, ammonium metatungstate (AMT) hydrate and ammonium niobium oxalate (ANO) ($C_4H_4NNbO_9{*}xH_2O$) were used as precursors of W and Nb, and sodium hydroxide (NaOH) was used as a promoter to increase the growth rate. Stock solutions of AMT, ANO, and NaOH were obtained by dissolving the calculated amount of powder in DI water. Medium solution (iodixanol)-Opti was used to improve adhesion to the substrate during the spin coating process. Various mixed solutions (AMT, ANO, NaOH and opti) with different molar ratios of Nb/(W+Nb) were prepared from stock solutions. MoS_2 growth is similar to WSe_2 growth. Our device exhibits a high Ilight / Idark ratio (10^5), which is about 100 times higher than the reported lateral 2D PN heterostructured photodiodes. These excellent performances indicate that the doping-controlled transition metal dichalcogenide PN heterostructure is a promising candidate for optoelectronic engineering.

Integrating 2D Materials in Silicon Microchips MarioLanza; King Abdullah University of Science and Technology, Saudi Arabia

Two-dimensional layered materials (2D-LMs) materials have outstanding physical, chemical and thermal properties that make them attractive for the fabrication of solid-state micro/nano-electronic devices and circuits. However, synthesizing high-quality 2D-LMs at the wafer scale is difficult, and integrating them in semiconductor production lines brings associated multiple challenges. Nevertheless, in the past few years substantial progress has been achieved and leading companies like TSMC, Samsung and IMEC have started to work more intensively on the fabrication of devices using 2D-LMs. In this talk, I will discuss the state-of-the-art on micro/nano-electronic devices made (entirely or partially) of 2D-LMs, the most sophisticated circuits ever constructed, and the fabrication of CMOS/2D hybrid microchips. I will put special emphasis on devices that employ hexagonal boron nitride, the only 2D-LM with an enough high band gap to be employed as dielectric. I will also discuss the main technological challenges to face in the next years and provide some recommendations on how to solve them.

Room Temperature Photoluminescence Mediated by Sulfur Vacancies in 2D Molybdenum Disulfide ManishChhowalla; University of Cambridge, United Kingdom

Atomic defects in monolayer transition metal dichalcogenides (TMDs) such as chalcogen vacancies significantly affect their properties. In this work, we provide a reproducible and facile strategy to rationally induce chalcogen vacancies in monolayer MoS_2 by annealing at 600 °C in argon/hydrogen (95%/5%) atmosphere. Synchrotron X-ray photoemission spectroscopy shows that a Mo $3d_{5/2}$ core peak at 230.1 eV emerges in the annealed MoS_2 associated with non-stoichiometric MoS_x ($0<x<2$), and Raman spectroscopy shows an enhancement of the ~380 cm^{-1} peak that is attributed to sulfur vacancies. At sulfur vacancy densities of ~2.4×10^{14} cm^{-2}, we observe a defect peak at ~1.72 eV (referred to as LX_D) at room temperature in the photoluminescence (PL) spectra. The LX_D peak is attributed to excitons trapped at defect-induced in-gap states and is typically observed only at low temperatures (≤77 K). Time-resolved PL measurements reveal that the lifetime of defect-mediated LX_D emission is longer than band edge excitons, both at room and low temperatures (~2.77 ns at 8 K). The LX_D peak can be suppressed by annealing the defective MoS_2 in sulfur vapor, which indicates that it is possible to passivate the vacancies. Our results provide insights into how excitonic and defect-mediated PL emission in MoS_2 are influenced by sulfur vacancies at room and low temperatures.

Atomically Thin SnO-Based *p*-Channel Thin-Film Transistor and Low-Power Complementary InverterChi-HsinHuang[1], YalunTang[2], Tzu-YiYang[3], Yu-LunChueh[3] and KenjiNomura[2,2]; [1]University of California, San Diego, United States; [2]University of California San Diego, United States; [3]National Tsing Hua University, Taiwan

Atomically thin oxide semiconductors play a crucial role in the development of next-generation, cost-effective, and energy-efficient electronics. In this study, we successfully developed a high-performance, fully depleted-type *p*-channel oxide thin-film transistor (TFT) utilizing an atomically thin *p*-type tin monoxide (SnO) channel with a thickness of approximately 1 nm. The SnO channel was grown using a vacuum-free, solvent-free, metal-liquid printing process at a remarkably low temperature of 250°C in an ambient atmosphere.
To enhance the performance of the *p*-channel SnO TFTs, we employed oxygen vacancy defect terminations for both the bulk-channel and back-channel of the SnO channel. As a result, the presented *p*-channel SnO TFTs exhibited favorable characteristics, including a reasonable TFT mobility of ~0.47 $cm^2V^{-1}s^{-1}$, a high on/off current ratio of ~10^6, a low-off current (<10^{12}A), and a subthreshold swing of ~2.5 V $decade^{-1}$, which was improved compared to the conventional *p*-channel SnO TFTs. Furthermore, we successfully developed a low-power oxide-TFT-based complementary metal-oxide-semiconductor (CMOS) inverter using the ultrathin *p*-SnO and *n*-In_2O_3 TFTs. The CMOS inverter demonstrated a high voltage gain of approximately 120 and achieved low-power operation, consuming less than 58 nW, for the *p*-SnO/*n*-In_2O_3-TFT-based CMOS inverter.
This work highlights the significant potential of oxide-TFT-based CMOS logic development by leveraging atomically thin oxide material channels. It offers new opportunities for next-generation, energy-efficient, and cost-effective oxide TFT technology, with the added benefits of vacuum-free, solvent-free, and low-temperature processing techniques.

Nanophotonic Force Nanoscopy for Ultrafast Dynamic Imaging of Nanostructures YangZhao; University of Illinois Urbana-Champaign, United States

Light and plasmonic nanoparticle interaction creates many physical effects, including the generation of non-equilibrium charge carriers, enhanced electromagnetic near-field, and photothermal effect. Particularly, the plasmonic photothermal effect, given by the optical absorption induced by surface plasmons, is well studied because of its broad applications. The plasmonic photothermal effect has been associated with fields as diverse as near-field optics, cell biology, drug delivery, cancer therapy, chemical reactions, nanofabrication, biomedical imaging, sensing, and so on. The photothermal effect of nanoparticles has been characterized by various tools and techniques. For example, photothermal dynamics of nanoparticles have been observed with optical microscopy using the pump and probe approaches but are diffraction limited. At the single particle level, electron microscopy can assess the nanoparticle's morphology, surface potential, and phase transformations, and cathodoluminescence has been used for probing the thermal profiles of nanowires. However, these methods based on electron microscopy require a vacuum environment and a conductive substrate. The measured thermal profiles oftentimes do not represent the nanoparticles in an ambient condition because the thermal properties of nanoparticles are highly associated with the environment. Moreover, because of the slow scanning speed of the electron beam, the dynamical evolution of the thermal profile due to non-stationary heat transfer is unmeasurable. On the other hand, nanoscopic thermal profiles have been measured using micromechanical probes, where the near-field energy extinction and the thermal relaxation govern the thermal field and heat flow. The thermal expansion triggered by a modulated laser resonantly drives a micromechanical cantilever, through which one can assess the thermal profile of nanoparticles in situ. However, the dynamic information can be lost due to the relatively slow response of the cantilever. Although improved mechanical designs of the scanner have enabled a high-speed atomic force microscope (Hs-AFM) that can reach up to 1300 frames per second, a single image -frame still takes hundreds of microseconds, significantly longer than the thermal relaxation time of nanoparticles, which is in the nanosecond regime.

In this talk, I will introduce an ultrafast visualization of dynamic heat transfer in the nanosecond temporal regime with a spatial resolution of around 10 nm. We show the heating and cooling stages of a single gold nanoparticle using nearfield optical force imaging, termed decoupled optical force nanoscopy (Dofn). Our technique, different from conventional near-field scanning

optical microscopy, probes optical forces originating from the interactions between the illuminated nanoparticle and the probe.

10:30 AM EL08.01.02
Boosting the Efficiency of Passive Upconversion Imaging using Engineered Nanostructures RabeeyaHamid[1], DemengFeng[1], EmmaBelliveau[2], ManchenHu[2], PournimaNarayanan[2], ChenghaoWan[2], JustinEdwards[1], DanielCongreve[2] and MikhailKats[1]; [1]University of Wisconsin-Madison, United States; [2]Stanford University, United States

Most existing technologies to enable vision in the near infrared (NIR) region rely on cameras, displays, and other powered optoelectronics. These devices capture NIR images and convert them to the visible. In contrast, we are working on a passive frequency-upconversion imaging system that directly converts NIR light to visible light, thereby eliminating the need for external power sources or electronic components. We use a photon upconversion process that involves a sequential transfer of energy from two low-energy incident photons, resulting in the emission of a higher-energy photon via triplet-triplet annihilation [1], enabling solid-state upconverting thin films [2]. However, the previously demonstrated efficiency of this upconversion process is not sufficient for passive night-vision imaging systems.
We designed and demonstrated several types of nanostructures that enhance the absorption, emission, and collection efficiencies of upconverting films, with the ultimate goal of enabling a wearable, all-passive, NIR-to-visible imaging system.
In our design, the upconverting material is a 100-nm thick bulk heterojunction comprising organic molecules Y6 (sensitizer) and rubrene (emitter; here, doped with DBP [2]), similar to the materials in the bilayer structure in ref. [3]. Our bulk heterojunction passively converts incident NIR light to orange light with peak emission at ~600 nm; however, the emission is incoherent and isotropic. To enable imaging, the directionality of rays needs to be preserved through the upconversion process. We address this issue by positioning the upconverter at the focal plane of a Keplerian telescope system, a strategy that we previously demonstrated for a down-conversion imaging system [4].
To enhance light extraction while operating in transmission mode, we developed a dichroic substrate that reflects visible light while transmitting NIR light, which allows us to recover visible light otherwise emitted backwards towards the source. To further improve the efficiency of the upconverter, we designed a superstrate that is transparent in the visible range but reflects in the NIR, enabling the recycling of unabsorbed NIR light back into the upconverting film, thereby enhancing the absorption and the subsequent emission.
We designed the multilayer substrates and superstrates such that they provide a consistent spectral response across a broad range of viewing angles (here, up to 30 degrees) for the desired wavelengths (500 – 650 nm in the visible, and 750 – 900 nm in the NIR). This functionality was implemented using niobium pentoxide (Nb_2O_5) and silicon dioxide (SiO_2) layers. To maintain our imaging resolution, we limited the total thickness of the combined structure to 2 microns, thus ensuring that we remain within the depth of focus of our imaging system.
Our approach has yielded an approximately 2-fold enhancement in collection efficiency and a 2.5-fold increase in absorption. As of this writing, we have verified the collection-efficiency enhancement in experiments using both a laser source (at 852 nm) and a broadband NIR source. We anticipate presenting the absorption-enhancement data at the conference.
In addition to power measurements, we have demonstrated imaging through the upconverter with the engineered substrate, observing an approximate doubling in brightness without compromising spatial resolution. We anticipate that our approach will be useful for a variety of incoherent upconverting schemes beyond the all-organic chemistry presented here (e.g., those based on inorganic nanocrystals [2, 4]) and can enable all-passive vision even under low-power NIR illumination and longer wavelengths.

10:45 AM EL08.01.03
Optical Loss Measurements of Silicon-Nitride Membranes using Photothermal Common-Path Interferometry TanujKumar[1], DemengFeng[1], ShenweiYin[1], PhyoLin[2], MerlinMah[2], MargaretFortman[1], GabrielJaffe[1], ChenghaoWan[1], ChengyuFang[1], RonaldWarzoha[3], VictorBrar[1], JosephTalghader[2] and MikhailKats[1]; [1]University of Wisconsin–Madison, United States; [2]University of Minnesota Twin Cities, United States; [3]U.S. Naval Academy, United States

Materials that feature low optical loss and relatively high refractive index are important for applications such as on-chip photonics[1], free-space optics for sensitive experiments like LIGO[2,3] and, more recently, laser-driven light sails comprising thin membrane-like structures that efficiently reflect a high-power drive laser[4]. We have been investigating stoichiometric silicon nitride (Si_3N_4) membranes as a candidate material for such laser-light sails, due to its [a] low loss in the near infrared, [b] a moderately high refractive index (~2), [c] a large bandgap (~4.5 eV) that prevents two-photon absorption[5,6], and [d] vibrational resonances in the mid infrared that can enable radiative cooling[7]. To our knowledge, the optical absorption of Si_3N_4 membranes has not been directly measured.

We used photothermal commonpath interferometry (PCI)[8], a sensitive pump-probe technique, to measure the absorption of Si_3N_4 membranes in the near infrared. We characterized membranes because they are the closest form factor to laser sails, and conventional techniques such as variable-angle spectroscopic ellipsometry are not sensitive enough to measure optical absorption in such thin low-loss membranes. PCI characterizes optical loss in a material by measuring the effect of the sample's absorption of a chopped pump beam on a probe beam via the thermo-optic effect. The amount of modulation in the probe beam carries information about the sample's absorptivity at the pump wavelength.

Translation of the PCI signal to the actual absorption value depends on the sample geometry and material properties, including the thermo-optic coefficient and thermal conductance of the sample. The translation is most-easily done using a reference similar to the sample in terms of optical and thermal properties, except with a higher, known absorbance. Here, we transferred a monolayer of graphene onto the SiN membranes we want to measure. Because it is thin and grown by chemical vapor deposition, the graphene does not significantly affect the overall thermal conductance of the sample; however, the presence of graphene increases the optical absorption from the ppm level to the ~1% level (the latter easily measurable using ellipsometry or reflection/transmission spectroscopy), and thus the resulting graphene/SiN structure can be used as a reference for PCI measurements of the SiN alone. To our knowledge, this technique of using a highly absorbing monolayer as a reference for PCI measurements has not been proposed or demonstrated previously.

Using graphene-referenced PCI, we found the absorption coefficient of stoichiometric Si_3N_4 to be ~1.3 x 10^{-2} cm^{-1} and that of non-stoichiometric SiN_x (x~1) to be ~6.7 cm^{-1}. These values of absorption are close to those reported in literature for waveguides.[1,3] Based on our measurements, stoichiometric Si_3N_4 is indeed a promising candidate for laser-light sails and other applications where low optical absorption is required.

Hybrid Plasmonic-Dielectric Geometric Metasurfaces for Emission Control and Chiral Sensing Wen-Hui (Sophia)Cheng, Yu-ChiaWang and Si-ChenLi; National Cheng Kung University, Taiwan

Metasurface has advanced the field of optics for the past decade thanks to the great turnability with multiple degree of freedom. By coupling the geometric plasmonic metasurfaces with the dielectric Si cavity mode, the direction and polarization of photon emission can be controlled. The hybrid structure with desired configuration presents the highest electric field and the best cross-polarization conversion efficiency while maintaining the Purcell factor. The Pancharatnam-Berry (PB) phase construction to manipulate the emission wavefront of both dipole emitter and chiral emitter is successfully demonstrated with simulation. The enantiomeric interaction between circular polarized light and the chiral molecule offers the significant feature for sensing application. To increase the selectivity for real-time chiral sensing, we employ the P-B phase antenna with silicon disk metamaterials. The improvement of Circular Dichroism (CD) measurement is also realized with the L-glucose and D-glucose.

Properties and Control of Excitons in 2D Semiconductor Heterostructures TonyF. Heinz[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

In this paper we will describe some of our recent progress in understanding fundamental aspects of excitons in 2D heterostructures in the transition metal dichalcogenide (TMDC) family. For many of these systems, type II band alignment is obtained in stacked layers, causing the lowest-lying optical excited state to be an interlayer exciton. Because of the static dipole moment of these charge-separated states, they are highly tunable by external electric fields, making them interesting sources with readily tunable photon energy by gating available in the visible and infrared spectral ranges. In addition, for crystallographically aligned samples, the moiré potential leads to distinctive exciton localization effects. We will present recent advances in characterizing these states, both through direct optical absorption measurements and through the use of time-resolved, angle-resolve photoemission spectroscopy (tr-ARPES). These methods give us new insight into the radiative lifetime of these states and the degree and nature of exciton localization in moiré structures. In addition to their intrinsic interest, the ability to transfer

Paradigms for Realizing Symmetry-Guaranteed Paris of Bound States in the Continuum and Identifying Super-Mossian Materials ChloeF. Doiron; Sandia National Laboratories, United States

Over the last decade, all-dielectric metasurfaces have emerged as a powerful platform for enhancing light-matter interactions, enabling device performance improvements across a range of applications. To increase light-matter interactions, photonic states with long lifetimes (high-quality factors) are desirable, requiring improvements in photonic designs, material quality, and fabrication tolerances. In this talk, I will present one structural design paradigm and one material search heuristic for improving all-dielectric metasurfaces.

Bound states in the continuum are states that are completely decoupled from a continuum leading to infinitely long lifetimes. In practice, while states with infinitely long lifetimes are undesirable, they enable a design paradigm that solves the photonic design component leaving material quality and fabrication tolerances as the primary means to achieve arbitrary lifetimes. Demonstrations using bound states in the continuum have enabled improvements for lasers, sensors, and frequency mixers. However, many applications require degenerate or nearly degenerate high-quality factor (Q) states, such as spontaneous parametric down conversion, non-linear four-wave mixing, and intra-cavity difference frequency mixing for terahertz generation. I will present a group theory approach based on lattices with six-fold rotational symmetry for creating symmetry-guaranteed pairs of bound states in the continuum. Using this design paradigm, the splitting and Q-factors can be independently and robustly controlled creating new pathways for improving metasurfaces for frequency conversion, heralded single-photon production, and sensing.

Finally, I will discuss a search heuristic for materials with refractive indices that surpass the common form of the Moss rule ($n^4E_g \approx 95$ eV) leading to the creation of super-Mossian materials. With this heuristic, I will present an experimental realization of a super-Mossian metasurface using iron pyrite (FeS_2), with refractive index greater than 4.37 and a bandgap of 1.03 eV, surpassing the common for of the Moss rule by nearly 40%.

Understanding the Origins of Low-Frequency Instability in Thin-Film Lithium Niobate Nanophotonic Devices DavidR. Barton[1], MatthewYeh[1], GavinSmith[2], EvelynHu[1] and MarkoLoncar[1]; [1]Harvard University, United States; [2]University of New Hampshire, United States

Thin-film lithium niobate on insulator (TFLN) is a promising platform for integrated classical and quantum photonics due to its intrinsically large electro-optic effect and wafer-scale availability. The direct connection between driving electric fields and refractive index in this platform has enabled new schemes for creating pulsed lasers on chip, high-bandwidth and energy-efficient modulators, and devices for integrated nonlinear photonics. However, it is generally recognized that the reliability of thin-film lithium niobate modulators is subject to unstable electro-optic response at low frequencies, and undesired photorefractive index changes due to defect absorption at high optical powers. Post-processing methods such as annealing have been developed to reduce these deleterious effects, but their microscopic origins remain unclear. It is also not known if these effects relate to fundamental materials issues, might be exacerbated for materials in thin-film form with possible strain inhomogeneities, and indeed might arise from thin-film preparation, which involves ion implantation, and chemical-mechanical polishing.

Here, we use a combination of materials characterization (XPS, Atom Probe Tomography, and electronic transport) and optical device characterization to explore the structure-device-processing parameter space in integrated lithium niobate devices and attempt to identify a mechanistic insight for low-frequency instability in our devices. All our devices are fabricated on 600 nm thick x-cut Lithium Niobate on insulator wafers, and we explore fabrication processes that impact both the bulk and interfaces in our devices. First, we show through XPS that the etch conditions and standard acid cleans used in our thin-film processing dramatically impact the surface by removing lithium from the surface, locally reducing Nb^{5+} to Nb^{4+}, and creating a damaged amorphous Lithium Niobate layer. Specific chemical cleans remove the damaged layer, while annealing at moderate temperatures in an oxygen environment restores the surface Li:Nb ratio to its unprocessed status. We gained additional insight by using APT to map out the material composition in 3D with ~nm-scale resolution. Surprisingly, we find that the lithium composition within the unprocessed material varies substantially over length scales on the order of 10 nanometers, suggesting that local defect structures such as the small polaron may exist in appreciable concentrations that could give rise to photorefraction. Annealing our samples temporarily increases quality factors and reduces photorefraction, indicating that diffusion of mobile species such as Lithium or Hydrogen may indeed play a role in long-term stability of our devices.

Finally, we find that the metal-Lithium Niobate interface is important for the low-frequency response of our devices. Etching through the oxide cladding in our structures dramatically improves the electro-optic response but leaves behind an amorphous lithium niobate interface for the electrical contacts. Surprisingly, any attempts to remove redeposition or clean the surface semiconductor-metal interface reduces the low-frequency response and degrades the response flatness. Together, these results point to the important of surface and bulk conductivity within our electro-optic devices for stable low-frequency tuning, a requirement for deployable devices and systems in thin-film Lithium Niobate.

To Be, or Not to Be: Labeled and Label-Free Raman Based Pathogen Detection in Water and Clinical Samples LozaTadesse[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Ragon Institute, United States

Raman spectroscopy promises a rapid and acciurate pathogen detection alternative compared to complex and tedious culture dependant alternatives. Although spontaneous Raman measurments could provide enough signal for detection, some applications such where a hand full of pathogen are present compared to liters of surrounding sample volume, may require specific labeling and isolation of cells. In this talk, I will discuss how the limits of Raman spectroscopy for biosensing can be pushed further in its resolution by demonstrating ~98% accurate classification of presence of anti-TB drug resistance using spontaneous Raman to expansion in its sample volume reach by demonstratig rapid magnetic isolation and detection of hand full of pathogenic bacteria from water and food contaminants using polymer coated magnetic beads as Raman reporters. We also demonstrate detection on home built hand held Raman systems for ease of deployment to clinical end users. Lastly, I will cover new teritories Raman spectroscopy can serve in next gemeratopm disease theraputics. Clinical and field translation of Raman based cell detection calls for careful analysis of the application at hand as either labeled or label free alternatives would best serve the target.

Plasmonic Ammonia Synthesis with a AuRu Bimetallic Alloy LinYuan, BrileyBourgeois, AlanX. Dai, PeiwenRen, FelipeJornada and JenniferA. Dionne; Stanford University, United States

The Haber-Bosch process has had a significant impact on global food production, enabling ammonia synthesis for nearly all agricultural fertilizers. However, ammonia production generally requires high operating temperatures (exceeding 300 °C) and high pressures (100 atm), leading to over 3% of annual global greenhouse gas emissions. To promote sustainable chemistry, ammonia synthesis must be accomplished under milder conditions while also eliminating the greenhouse gas footprint. In this presentation, we describe bimetallic plasmonic nanoparticles that enable high-efficiency and sustainable nitrogen fixation at room temperature and pressure. We utilize AuRu metallic nanoparticles, where Au serves as the plasmonic optical absorber, and Ru

acts as the catalyst for nitrogen bond-breaking. We develop a colloidal synthesis to create AuRu nanoparticles with controlled phases, including the fcc phase and hcp phase. We vary the Au and Ru composition from 1:0.1 to 1:0.3. We then load the nanoparticles onto a commercial MgO substrate at 5% mass-loading. Using UV-Vis spectroscopy, the nanoparticles show strong optical absorption at wavelengths of 520 nm. We use our bench-scale photoreactor to characterize the ammonia synthesis($N_2+3H_2 \rightarrow NH_3$), using nitrogen and hydrogen as a feeding gas, at various temperatures, pressures, and under various illumination conditions. Our observations indicate an ammonia rate of 60 μmol/g/h under 100 mW/cm^2 visible light irradiation, and a 0.12% external quantum efficiency on our fcc $AuRu_{0.2}$ catalyst. By correlating the wavelength-dependent reactivity and electromagnetic hot carrier calculations, we have identified the potential contributions from phonon-assisted intraband and interband transitions in driving the photochemical transformation. Our study provides a solution for designing photocatalysts to drive nitrogen fixation under mild conditions and an understanding of the mechanisms that can inform future applications.

Single Particle Plasmonic Nanocativy-Based Strong Coupling with Intrananogap Nanostructure KyungwhaChung[1,2], SoohyunLee[2], NathanGrain[3], SubinYu[1], SeokhyoungKim[3], Sung HoPark[2] and LukeLee[1,2]; [1]Harvard University, United States; [2]Sungkyunkwan University, Korea (the Republic of); [3]Michigan State University, United States

Achieving strong coupling in practical applications of cavity quantum electrodynamics (CQED) often poses significant challenges due to the delicate conditions required. In particular, the realization of strong coupling with single nanoparticles has been predominantly demonstrated using J-aggregate dye molecules. In this work, we present a novel CQED probe capable of transforming a nanocavity within a single nanoparticle. Our approach utilizes a plasmonic CQED structure based on a gold double nanoring (Au DNR) that incorporates an intraparticle nanogap. Through dark-field measurements on individual particles, we observe the emergence of exciton-plasmon polaritons, known as plexcitons, evidenced by the bifurcation of the scattering peak into two distinct resonances. Finite-element modeling is employed to elucidate the correlation between the Au DNR morphology and the cavity resonance wavelength relative to the exciton absorption, while temporal coupled-mode theory quantifies the strength of coupling. Verification of plexciton states is accomplished through photoluminescence measurements, which demonstrate light emission from the lower plexciton state. The proposed CQED nanocavity serves as a promising nanoprobe for the detection of small molecules within cells and offers a platform for groundbreaking biomolecular studies.

4:00 PM EL08.02.07
Crystalline AuNP with Strain-Controlled Morphologies and Optical Properties QiaomuYao and PeterK. Petrov; Imperial College London, United Kingdom

Metallic nanoparticles (NP) decorated with thin films have been extensively studied and exhibit promising performance in a wide range of applications, including biosensing, electrical devices, photocatalysis, and solar cells. For perovskite thin films, the decoration can produce an enhanced plasmonic response, which indicates a promising future in nano-waveguides, energy harvesting, and chemical sensing applications. The morphologies and chemistries of NPs strongly govern plasmonic performance. The size and density of AuNPs dramatically influence the absorption, surface plasmonic resonance peak intensity, and the second harmonic generation responses. It also alters the so-called epsilon-near-zero (ENZ) effects, where the interplay between real and imaginary parts of permittivity results in the strong enhancement and local confinement of the normal field inside ENZ materials.
Here we present a study of the formation of gold nanoparticles (AuNP) grown by PLD onto perovskite strontium niobate (SNO) thin films deposited on both MgO and $SrTiO_3$ substrates. The strain-free SNO_3 (a = 4.023 Å) has a -3.0% lattice mismatch with the STO (a = 3.905 Å) and 4.5% with MgO (a = 4.212 Å) which leads to compressive and tensile in-plane residual strains, respectively. We observed that the formation of Au NPs and their morphology depends on the structure of the underlying SNO film. It conveys the surface structure and controls nanoparticle formation. The morphologies of AuNPs were measured using SEM and AFM. The residual strain in the SNO thin films and AuNPs was evaluated by X-ray diffraction (XRD). Finally, the complex permittivity of AuNP-decorated SNO films was measured using Variable Angle Spectroscopic Ellipsometry (VASE).
In summary, AuNP-decorated SNO/MgO and SNO/STO thin films exhibit different optical properties with only gold-decorated SNO/MgO samples showing nano particles' size-dependent epsilon-near-zero behaviour. These results provide an additional route to control the structure of AuNPs. They can be used for the design and development of strain-engineered gold nanoparticle decorated devices for surface-enhanced Raman spectroscopy (SERS) and photocatalysis.

4:15 PM EL08.02.08
Scalable Plasmonic Superstructures for Colorful Dichroism Jang-HwanHan, JuhwanKim, GyurinKim, Hyun MinKim and Hyeon-HoJeong; Gwangju Institute of Science and Technology (GIST), Korea (the Republic of)

Flat optics based on metasurfaces has emerged as a promising approach to achieve compact and efficient optical systems.[1,2] However, the development of optical color filters using single or multilayered thin film resonators or reflectors has received less attention, although their structural thickness still needs to exceed at least a quarter of a wavelength, resulting in bulky optical system.
Herein, we present scalable plasmonic superstructures comprising randomly but uniformly distributed metallic nanoparticles embedded within a glass matrix. These superstructures are fabricated using a metal-dielectric co-deposition method with substrate cooling, allowing for precise control over the sizes, densities, and materials of the plasmonic nanoparticles in the form of wafer-scale nanocomposite film. Crucially, we introduce 'scattering-free' plasmonic resonators with diameters below 10 nm,[3] so the reflected colors from these superstructures can be engineered primarily based on the film thickness, covering a wide range from ultraviolet to near-infrared regions, analogous to the conventional dielectric thin film reflectors. In contrast, the transmitted colors through the same structures exhibit weak dependence on the film thickness, but give rise to the vibrant colors due to strong plasmonic absorptions. This unique property of the plasmonic superstructure films enables independent engineering of reflected and transmitted colors by controlling their thickness and materials, thus demonstrating applications such as dichroic imaging and encryption systems.
In this presentation, the design rule, fabrication method, and optical features of the plasmonic superstructures will be discussed. Especially, we will demonstrate how to achieve full colors in both the reflection and transmission modes, featuring their potential for colorful imaging applications.

4:30 PM EL08.02.09
Simulation and Fabrication of Tunable Metal-Insulator-Metal Bow-Tie Antenna Arrays for Surface Enhanced Raman ScatteringSümeyraVural Kaymaz[1,2], HasanSarigül[2], CanerSoylukan[2], SelimTanriseven[2], HasanKurt[3] and MeralYuce[2]; [1]Sabanci University, Turkey; [2]SUNUM Nanotechnology Research and Application Center, Sabanci University, Turkey; [3]Imperial College London, United Kingdom

Surface plasmons in metal/dielectric interfaces provide significant levels of electric field enhancements in the subwavelength resolution, enabling a wide range of applications. One such application is surface-enhanced Raman scattering (SERS), a powerful analytical method for label-free molecular fingerprinting of various analytes. A careful design and nanofabrication of SERS substrates with a considerable Raman enhancement factor (EF) at the wavelength of interest are imperative for SERS applications. SERS substrates based on noble metal colloids, roughened nanosurfaces, nanospheres, and nanotips have been previously reported. Nevertheless, the low reproducibility of electric field hot spots has limited the utilization of these inherently random structures with high EF. The period arrays of plasmonic nanostructures offer the potential for generating reproducible SERS substrates. Specifically, metal-insulator-metal (MIM) based nanostructures exhibit substantial gap resonance due to the coupling of localized fields between two metal layers underlying the dielectric layer. By adjusting the geometric parameters of metal nanostructures and dielectric layer thickness, gap resonance can be tuned for application-specific requirements. In this work, we investigated the performance of gold (Au) bow-tie antenna arrays on insulator-metal substrates for SERS applications. The Finite-difference time-domain (FDTD) method was used to simulate the effects of parameters such as bow-tie apex angle, gap size, length, and dielectric layer thickness. We achieved an electric field enhancement of up to 630 times the incoming electric field intensity, corresponding to a SERS EF factor improvement of ~3.9×10^5 in our final optimized design at an excitation wavelength of 785 nm. Later, we fabricated Au MIM bow-tie antenna arrays using electron beam lithography and investigated their optical characteristics with an in-house modular reflection/transmission-based Microspectroscopy system.

4:45 PM EL08.02.10
Electro-Optical Chromophores and Polymers for Short NIR-Wavelengths – Materials to Application FlorensR. Kurth[1,2], Sophie-LuiseHachmeister[1], LiZhao[1,2], Anna K.Rüsseler[3,2], Jonas N.Matthes[3], TasjaSchwenke[4,2], OnsAmira[4], EmilAgocs[1,2], MarcoJupé[3,2], Hans-HermannJohannes[1,2], HenningMenzel[4,2] and WolfgangKowalsky[1,2]; [1]TU Braunschweig, Bienroder Weg 94, Germany; [2]Leibniz University Hannover, Welfengarten 1a, Germany; [3]Laser Zentrum Hannover e.V., Hollerithallee 8, Germany; [4]TU Braunschweig, Hagenring 30, Germany

The development of photonics in communication and sensing, particularly in integrated circuits, relies heavily on functional optical materials. These materials play a central role in converting external impulses into optical signals and vice versa. Examples include piezo-optic, elasto-optic, magneto-optic, acousto-optic, and electro-optic materials, which find applications in modulators, sensing resonators, and beam steering devices.
In the field of electro-optics (EO), traditionally dominated by periodically poled LiNbO3, there is an ongoing demand for alternative materials with distinct properties to cater to specialized applications. Organic electro-optic chromophores, as part of composite polymer materials, exhibit the Pockels effect. This effect occurs when electrons move along the molecular axis within a donor-acceptor structure in response to external stimuli in an electric field. These chromophores can be easily integrated into waveguides using common spin-coating and molding techniques, offering convenient fabrication.
This work specializes on the 980 nm wavelength at the short end of the NIR spectrum. The active component of such materials are electro optical (EO) chromophores, which are integrated in a suitable host polymer, mostly amorphous polycarbonate (APC) and methacrylate polymers/copolymers and are electropoled to achieve the parallel orientation necessary for a strong electro-optic effect. A range of chromophores has previously been synthesized, guided by DFT calculations, with consideration on high-dipole moments μ, good hyperpolarizability β, optical

transmission in the desired spectral window and shielded side-groups that improve electropoling quality due to decreased intermolecular interactions. These materials also exhibit strong solvatochromism with differences in absorption maxima ranging between 60 nm and 90 nm depending on solvent polarity. The materials are characterized regarding their optical and materials property, specifically the electro-optical coefficient r_{33}, which is measured using Teng-Man ellipsometry.
These materials have been successfully used in electro-optical Fabry-Pérot switches in a cooperation with the Laser Zentrum Hannover e.V. to translate an electrical field-shift into a transmission wavelength shift of up to 20 nm with the desired application of miniaturized optical switches.
With the transition from materials research towards device applications, long-term stability has come into focus. Different polymer host-materials and covalently integrated chromophore polymer composite materials have been exposed to high-temperature aging experiments to compare their ability to maintain the parallel chromophore orientation that was obtained during the electropoling step.

SESSION EL08.03: Advanced Nanophotonic Materials and Devices

Low-Cost and Scalable Manufacturing of Optical Metasurfaces in the Visible using Engineered Optical Materials (PER, Low-Loss a-Si:H, and Hybrid ALD Structural Resin) JunsukRho; Pohang University of Science and Technology, Korea (the Republic of)

Here, we demonstrate low-cost, scalable manufacturing of optical metasurfaces with three approaches: 1) increasing a refractive index of resin with dielectric particle embedding for single-step nanoimprinting, 2) suppressing optical losses of hydrogenated amorphous silicon (a-Si:H) to apply complementary-metal-oxide-semiconductor technologies, and 3) high-index atomic layer deposited (ALD) structural resin. We demonstrate the effectiveness of these materials in creating optical metasurfaces operating at different wavelengths in the infrared, visible, and ultraviolet spectra. Firstly, we achieve high efficiencies of up to 90.6%, 47%, and 60% with a-Si, TiO_2, and ZrO_2 PER at wavelengths of 940, 532, and 325 nm, respectively. Furthermore, we obtain a measured efficiency of 30% at a wavelength of 248 nm using ZrO_2 PER metasurfaces. Secondly, by adjusting the deposition conditions of plasma-enhanced chemical vapor deposition, we engineer the bandgap of a-Si:H to enable low-loss operation, with minimum extinction coefficients as low as 0.082 at 450 nm. Using low-loss a-Si:H, we demonstrate efficient beam-steering metasurfaces with measured efficiencies of 42%, 65%, and 75% at 450, 532, and 635 nm, respectively, marking the first Si-typed metasurfaces working at the full visible. Finally, we manufacture highly efficient metalenses using hybrid ALD structural resin with deep-ultraviolet lithography at visible wavelengths. Their measured efficiencies approach 60.9%, 77.8%, and 64.8% at 450, 532 and 635 nm, making them suitable for ultrathin virtual reality devices. Our approaches using PER, low-loss a-Si:H, and hybrid ALD structural resin enables the low-cost, large-area manufacturing of efficient optical metasurfaces across different wavelengths, facilitating the commercialization of metasurface-based photonic devices.

11:00 AM EL08.03.02
3D Interior Plasmonic Nanocavities for Sensitive and Selective Recognition of Hazardous Substances in Plastic Products Sung-GyuPark; Korea Institute of Materials Science, Korea (the Republic of)

Surface-enhanced Raman scattering (SERS) utilizing plasmonic nanomaterials and nanostructured substrates has been extensively investigated to directly recognize substances because the energy differences between the incident and scattered lights correspond to the molecular vibrational energy states of the substances. SERS performance is dominantly derived from electric fields confined in dielectric media, called hotspots, between adjacent plasmonic nanostructures. Recently, the 3D interior hotspots templated with dielectric media surrounded by plasmonic materials have attracted great attention [1]. Various electrochemical techniques such as catalytic reaction, electrodeposition, and galvanic reaction (GR) have been exploited to realize the 3D interior hotspots. Particularly, a GR process spontaneously originates from energy differences in the reduction potential of two or more materials [2]. An imbalanced atomic exchange strategically defines narrow hollow regions which have dual functions of electric field confinement domains and molecular diffusion paths. For deeper comprehension of interior hotspots, the Ag nanocavities galvanically replaced by Au (Au/AgNC) on the silicon substrates were prepared. The proposed Au/AgNC platforms were used to trace hazardous substances such as phthalates. The activation of interior hotspots with superior density in a unit volume enabled reliable sensing operations at ppb levels. From the collected dataset, a machine-learning model was designed to predict various combinations (i.e., single, binary, ternary, and quaternary) of four major phthalates. Subtle differences in the phthalates' spectral characteristics were successfully classified using a machine learning algorithm based on a principal component analysis–linear discriminant analysis model.

11:15 AM EL08.03.03
Multifractal Photonic Membranes for Random Lasing Devices TornikeShubitidze, YilinZhu and LucaDal Negro; Boston University, United States

Random lasers are at the center of an intense research activity due to their ease of fabrication and robustness combined with small-size (micron-scale) of the order of the lasing wavelength as well as their unique characteristics that include low-spatial coherence, lack of directionality, and bio-compatibility. In particular, non-resonant random laser devices rely on uncorrelated random fluctuations of the dielectric environment that give rise to traditional photon diffusion. On the other hand, anomalous light transport phenomena with significantly slower dynamics, or sub-diffusive transport, occur in engineered random media with correlated disorder, providing opportunities to further enhance optical amplification and reduce device footprints. In this talk, we present our work on the design and fabrication of active photonic membranes with multifractal structural correlations and we characterize their optical emission properties using leaky-mode and photoluminescence spectroscopy.
Photonic multifractals are heterogeneous optical media with complex spatial fluctuations at multiple length scales characterized by a rich spectrum of local scaling exponents, i.e., a multifractal spectrum. Differently from well-known fractal structures, which possess only one global scaling quantified by a single fractal dimension, multifractals feature a continuous distribution of generalized fractal dimensions and can be considered as "intertwined sets" of self-similar structures. While the optical properties of fractal structures are well-understood, photon transport and light emission in multifractals remain fundamentally open problems. Here, we discuss photonic structures with tailored multi-scale correlations generated by iterative and multiplicative cascades of random fields. Localization and transport properties are explored and optimized using rigorous multi-particle Mie theory in combination with efficient tight-binding models. Based on this approach, using electron beam lithography and high-quality deep reactive ion etching, we demonstrate multifractal nano-hole arrays in both passive (a-Si:H, Si_3N_4) and active (ZnO) photonic membrane geometries. We report on the characterization of the optical and structural properties of each membrane structure with variable angle spectroscopic ellipsometry (VASE), photoluminescence spectroscopy, x-ray diffraction measurements, scanning electron microscope imaging(SEM) and atomic force microscopy.

11:30 AM EL08.03.04
Eu,O-Codoped GaN-Based High-*Q* Two-Dimensional Photonic Crystal Cabvities in the Red RegionTakenroiIwaya[1], ShuheiIchikawa[1,2], DolfTimmerman[1], JunTatebayashi[1] and YasufumiFujiwara[1]; [1]Osaka University, Japan; [2]Research Center for Ultra-High Voltage Electron Microscopy, Osaka University, Japan

Eu,O-codoped GaN (GaN:Eu,O) is an efficient red light emitting material based on the GaN platform. We have demonstrated red light-emitting diodes using GaN:Eu,O grown by organometallic vapor phase epitaxy method and reported a high light output power of 1.25 mW at 20 mA operation with a maximum external quantum efficiency over 9% [1,2]. Furthermore, we have shown that GaN:Eu,O has a moderate value of gain of 6.6 cm^{-1} [3]. This observation suggests the possibility to develop a novel GaN:Eu,O-based red laser diodes (LDs). The emission wavelength from Eu^{3+} ions is highly stable with respect to the surroundings, thus GaN:Eu,O-based red LDs have a large potential applications including high-resolution laser displays and optical communications. In this contribution, we designed and fabricated an optical cavity with a high *Q*-factor in the red region, which is required for the realization of a laser based on this material [4].
Although two-dimensional photonic crystal (2D-PhC) cavities are prominent candidates to achieve high *Q*-factors, they typically show relatively low *Q*-factors (< 5000) due to structural disorder that is inevitably introduced during the fabrication stages [5]. From an extensive analysis of the influence of such disorder for various cavity designs, we have shown that especially H3-type cavities are much less sensitive to optical losses, when compared to linear (L*N*) cavities [4]. We have fabricated H3-type cavities and demonstrated a highest value of *Q* of 7900. This value is much higher than previously reported *Q*-factors (~5500) of III-nitride-based 2D-PhC cavities in the visible range, and approaches the theoretical *Q*-factor of this cavity design. These results demonstrate that H3-type cavities can indeed effectively suppress the disorder-induced optical losses, and that a further improvement of the design is required with a higher

theoretical *Q*-factor, in order to achieve higher experimental values.
We propose a 2D-heterostructure with core, trans and clad region. By designing the radii as $r_{core} > r_{trans} > r_{outer}$, the photonic band structure is modified and light at the photonic band-edge is well confined in the core region. For the optimal design parameters, a theoretical value of the *Q*-factor of 1.1×10^5 was obtained.
The fabricated structure of this design shows a few resonant modes, with the mode with the largest *Q*-factor reaching a value of $Q = 10500$ [6], which is almost twice that of previously reported values. Thus, we conclude that this type of III-nitride-based 2D-PhC cavity is effective for confining light, and has a great promise for obtaining ultrahigh *Q*-factors in the visible region. This study shows the guideline to achieve high *Q*-factors with III-nitride-based 2D-PhC cavities in the red region, which would open up a larger potential application.

11:45 AM EL08.03.05

Gate-Tunable Optical Anisotropy in Wafer-Scale, Aligned Carbon Nanotube Films JasonLynch[1], Evan SmithSmith[2], AdamAlfieri[1], BaokunSong[1,3], Cindy YueliChen[1], ChavezLawrence[1], CherieR. Kagan[1], HonggangGu[3], ShiyuanLiu[3], Lian-MaoPeng[4], ShivashankarVangala[2], JoshuaHendrickson[2] and DeepM. Jariwala[1]; [1]University of Pennsylvania, United States; [2]Air Force Research Laboratory, United States; [3]Huazhong University of Science & Technology, China; [4]Peking University, China

Modern telecommunications and polarimetry systems require active control of the polarization of light. This is currently done by either combining an intrinsically anisotropic material with a tunable isotropic one in a heterostructure or by nano-patterning a tunable material to give it optical anisotropy. Both of these processes complicate the fabrication process of real-world devices. Although materials that are both highly anisotropic and highly tunable can actively control the polarization of light on their own, materials that possess both properties are scarce and rarely available in high-quality thin films over wafer scales. Here, we present optical anisotropy and gate-tunability in semiconducting, highly-aligned, single-walled carbon nanotubes (SWCNTs) over 4” wafers in the visible and near infrared (IR) regimes. SWCNTs were found to have a normalized birefringence value of up to 0.09 in the near IR which is larger than common anisotropic crystals such as liquid crystals (0.06), calcite (0.05), and $LiNbO_3$ (0.02). The optical selection rules of SWCNTs result in a large optical band gap difference in the ordinary and extraordinary directions of 210 meV enabling its normalized dichroism to reach 0.58 which is only exceeded bulky, unstable crystals. SWCNTs were found to have record normalized birefringence and dichroism values for thin films (< 4 nm thick). Additionally, the optical properties of SWCNTs can be modulated using carrier injection to induce the plasma dispersion effect. The real and imaginary parts of the extraordinary refractive index were tuned by 5.9% and 14.3% in the near infrared at 2200 nm and 1660 nm, respectively. This outperforms popular semiconductors for near IR telecommunications systems such as Si, $LiNbO_3$, and graphene. Highly-aligned SWCNTs are among the most optically anisotropic and tunable materials and promise to open new avenues for their application in integrated photonics and telecommunications.

Characterization of Iridium Films for Emerging Optical Applications ZacharyKranefeld, PanMenasuta, KevinGrossklaus, JohnMcElearney and ThomasVandervelde; Tufts University, United States

Iridium (Ir) is a refractory metal with optical properties that make it an excellent candidate for a wide range of optical applications, including metamaterials; such as, selective-emitters for thermophotovoltaic (TPV) cells. Metamaterial applications require patterning with nanofabrication techniques, but these processes are still relatively unexplored for Ir films. In this work, various density Ir films were characterized throughout wet and dry etch fabrication processes. Electrical properties were measured as a function of film thickness via 4-point probe. Complex refractive index (n and k) was measured with variable angle spectroscopic ellipsometry (VASE) and reported as a function of film thickness and density. Surface morphology was determined by AFM and SEM, as a function of etch depth. Additionally, well-defined etch rates as well as etchant selectivity are reported for each etch recipe.

8:00 PM EL08.05.02

Hydrogen-Free PVD SiN for Low-Losses 300 Mm Photonics Waveguides EleonoraGaroni[1], LauraSauze[2], QuentinWilmart[1], Lavinia E.Nistor[2], DominiqueCerqueira[2], AhmedGharbi[1], VincentMathieu[1], TristanDewolf[1], ChristopheLecouvey[1], RémiCoquand[1] and GuillaumeRodriguez[1]; [1]University Grenoble Alpes, CEA, LETI, France; [2]Applied Materials France Sarl, France

Silicon nitride (SiN) has recently become a particularly successful material for integrated photonics platforms. Its use as an optical waveguide has been reported for a wide range of applications: LiDAR, microwave optics, quantum photonics, neuromorphic computing, telecommunication and sensors. Indeed, SiN can be a possible substitute of silicon waveguides for applications requiring ultra-low optical losses, thermal stability or in wavelength regimes where silicon is non-transparent (<1.1µm). It can also be integrated in a silicon photonic platform to combine the properties of both materials. [[1]]
In addition, SiN photonics offers a good level of versatility depending on the integration constraints and the targeted application. However, the combination of low deposition temperature and low optical losses is still elusive. In particular, the presence of hydrogen in SiN film deposited by chemical vapor deposition (CVD) causes optical absorption in the C-band. [[2]]
Contrarily to CVD, physical vapor deposition (PVD) technique for SiN film growth has two main advantages: the ability to deposit a hydrogen-free film and a low deposition temperature. Intuitively, propagation losses in the near-infrared region are expected to be low. On the other hand, PVD SiN can be highly stressed, which can be detrimental for integration. [[3]]
In this work, the process, characterization and integration in devices for waveguides applications of a PVD-deposited SiN thin film will be discussed.
The films were prepared by magnetron reactive pulsed-DC sputtering on 300 mm silicon wafers at low temperature (200°C) in an Ar/N_2 gas mixture. Deposited film thicknesses were in the range from 400 nm to 800 nm.
By tuning the Ar/N_2 gas ratio, we managed to obtain a film with refractive indexes corresponding to the targeted stoichiometric Si_3N_4, also confirmed by RBS-NRA measurements.
The film stress was found to be compressive and can be tuned close to zero by increasing the power and the pressure in the deposition chamber. The gas ratio and pressure conditions needed to achieve lower stress also give a film with optical properties adapted for the waveguides applications specifications.
In-film particles are detrimental for waveguides performances, since they can increase scattering phenomena and thus enhance waveguide losses. We managed to minimize in-film particles by improving the deposition sequence, succeeding in keeping low values even for 800 nm thick films.
FTIR analysis allowed to assess the absence of N-H and Si-H absorption bands, visible between 1150 cm^{-1} and 3500 cm^{-1} in CVD deposited SiN films to which PVD SiN was compared, confirming that the latter is hydrogen-free.
In a second time, waveguides integration will be discussed. SiN deposited by PVD is known to be rougher than CVD SiN: the waveguides side roughness can be improved thanks to lithography and etching optimization. Side roughness values comparable to CVD were obtained, for the same film thickness and design.
Finally, we will present some optical results including propagation losses in the C-band for three PVD-deposited SiN film thicknesses (400 nm, 600 nm, 800 nm) on a 300 mm photonic platform. PVD SiN waveguides outperform CVD SiN waveguides in the C-band where the presence of hydrogen in the SiN film is critical for optical losses.

Omni-Directional Improvement for Organic Solar Cells by Quasi-Random Nanostructures DevinKrystek, SeokhunLee and HuiZhao; University of Nevada, Las Vegas, United States

Organic solar cells provide many hopes for the future: potential for mass manufacturing, cheap materials, flexible substrates. However, they also pose many problems that have yet to be solved, namely relatively low efficiency and instability. This work attempts to improve the efficiency of organic solar cells by using a quasi-random nanostructured active layer. While many methods exist for manufacturing nanostructures, we utilize a soft lithography approach using Digital Video Disks (DVDs) as molds. DVDs provide a low cost, programmable alternative to conventional manufacturing methods, which aligns with the goals and prospects of organic solar cells. Previous papers have explored this DVD soft lithography method, but we propose further improvements by using the optimized quasi-random sequence into the DVD before the soft lithography process. The optimized quasi-random structure increases the local surface randomness thus increasing the light trapping properties of the active layer. Additionally, the tiered structures generated by DVD nanoimprinting reduce reflectance at higher angles of incidence, leading to improved performance at all angles.

8:00 PM EL08.05.04
Enhancing the Electrical and Optical Properties of Thermochromic VO_2: The Impact of Nanostructuring and Gold Nanoparticles GregorySavorianakis[1], StephanosKonstantinidis[1], MichelVoué[1], BjornMaes[1], NicolasMartin[2], CedricRousseau[1] and GillesRosolen[1]; [1]UMONS, Belgium; [2]Femto-ST, France

Monoclinic VO_2 (m-VO_2) exhibits a Metal-Insulator Transition (MIT) at around 67°C, earning it the label of a thermochromic material. In this study, we show how to optimize the magnetron sputtering process using a vanadium target in an Ar/O_2 mixture to synthesize 200 nm thick films composed of m-VO_2 crystals. Our synthesis method involves regulating the oxygen flow rate and annealing the samples for 120 minutes at 500 °C in an O_2 environment, as confirmed by Raman spectra and XRD.
In the second part of our study, we validate the numerical results obtained using the Cavity Modelling Framework (CAMFR) by comparing them to the optical properties of the synthesized films. Through simulations, we demonstrate the ability to improve the properties of the films for use as smart windows by tuning the nanostructures of a VO_2 nano-ribbons configuration. By adjusting the width, periodicity, and thickness of the nano-ribbons, we can achieve improved energy efficiency and a less opaque appearance which means it's a stronger contender, when compared to a dense film of the same thickness, for smart windows application.
In the final part of our research, we experimentally combine dense m-VO2 films with gold nanoparticles (AuNPs) to achieve a tunable plasmonic signal based on temperature changes. We demonstrate the use of (3-aminopropyl) trimethoxysilane (APTMS) linkers for grafting AuNPs onto the surface of VO_2 films. By optimizing the protocol, we can obtain a well-spread monolayer of NPs without clustering. From the absorption spectra, we observe a 10nm shift in the plasmonic peak wavelength as a function of temperature. Furthermore, resistivity and optical hysteresis measurements reveal that AuNPs amplify by one order of magnitude the resistivity drop and by 15% the transmission drop, as well as decreasing the critical temperature by 5°C and narrowing the hysteresis width. Additionally, by depositing a second m-VO_2 layer above the AuNPs, we created another hybrid platform, which lead to even greater improvements in resistivity and transmission modulation compared to bare m-VO_2. Hall measurements were performed on these hybrid platforms, revealing the important role played by AuNPs in improving carrier density. About the plasmonic wavelength shift according to the temperature, it reaches now a value of 60 nm. This second platform have been simulated as well in order to optimize the plasmonic shift by varying the NPs size and their coverage. Here again, an optimized plasmonic wavelength shift of 130 nm is obtained for a coverage around 60%.
The here-mentioned work may pave the way towards the elaboration of thin film materials with high optical accordability which can potentially be used in applications as color display, protection against counterfeiting and opto-electronics chips.

Improvement of Light Extraction Efficiency and Viewing Angle Characteristics of Organic and Quantum Dot Light Emitting Diodes with Spontaneously Formed Buckling Patterns of Soft Materials Yoon-JeongChoi, Jeong-YeolYoo and Byung DooChin; Dankook University, Korea (the Republic of)

There exist a lot of technologies for a light extraction (LE) of organic light emitting diodes (OLEDs). However, for the successful commercial application, the restriction on the cost of manufacturing, directionality of color, and the requirement to maintain a high-quality image are severe for devices with LE structure. Insertion of scattering medium in the OLED with microcavity (mostly popular for commercial panels) can be generally effective but reduces the function of polarization, which blocks the reflection from the external light. Recovering of the lost power from surface plasmon (SP) is also effective strategy for an enhancement of LE, and a method of grating coupling by a generation of corrugate the organic/metal interface causes Bragg scattering. Several kinds of periodically corrugated or “buckled” patterns were proposed, showing a reduction of light loss (LE effect) by a scattering of SPs [1,2].
In this work, simple fabrication processes for the micro-scale LE pattern formation is introduced. For a top-emitting OLED (TOLED), a useful platform of commercial panels for high-resolution mobile on the non-transparent polymeric substrates, colors and spectra are significantly sensitive to those specific LE structures and intrinsic micro-cavity effects of TOLED having translucent electrodes. Here, a quasi-periodic and controllable buckling patterns with broad size/scale distribution are described in detail [3,4]. The formation of buckling patterns is spontaneously driven by the mismatch of thermal expansion coefficient of the stacked organic and polymeric layers, which are easily deposited by a simple deposition process in the vacuum or solution coating environment on top of the translucent cathode of TOLED structure. Further experimental studies on the effect of molecular weight, glass transition temperature with segmental softness/rigidity, and phase separation behavior of material combination will be presented for the understanding of the mechanism of quasi-periodic 3-dimentional buckling structure formation. As for OLED and QD-LED performance with buckling LE structure, luminous efficiency of device with buckling patterns in a various position of device was characterized. The results on the microcavity-driven, top-emitting type OLED showed the improvement of the luminous efficiency of phosphorescent device (68 cd/A) more than 40% of the pattern-less control devices (47 cd/A). Such a result, observed in case of optimum buckling structure formed on top of the translucent electrode of device, can be explained by the suppression of light loss by the SP mode at semi-transparent metal/air interface without losing the control of polarization of light. Moreover, the shift of the maximum peak of electroluminescence for buckling patterned device was less than 4nm with the viewing angle range of 0 to 75 degree (>20nm shift for control device), securing a negligible change of the spectral characteristics and color stability (robust viewing angle behavior) [5]. Our corrugated pattern structure was also successfully applied to the electroluminescent quantum dot (QD) device, where the intrinsic pure and saturated emission colors and narrow FWHM (full width at half maximum) could be further improved.

Flexible Route to AuNP-Cluster Arrays for Plasmonic Sensing PooriaGolvari[1], TyroneMorales[1], StephenM. Kuebler[1,1,1] and JimmyTouma[2]; [1]University of Central Florida, United States; [2]Air Force Research Laboratory, United States

Periodic assemblies of gold-nanoparticle (AuNP) clusters are attractive as tunable substrates for surface-enhanced Raman spectroscopy (SERS)[1], as well as analyte sensors based on coupled localized surface plasmon resonance (LSPR)[2] and diffractively-coupled plasmonic surface lattice resonances (SLR)[3, 4]. We report an approach for fabricating two-dimensional lattices selectively filled with mono- or multi-layers of AuNP films. The lattices are prepared using e-beam lithography and then transferring the pattern into fused silica by reactive ion etching. Centrifuge-aided deposition assisted by a protein binder is then used to load dense mono- and multi-layers of AuNPs into the silica arrays, in one tenth of the time required for immersion methods. Post-assembly cross-linking of the binder prior to drying the AuNP film is used to control the spacing between the deposited layers and to tune the LSPR coupling. Masking and lift-off can be used to selectively deposit AuNP-clusters inside the prepatterned arrays. The AuNP-filled arrays are optically characterized in reflection and transmission modes in the visible and near-infrared. The method provides a means for independently controlling properties of the AuNP-clusters (e.g., size and interparticle spacing) and properties of the lattice (e.g., symmetry, the size, the depth, and periodicity). As such, the method should be useful for preparing sensors based on hybrid-LSPR with controlled coupling between AuNPs and SLR modes.

Hot-Carrier Multi-Junction Solar Cells: The Best of Both Worlds MaximeGiteau[1,2], SamyAlmosny[1,3], Jean-FrançoisGuillemoles[1,4] and DanielSuchet[1,4]; [1]NextPV, CNRS, The University of Tokyo, Japan; [2]ICFO, Spain; [3]Saule Technologies, Poland; [4]CNRS, Ecole Polytechnique, ENSCP, Institut Photovoltaique d’Ile de France (IPVF), UMR, France

Conventional single-junction solar cells are limited in power conversion efficiency at around 33% (Shockley-Queisser limit) due to the mismatch between the broadband solar spectrum and the fixed bandgap of the cell. Multijunction solar cells (MJSCs) can overcome this limit by combining multiple subcells with decreasing bandgaps, allowing them to extract more energy per

photon. These are the most efficient cells manufactured today, but they remain expensive and offer limited material combinations. An alternative approach is the hot-carrier solar cell (HCSC), which converts the extra kinetic energy of the (hot) carriers into electricity before it is dissipated by interaction with the lattice, in a process called thermalization. However, despite significant progress, thermalization rates remain too fast for hot-carrier devices to operate efficiently as solar cells. In essence, the main issue is that HCSCs should be ultrathin to significantly reduce thermalization, while nonetheless absorbing most of the incident illumination (optically thick).
To alleviate this issue, we introduce the hot-carrier multi-junction solar cell (HCMJSC) concept [1,2], a 2-junction MJSC in which the top subcell is an HCSC. With this configuration, photons not absorbed in the ultrathin hot-carrier subcell can be harvested by the bottom subcell, thereby not sacrificing absorption. As a result, HCMJSCs make it much easier to benefit from hot-carrier effects than HCSCs, leading to large efficiency gains for realistic thermalization rates. HCMJSCs also offer a significant advantage over MJSCs: the efficiency shows little dependence on the bandgap of the subcells. As a result, HCMJSCs can be designed for whatever bandgap combination is most practically achievable, which is especially relevant for lattice-matched III-V multi-junction devices. We will highlight some promising material combinations, including double homo-junction configurations, in which both subcells use the same material. After illustrating the advantages of HCMJSCs over both MJSCs and HCSCs, we will look at their resilience under operation conditions, focusing on the influence of the cell temperature and variations in the illumination spectra [3].

Gap-Plasmon Crystallography PeeranuchPoungsripong, VyshnavKannampalli, LionelSantinacci, DominiqueChatain, OlivierMargeat and BeniaminoSciacca; Aix-Marseille Université, France

Plasmonic nanocavities have the ability to confine light in extremely small volumes, enhancing the electromagnetic field and providing a highly sensitive and reproducible platform. Using plasmonic nanocrystals, this tunability is achieved by adjusting the nanoparticle size, the gap spacing, and the gap spacer refractive index. These phenomena are receiving increasing attention by the nanophotonics and nanoelectronics communities due to their potential applications in optoelectronics, quantum optics, and novel nanophotonic and plasmonic-circuit devices. In this study, we investigated gap plasmon resonators made of silver nanocubes separated from a gold mirror by thin dielectric layers (Al2O3, TiO2). First, we studied the impact of dielectric thickness, refractive index and nanocube size on individual resonators, supported by correlative SEM microscopy. This enabled us to gain insights on the system sensitivity to various parameters. Next, we show that this platform can be used to assess the removal of residual capping ligands (such as PVP) on the nanocube surface, which hampers use in nanoelectronics applications. Finally, by performing polarisation-resolved measurements on birefringent anatase layers (2-10nm), we show that we can identify their crystal orientation with a sub-100nm spatial resolution, despite their extremely small thickness. We found a wide range of possible orientations and no specific epitaxial relationships with the underlying polycrystalline gold film. EBSD measurements on thicker anatase layers confirmed these findings. This work further extends the use of gap-plasmons to a new domain.

Engineering Exciton Emission in Monolayer MoS_2 by using Electroplated Gold Plasmonic Nanodiscs AbhayA. V S[1], MihirK. Sahoo[1], FaihaMujeeb[1], AbinVarghese[1], SubhabrataDhar[1], SaurabhLodha[1], SandipGhosh[2] and AnshumanKumar[1]; [1]Indian Institute of Technology Bombay, India; [2]Tata Institute of Fundamental Research, India

Transition metal dichalcogenides (TMDCs), such as MoS_2, hold great promise as 2D semiconductors, making them suitable for various applications in optics and novel electrical devices. However, their atomically thin thickness and low quantum yield have hindered their practical application due to limited light absorption. Integrating subwavelength plasmonic nanostructures with monolayer TMDCs is a promising method to address these challenges effectively and manipulate the optical properties. In this study, we utilized electron beam lithography and electroplating techniques to fabricate an array of gold nanodiscs (AuNDs) capable of significantly enhancing the photoluminescence (PL) of monolayer MoS_2. The monolayer MoS_2 on the gold nanodisc array resulted in an impressive photoluminescence enhancement compared to as-grown MoS_2 on sapphire and a monolayer MoS_2 on a plane gold film. To gain insights into the underlying mechanism behind this enhancement, we conducted Finite-Difference Time-Domain (FDTD) simulations.

8:00 PM EL08.05.10
Highly Efficient Near-Infrared Light-Emitting Diode Based on CdHgSe/ZnCdS Core/Shell Nanoplatelets HosseinRoshan[1], AnatolPrudnikau[2], FabianPaulus[2,3], BeatrizMartín-García[4], RenéHübner[5], HoumanBahmani Jalali[1,1], ManuelaDe Franco[1], MirkoPrato[1], FrancescoDi Stasio[1] and VladimirLesnyak[6]; [1]Istituto Italiano di Tecnologia, Italy; [2]Helmholtzstraße, Germany; [3]Universitat Dresden, Germany; [4]Tolosa Hiribidea, Spain; [5]Helmholtz-Zentrum Dresden-Rossendorf e.V., Germany; [6]Technische Universität Dresden, Germany

Luminescent Quantum dots (QDs) have gathered significant attention over the past decade. Their distinct chemical and optical properties, including size-adjustable light emission, remarkable photostability, and a range of fluorescence colors, have motivated extensive investigations. In recent years, near-infrared (NIR) quantum dots have emerged as a promising avenue for a new generation of optoelectronic devices including infrared detectors and light sources. This study presents the fabrication of NIR-LEDs operating at the o-band optical telecommunication wavelength (1300 nm) using novel CdHgSe/ZnCdS core/shell nanoplatelets with a photoluminescence quantum yield of 70%. The nanoplatelets achieve a remarkable external quantum efficiency (EQE) of 7% in the final device. Notably, the resulting EQE of the fabricated NIR-LED sets a new benchmark for mercury-based QD LEDs.

Utilizing Short-Pulsed Laser Ablation to Create Plasmonic Colloidal Nitride Nanoparticles for Biomedical Applications NikolaosPliatsikas, SpyridonKassavetis, StavrosPanos, TamaraOdutola, IliasFekas, ChrysanthiPapoulia, JohnArvanitidis, DimitrisChristofilos, MariaGioti and PanosPatsalas; Aristotle University of Thessaloniki, Greece

The field of plasmonics is currently witnessing rapid growth and advancement, offering exciting prospects for various scientific and technological applications. In particular, metal nanoparticles (NPs) exhibiting plasmonic behavior in the Near-Infrared (NIR) spectral range have gained significant attention for their potential in biological applications. These NPs possess exceptional abilities to efficiently absorb and generate heat within a highly confined volume surrounding them. However, conventional plasmonic metal NPs like gold (Au) and silver (Ag) face limitations when exposed to the high temperatures and intense electric fields required for biomedical applications involving NIR concentrated light [1]. To overcome these challenges and unlock new possibilities in plasmonic bio-applications, the fabrication of refractory transition metal nitride NPs has emerged as a promising avenue. Among them, Titanium Nitride (TiN) stands out, as it offers plasmonic performance that extends into the NIR spectral range through stoichiometry variations and/or doping [2]. Pulsed laser ablation in liquids (LAL) has emerged as the most favorable method for producing plasmonic TiN NPs, offering advantages in terms of reproducibility and scalability. LAL ensures that the ablated NPs maintain the elemental composition of the solid target, a crucial factor considering the sensitivity of NIR plasmonics to the stoichiometry and doping of TiN. By leveraging LAL, researchers can explore and optimize the plasmonic properties of TiN NPs, paving the way for groundbreaking advancements in the field of plasmonic biomedical applications.
In this study, we demonstrate the fabrication of refractory and stable plasmonic TiN NPs with absorption characteristics within the NIR biological window using LAL. To achieve this, we initially developed target materials through reactive Magnetron Sputtering at room temperature. Subsequently, the colloidal NPs were shaped using a nanosecond Nd:YAG pulsed laser system at different wavelengths (1064, 532, and 355 nm) via the LAL. To assess the structure, morphology, and material quality of the TiN NPs, we conducted comprehensive analyses employing Raman spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS). Additionally, the optical properties of the TiN target materials were evaluated using NIR-Vis-UV spectroscopic ellipsometry, while optical absorbance characterization was performed on the colloidal TiN NPs. Furthermore, we investigated the photothermal properties of these colloidal NPs and conducted preliminary biocompatibility tests using proteins such as albumin and fibrinogen in a PBS solvent.

Novel Synthesis and Characterization of Magneto-Plasmonic Core-Shell Nanoparticles CarlosA. Marquez Ibarra[1], NatashaEngel[1], GesuriMorales-Luna[2], NicolasLarge[1], NancyOrnelas-Soto[3] and KathrynMayer[1]; [1]The University of Texas at San Antonio, United States; [2]Universidad Iberoamericana, Mexico; [3]Tecnológico de Monterrey, Mexico

Advancements in numerous technologies including chemical sensing are spurring progress in the development of novel composite nanostructures that integrate magnetic and plasmonic materials. These nanostructures exhibit a unique amalgamation of plasmonic and magnetic properties, positioning them at the forefront of scientific research. The magnetic properties facilitate precise control and manipulation of the nanoparticles in the presence of magnetic fields. Furthermore, materials with plasmonic activity, such as gold, offer outstanding biocompatibility, along with exceptional optical features that include enhanced scattering and high sensitivity to changes in refractive index. The aim of this research is to analyze and describe core-shell nanoparticles (CS-NPs) comprising a magnetite core enveloped by a gold shell (Fe@Au CS-NPs). These nanoparticles are synthesized through a novel method that integrates established wet lab synthesis techniques under ambient conditions. A comprehensive characterization approach was employed. Electron microscopy techniques including Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM) were utilized to examine and analyze the structure and surface morphology of the investigated materials. Additionally, analytical techniques including Energy-Dispersive X-ray Spectroscopy (EDS) and Fourier Transform Infrared Spectroscopy (FTIR) were employed to investigate the chemical composition of the samples and the presence of surface ligands. Furthermore, computational methods including finite difference time domain (FDTD) and finite element method (FEM) modeling were applied to confirm the plasmonic properties of the composite materials. Calculated optical properties of light absorption and scattering cross-sections were compared with experimental characterization data obtained via techniques including UV-vis absorbance spectroscopy and darkfield scattering microspectroscopy. By employing these extensive characterization methods, the research aims to obtain valuable insights into the composition and properties of the materials under investigation. These insights will serve as a foundation for the development of sensing technology for water quality monitoring.

8:00 PM EL08.05.13
Simulating the Co-Assembly of Cellulose Nanocrystals and Gold Nanorods - Effect of Size Distribution and Density JiaxinHou, YuchenZhu, WilliamSampson and Ahu GumrahDumanli; University of Manchester, United Kingdom

The self-assembly of anisotropic particles holds great potential in fabricating multifunctional optical materials through cholesteric structures. Specifically, cholesteric structures formed by these particles can exhibit unique optical properties, making them ideal for various applications for sensing and fabrication of optical security features. In particular, integrating plasmonic materials into cholesteric phases that can interact with the visible spectrum can be used in building metasurfaces that can alter the interaction of the light completely. While there have been efforts to validate this hypothesis, the experimental work on combining the self-assembly of gold nanorods (Au-NRs) with cellulose nanocrystals (CNCs) had limited success as the plasmonic particle loading was minimal and didn't allow coupling between the plasmonic states of the Au-NPs possible without disrupting the cholesteric order. To understand the physical and theoretical limitations of this co-assembly system, we used molecular dynamic coarse-grained methods with Gay-Berne potential with anisotropic particle systems of different aspect ratios and densities to complement our experimental work.
Our experimental and modeling work demonstrated good agreement with regard to identifying the surface charge and the density of Au-NRs as the main driving force on the co-assembly. Negatively charged AuNRs can distribute uniformly and align in the same direction with CNCs and the particle systems with higher aspect ratio distributions would have successfully co-assembled, as AuNRs would prefer to fill the vacancy between the cholesteric structures formed by CNC particles. Our further studies explain the limit of maximum concentration from density, as lighter particles (CNCs) would reach assembly conditions compared to the AuNRs. Our work sheds new light on the understanding of the self-assembly of multi-component systems with polydispersity and charge variations and takes our understanding one step further in developing optical materials.

Photoinduced Electric Effects in Magnetic Metasurfaces of Various GeometryMD AfzalurRab, SeanNesbit and NataliaNoginova; Norfolk State University, United States

Permalloy metasurfaces with design-controlled magnetic uniaxial anisotropy have been fabricated and studied for plasmonic behavior and photoinduced electric effects. Significant photovoltages are observed as the response to the pulsed laser illumination, and are maximized at the plasmon resonance conditions. The voltage sharply changes its polarity at certain fields which are different for systems of different geometry. The switching fields are found to be in good correlation with the magnetic anisotropy fields determined by the ferromagnetic resonance method. The effects are discussed taking into account non equilibrium heating of the electron subsystem by the laser pulse and the Nernst effect.

8:00 PM EL08.05.16
Optical Characteristics of Superconducting Plasmonic Transition Metal Nitrides Li-ChungYang[1,2], JingweiYang[1], Jing-YuanChen[3], Tzu-YuPeng[1,2], Chung-TingKe[1] and Yu-JungLu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]National Taiwan University of Science and Technology, Taiwan

Transition metal nitrides (TMNs) exhibit exceptional promise due to their elevated melting points, metallic optical characteristics, and superconductivity at cryogenic temperatures. Recent attention has turned toward TMNs as potential substitutes for conventional plasmonic materials like gold and silver due to their unique plasmonic properties. However, the optical properties of plasmonic TMN films in the superconducting state have remained uncharted territory. In the past, we have demonstrated the utility of plasmonic TMN films (including TiN, ZrN, HfN, and NbN) as alternative plasmonic materials for various applications [1-3]. Here, we sputtered a thin film of NbN onto a MgO (100) substrate at 800°C, revealing a measured critical temperature (T_C) of 10.5 K. Employing temperature-dependent spectroscopic ellipsometry, we systematically characterized the optical behavior of NbN films from 4 K to 300 K within a wavelength range spanning 300 nm to 2 μm. As the temperature decreased, we observed a remarkable reduction in the magnitude of the imaginary part of the permittivity, the magnitude dropped by 13.8 times at 1550 nm. Subsequently, we applied the Drude-Lorentz model for parameter fitting, elucidating that the substantial reduction in the imaginary component primarily resulted from a sharp increase in the relaxation time. These findings underscore NbN's potential as a highly promising material for the development of low-loss superconducting plasmonic devices.

8:00 PM EL08.05.17
Light Extraction and Stability of Fluorescent and Phosphorescent Organic Light-Emitting Diodes Incorporating Plasmonic Ag Nanoparticles SnehaSreekumar[1] and DeirdreO'Carroll[2,1]; [1]Rutgers University, United States; [2]Rutgers, The State University of New Jersey, United States

In recent years, organic light-emitting diodes (OLEDs) have gained great popularity in the display industry due to their thin form factor, high color quality and the ability to be fabricated onto flexible substrates. However, OLED stability and efficiency, particularly at blue wavelengths, need significant improvement for future, more demanding display applications, such as micro displays. Several methods have been employed to increase the light-extraction efficiency (LEE) and stability in OLEDs, including the development of new active-layer materials, interfacial layer modifications, addition of nanoparticles or nanopatterns into various layers of the devices, optimization of the structural design and the application of microlens arrays. The LEE in an OLED is typically ~20% with the rest of the 80% of photon energy being lost to substrate, surface plasmon and thin-film waveguide modes. While these approaches are effective for improving LEE of red and green OLEDs, very few of these approaches have significantly improved the efficiency of blue OLEDs. We have shown in previous studies that plasmonic Ag enhances the quantum yield in fluorescent materials through the Purcell effect and improves the photostability of phosphorescent OLED materials by a factor of 3.6 by reducing the triplet emission lifetime. Here, we present a study of the use of silver nanoparticles introduced at different device interfaces and within different layers from the anode to the cathode to combat the various optical losses that reduce LEE. The results show improvements in blue OLED stability and luminescence lifetime in addition to improved LEE We have chosen a blend of PFO: F8BT to study fluorescent OLEDs and a blend of PVK:FIrpic to study blue phosphorescent OLEDs as a function of different nanoparticle additions. The devices are built on ITO on glass substrates

with different formulations of PEDOT:PSS to get the highest conductivity. We vary the Ag nanoparticle size from 15-50 nm and introduce them into different layers of the OLED including: (i) on ITO directly, through spin coating or de-wetting methods, (ii) doped into the PEDOT:PSS layer; (iii) grown on the PEDOT:PSS layer; (iv) within and on top of active layer; and finally (v) deposited on top of the active layer before depositing the Ca/Al cathode. We present current-density measurements, luminance, electroluminescence measurements, external quantum efficiency and stability measurements in addition to lifetime and quantum yield measurements to investigate how positioning of the plasmonic structures effects the stability and lifetime of the OLEDs.We are hoping to contribute to solving the issue of low efficient blue OLEDS by improving the lifetime and stability of the devices as well as achieving the required “true blue” color that is required by the display industry by manipulating the interactions between the plasmonic Ag particles and the emissive layers.

Ultra Short Pulse Laser Ablation of Titanium Nitride Nanoparticles in Solvent for Biomedical Applications IliasFekas, NikolaosPliatsikas, SpyridonKassavetis, StavrosPanos, TamaraOdutola, EviRampota, ChrysanthiPapoulia, ChristosKapnopoulos, MariaGioti, StergiosLogothetidis and PanosPatsalas; AUTH, Greece

Titanium Nitride (TiN) has emerged as a promising alternative plasmonic material that may outperform the traditional plasmonic metals, such as Au and Ag in terms of durability to high temperatures and/or to the high electric fields of concentrated light present in most realistic plasmonic applications. TiN is a well-known conductor of high mobility, widely used in the mainstream microelectronics industry, and it owes its electronic conductivity to the partially filled valence d orbitals that are not completely hybridized with the N-2p electrons and presents high optical response similar to that of Au, hence its golden optical appearance, when in stoichiometric form; non-stoichiometric $TiN_{x>1}$ films are also reported and are predicted to exhibit Localized Surface Plasmon Resonance (LSPR) in red and Near-Infrared (NIR) ranges. TiN is usually grown in thin film form by sputter deposition, its bottom-up nanostructuring was not successful so far, and the formation of colloidal TiN is exceptionally rare, both due to the refractory character of TiN, which is a major obstacle for its wide range implementation [1, 2].
The scope of this work is the fabrication of colloidal TiN nanoparticles with tunable LSPR from the visible to the NIR spectral ranges, thus covering the biological window, a property that can find use in many different biomedical applications. The TiN nanoparticles were fabricated by Ultra Short Pulse Laser ablation (USPL) of TiN in liquid media irradiated at 532nm laser wavelength [1, 3].
USPL corresponding to a shorter thermal relaxation time and would be expected to more effective than nanosecond. USP lasers can reach a higher peak intensity and induce a stronger photoacoustic effect than nanosecond lasers, they can be used with reduced laser fluence compared to that utilized for nanosecond lasers for the TiN nanoparticles fabrication.
The TiN films were grown by reactive magnetron sputtering at room temperature. The chemistry, crystallinity, optical properties, and the point defects of the target materials were evaluated by X-Ray Diffraction, X-Ray Photoelectron Spectroscopy and Scanning Electron Microscopy, respectively.
Then, the major laser ablation parameters were investigated, in particular, low power (up to 2 W) and solvent (water, aceton, and isopropanol). The optical properties, the size, and the structure/defects of the produced nanoparticles were assessed by optical transmittance spectroscopy, Scanning Electron Microscopy and atomic force microscopy, respectively.

IGZO Based Oxide Heterostructured Phototransistor for Widening The Detection Limit up to 1000 nm Wavelength Jun HyungJeong and Seong JunKang; KyungHee University, Korea (the Republic of)

On the rapidly developing technologies for light communication, night vision system, invisible security system, and health care system industries, detecting near infrared (NIR) wavelength light is becoming a crucial component for electronic devices. Among various structures of photodetectors, such as phototransistors, photodiodes, and photoresistors, phototransistors possess much higher potential compared to other structures photodetectors, such as ultra-low dark current, facile tunable photocurrent by modulating gate and drain bias, which leads to the much higher photodetection characteristics. Numerous materials, such as organic semiconductors (OSCs), quantum dots(QDs), or perovskite materials have widely investigated for transparent NIR detection owing to their adequate photon-electron conversion efficiency maintaining relatively high transparency. However, these materials are intrinsically suffered from environmental moisture or oxygen, which leads to the accelerated degradation of the device. Here, to avoid the above issues, oxide phototransistor with IGZO/Ag_2O was fabricated for the detection of NIR wavelength light. The detectable wavelength range of IGZO phototransistor was highly enlarged from ultraviolet(UV)-visible (vis, 450 nm) to UV-vis-NIR(1000 nm). The device exhibited high photoresponsivity and photodetectivity characteristics of 9.9 A/W and 5.55×10^{14} Jones, respectively. Our results suggest a useful method for fabricating metal oxide hetero-structured NIR phototransistors.

SESSION EL08.06: Tunable Metasurfaces and Nanophotonics
Session Chairs: Deep Jariwala and Benjamin Vest

Plasmonic Tip-Enhanced Probing of Excitonic Materials and Heterostructures DeepM. Jariwala; University of Pennsylvania, United States

Two-Dimensional (2D) chalcogenides of Mo and W are semiconductors that show strong excitonic responses due to their highly quantum-confined character. [1, 2, 3, 4] This talk will discuss our recent work on optical phenomena and electronic phenomena in 2D semiconductors when they are placed in close proximity on plasmonic substrates such as Au, Ag and Al.
For a bulk of this talk, I will be presenting our work on near-field optical spectroscopy using a plasmonic tip. I will also show how using a plasmonic tip once can use near-field tip based micro-spectroscopy to probe defects,[5, 6] interfaces[7, 8] and hybrid states in 2D excitonic semiconductors. I will start by showing how tip-enhanced micro-spectroscopy can be used to probe buried metal-semiconductor interfaces in 2D MoS_2.[7] Specifically, I will focus on how scanning potential probe and scanning conductance probe can be correlated with near-field photoluminescence (PL) to understand the nature of contact between metal and the semiconductor. Next, I will show that the same technique can be used to probe defects,[5] heterointerfaces, heterogeneities and strain[9] in 2D semiconductor layers. I will also show how strong-light matter coupling between excitons and plasmonic gap modes can be probed directly using this technique[10] including observation of interlayer excitons.[11, 12]

Materials with Ultrastrong Light-Matter Coupling using Nanooptical Building Blocks StephanieReich[1], NiclasS. Mueller[2] and EduardoB. Barros[3]; [1]Freie Universitaet Berlin, Germany; [2]Fritz-Haber-Institut, Germany; [3]Universidade Federal de Creará, Brazil

The localized excitations of nanooptical building blocks such as molecules, quantum dots, and plasmonic nanoparticles may be used to design complex optical excitations and engineer light-matter coupling in materials. The underlying concept is that excitation centered on different particles interact through dipole-dipole coupling of their transition moments creating hybridized optical excitation in a similar way as the electrons of atoms hybridize into molecular or crystal states. A second important ingredient is the interaction between photons and the optically excited states. It has been engineered through photonic and plasmonic cavities that locally change the density of electromagnetic states as well as their dispersion.

In this talk we discuss how to obtain three-dimensional materials out of nanooptical building blocks and what kind of properties to expect for such systems. We show that three-dimensional lattices of localized optical excitations create materials with superior strength of light-matter coupling, often reaching the regime of ultrastrong interaction, where light-matter coupling affects the material ground state. We discuss how to realize such optically driven materials artificially, but also show that light-matter coupling is surprisingly strong in most naturally occurring crystals. We envision photonic degrees of freedom as a powerful general tool for materials tailoring and manipulation.

9:00 AM EL08.06.03
Multi-State Control Of Spectral Response In Coupled 2d Material Systems YujieLuo and OgnjenIlic; University of Minnesota, United States

Reconfigurable optical systems capable of reproducing complex spectral profiles have broad relevance across optics and photonics. Here, we present a framework for designing reconfigurable metamaterials using active cells that incorporate gate-tunable two-dimensional (2D) materials. Due to their reduced dimensionality, 2D materials exhibit high sensitivity to electric fields, allowing for the tuning of their optical properties through the application of external voltage. By assembling nanopatterned 2D materials into coupled arrays, a single solid-state device can be used to synthesize a wide range of spectral responses. However, the design of such multi-state devices is challenging due to the inherently high-dimensional parameter space involved.

To address this challenge, we present a coupled-mode analytical framework to model the relationship between system control inputs (e.g., voltage) and the manifold of optical outputs embodying multiple spectral resonances. Using graphene as a model 2D material, we investigate the potential for synthesizing complex thermal-infrared spectral absorption profiles within the spectral range where graphene supports surface plasmon polaritons. By employing this coupled framework, we demonstrate that a single judiciously designed array of graphene resonators can dynamically switch between distinct absorption spectra of multiple gases, mimicking both narrow spectral features and broad spectral envelopes. We validate our model by comparing it to full numerical EM simulations, demonstrating a high level of agreement with orders of magnitude speed up in computation time. In addition, through the integration of auto-differentiation algorithms, our model enables efficient gradient-based optimization over the multi-state, multi-spectral design space. We elucidate the tradeoffs between the device complexity, number of resonators and their spectral performance, in both planar and stratified configurations. This approach has potential for various applications in sensing, energy harvesting, and signature management.

Photonic Properties of Thin Film $BaTiO_3$ Grown via Molecular Beam Epitaxy LarissaLittle, DavidR. Barton, KeithPowell, AshleyCavanagh, NeilSinclair, JasonHoffman, CharlesBrooks, RobertWestervelt, MarkoLoncar and JuliaMundy; Harvard University, United States

Electro-optic modulators form the backbone of efficient data transfer necessary for modern optical communications. These modulators directly connect a driving electric field with optical properties of a material, efficiently converting an electrical signal to an optical signal. Modern data centers and high speed internet, as well as sensing systems, heavily rely on these devices. The electro-optic modulators are often bulk crystals of lithium niobate with indiffused waveguides, limiting their size, speed, and efficiency.
Although thin film lithium niobate offers improved scalability and higher bandwidth over its bulk counterpart, lithium oxides are not CMOS compatible and there is a growing need for higher bandwidth modulators with lower voltage requirements. Barium titanate ($BaTiO_3$) is an alternative material platform which exhibits an extremely high electro-optic coefficient (r_{42} ~ 900 pm/V), a reasonably high band gap (> 3eV), a relatively high refractive index (n = 2.4), and is compatible with traditional CMOS processing. Scalable methods for creating high quality, single ferroelectric domain films of barium titanate are therefore extremely attractive for highly efficient modulators and integrated optical devices.
In this work, we use molecular beam epitaxy to grow high quality $BaTiO_3$ films on a variety of substrates and use electron microscopy, electronic measurements, and confocal optical measurements to evaluate the optical and electro-optic properties.

Quantum Photonics with Emerging Single-Photon Emitters in Silicon Nitride AlexanderSenichev, ZachariahO. Martin, SamuelPeana, DemidSychev, XiaohuiXu, OmerYesilyurt, VahagnMkhitaryan, AlexeiS. Lagoutchev, AlexandraBoltasseva and VladimirM. Shalaev; Purdue University, United States

The use of photonic-based quantum platforms shows great potential in both fundamental research and practical applications in the field of quantum information science. This is primarily due to the inherent advantages of photons, such as their extremely high speed, weak interactions with matter, and resistance to decoherence. To make practical quantum photonic information processing a reality, it is crucial to have thousands of optical components working together in a controlled and reconfigurable manner. This level of integration can only be achieved using integrated photonics. Hence, there is an urgent need to discover and explore on-chip photonic elements that can efficiently generate, manipulate, and detect quantum states of light. Additionally, it is essential to enhance light-matter interaction to speed-up quantum photonic processes such as single-photon generation rate employing optical resonators and metamaterials. Silicon nitride (SiN) is one of the most promising and established material platforms for integrated nanophotonics and an emerging platform for quantum applications. It possesses ultra-low losses, absence of two-photon absorption in the telecommunication bands, high refractive index, strong optical Kerr nonlinearity, and CMOS-compatible and foundry-friendly fabrication. However, until recently, SiN lacked an intrinsic atomic-like source of single photons, which are essential resources for quantum photonic applications. Hence, it required probabilistic nonlinear sources or hybrid heterogeneous integration with other materials hosting quantum emitters. Recently, we discovered intrinsic color centers in the low-autofluorescence SiN material platform [1],[2]. We established methods of creation of these quantum emitters and performed foundational photophysical studies at room and cryogenic temperatures. These emitters exhibit high single-photon purity and brightness at room temperature and narrow zero-phonon lines (ZPL) at cryogenic temperature [3]. Furthermore, they can be monolithically integrated with the technologically favorable silicon nitride photonics platforms, which holds great potential for various applications in the quantum domain [2]. Moreover, we developed a novel technique for the site-controlled fabrication of quantum emitters in SiN achieving high yield with a sub-100-nm lateral placement accuracy. In our study, we explore the possibility of generating indistinguishable photons at high repetition rates at cryo-temperatures as well as at non-cryogenic temperatures, with the use of plasmonic metamaterials, which may enable broader applications of SiN quantum emitters. Plasmonic speed-up of spontaneous emission rate beyond the rate of quantum decoherence processes may enable the generation of indistinguishable photons that could lead to important quantum photonics applications, including quantum communication and quantum computing even at non-cryogenic temperatures. In my talk, I will delve into our research effort to engineer these novel quantum emitters in SiN and explore potential avenues for their improvement and application.

Novel Tunable Low-Index Materials for Metaphotonics Applications KristianW. Munnikhuis[1], SmridhiChawla[1], TornikeShubitidze[1], WesleyBritton[2], DavidWoolf[2] and LucaDal Negro[1]; [1]Boston University, United States; [2]Physical Sciences Inc, United States

Low refractive index and epsilon-near-zero (ENZ) materials give rise to many fascinating optical properties driven by strongly enhanced nonlinear optical processes such as harmonic generation, frequency mixing and conversion, electro-optical modulation, and order-unity light-induced refractive index changes. These effects are important requirements to enable reconfigurable optical devices and metamaterials with ultrafast (sub-picosecond) response times for active device in the photonics and metaphotonics domains. However, ENZ materials operating in the near- and mid-infrared spectral ranges often rely on metallic components with limited tunability of the optical permittivity and high absorption losses. Likewise, they traditional platforms are not compatible with the widespread silicon technology, severely limiting their scalability and device integration. Here we report on a novel and largely tunable Si-compatible low-index material platform based on zirconium silicon oxynitride (ZrSiON). In particular, using co-deposition RF magnetron sputtering with Nitrogen gas, we have developed ZrSiON thin films and investigated their structural and optical properties using X-ray diffraction (XRD) and variable angle spectroscopic ellipsometry (VASE) in a broad spectral range. We find that resistivity decreases as SiO2 incorporation is increased, becoming a dispersionless dielectric material with n approx. 2.5 and negligible dispersion losses in the infrared spectral ranges. On the other hand, when SiO2 incorporation is comparable to Zr, we found the material becomes metallic with an ENZ transition in the near-infrared spectrum around 830 nm. We found that upon post-deposition annealing at 500C these materials exhibit a transition to the metallic regime that can be controlled with the sputtering and annealing conditions. In addition, we

measure the optical bandgaps and resistivity and the nonlinear optical responses of the fabricated materials via Z-scan technique. Finally, we identify optimal etching conditions for achieving resonant nanostructures for integration into nonlinear optical devices and metasurfaces.

Full-Colored, Large-Area, Electrically Reconfigurable Photonic Resonator with Low-Power Consumption Hyo EunJeong, Joo HwanKo, Se RimKim, Hyeon-HoJeong and Young MinSong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Display technology plays an essential role in effectively delivering visual information in contemporary daily life. Reflective display, which uses external ambient light as a source, can operate without a backlight panel electronic paper, enabling low energy consumption. In the past few years, there have been various approaches implemented to improve the performance of electronic paper (e-paper), particularly in terms of switching time and on/off ratio. As a result, leading electronics companies (e.g., *Amazon Kindle*) have introduced e-papers with enhanced capabilities. While e-papers serve as excellent display devices, they have certain limitations, such as the necessity of high operating voltages and monochromatic image operation, restricting colorful output. Recently, a new strategy has emerged focusing on the active modulation of plasmonic structural colors based on nanostructured photonic systems [1]. This progress successfully demonstrates the switchable structural colors based on the optically active materials, including phase change materials and conducting polymers, which modulate its complex refractive index by external energy [2]. Especially, conducting polymer, which controls the optical property by an electrochemical redox reaction, has attracted great attention due to its low power consumption. However, the limited complex refractive index and minimal variation levels impede strong interaction between light and matter on plasmonic structures, leading to a diminished ability to express vibrant colors [3].
In this study, we present the milliwatt-level controllable electrochromic thin-film resonator capable of full-color generation based on polyaniline (PANI). To overcome the low complex refractive index variation level of PANI ($\Delta n \sim 0.6$), we designed a highly resonant planar photonic structure based on a refractive index engineered layer on the metal film, resulting in diverse coloration over an entire visible wavelength range. In particular, the electrochemical redox reaction is enabled by the exchange of proton, which controls the doping level of PANI, leading to the fast/efficient modulation of optical properties. The protonation process is achieved in the narrow voltage range from -0.2 V to 0.8 V. The voltage level significantly contributes to low power consumption (~1.32 mW cm^{-2}), which is 20 times lower than commercial displays such as OLED, and even half the power consumption of e-paper. In addition, the active resonant structure based on PANI demonstrates stable reversibility without any degradation over 200 cycles. Moreover, this device achieves a fast-switching time (~34 ms), and also, shows operation capability compared to a commercial video rate of 30 Hz. In conclusion, we present an electrochemically switchable reflective display based on PANI, enabling remarkably efficient and dynamic coloration. We also suggested a passive matrix display module; thus, the pixel-by-pixel control of potential enables diverse pattern generation. We believe that our suggested platform will be utilized as a promising display application including smart windows, electronic wallpapers, attachable displays, and many types of electronics based on its ultra-thin scale, large color space, and low power consumption.

Colloidal Crystal Engineering for Programmable and Stimuli-Responsive Optical Metasurfaces and Metamaterials KorayAydin; Northwestern University, United States

Metasurfaces and metamaterials emerged as promising nanophotonic material and device platforms to control light-matter interactions at the nanoscale. In such materials, the collective and effective optical response is dictated by individual building blocks and controlled by the geometrical parameters forming the crystal structure. I will introduce DNA-assembly of gold nanoparticles as a fabrication method to realize bottom-up, programmable, and stimuli-responsive nanophotonic hybrid metamaterials and metasurfaces. The ability to control the distance, size, shape, architecture of nanoparticles and overall crystal structure enables access to optical properties that are not accessible readily in nature. I will highlight wide range of functional nanophotonic device architectures including epsilon-near-zero metasurfaces, negative index metamaterials and broadband absorber meta-films. The synthesis of plasmonic nanoparticle architectures with structures and stimuli-responsive behavior that are not accessible in lithographically defined plasmonic nanostructures provides an opportunity to design materials with emergent optical properties that offer new fundamental insights and previously inaccessible functionalities.

SESSION EL08.08: Tunable Plasmonics/Nanophotonics and Breaking News Presentation
Session Chairs: Koray Aydin and Yu-Jung Lu
Tuesday Afternoon, November28, 2023
Hynes, Level 3, Room 312

Plasmonic Transmission-Line-Based Logic Circuitry Pei-YuanWu and Chen-BinHuang; National Tsing Hua University, Taiwan

We experimentally demonstrate OR, XOR, NOT, and AND Boolean operations can be achieved in plasmonic two-wire transmission-line devices. A plasmonic half-adder is also designed and realized. In all operations, only four predefined polarizations of a single laser beam are required. All devices and circuits operate with greater than 12.5 THz optical bandwidth.

2:00 PM EL08.08.02
High Quality Ordered Titanium Nitride Nanotriangles and Nanowires for Plasmonic Applications SpyridonKassavetis, EviRampota, StavrosPanos, NikolaosPliatsikas, DespinaTselekidou and PanosPatsalas; Aristotle University of Thessaloniki, Greece

Novel and cost-efficient fabrication techniques of alternative plasmonic nanostructures pave the pathway for practical applications in various fields such energy harvesting, microelectronics and medicine. Transition metals nitrides (TMNs) emerge as alternative plasmonic nanomaterials suitable for a wide range of applications from photovoltaics to photonics and medicine. The TMNs are conductive ceramics that combine exceptional properties such as substantial electronic conductivity, high melting point (>3000 K) and tunable work function, while the TMNs are particularly stable in hostile chemical environments, high temperature, and strong electric fields, such as in lasers. Among them, Titanium Nitride (TiN) is emerging as significant candidate material for practical plasmonic applications (biosensors, catalysis and photochemistry, solar energy harvesting, photo-detection, and optical storage of information).
In this work, we focus on the low-cost fabrication of TiN nanotriangles with controlled spacing and tunable dimensions (thickness and lateral dimensions) using a combination of Nanosphere Lithography (NSL) and several reactive magnetron sputtering (MS) deposition techniques such as DC, Closed-Field Unbalanced MS or Highly Power Impulse MS (HIPMS) on rigid and flexible substrates and with the aim to study the fundamentals that will unlock the fabrication of high quality TMNs nanotriangles and nanowires for plasmonic applications.
NSL appears as a very promising approach, due to its rapid implementation and compatibility with wafer-scale processes, combines the advantages of both top-down and bottom-up approaches and includes: (a) development of the nanospheres monolayer colloidal mask, (b) deposition of the desired material in the empty space between the nanospheres and (c) removal/lift-off of the nanosphere colloidal mask to “reveal” the deposited material that keeps the ordered patterning of the mask interstices. Specifically, a suspension of monodisperse polystyrene nanospheres (diameter, d=552 nm or d=175 nm) was spin coated on a substrate (such as Si (001), glass, flexible PET) to form the colloidal mask. A UV ozone process was used to confine the triple-junction vias of the polystyrene mask. Subsequently, the selective growth of TiN was made by the above mentioned MS in Ar/N atmosphere by varying the TiN thickness from 10 to 30 nm, while the MS process parameters were also fine-tuned to increase the directionality of deposited species, and the TiN crystal quality (low concentration of point defects). In particular, the substrate-to-target distance was maximized to improve geometrical directionality, and a negative bias voltage during the growth of the TiN was used to “guide” the ionic species deep into the vias between the nanospheres.
The arrays of ordered TiN nanostructures and nanowirers appear after the lift-off of the mask. Atomic Force Microscopy characterization of the samples showed the fabrication of TiN nanotriangles, with low concentration of point defects, similar structure with the continuous TiN films of high electrical conductivity and plasmonic performance, and durability at least up to 400° C.

2:15 PM EL08.08.03
Tunable Plasmonic Properties in Silicon Nanostructures RosariaA. Puglisi[1], AntoninoLa Magna[1], GiovanniMannino[1] and JostAdam[2]; [1]CNR-IMM, Italy; [2]Mads Clausen Institute, Denmark

The scientific literature on plasmon resonances in metallic nanostructures is quite extensive thanks to their interesting physical characteristics and for their numerous applications. It is known that their plasmonic properties can be controlled by changing the metallic nanostructure geometry and the characteristics of the medium surrounding it, allowing for the tunability of the plasmonic response. The possibility to exploit these properties in semiconducting nanomaterials, particularly in silicon, thanks to its exceptional CMOS compatibility, would allow for an extensive industrial application. Electron plasma oscillations have been demonstrated in Si/SiO2 nanowires, in structures with diameters as large as 100 nm. But some of their properties are still not deeply investigated or understood, for the limits of the standard characterization techniques, and for the difficulty to interpret the data. Moreover, despite the potential to deliver an intense optical energy below the diffraction limit offered by a plasmon-induced resonant cavity smaller than 100 nm, little is known about the plasmon properties of silicon nanostructures smaller than this size. In this talk we will present the results of an experimental and theoretical investigation performed on silicon nanowires as small as 30 nm and less. Thanks to the use of a high-resolution STEM coupled with electron energy loss spectroscopy in situ, supported by finite-element method simulations to model the optical response, we will present a study on the plasmonic resonances in such small nanostructures. We will demonstrate how it is possible to change their features by changing the nanostructure size and where the plasmon effect stops, in terms of energy and geometry, to give space to other concurring phenomena.

2:30 PM EL08.08.04
Tuneable Anisotropic Plasmonics with Shape-Symmetric Conducting Polymer Nanoantennas YulongDuan; Linköping University, Sweden

Plasmonic nanoantennas with polarization-dependent resonances have widespread application in photonics, yet their design has been limited to antennas with anisotropic shapes such as nanorods. We proposed an alternative approach to overcome this limitation, wherein shape-symmetric nanoantennas are fabricated from aligned conductive polymer materials possessing anisotropic permittivity.
Conventional plasmonic metals, like gold and silver, possess highly cubic symmetry and exhibit isotropic permittivity. Although researchers can artificially induce anisotropy in various isotropic metallic materials using nanoscale lateral gratings which results in hyperbolic metasurfaces, materials with naturally in-plane hyperbolic permittivity or in-plane anisotropic negative permittivity, along with in-situ tunability, are rare. We have recently introduced a new type of tunable plasmonic material based on conducting polymers of PEDOT:Sulf (poly[3,4-ethylenedioxythiophene]:sulfate) (1). The unique capability to switch the material between metallic and dielectric states via its redox state enables the reversible operation of plasmonic nanoantennas, as validated both chemically and electrically (2, 3). Moreover, research in the field of stretchable electronics has shown that adding strain to these materials can align the polymer chains in certain directions, resulting in different conductivities in different in-plane directions. The molecular alignment of the conducting polymer not only influences anisotropic charge mobility but also induces anisotropy in the effective mass of the charge carriers. Consequently, we achieve a material with polarization-dependent plasma frequency and an accompanying region of in-plane hyperbolic permittivity.
Utilizing this unique characteristic, we present the design of circularly symmetric nanoantennas capable of exhibiting anisotropic localized plasmonic resonances in parallel and perpendicular orientations to the polymer alignment direction. The anisotropic nanoantennas are further tuneable via the redox state of the polymer. Notably, the polymer alignment can blue-shift the plasma wavelength by several hundreds of nanometers, thereby forming a novel approach towards reaching the goal of redox-tunable conducting polymer nanoantennas for visible light.

Moiré Nanoplasmonics TeriW. Odom; Northwestern University, United States

Moiré patterns can be described as the superposition of two or more periodic structures rotated by a relative twist angle. These patterns can be formed either from the vertical stacking of periodic lattices or the projection of two periodic lattices into the same horizontal plane. Photonic moiré lattices have exhibited broadband light trapping, optical chirality, and spatially-confined as well as long-range lasing. This talk will describe optical moiré phenomena in different plasmonic architectures. First, we will discuss how to design moiré nanostructures using scalable nanofabrication tools. Next, we will characterize and model their optical properties at different twist angles. Finally, we will integrate the plasmonic moiré nanopatterns with emissive materials and discuss potential applications of their short-range and long-range responses.

3:45 PM EL08.08.06
Reaching a Strong Coupling Regime between Quantum Emitters and Plasmonic Resonators using DNA JeanneHeintz and SebastienBidault; ESPCI Paris, France

Light-matter interactions in condensed media at room-temperature are fundamentally limited by electron-phonon coupling. For instance, while the excitation cross-section of an isolated atom, or of a single quantum emitter at cryogenic temperatures, can reach one half of the wavelength of light squared (the so-called unitary limit); this value is reduced by 6 orders of magnitude for a fluorescent molecule or for a colloidal quantum dot at room temperature because of homogeneous phonon broadening. In order to render the exceptional optical properties of single quantum systems (such as single-photon emission and nonlinearities) efficiently accessible at room temperature and in condensed media, it is essential to enhance and optimize these interaction cross-sections.
Over the last decade, gold nanostructures have shown amazing promise towards this goal thanks to their ability to enhance optical fields by several orders of magnitude in deeply sub-wavelength volumes. However, the nanoscale dimensions of these field enhancements mean that it is extremely difficult to address them in a controlled and reproducible way. To this end, we exploit DNA molecules to create plasmonic resonators with a control over both their nanoscale dimensions and their chemical environment. Using this strategy, we were able to enhance single-photon emission from fluorescent molecules by more than two orders of magnitude in a weak-coupling regime (ACS Nano 10, 4806 (2016)) and to reach a strong-coupling regime between a plasmonic resonator and 5 organic molecules, albeit with low reproducibility (ACS Nano 15, 14732 (2021)). We propose the DNA-based assembly of dimers of plasmonic nanocubes in order to provide reproducible single-molecule strong coupling and to make the coherent interaction of light with single quantum emitters feasible at room temperature (J. Phys. Chem. Lett. 13, 11996 (2022)).

4:00 PM EL08.08.07
Photon Avalanches in Nanoparticles BruceE. Cohen; Lawrence Berkeley National Laboratory, United States

While the original applications of nanoscience to bioimaging used luminescent nanocrystals whose properties largely mirrored those of traditional probes, newer nanocrystals have been engineered with optical properties unlike anything found in organics or proteins. These include perfect photostability, multiphoton emission a billion-fold more efficient than standard multiphoton techniques, and most recently, photon avalanches hosted within nanostructures. In two recent studies,[1,2] we describe the engineering and imaging of avalanching nanoparticles (ANPs), which are Tm^{3+}-doped $NaYF_4$ upconverting nanoparticles that efficiently convert near infrared excitation to higher energy emission. Avalanches are steeply nonlinear events in which outsized responses arise from a series of minute inputs and, with light, photon avalanching had been observed only in bulk materials, often at cryogenic temperatures. The extreme nonlinearity of ANP emission enables sub-70 nm spatial resolution using only simple scanning confocal microscopy and before any computational analysis. Two-way NIR photoswitching of ANPs enables full optical control of photodarkening and photobrightening, and we find indefinite photoswitching of individual nanoparticles in ambient or aqueous conditions without measurable photodegradation. This enables unlimited photon collection for calculation of sub-Ångstrom localization accuracies, and we can distinguish individual ANPs within tightly packed clusters.

4:15 PM EL08.08.08
Strong Emission Enhancement of Rare Earth Quantum Emitters in an Integrated Waveguide Nano De-Focusing Platform NicholasA. Gusken[1], MingFu[2], MaximilianZapf[3], MichaelNielsen[4], RobertRöder[3], StefanMaier[5,2], MarkL. Brongersma[1], CarstenRonning[3], RupertOulton[2] and AlexClark[6]; [1]Stanford University, United States; [2]Imperial College London, United Kingdom; [3]Friedrich-Schiller-Universität Jena, Germany; [4]University of New South Wales, Australia; [5]Monash University, Australia; [6]University of Bristol, United Kingdom

As demonstrated in our recent publication, we present a novel reverse nanofocusing platform which allows to boost, extract and guide quantum emission at and from the nanoscale efficiently.

Enhancing fluorescence of quantum emitters while allowing for efficient extraction of emission in an integrated fashion is of great interest for future photonic quantum networks. Optical and electrical control at the emitter level is important in different fields of research and applications ranging from sensing and quantum networks to active metasurfaces. Dielectric as well as metallic cavities can accelerate radiative transitions of emitters by orders of magnitude based on the Purcell effect. For dielectric cavities, emission enhancement can be achieved by efficient modal coupling to high quality cavities. One drawback of this approach however is the fundamental limit in bandwidth and mode size. Plasmonic metal structures in contrast, are not diffraction limited and allow for the creation of cavities with mode volumes far below the wavelength scale and electrical control for direct emitter manipulation. One emitter which has raised significant interest is erbium, due to its C-band emission which is of strong technological significance for optical communications.

Here we demonstrate a strong radiative emission enhancement of Er^{3+}- ions based on efficient coupling to and de-focusing from a hybrid plasmonic waveguide platform. Our results show acceleration of quantum emission over several orders of magnitude across the entire C-band based on a single hybrid plasmonic waveguide. Additionally, efficient coupling to a highly confined waveguide mode allows to resolve single electric dipole transitions which can be attributed to Stark-split energy levels of Er^{3+}.

Core-Shell Au@ZnO Nanocomposite for the Photocatalytic Degradation of Toxic Dyes AnjaliVijeata[1,2], Ganga RamChaudhary[1], AlastairWark[2] and SavitaChaudhary[1]; [1]Panjab University, Chandigarh, India, India; [2]University of Strathclyde, United Kingdom

Abstract
An advanced synergistic Au nanorods and metal oxide (ZnO) nanoparticles-based nanocomposite was synthesized in order to get insight into plasmonic control over photocatalysis. The absorption power of the complex shifts towards the visible range of the spectrum due to the interference of plasmonic effects of Au nanorods with the surface defects in ZnO nanoparticles. Manipulating such design gives highly active surface sites and results in productive outcomes. In this report, the positively charged ZnO nanoparticles are coated with poly-tannic acid to make the surface highly negatively charged which was then bonded to Au nanorods through thiol linkage. The surface chemistry of CTAB-stabilized Au nanorods was altered with a small chain cysteamine group which can readily bind to the surface-active sites of PTA-coated ZnO nanoparticles. We demonstrated that the plasmonically active nanocomposite efficiently supports the catalytic activity under a 300W xenon lamp. Notably, surface plasmonic energy-based electron transfer boost up the light absorption power of the nanocomposite during the process of photocatalysis. This metal oxide and nanorods complex provides a breakthrough in generating free radicals which can readily degrade the cationic dyes with outstanding reproducibility. This work exploited the promising aspects of using plasmonic nanoparticles in the photocatalysis of toxic dyes.

Precision Patterning of ZnO using Femtosecond Laser: Opening Doors to Nanophotonic Device Innovations AjinkyaB. Palwe, SonuK. Singh, GauravP. Singh, SoumiMukherjee, SwetaRani, ArunJaiswal, ShobhaShukla and SumitSaxena; IIT Bombay, India

Patterned nanostructure exhibits interesting optoelectronic characteristics due to light-matter interaction at comparable dimensions. The optical response of the nanostructure-based devices is modulated by the size and the periodicity of the structure. Numerous techniques based on top-down and bottom-up approaches are used to obtain patterned nanostructure. However, top-down methods provide more precise control over the patterning of the surfaces. Recently patterned structures of metal oxide semiconductors are getting attention for various electronic devices like photodetectors, solar cells, etc. The femtosecond laser has shown the capability to precisely pattern the surfaces with regular and smaller structures. In this work, we have fabricated ZnO nanopillars by patterning the ZnO thin film using a femtosecond laser. ZnO film (thickness ~600 nm) is deposited on a glass slide using an organic salt solution of zinc in isopropanol and annealed at 400°C. The ultrafast mode-locked Ti: sapphire-based femtosecond pulsed laser (Coherent made, Chameleon Ultra I) with fixed pulse width (140 fs) and a repetition rate (80 MHz) is used for this patterning. The laser beam of 800 nm with a beam diameter of 1.2 mm at $1/e^2$ tightly is focused onto the ZnO film for the selective patterning (ablation). The patterns are prominent after increasing the laser power beyond 1.5 W. ZnO is patterned in a square mesh with a periodicity of 1 um, which resulted in the formation of ZnO nanopillars with a side of ~500 nm and a height of 600 nm. The fabricated structure exhibits different colors at different angles due to the scattering of the light. These reflected colors are analyzed with the camera by varying the incident angle of the white light. It is observed that the photo emitted light colour changes from colourless to blue, orange, pink, green, red, and finally deep red. Due to the multiple scattering, the overall path length of the light inside the active material increases. Also, the total surface area of the active material in the patterned film is larger as compared to the plane film. The array of semiconducting ZnO nanopillars exhibits unique electronic and optical characteristics for optoelectronic and photonic applications. Similarly, the femtosecond laser can pattern different metal oxide layers and incorporate the fabricated structures in optoelectronic devices to improve their performances.

8:00 PM EL08.10.03
Computational characterization of optical response in noble metals and plasmonic ceramics XiaoZhang and EmmanouilKioupakis; University of Michigan at Ann Arbor, United States

Understanding the optical response of plasmonic materials is essential for understanding the physics and functionality of plasmonic devices. While traditional plasmonic materials such as noble metals have shown great success, the search of alternative materials for high-temperature applications remains open in the community. In recent years, several transition-metal nitrides and carbides have emerged as a promising new family of plasmonic materials. Benefiting from their high thermal stability, these materials are expected to be promising for easy processing and for high-temperature applications. To better understand and guide the discovery of new plasmonic materials, a reliable computational first-principles framework to characterize optical properties of metallic systems is important. These characterizations require a predictive treatment of free-carrier absorption considering both inter- and intra-band single particle excitation, and the collective oscillation of electrons (Drude contribution) on the same footing.

In this work, we present a computational framework that combines density functional theory, density functional perturbation theory, many-body perturbation theory, the maximally localized Wannier function approach, and the special displacement method to capture the direct and phonon-assisted single-particle process, as well as the Drude contribution, to provide a consistent, predictive description of the optical response of metallic systems. We show that with our framework, we can characterize the optical response both of noble metals (Ag, Au, and Cu) and of TiN, a promising plasmonic ceramic material. We achieve excellent agreement with experimentally measured dielectric functions, and we successfully characterize the temperature dependence of the optical response of TiN. We show that in the IR to visible region, both single-particle phonon-assisted indirect transitions and the Drude contribution are important to understand optical response of metals. Our framework is general and is available as a community tool implemented in the open source EPW code. It can be extended to other metallic materials, thus provides a general platform to accurately model the optical properties of metallic materials. Our platform creates an excellent opportunity to enable rational design of new plasmonic materials for nonconventional applications.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award No. DE-SC0020129. It used resources of the National Energy Research Scientific Computing (NERSC) Center, a DOE Office of Science User Facility supported under Contract No. DE-AC02–05CH11231.

Low-Powered, Electrically Controllable Tamm Plasmons for High On/Off Ratio Optical Switch Joo HwanKo[1], Dong HyunSeo[1], SejeongKim[2] and Young MinSong[1]; [1]Gwangju Institute of Science and Engineering, Korea (the Republic of); [2]The University of Melbourne, Australia

Recent advances in reconfigurable photonics have attracted attention for enabling the active manipulation of light, facilitating rapid information transfer and high-density multi-spectral operations. The fundamental requirements of active photonics are the photonic structure, which confines a specific wavelength range at the target resonance, and the active material that modifies the condition of light-matter interaction using external stimuli or control mechanisms [1]. To confine and propagate electromagnetic waves effectively, these resonators rely on photonic structures. Specifically, in metasurfaces-driven reconfigurable photonics, photonic structures have emerged as highly promising, leveraging resonant properties to interact with light and enable localized manipulation, detection, or confinement at subwavelength scales. However, the intricate design and complexity of fabrication processes have posed challenges. Alternatively, thin-film-based optical modulators have shown significant potential for strong light-matter interaction, even with simplified configurations. Tamm plasmon (TP) structures, as powerful planar plasmonics, offer efficient light absorption. Optical TPs can occur at the interface between distributed Bragg reflectors (DBRs) and an absorbing layer with layers of optical thickness half the light wavelength [2]. While the lossy layer efficiently absorbs the confined electric field density at the interface in the Tamm plasmon state, complete elimination of the lossy property is necessary to deactivate the absorption. To unlock their active functionality, the ability to perform optical mode conversion between lossless and absorption states is essential.

In this study, we introduce the active Tamm resonator, which utilizes poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) as the active material for optical modulation. By applying a voltage range of ±1 V, the resonator transitions from a Tamm resonant state (complete absorption) to a mirror state (total reflection). PEDOT:PSS possesses optical characteristics that enable efficient and rapid conversion of the optical mode between a lossless state (dielectric) and an absorption state (metallic) through a redox electrochemical reaction [3]. This conversion is achieved through an electrochemical redox reaction involving proton exchange, facilitated by self-aligned Au nanocolumns acting as a membrane between TPs and electrode for

fast proton permeability. The active Tamm resonator exhibits reversible and fast response, characterized by triggered stimulation. Notably, cyclical writes and erase states generate a hysteresis loop, enabling the development of a non-volatile memory device. By sequentially programming the input electrical signal, the fabricated device demonstrates optically readable information with excellent retention. Moreover, by designing a circuit that can address each pixel, we have developed an information storage system that uses square pulsed potentials for optical recording and reading. Overall, this research emphasizes the design of optical structures and material selection for the active Tamm resonator as a powerful tool in reconfigurable photonics.

Design of Plasmonic Nanoantennas Coupled to Ultra-Fast Molecular Diodes to Produce Electricity HalidouHalidou Abdoul-Yasset[1], PeeranuchPoungsripong[1], BeniaminoSciacca[2], OlivierMargeat[2,1], DavidDuché[3,1] and JudikaelLeRouzo[3,1]; [1]Aix-Marseille Université, France; [2]CINAM-CNRS, France; [3]IM2NP, France

Current PV technologies are the leading technologies used to harvest visible light with good efficiencies. However, their overall performance is limited by the band gap of the semiconducting material used as an active layer.

A promising way to overcome this limitation is to rely on a technological breakthrough, mostly known as rectenna solar cells. Rectennas or rectifying antennas are devices that capture light as a wave, then generate an alternating current which is rectified by a diode producing finally usable or storable direct current. Rectennas are not a recent concept. They have been developed since the '60s for microwave frequencies and were able to yield efficiencies close to 90% [1]. Today, the challenge is to translate their high efficiencies from microwaves to infrared and optical frequencies. The primary obstacle lies in designing and fabricating rectifying diodes that can rectify high-frequency optical signals efficiently.

A rectenna composed of patch nano-antennas associated with molecular diodes has been fabricated using an original bottom-up process which has been patented [2]. Thanks to this design, we demonstrated a photo-electrical effect at a bias voltage higher than 0.3V resulting from rectification of light under illumination at 1,55µm. These promising results allow IM2NP to be one of the few groups in the world able to rectify optical frequencies. In the present work, we explore the possibility of using plasmonic nanocubes and molecular diodes to have a functional device. Our rectenna architecture enables us to leverage the unique properties of nanostructures such as surface plasmons and gap plasmons. By coupling these nanoantennas with ultrafast molecular diodes, we exploit the diodes' unique nonlinear electron transport properties to convert gap plasmons into electrical currents. To this end, we employ advanced bottom-up fabrication techniques to self-assemble patch nano-antennas made of plasmonic nanocubes with tailored sizes, optimizing their resonant characteristics to efficiently capture and concentrate optical frequencies of light. In addition, we integrated self-assembled molecules by click chemistry as ultra-fast diodes. Finally, we investigate the performance of the plasmonic nanoantenna-molecular diode system through rigorous theoretical simulations and experimental characterizations.

8:00 PM EL08.10.06
Combining Plasmonic Nanostructures and Diamond for Emission of Electrons using Visible Light DanieleCatone[1], GiuseppeAmmirati[1], AlessandroBellucci[1], ValerioCampanari[1], FaustinoMartelli[2], MatteoMastellone[1], PatrickO'Keeffe[1], SilviaOrlanducci[3], AlessandraPaladini[1], RiccardoPolini[3], FrancescoToschi[1], DanieleTrucchi[1], StefanoTurchini[1] and VeronicaValentini[1]; [1]Istituto di Struttura della Materia - CNR, Italy; [2]CNR, Italy; [3]Università di Roma "Tor Vergata", Italy

Combining plasmonic metal nanoparticles with wide bandgap semiconductor materials has been demonstrated to be an effective way to sensitize these materials to sub bandgap light.[1] This is often used as a strategy improve the photocatalytic properties of these materials.
In this work we focus our efforts on diamond as it has the very interesting property of having a negative electron affinity at its surface when it is hydrogenated. The result is that when electrons are excited into the conduction band in the vicinity of a diamond/vacuum or, indeed, a diamond/water interface they are ejected from the diamond into the vacuum or water. This property can lead to numerous useful applications such as a cold cathode or as a clean source of solvated electrons. The problem is that diamond has a band gap of 5.5 eV and therefore this process only works with VUV light (wavelength < 213 nm).
We have fabricated two separate systems based on the combination of plasmonic nanoparticles with diamond which show that the exciting the plasmonic resonance of the metal nanoparticles can lead to a strong enhancement of the emission of electrons from the diamond surface. The process is demonstrated using an array of nanoparticles embedded below the surface of a thin film of diamond for the emission of electrons into vacuum using visible light. The increased electron emission efficiency was verified by photoemission and photoconduction measurements. Initial attempts with Aluminum as the plasmonic material were not successful[2] while successive fabrication using silver showed the required properties. Furthermore, a second system involving detonation nanodiamonds coupled with gold nanoparticles in aqueous solution has been shown to be source of solvated electrons following interaction with visible light. In this case the presence of solvated electrons was verified by using an ultrafast pump-probe experiment in which a visible light pump was used to excite the plasmon resonance of the gold nanoparticles while the white light probe was used to optically detect the formation of the solvated electron in the first picoseconds after the excitation.
Based on the details of the above measurements we propose slightly different mechanisms to explain the photoemission in the AgNP@Diamond system with respect to the formation of hydrated electrons in the AuNP@Nanodiamond system.

Thermal Radiation Around a Nanobubble Generated by a Heated Gold Nanoparticle SreyashSarkar, JerômeSarr, OlivierMerchiers and Pierre-OlivierChapuis; University Lyon, CNRS, INSA Lyon, Université Claude Bernard Lyon 1, France

By injecting metallic nanoparticles into a liquid, localized heating without physical contact is achieved, facilitated by steady-state or pulsed illumination that generates nanobubbles around the particles. This technique has applications [1] in optical hyperthermia for local therapy, microbiology, and solar thermal water heating. The complex dynamics of bubble formation involve vaporization, heat transfer by vapor molecules, and multiple scattering [1]. However, the thermal radiation between nanoparticles and the liquid has not been adequately studied due to the size of the nanoparticles being below the characteristic wavelength (Wien’s wavelength). To accurately assess the sub-wavelength thermal radiation emission, fluctuational electrodynamics calculations are necessary. These calculations reveal that the effective emissivity of small objects can exceed unity [2]. Furthermore, due to the small distance between the nanoparticle and the fluid, the radiative transfer occurs through photon tunneling, in the near field. Fluctuational electrodynamics provides also a suitable approach for considering this phenomenon. This work focuses on evaluating these radiative contributions. The analysis considers the dipole approximation, encompassing both electric and magnetic dipole cases within a cavity immersed in a dissipative medium. Multireflection scattering solutions account for wave-related effects in the vacuum cavity. The results obtained in spherical geometry, using the Mie theory, demonstrate the significance of both wave effects. The volumetric near-field absorption in water varies as almost a sixth power of the distance from the origin and as a third power of the cavity radius, exhibiting observable interferences when approaching the far-field regime. Spectral signature resonances of water dominate the radiative exchange in this scenario. This work will contribute to a more comprehensive understanding of radiative exchange in nanoparticle-liquid systems ultimately aiding the development of thermal engineering, bioengineering, and biomedical applications

Furthering Nano-Optical Techniques by Integrating Tapping-Mode AFM and TCSPC KevinW. Kwock[1], ThomasP. Darlington[1], EmanuilYanev[1], MatthewC. Strasbourg[2], JamesHone[1], NicholasJ. Borys[2] and P. JamesSchuck[1]; [1]Columbia University, United States; [2]Montana State University, United States

Scanning tip-enhanced optical spectro-microscopy techniques are powerful tools for investigating the opto-electronic properties of materials surfaces. However, the improved resolution comes at the significant expense of optical signal, requiring the use of higher excitation powers which can be detrimental to samples and nano-optical probes.[1-2] This current experimental paradigm is heavily dependent on of fabrication of extraordinary nano-optical probes that can simultaneously tolerate high excitation densities and greatly enhance the signal of interest for a measurement's duration. Methods to increase signal/noise in a system without high photon fluences on the sample/tip are thus needed for imaging weak optical interactions, including Raman and nonlinear optical (e.g. SHG) scattering signals. In this study, we present efforts to improve our nano-optical studies through the incorporation of lock-in detection of tip-enhanced signals using tapping-mode atomic force microscopy scanning. We correlate fast single photon sensitive avalanche photodiodes and time-correlated single photon counting electronics, following the system design first demonstrated by Gerton et al.[3] We show successful imaging of the nano-PL from a nanobubble in monolayer WSe_2 on Au, achieving resolutions ~ 10 nm. Our results show the viability for lock-in detection in tip-enhanced experiments and show a potential path for high-sensitivity nano-optical measurements utilizing photon correlations.

Bioinspired Colorimetric Metasurfaces for Next Generation, On-Chip Imaging of Tissue Microstructure LisaV. Poulikakos, ZaidHaddadin, PaulaKirya, ShahroseKhan, DevShah and LorenPhillips; University of California, San Diego, United States

The origin and progression of a variety of leading health challenges, encompassing Alzheimer's disease, heart disease, fibrosis and cancer, are directly linked to changes in the presence and orientation of fibrous matter in biological tissue. Fibrous biological tissue exhibits distinct anisotropic optical properties, which can be leveraged for selective imaging. However, these naturally occurring light-matter interactions are inherently weak, posing barriers to their visualization in a clinically translatable manner. Existing imaging techniques which visualize the fibrous properties of biological matter face challenges in complexity, cost, destructiveness, or precision. Thus, innovation in imaging technology of fibrous tissue with facile clinical implementation is urgently needed.

To address this challenge, we develop a new class of anisotropic, colorimetric metasurfaces to selectively visualize disease-relevant fiber density and orientation in biological tissue. We draw inspiration from iridescent structural color which is abundant in nature, arising in the saturated blues of the Morpho butterfly wing or the greens of jeweled beetle shells. At the micrometer scale and smaller, these naturally occurring, three-dimensionally (3D)-architected photonic crystals are composed of ordered, geometrically anisotropic features which exhibit distinct interactions with light at varying angles of incidence or polarization state. Due to their 3D hierarchical architecture, these nature-derived systems are unique sources of polarization-sensitive structural color with high color purity and brightness. Based on these principles, our colorimetric metasurfaces are designed to exhibit a high sensitivity to varying polarization states of light. We implement our colorimetric metasurfaces as a next-generation tissue microstructure imaging technology. Starting with the example of breast cancer diagnostics, we then expand our view to the rich palette of fiber-affecting diseases where metasurfaces hold great potential to achieve rapid, precise and low-cost tissue diagnostics with facile clinical implementation.

Metamaterials Concepts for Active Photonics and Laser-Based Nanofabrication GennadyShvets; Cornell University, United States

Theoretical and experimental results demonstrating reversible and irreversible regimes of light-metasurface interactions will be described. First, I will describe how all-dielectric metasurfaces can be combined with liquid crystals to develop a new class of electrically-controlled varifocal metalenses operating at multiple wavelengths. New design strategies aimed at simplifying metalens fabrication and producing high-NA tunable meta-optics will be discussed. Finally, I will demonstrate how semiconductor metasurfaces enable the strongly-driven regime of laser-metasurface interactions manifested as (a) enhanced high harmonics generation, and (b) laser-assisted material nanostructuring.

9:00 AM EL08.11.03
Active Metal-Dielectric Photonic Crystals DavidAllemeier; Boston University, United States

Metal-dielectric photonic crystals (MDPCs) are periodic structures realized by vertically stacked metallic microcavities, resulting in alternating layers of semi-transparent metals and relatively thick dielectrics. Unlike plasmonic metamaterials, MDPCs rely on the hybridization of the underlying microcavity states rather than the coupling of surface plasmons, which produces multiple optical Bloch states arranged in photonic bands. This hybridization can be accurately described using coupled-mode theory, exactly analogous to the formation of molecular orbitals and the electronic energy bands in atomic crystals.

The high conductivity and carrier density of the metallic layers makes MDPCs ideal for active photonic devices and enables a significant reduction in physical thickness due to the high reflectivity at the metal-dielectric interfaces. We have recently exploited this to develop organic light-emitting diodes (OLEDs) that directly express the photonic band structure in their electroluminescence spectrum in the weak coupling regime. In this presentation, we discuss the theoretical foundations of MDPCs using quasi-normal mode formalism and coupled-mode theory. We apply this theory to demonstrate control over the emission spectrum of electrically-driven MDPC OLEDs in both simple and binary crystal configurations by varying the density-of-states and introducing a photonic band gap.

Plasmonic Optomechanical Switch IreneCastro Fernández[1], DanielR. Vega[1], AntonioGarcia-Martin[2] and ManuelMarques[3]; [1]Materials Science Institute of Madrid (Spanish National Research Council), Spain; [2]Instituto de Micro y Nanotecnología (CSIC), Spain; [3]Universidad Autónoma de Madrid, Spain

In this work we theoretically demonstrate the use of a two-level optomechanical system actuated by plasmon-mediated optical forces as a reconfigurable nanophotonic switch. We have simulated a nanostructured suspended gold membrane allowing the normal excitation of a Surface Plasmon Polariton by patterning an air nanohole array. By placing the membrane in a close proximity of a reflecting substrate, we observe a mode splitting which provides two stable mechanical states accessible by tunning the illuminating wavelength.

In recent years the active control of optical forces is attracting more and more attention from the scientific community ranging from the fundamental physics [1] to diverse applications such as optical (and plasmonic) tweezers [2], optically reconfigurable nanophotonic devices and cooling and/or amplification of the mechanical modes to reach the fundamental ground state [3] or to increase the sensitivity of inertial sensors [4]. In this work, we present a two level optomechanical system that can be statically or dynamically manipulated to act as an optical bit in photonic nanoprocessors or as an optical switcher. The accomplishment of the optical force modulation is theoretically demonstrated by means of the mechanical excitation of a suspended membrane consisting of an array of air nanoholes in a gold layer supporting surface plasmon polariton modes [5]. The nanostructured membrane is suspended over a silicon substrate assembling a Fabry-Perot microcavity that enables strong coupling between cavity and plasmonic modes [6].
We simulate the whole optomechanical device through finite element simulations, including the coupled Fabry-Perot cavity. The optical force is calculated by the asymmetries in the integral of the Maxwell stress tensor over a closed surface around the suspended membrane. The Surface Plasmon Polariton and its influence on the optical force is calculated as a function of the cavity length. From the force calculation at a fixed wavelength a double potential well is obtained, showing two stable states with a central energy barrier. It is possible to dynamically actuate on the length of the cavity by introducing a mechanical actuation on the membrane by means of a harmonic displacement. The oscillatory movement of the suspended membrane can be modeled by a Duffing non-linear mechanical oscillator whose amplitude can be manipulated via optomechanical amplitude modulation (cooling or amplification). Therefore, the final state

(stable) of the dynamical system can then be actively chosen, opening the door for the development of an optomechanical switch.

Controlling Spontaneous Emission from Semiconductor Metasurfaces: From Reconfigurability to Single Photon Sources PrasadIyer; Sandia National Labs, United States

The ability to achieve spatiotemporal control of incoherent (thermal and quantum) light emission has been a critical challenge in the field of optics with far ranging applications from remote sensing, holographic displays and quantum information processing. Here we present our results on two light emitting metasurfaces systems: 1) Ultrafast dynamic steering of spontaneous light emission from high-density InAs quantum dots (QDs) embedded inside GaAs resonators under structured optical pumping and 2) Enhancement of single-photon emission from single GaAs local-droplet epitaxial QDs from within AlGaAs Huygens’ metasurfaces.

Spatially varying refractive index profiles are the key to steer incoherent light, since reconfigurable metasurfaces operating as phased-antenna arrays can only steer coherent (laser) light. We discover spatial refractive index profiles beyond human intuition that enable high efficiency (77%) steering of incoherent emission from reconfigurable dielectric metasurfaces over an 80° field of view, using generative models and active learning. We developed a machine learning framework where an active learning agent drives a generative model (variational autoencoder-VAE) to predict a spatially structured optical pump pattern which, when imaged onto the metasurface, generates a highly directional emission of incoherent light. This was achieved by creating a dynamic spatially varying resonant phase gradients across the metasurface using an ultrafast (80fs, 1 Khz rep rate, 3mJ/cm^2) 800nm pump which images the pattern from a spatial light modulator (SLM) onto the metasurface. The photoluminescence (beam) steering is initially demonstrated using a periodic blaze (saw-tooth) grating patterns, which created a periodic refractive index profile using Drude free-carrier refraction, resulting in a spatial phase gradient on the metasurface and ultimately directing the momentum of the light emission. We find that AI-generated pump patterns are 10x more efficient in beam steering compared to the initial periodic blaze grating pump pattern designed using human intuition. Our work provides a novel machine learning driven closed-loop platform to understand and discover the physics of incoherent emission steering from metasurfaces with potential applications for augmented and virtual reality displays.

Epitaxially grown III-V QDs are promising sources for single photons with some of the highest metrics in purity, emission efficiency, brightness and indistinguishability reported to date. Here, we explore $Al_{30}Ga_{70}As$ Huygens’ resonators with spectrally overlapping the electric and magnetic dipole modes at the emission wavelength of a GaAs local droplet etching quantum dot for enhancing the emission of single photons. We enhance the emission rate of a single QD by an order of magnitude in comparison to an unstructured layer. We demonstrate anti-bunched single photon emission ($g^2(0) < 0.2$) under continuous wave (515nm) pumping with less than 45nW of pump power. Additionally, we report a 5x life-time reduction of the GaAs QD emission under increased pump fluence from 45 to 400nW. Finally, we demonstrate that the enhancement of the QD emission is independent of the position of the QD within the metasurface which alleviates a major challenge of placing these QDs with resonant nano-cavities. For semiconductor metasurfaces, the control of mode properties can open incredible opportunities in quantum information sciences, for manipulation of single photon qubits, and for enabling photon entanglement schemes and architectures.

Nanoimprinted PEDOT:PSS Polymer Metasurfaces with Metal-Like Infrared Optical Properties HaydeePacheco and DeirdreO'Carroll; Rutgers, The State University of New Jersey, United States

Polymer plasmonics offer exciting opportunities for the development of infrared nanophotonic devices. Notably, the high conductivity of heavily doped polymers allows for plasmonic properties and local electric field enhancement, resulting in enhanced infrared absorption and antenna effects. Understanding and controlling the shift in the plasma frequency of doped conductive polymers is crucial for designing and optimizing plasmonic devices and metasurfaces with tailored optical properties in various spectral ranges, including the infrared region.

Here, we report the fabrication and characterization of a nanoimprinted poly(3,4ethylenedioxythiophene) polystyrene sulfonate (PEDOT: PSS) polymer metasurfaces with metal-like optical properties in the infrared and high electrical conductivity. We focus on investigating the shift in the plasma frequency of nanoimprinted PEDOT:PSS polymer metasurfaces relative to planar-doped and undoped PEDOT:PSS surfaces. By adding dopants, such as DMSO, aniline, and ethanolamine, during film fabrication, we significantly enhance the film conductivity while inducing a corresponding shift in the plasma frequency. The heavily doped PEDOT:PSS films exhibit high electrical conductivities ranging from 10 to 1000 S/cm, making them suitable for plasmonic applications. Doped PEDOT:PSS metasurfaces were fabricated by spin-coating dopand-PEDOT:PSS solutions into films onto glass substrates and nanoimprinting the film using a custom-designed mold with a periodic array of nanostrips. We find that the resulting metasurface exhibits infrared absorption peaks in the 1.5 μm to 15 μm wavelength range, which we attribute to the excitation of surface plasmon resonances. We also characterize the metasurfaces using scanning electron microscopy (SEM) to confirm the morphology of the nanostrips, and Fourier-transform infrared (FTIR) spectroscopy to identify the chemical composition of the various doped PEDOT:PSS films. Our results show metasurface-induced significant changes in the reflection spectrum, with a pronounced dip at the resonance wavelengths, demonstrating efficient manipulation of infrared light by the metasurface structure.

Optical and Structural Characterization of ScO_xN_y and $ScSi_zO_xN_y$ Thin Films as Dispersion Engineered Optical Materials SmridhiChawla[1], KristianW. Munnikhuis[1], TornikeShubitidze[1], WesleyBritton[2], DavidWoolf[2] and LucaDal Negro[1]; [1]Boston University, United States; [2]Physical Sciences, Inc., United States

The development of compact diffractive optical elements with tailored optical phases has revolutionized the field of photonics, enabling the creation of high-efficiency photonic components with unprecedented functionalities. This research contributes to developing novel ScO_xN_y and $ScSi_zO_xN_y$ thin films, providing valuable insights into their optical properties, structural characteristics, and patterning potential. We studied the optical and structural properties of ScO_xN_y and $ScSi_zO_xN_y$ thin films, synthesized using reactive RF magnetron sputtering. By modulating the growth conditions and incorporating SiO_2 components through co-deposition and post-deposition annealing, we achieve tunability in the optical constants of the materials with refractive indices ranging from 1.7 to 3 with negligible absorption losses across the visible spectral range. Variable angle spectroscopic ellipsometry (VASE) is employed to determine the dielectric function of each sample in a broad spectral range extended from the ultraviolet to the mid infrared wavelengths. Furthermore, the structural properties of the thin films are investigated using atomic force microscopy (AFM), X-ray diffraction (XRD), and scanning electron microscopy (SEM). These characterization techniques provide insights into the surface morphology, crystal structure, and composition of the films, essential for understanding their optical performances. In addition, our study explores the suitability of different reactive ion etching (RIE) processes for the fabrication of nanopatterns in these materials. The etching behaviour and selectivity of the thin films is investigated with an aim to identify optimal etching conditions for achieving precise patterning and integration into functional photonic devices such as ultracompact imaging components and broadband dielectric metasurfaces.

Nonreciprocal Free Space Electromagnetic Wave Propagation Enabled by Magnetic Metasurfaces WeihaoYang, ShuangXia, YucongYang, WeiYan, JunQin and LeiBi; University of Electronic Science and Technology of China, China

Controlling the propagation of free space electromagnetic (EM) waves is of key importance in wireless communication, LIDAR and thermal energy harvesting applications. Nonreciprocal metasurfaces break Lorentz reciprocity, which may enable higher communication bandwidth and thermal energy harvesting efficiency. Nevertheless, experimental study on such devices have just emerged. In this report, I will present our recent progress on magnetic nonreciprocal metasurfaces. We demonstrate nonreciprocal phase gradient metasurfaces in the microwave frequencies (X and Ku bands) by using ferrite (BaM, YIG) based metaatoms. We designed the metaatoms by simulating their forward and backward scattering cross-section, amplitude and phase under the magnetized state. We designed the nonreciprocal metasurface by forming different phase gradients in the forward and backward directions based on the digital coded metasurface design method. In one experimental demonstration, we fabricated magnetic-bias-free metasurfaces using self-biased BaM materials, showing unidirectional EM wave transmission, nonreciprocal beam steering, nonreciprocal wave focusing and nonreciprocal holography at around 15 GHz. (Nat. Electron. 6,225, 2023) In a second work, we demonstrated reflection phase modulation in YIG meta-atoms by shifting their Larmor precession frequency using gradient magnetic fields, realizing nonreciprocal beam steering up to 28 deg. at 6.5 GHz. I will also present preliminary results on how to fabricate such devices in optical and thermal infrared frequencies. Our work provides a general strategy for design and fabrication of magnetic nonreciprocal metasurfaces, providing a practical solution for nonreciprocal EM wave propagation manipulation for wireless communication, LIDAR and thermal energy harvesting applications.

Light Source Engineering of Directive Photoluminescent Metasurfaces with the Local Kirchhoff's Law EliseBailly, Jean-PaulHugonin, BenjaminVest and Jean-JacquesGreffet; Institut d'Optique Graduate School, France

Controlling spontaneous is the key to build efficient sources with controlled spectrum, angular emission pattern or polarization. This can be traditionally performed by adding external components, such as filters, lenses or polarizers that shape the wavefront emitted by an external source – but this all results in bulky and expensive system.

Over the past few years, progress in nanophotonics showed the extreme versatility of metasurfaces, designed as thin multifunctional components operating via the interaction between an incident wavefront and periodic elements covering the surface. The shaping of light features comes from the local scattering of a coherent wavefront by meta-atoms. Spatial coherence is therefore critical to engineer directional light sources, and is challenging to maintain when working with ensembles of emitters, as required in order to build bright sources delivering enough sufficient levels of optical power.

In this presentation, we investigate designs of light-emitting metasurfaces, or in other words, nanostructured surfaces covered with emitters. In these systems, the interaction between emitters and the metasurface enables a precise control of the emission properties. In particular, spatially extended modes can be exploited to restore spatial coherence between initially independent emitters, and therefore to shape the angular distribution of emitted light.

A first part of our presentation will comment on our design approach. The standard approach way to proceed is to calculate the field emitted by a dipole placed in the electromagnetic environment of the structure, and by summing and averaging out incoherently over all positions of the dipole. We follow here a radically different approach that exploit reciprocity : we use the local Kirchhoff's law to optimize the emission features in terms of spectrum, polarization and directivity by optimizing the absorption features of the same structure in the reciprocal picture.

This approach gives us the possibility to access quantitatively to the performances of the structure, in terms of efficiency or total emitted power. The latter for instance can be maximized by maximizing the local absorptivity of the structure within the active layer, and making it as cloSe as possible to unity.

In a second part, we will present devices consisting of a 2D metallic (silver) grating covered with a thin layer of nanoplatelets deposited by spin coating on the metasurface. The samples were designed following the Kirchhoff's approach, then fabricated in a clean room environment. Our samples provide highly directional photoluminescence at 605 nm, both in s and p polarizations, with an emission cone around 13.4° half angle.

This work paves the way towards new paradigms in metasurface designs and to a new generation of ultra-thin photoluminescent sources providing highly-controlled wavefront all in a device incorporating both the active medium and the electromagnetic environment that shapes the emission.

Adaptive Photonic Platforms for Radiative Thermal Management in Near-Space and Space Environments DanielK. Kindem, KarlPederson, SamKeller and OgnjenIlic; University of Minnesota, United States

Materials with tunable optical properties offer exciting opportunities for dynamic control of thermal emission and radiative heat transfer. Among such materials, solid-state chalcogenide glasses are characterized by a reversible amorphous-crystalline phase change process with benefits such as substantial refractive index contrast, stability of both phases over a broad range of temperatures, and the ability to maintain state without the use of energy. In this work, we discuss how these desirable properties can be implemented into photonic platforms for near-space and space environments where the radiative contribution to heat transfer is dominant.

We present a systematic approach for modeling and optimizing multi-state thermal emissivity spectral profiles that are relevant in this radiative environment. Using this model, we explore viable candidate metamaterial and metasurface platforms capable of minimizing or maximizing their temperature profiles, depending on the desired target behavior. Our analysis further elucidates the appropriate experimental parameters governing the thermal behavior of these photonic structures in near-space and space environments. This enables reliable prediction of temperature profiles of different adaptive photonic platforms under various heat transfer modes. The proposed approach has promise in realizing efficient and dynamic thermal management of satellites and spacecraft.

2:15 PM EL08.13.04
What Can a Laser-Induced Microbubble Do for Photonics?MonikaKataria and ZijieYan; University of North Carolina at Chapel Hill, United States

Upconversion nanoparticles (UCNPs) have proven their remarkable versatility and importance in a wide range of applications, including displays, bio-imaging, sensing, optoelectronics, photovoltaics, photocatalysis, therapeutics, and diagnostics. These nanoparticles possess the unique capability to emit ultraviolet and visible photons by absorbing multiple near-infrared (NIR) photons, thanks to their multi-energy level systems derived from the $4f^n$ electronic configuration of lanthanides. However, their practical utilization is impeded by the low quantum yield of upconversion emission, resulting from limitations such as multiphoton processes and low absorption cross-section. To overcome this challenge, we have devised and successfully demonstrated an innovative strategy to enhance the emission of a UCNPs film utilizing laser-induced microbubbles. The microbubble shoulders multiple functionalities, including the collection of plasmonic silver nanoparticles (Ag NPs) *via* the Marangoni effect, their controlled deposition onto the UCNPs film to amplify emission through localized surface plasmon resonances (LSPR), and the creation of a bubble micro-resonator enabling optical whispering gallery modes (WGMs). The experimental setup involved an optical trapping system operating at $\lambda = 800$ nm, an upconversion excitation laser at $\lambda = 980$ nm, an optical microscope, and a spectrometer. The UCNPs ($NaYF_4$: 30 % Yb, 1 % Tm @ SiO_2) employed in this study were monodispersed with an average particle diameter of 24.7 ± 1.8 nm. Dispersed in ethanol, they exhibited multimodal upconversion emissions centered around 449 nm and 475 nm upon excitation at 980 nm. To achieve maximum extinction at approximately 450 nm, silver metal nanoparticles (Ag NPs) of size ~70 nm were selected based on localized surface plasmon resonance (LSPR) matching. The developed platform employs laser-induced bubbles to establish a micro-resonator atop a bilayer film composed of poly(methyl methacrylate) (PMMA) and

UCNPs within a sample cell. At the interface of the microbubble and the PMMA/UCNPs film, Ag NPs are efficiently collected. This integration synergistically enhances upconversion emissions by combining resonant plasmonic Ag NPs with the optical WGMs provided by the bubble micro-resonator. Consequently, the emission intensity from the UCNPs is amplified by over 200 times compared to the case of UCNPs alone. Moreover, the controlled growth and gradual disintegration of the bubble enabled the precise imprinting of Ag NPs onto the PMMA/UCNPs film, enabling the creation of intricate metallic nanoparticle patterns through bubble-pen lithography. The versatile properties exhibited by microbubbles make them highly suitable for the development of multifunctional devices that effectively address the prevailing demands of sustainable technologies. Furthermore, the integration of UCNPs films and laser-induced microbubbles in a solution successfully overcomes the challenges associated with the manipulation and control of micro-bubbles at solid-liquid interfaces, thereby presenting new opportunities for real-time applications. This interdisciplinary research not only highlights the immense potential of laser-induced microbubbles but also underscores their promising applications in the fields of photonics and biomedicine.

Advances in Strong Coupling Between CdSe Nanoplatelets and Fabry-Pérot Microcavities RobertCollison, NicoleM. Cogan, OvishekMorshed, MiteshAmin, LiangyuQiu, TrevorTumiel, TrevorOllis, WilliamF. Girten, FarwaAwan, PengfeiHuo, ToddKrauss and NickolasVamivakas; University of Rochester, United States

Fabry-Pérot (FP) cavities containing CdSe nanoplatelets (NPLs) were fabricated by three methods. In the first method, NPLs were dispersed in a polymer film on top of a distributed Bragg reflector (DBR), and overcoated with silver[1]. The resulting cavity exhibited strong coupling, with a Rabi splitting of 50 meV and a Q-factor of 270. However, the presence of the polymer and resulting phase segregation between polymer and NPLs limited the concentration of NPLs within the cavities, thereby limiting the strength of the coupling between the NPLs and the cavity photon.

In the second method, the NPL/polymer layer was replaced with a single layer of neat NPLs. These cavities exhibited larger Rabi splittings, up to 80 meV, but with Q-factors around 50, lower than the Q of the NPL/polymer cavity, which we attribute to the increased absorption and scattering losses of the concentrated NPL films, and to the roughness of silver mirror deposited onto the neat NPL film.

To improve the Q factor of the cavities, a third iteration of cavities were made having thinner layers of neat NPLs enclosed between two SiO_2 spacer layers. This arrangement reduced the average absorption and scattering losses of the film stack and planarized the Ag top mirror. A Rabi splitting of up to 60 meV and a Q a 360 was achieved.

These results demonstrate the importance of concentration and uniformity in the assembly of FP microcavities with colloidal semiconductor nanoplatelets, and how these factors meaningfully affect the degree of strong coupling.

Quantum Nanoplasmonic Networks at Ambient Temperature OrtwinHess; Trinity College Dublin, The University of Dublin, Ireland

Quantum technologies are widely expected to bring a revolution in communications and information technologies in the coming decade allowing, for example, un-paralleled levels of secure communications. For quantum communication, photonic quantum effects have played a central role, but most photonic solutions and systems based on light-matter interaction also require cryogenic environments. Strong coupling of light and matter at the single emitter level is a fundamental quantum resource offering deterministic energy exchange between single photons and a two-level system, and the possibility to achieve single-photon nonlinearities via the anharmonicity of the Jaynes-Cummings ladder. Until recently, however, the conditions for achieving strong light-matter coupling were most commonly met at cryogenic temperatures such that de-coherence processes are suppressed. As a major step forward, we have recently demonstrated room-temperature strong coupling of single molecules [1] and single quantum dots [2] to ultra-confined light fields in plasmonic resonators at ambient conditions. The fact that strong-coupling conditions may be reached at room temperature is of immense interest because it represents a clear route to a practical implementation and use of quantum behaviour in nanophotonic systems and its application in bio-sensing [3].

The talk will discuss how nanoplasmonics can be an enabler of ultrafast quantum nanophotonic networks via strong coupling and ultrafast quantum dynamics [4]. We will highlight the physics associated with recently demonstrated room-temperature strong coupling of single molecules in a plasmonic nano-cavity [1] and near-field generated strong coupling of single quantum dots [2] and single quantum emitter Dicke enhancement [5] paving the road towards single-photon quantum nonlinearities. The presentation will also explain near-field enhanced single-photon emission in near-zero index materials [6] and ultrafast multi-partite quantum entanglement [7]. This provides the foundation for unprecedented control over photon number, single photon dynamics, and dynamic multi-photon coherence. These properties are all imperative for the development of next-generation, nanoscale building blocks in ambient-temperature quantum communication technologies.

Design of Different Leaky MoS_2 Nanoresonators Focusing on Biosensing Application DipanjanNandi and ManishaGupta; University of Alberta, Canada

Novel atomically thin layered two-dimensional transition metal-dichalcogenides (TMDCs) such as MoS_2 are a promising material for different for optoelectronic applications [1] as well as

biosensing [2,3]. In recent reported works, MoS_2 based field-effect transistor platform was demonstrated for sensing of protein and DNA molecules [4,5]. Stacked heterostructure of MoS_2 and graphene were also explored for detecting Rhodamine 6G (R6G) molecules [6] and DNA hybridization [7].
In this work, we propose different metasurface designs with MoS_2 for biosensing applications. The reason of using MoS_2 is due to its high refractive index (n > 4 [8]) contrast with air and low absorption (k < 1 [8]) in the visible wavelength range both at monolayer and bulk thicknesses. Also, MoS_2 surface favours bonding with carboxyl (-COOH) group, which makes it compatible for biofunctionalization. We have explored designs with MoS_2 split-nanorings and nanotriangles. Finite difference time domain (FDTD) simulations were performed to optimize the different design parameters such as, inner and outer diameter, pitch, and split gaps of nanorings and side length and gap between nanotriangles, height of MoS_2 to study the leaky resonances for biosensing applications. Simulations have been performed with polystyrene particles (100 nm diameter) distributed (Gaussian distribution) over the device surface and the resonance wavelength shift was calculated with respect to the number of particles. The size of polystyrene particles was chosen as 100 nm because, because it matches with the size of small virus such as, SARS-CoV-2 and Influenza (H1N1). Here, we have considered polystyrene particles as most of the bioanalytes have similar refractive index to the polystyrene [9].
One of the best design parameters for split-nanorings resonators are: diameter: nanoring's outer diameter- 200 nm, inner diameter- 100 nm, height of MoS_2 nanoring- 150 nm, split gap- 50 nm with gap between two adjacent nanorings- 200 nm, and sensitivity achieved 59.49 nm/decade. The best sensitivity achieved with MoS_2 nanotriangles array is 305.31 nm/decade with 100 nm side length of 100 nm of equilateral triangle. In this study our primary goal is to introduce a symmetry breaking structure to leak out the resonance field to attain high detection sensitivity for small size bioanalytes detection. Attachment of target bioanalytes on the MoS_2 nanoresonators surface disturbs the resonance field and induces a red-shift at the resonance wavelength and detection sensitivity is obtained by calculating the slope of resonance shift curve with respect to the bioanalytes concentrations. We will present the design optimization and comparison between different MoS_2 nanoresonators detection performances.

8:00 PM EL08.14.02
Photo-Induced Enhanced Raman Spectroscopy from β-glucan-AuNPs-Thiram Films Douglasd. Lopes[1], RafaellaF. Fernandes[1], PaolaCorio[1] and AlexandreBrolo[2]; [1]University of Sao Paulo, Brazil; [2]University of Victoria, Canada

Photo-Induced Enhanced Raman Spectroscopy (PIERS) is an exciting novel technique for the enhancement of the Raman signal of molecular adsorbates. By irradiating semiconductor and plasmonic nanoparticles hybrid substrates using UV photons, the vibrational signal can be enhanced beyond the typical electromagnetic mechanism of Surface Enhanced Raman Spectroscopy (SERS), through resonant Charge-Transfer (CT) transitions. The creation of oxygen vacancy defects (V_O) in semiconductor materials is universal to explain PIERS. The presence of such defects alters the local surface charge and is reported to be responsible for the increase in the density of donor electronic states within the semiconductor bandgap, leading to the absorption of visible radiation. During exposure to Raman laser radiation, electrons occupying V_O defect states can be promoted to the conduction band (CB) of inorganic semiconductors to be transferred to metallic nanoparticles on the semiconductor surface. This charge migration and consequent increase in charge density shifts the Fermi level of plasmonic nanoparticles and significantly increases the probability of CT transitions with molecular orbitals of the analyte under investigation. The synthetic approach to obtain semiconductor materials with such properties can be not as straightforward and time-consuming, usually requiring several steps and chemicals. Organic semiconductors can arise as an alternative material to more traditional semiconductors, such as TiO_2, as templates for PIERS-active substrates.
Herein, β-glucan films (extracted chemically from Usnea lichen (*Usnea* sp.) through a low-cost methodology) were used as an organic template for Gold Nanoparticles functionalized with Thiram (AuNPs-Thiram), a widely used dimethyl dithiocarbamate fungicide to prevent crop damage in the field and to protect harvested crops from deterioration in storage or transport. Thiram is cleaved upon interacting with the AuNPs' surface and its S–S bond is broken, yielding two dimethyldithiocarbamate ions. Thiram is chemically adsorbed on AuNPs through S–Metal bonds and results show that UV pre-irradiation of β-glucan-AuNPs-Thiram films leads to an enhancement of Thiram Raman signal beyond SERS intensities. Although the detailed mechanism for the PIERS effect in organic semiconductors and plasmonic nanoparticles hybrid substrates remains rather unclear, charge separation and migration between the β-glucan biopolymer phase and AuNPs were successfully probed in our experiments. Our results demonstrate that our substrate can be used as a greener alternative material to typical semiconductors employed for PIERS applications and could potentially provide a deeper understanding of the mechanism for the enhancement effect in alternative materials in which the typical UV photo-induced formation of V_O defects is not expected.

8:00 PM EL08.14.03
Geometrical Hierarchy-Derived Optical Asymmetry for Photovoltaic Application ByunghoonKim[1], Gyu-HeeKim[2], LeeChihyung[2], Yong JaeCho[2] and Doo-HyunKo[2]; [1]Princeton University, United States; [2]Sungkyunkwan University, Korea (the Republic of)

In the quest for efficient and sustainable energy sources, a photovoltaic technique has emerged as a promising solution for harnessing solar energy. The primary strategy for facilitating this technique is to achieve efficient light absorption and/or manipulation of light propagation inside the media. This study presents a novel design to remarkably improve the efficiency of photovoltaic devices by incorporating the concept of optical asymmetry. The proposed structure features multidimensional and hierarchical geometry that differ hundreds of times, allowing anomalous light propagation within the media. It phenomenologically shows the notable light-trapping effect at a wide wavelength regime, thereby enhancing the overall short-circuit current by up to 46.19%. Taking a step forward, we explored the leverage of this structural design for the wavelength-converting material. Targeting the photon excitation regime of the photoactive layers, we observed a significant improvement of short-circuit current density up to 25.97% in the semi-transparent photovoltaic system at indoor light illumination. We believe this research opens up new avenues to externally optimize such photovoltaic systems, paving the way for more efficient and sustainable solar energy utilization.

8:00 PM EL08.14.04
Au@Ag Nanostructures for the Sensitive Detection of Hydrogen PeroxideI-HsiuYeh[1], SirimuvvaTadepalli[2] and Keng-KuLiu[1]; [1]National Tsing Hua University, Taiwan; [2]Stanford University, United States

Hydrogen peroxide (H_2O_2) is an important molecule in biological and environmental systems. In living systems, H_2O_2 plays essential functions in physical signaling pathways, cell growth, differentiation, and proliferation. Plasmonic nanostructures have attracted significant research attention in the fields of catalysis, imaging, and sensing applications because of their unique properties. Owing to the difference in the reduction potential, silver nanostructures have been proposed for the detection of H_2O_2. In this work, we demonstrate the Au@Ag nanocubes for the label- and enzyme-free detection of H_2O_2. Seed-mediated synthesis method was employed to realize the Au@Ag nanocubes with high uniformity. The Au@Ag nanocubes were demonstrated to exhibit the ability to monitor the H_2O_2 in the range of concentration from 0 μM to 200 μM with r^2=0.904 of the calibration curve and the limit of detection (LOD) of 1.11 μM. In the relatively narrow range of the H_2O_2 concentration from 0 μM to 40 μM, the LOD was calculated to be 0.60 μM with r^2=0.941 of the calibration curve of the H_2O_2 sensor. This facile fabrication strategy of the Au@Ag nanocubes would provide inspiring insights for the label- and enzyme-free detection of H_2O_2.

8:00 PM EL08.14.05
Plasmonic Nanomaterials-Based Flexible Strip for the SERS Detection of Gouty Arthritis Mei-ChinLien, I-HsiuYeh, Yin-ChengLu and Keng-KuLiu; National Tsing Hua University, Taiwan

Flexible biochips that enable sensitive detection and simultaneous quantification of biomarkers are of great importance in the field of point-of-care testing. Cellulose paper-based biochips have been employed for the diagnostics and biosensing owing to their unique advantages such as high specific surface area, flexibility, and abundance. Recently, surface-enhanced Raman scattering (SERS)-based flexible biochips have attracted a great deal of research attention for disease detection due to their rapid, sensitive, and noninvasive sensing abilities. Phenomenal progress in the synthesis of structure-controlled plasmonic nanomaterials has made SERS a powerful sensing platform for disease diagnosis and trace detection. Owing to their outstanding optical properties, noble metal nanomaterials are excellent candidates for chemical and biological sensing applications. Yolk-shell structured plasmonic nanomaterials, which consist of solid nanomaterials as the core and nanocage as the shell, have been demonstrated to exhibit extraordinary optical properties due to their high surface to volume ratio and the high density of the electromagnetic fields compared to their solid counterparts. Here, we demonstrate the flexible plasmonic biochips for the SERS-based detection of uric acid (UA). Flexible strips exhibited excellent sensing performance with a detection limit of around 10 μM of UA, which is lower than the average level of UA in tears. This rapid and sensitive detection method enables the noninvasive diagnosis of gouty arthritis.

8:00 PM EL08.14.06
Comprehensive Development of Reactive Sputtering Parameters for High-Performing Zirconium Nitride Thin Films for Earth-Abundant Plasmonics KyleHaas[1] and VivekSubramanian[1,2]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Institute of Electrical and Microengineering, Switzerland

Zirconium Nitride (ZrN) is a highly promising earth-abundant alternative for plasmonic materials due to its lower cost, high electrochemical stability, and greater mechanical durability than traditional metals like Au and Ag. While epitaxial films enable longer plasmonic propagation lengths than their polycrystalline counterparts, epitaxial ZrN has so far only been achieved with expensive, MgO substrates via unbalanced magnetron reactive sputtering. Therefore, research efforts have been focused on developing ZrN films on Si/SiO_2 substrates to achieve low-cost films with optical performance suitable for commercial plasmonic applications such as on-chip waveguiding and catalysis enhancement. However, a comprehensive understanding of the reactive sputtering deposition conditions necessary for high-performing ZrN thin films on Si/SiO_2 substrates is lacking; most research has relied on high-deposition temperatures and the tuning of N_2 flow rates to produce films of acceptable quality. Most notably, the influence of large substrate biases (>100V) on ZrN film formation and its corresponding optical properties has been largely unexplored; given the strong impact of the increased kinetic energy that results from bias, this is a shortcoming of the existing studies.

Herein, for the first time, we explore the systematic tuning and effect of deposition temperature, nitrogen flow rate, and substrate bias, on the optoelectronic properties of ZrN thin films via XRD, XPS, and spectroscopic ellipsometry. First, to optimize the nitrogen concentration and generate stoichiometric ZrN, the ideal gas flow rate was found to be 2.0:30sccm N_2:Ar at a plasma power of 150W. Next, we demonstrate that a large, applied RF bias of 400V to the Si substrate enables optimum film formation conditions, likely arising from increased film densification, as evidenced by improved optical properties and higher surface plasmon polariton figures of merit (Q_{SPP}). Lastly, we show the effect of moderate, elevated temperatures of 400C, on improved film performance likely from decreased microstrain as evidenced similarly.

As a result, our highest performing ZrN films demonstrate a Q_{SPP} over 50 in the VIS-IR spectrum rivaling the best silicon-based ZrN films across literature. Without relying on expensive MgO substrates or extremely high deposition temperatures, we demonstrate the comprehensive effect of sputtering conditions on film formation and plasmonic performance. Given the significant performance achievements, this work can open the door for widely accessible, earth-abundant plasmonic materials suitable for electrochemical and optoelectronic systems and devices operating within the VIS-IR spectrum.

8:00 PM EL08.14.07
Engineering Photonic Nanodevice by Prescribed Particles Organization and DNA-Based Self-Assembly AlexiaYun[1], BrianMinevich[1], HuajianJi[1], JiahaoWu[1,1], KaterinaDeOlivares[1], DanielRedeker[1], GloriaLee[1], NanfangYu[1] and OlegGang[1,2,1]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States

Engineering novel optical properties via self-assembly is a promising approach for the fabrication of complex photonic devices with light harvesting, light manipulation, and optical communication capacities. The ability to organize nanoparticles with precise spacing at different scales can enable the structured nanomaterial with emergent optical properties. However, the realization of such materials remains a challenge. We use a DNA-based self-assembly platform to fabricate three-dimensional (3D) optical materials with ordered nanoparticles. DNA origami frames with DNA complementary bonds can capture selective nano-cargo in prescribed spatial positions with nano-scale precision. Programmable bonds enable DNA origami to serve as building blocks that can self-assemble into 3D lattices with repeating and highly organized nanoparticle motifs. By designing an organized structure that couples plasmonic and light-emitting nanoparticles, we investigated the light-emitting properties of the assembled 3D arrays. The optical properties were strengthened by the site-specific growing of the plasmonic particles within the lattice. To enhance stability, the assembled materials were silicated prior to advanced material characterization and optical measurements. To characterize the assembled materials and to achieve the desired optical response, we used electron microscopy and small-angle X-ray scattering (SAXS) to optimize the assembly process, particle sizes, and particle organization. We further investigated the optical properties by optical microscopy and spectroscopy.

8:00 PM EL08.14.08
Integration of Nanophotonic Structures with a Metallic Nanoporous Air Filter for Particulate Matter Monitoring SeongjaeKim[1], GaabhinRyu[1], JihaeChang[1], YongtaekIm[1], Jessie SungyunJeon[1], HanaLim[2], Hyun-JongKim[2] and SanhaKim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

The filtration and analysis of airborne particles have received substantial attention since the COVID-19 pandemic. Previous methods of analyzing airborne particles were conducted independently using a sampler, which requires a lengthy and complicated preparation process. In this research, we introduce a new concept of filter-type surface-enhanced Raman spectroscopy (SERS) substrate that allows the simultaneous collection and analysis of ultrafine nanoparticles in the air. SERS is an analytical technique that investigates small amounts of molecules without labeling, which predominantly utilizes the localization effect of an electric field on the nanophotonic surface. Such an analysis method is advantageous over conventional chemical sensors, as a wide range of analyte molecules are detectable. Furthermore, with the recent advance in the miniaturization of spectroscopic devices, there is an increasing potential for integration with Internet of Things (IoT) applications. The proposed substrate in this study is fabricated using the scalable electrochemical deposition of copper nano-dendrites followed by appropriate post-engineering processes to create a nanoporous metal membrane. The thin porous media is suitable for the physical filtration of small particulate matter in the air, and the excellent electrical conductivity of copper allows the capture of particles via electrostatic attraction. In addition, the SERS activation capability is achieved via electron beam deposition of gold. The gold-copper nanoporous membrane demonstrates a particle capture efficiency of ~96% for 300 nm particles under a charging condition of 5 kV with a differential pressure of 121 Pa. The captured particulates on the substrate can be monitored via Raman spectroscopy. We evaluate the performance of the substrate by measuring the Raman spectra of a 1 μM Rhodamine 6G solution and a bacterial sample (*P. aeruginosa*). Characteristic peaks are observed in both cases, which indicates successful detection. Additionally, we measure the Raman spectra from aerosolized Rhodamine 6G particles as small as 150 nm. The substrate exhibits excellent mechanical properties due to the roll pressing process, which simultaneously allows it to be reused via liquid phase rinsing. Even after undergoing repeated compression tests of ~22,000 cycles at 177 kPa, the substrate maintains functionality along with its filtering and sensing properties. We further conduct numerical simulations to elucidate the localized enhancement of the Raman signal from the nanoporous metal membrane. Finite-difference time-domain (FDTD) simulations of Maxwell's equations reveal amplification of the near field between the nanorod structures. Moreover, by analyzing the electrostatic potential using the finite element method (FEM), we confirm that the particles can be spontaneously transported toward the electromagnetic hotspot.

8:00 PM EL08.14.09
Plasmonic External Nanogap Dumbbells for On-Particle Direct Raman Assays KyunginChoi and Jwa-MinNam; Seoul National University, Korea (the Republic of)

Metal nanostructures with a plasmonic nanogap are useful for surface-enhanced spectroscopy, and many bio-applications like biosensing and bioimaging. The use of these structures as chemical and biological sensing/imaging probes typically requires an ultra-precise synthesis of the targeted nanostructure and skill in complex assay techniques are required. Here, we designed and synthesized a plasmonic nanostructure based on Au nanorod cores with two types of external nanogap particles with different gap positions. Au dual-gap nanodumbbells (AuDGNs) were synthesized via the anisotropic adsorption of polyethyleneimine (PEI) on Au nanorods to facilitate tip-selective Au growths on nanorod tips for forming mushroom-shaped dumbbell-head structures at both tips. The dual gaps (intra-head and inter-head gaps) were formed within a single particle. Au tip-intragap nanodumbbells (AuTIDs) were synthesized based on co-reduction and dealloying process of Ag and Au on the tip of Au nanorods. Two heads with closed intra-head gap were grown on the tips of Au nanorod and inter-head gap exposed to outer environment were formed within a single particle. Importantly, these particles enabled facile on-particle SERS detection assays in a short period of time through the diffusion of target molecules into the gap exposed to outer environment.

8:00 PM EL08.14.10
Phase Modulator Ellipsometry Based Biosensor for Detection of *E. coli* K12SorayaZangenehzadeh[1], FenjaSchröder[1], SvenjaHerdan[1], EmilAgocs[1], NassimaAmroun[1], RebekkaBiedendieck[2], BernhardW.Roth[3], Hans-HermannJohannes[1], DieterJahn[2] and WolfgangKowalsky[1]; [1]Institute of High Frequency Technology, Germany; [2]Braunschweig Center for Systems Biology, Germany; [3]Hanover Center for Optical Technologies, Germany

In recent years, rapid detection of pathogenic microorganisms in human food and water resources has been widely investigated to reduce the number of deaths as well as economic loss. Surface plasmon resonance (SPR) sensors as an optical method is used for detection of biological and chemical targets. These biosensors are extensively applied for monitoring of microorganisms such as bacteria. While most strains of *E. coli* are harmless, there are certain pathogenic strains that can cause illnesses in humans. Due to the size of *E.coli* bacteria (~ 1 micron), detection of these microorganisms brings challenges in experimental measurement. In this study, we aim to apply phase-modulator based ellipsometer to enhance the performance of conventional SPR sensors for E. coli detection.
Surface plasmons as an surface charge density waves of free electrons at a metal surface propagate at metal-dielectric interface. In specific angle, the p-polarized incident light is strongly absorbed in consequence of coupling the evanescent wave generated at metal-dielectric interface and surface plasmon waves. Hence, the resonance can be observed as an sharp dip in reflectivity profile. Conventional SPR sensors monitor the changes in the intensity of reflected light according to the changes of refractive index of target sample. In resonance condition, not only the intensity of the incoming light changes, but also the phase change is strongly modulated. Due to the significant phase jump, this sharper shift can be studied to improve the performance of SPR sensors. Spectroscopic ellipsometry provides this opportunity to study both reflectance ratio and phase changes in reflected light from the sample of interest. Spectroscopic ellipsometry analyzes the changes in the polarization state of light after reflection or transmission from a surface and determines the optical properties and thickness of thin films. These changes in polarization states are studied by the amplitude ratio (Ψ) and the phase difference (Δ) between p- and s-polarized light, respectively. There are different measurement methods of ellipsometry based on the optical elements configuration and arrangement. Barium borate crystal based phase-modulator has been used in our optical setup to induce phase changes in the incoming light beam. Using a phase-modulator in optical design of ellipsometer makes it a faster measurement tool compared to the conventional ellipsometric measurement methods. Using this method each measurement takes around micro second. Therefore, this method can be used for detection of microorganisms with higher time resolution.
This project has been focused on using conventional Kretschmann configuration including quartz prism and ~45 nm of homogenous gold film to support propagation of surface plasmon waves. Gold film is functionalized with porphyrin molecules as a linker with specific peptide group to bind with outer membrane of Gram-negative bacterium. This configuration has been used upon phase-modulator ellipsometer to monitor E. coli K12.

8:00 PM EL08.14.11
Abnormal In-Plan Epitaxy and Formation Mechanism of Vertically Aligned Au Nanopillars in Self-Assembled CeO_2-Au Metamaterial System JuanjuanLu[1], DiZhang[2], RobynneL. Paldi[3], ZihaoHe[1], PingLu[3], JuliaDeitz[3], AhmadAhmad[1], HongyiDou[1], XuejingWang[2], JunchengLiu[1], ZedongHu[1], BoYang[1], XinghangZhang[1], AnterA. El-Azab[1] and HaiyanWang[1]; [1]Purdue

University, United States; [2]Los Alamos National Laboratory, United States; [3]Sandia National Laboratories, United States

Metamaterials present great potential in the applications of solar cells and nanophotonics, such as super lenses and other meta devices, owing to their superior optical properties. In particular, hyperbolic metamaterials (HMMs) with exceptional optical anisotropy offer improved manipulation of the light-matter interactions as well as a divergence in the density of states and thus have enhanced performances in related fields. Recently, the emerging field of oxide-metal vertically aligned nanocomposites (VANs) suggest a new approach to realize HMMs with flexible microstructural modulations. In this work, a new oxide-metal metamaterial system, CeO_2-Au, has been demonstrated with variable Au phase morphologies from nanoparticle-in-matrix (PIM), nanoantenna-in-matrix, to VAN. The effective morphology tuning through deposition background pressure, and the corresponding highly tunable optical performances of three distinctive morphologies, were systematically explored and analyzed. A hyperbolic dispersion at higher wavelength has been confirmed in the nano-antenna CeO_2-Au thin film, proving this system as a promising candidate for HMM applications. More interestingly, a new and abnormal in-plane epitaxy of Au nanopillars following the orientation of CeO_2 matrix instead of the $SrTiO_3$ substrate, was discovered. Additionally, the tilting angle of Au nanopillars, α, has been found to be a quantitative measure of the balance between kinetics and thermodynamics during the depositions of VANs. All these findings provide valuable information in the understanding of the VAN formation mechanisms and related morphology tuning.

8:00 PM EL08.14.12
Alternative Platform for COVID-19 Diagnosis Based on AuNPs Modified Lab-On-Paper PornchanokPunnoy, TatiyaSiripongpreda, TrairakPisitkun, NadnuddaRodthongkum and PranutPotiyaraj; Chulalongkorn University, Thailand

Since the SARS-CoV-2 virus was first discovered in 2019, it has spread over the world. Rapid testing is critical to retard the spread of the virus. Herein, a Lab-on-Paper for diagnosis of COVID-19 is developed applying a colorimetric method for screening test, along with high precision SARS-CoV-2 antigen detection on paper using a laser desorption ionization mass spectrometry (LDI-MS). Gold nanoparticles (AuNPs) were modified on paper for both colorimetric and LDI-MS detection. The colorimetric detection is based on the color change occurring on the paper from pink to purple as a result of AuNP aggregation which can be regulated by antigen−antibody bioconjugation. AuNPs on paper can be used directly as an LDI-MS substrate for direct quantitation of SARS-CoV-2 antigen in saliva without sample preparation for SARS-CoV-2 quantitative detection. In comparison to RT-PCR, LDI-MS provides early diagnosis with high sensitivity, rapidity without sample preparation, as well as a lower cost/test, which is crucial for preventing mortality of patients with underlying conditions. This approach demonstrated linearity between 0.01 and 1 μg mL^{-1}, covering a cut-off value of 0.048 μg mL^{-1} for COVID-19 indication in saliva. Hence, this platform might be a potential device for applying as non-invasive diagnosis of COVID-19 Omicron BA.2 variant.

8:00 PM EL08.14.13
***In Vivo* Real-time Multiplex Detection of Plant Signalling Molecules using Surface-Enhanced Raman Scattering Nanosensor**Won KiSon, Seon-YeongKwak and Dae HongJeong; Seoul National University, Korea (the Republic of)

To understand the biological and chemical dynamics of plants is essential in agriculture, and various sensor technologies have been studied. 'Plant signalling molecules' released against stimuli are drawing attention as a key to understand plant's status under stressors. Surface-enhanced Raman scattering (SERS)-based nanosensor has shown strong potential for its non-invasiveness and capability of real-time detection from fingerprint spectra. In our research, we fabricated PDDA-capped Ag nanoshell (AgNS@PDDA) and introduced it into plants through stoma. Due to AgNS@PDDA's optical activity in NIR, it was possible to evade chlorophyll’s autofluorescence and obtain SERS signals with fine quality. Also, PDDA polymer effectively attracted signalling molecules by coulombic interaction.
Then, we studied the plant's reaction against biotic and abiotic stress with SERS signal monitoring. When plants leaf was under wound stress or cold stress, nasturlexin B, extracellular ATP and glutathione were successfully detected *in vivo* environment. Meanwhile, biotic stress was studied for the plants infected with fungal disease. *F. Graminearum* was injected into the plant, and signaling molecules was monitored with nanosensors according to the elapsed days after injection. Even only 2 hours after the fungi injection, when no lesion was detectable, SERS signals of eATP and salicylic acid related to systemic acquired resistance were successfully detected.

8:00 PM EL08.14.14
Pulsed Laser Ablation for Flexible Printed Electronics Applications: Harnessing the Power of Colloidal Nitride Nanoparticles StavrosPanos, NikolaosPliatsikas, SpyridonKassavetis, MariaGioti and PanosPatsalas; Aristotle University of Thessaloniki, Greece

Nitrides are of the most prominent families of materials dominating nowadays. They can be divided into two distinct sub-categories: i) III-nitride wide-gap semiconductors (GaN, AlN) and ii) Conducting nitrides of IIIb-Vb transition metals (TiN, ZrN, $Ti_{1-x}Sc_xN$, $Ti_{1-x}Ta_xN$) that have recently emerged as important plasmonic materials.
Despite the intrinsically superior electrical and optical performance of nitrides compared to conductive oxides, there is a continued and strong prominence of oxides over nitrides in flexible printed electronics due to the compatibility of oxides with solution methods that provide enormous scale up and have allowed oxides to enter the field of printed electronics. The refractory nature of nitrides and the use of high vacuum, introduce industrial costs, reduced scalability and increased power consumption. Therefore, alternative technologies for the fabrication of nitrides are required to be adapted to the needs of printed electronics such as R2R printed sensors and optoelectronic devices.
In this study we propose a radical solution to overcome all the aforementioned obstacles by applying laser fabrication processes that promises to produce colloidal nitride nanoparticles with the desired optoelectrical or plasmonic performance compatible with printed technologies. The colloidal nanoparticles were fabricated through laser ablation of Titanium Nitride (TiN), Gallium Nitride (GaN) and Aluminum Nitride (AlN) thick coatings using a nanosecond Nd:YAG pulsed laser at 355, 532 and 1064 nm wavelengths in various liquids. The colloidal NPs’ structure, morphology as well as quality have been analysed by Raman, SEM, AFM. The optical properties of the target materials have been evaluated by NIR-Vis-UV, Spectroscopic Ellipsometry, while an optical absorbance characterization was performed on the colloidal TiN NPs.

8:00 PM EL08.14.15
Color Purity Enhancement Through Effective Index Modulation of GST for Applications in Reconfigurable Displays YubinLee[1], Joo HwanKo[1], Sung-HoonHong[2] and Young MinSong[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Electronics and Telecommunications Research Institute Materials and Components Research Division, Korea (the Republic of)

Phase-change materials (PCMs) have been emerged owing to their reconfigurable physical properties such as refractive index, light absorption, electrical conductivity, and Young's modulus by switching between amorphous and crystalline phases [1]. $Ge_2Sb_2Te_5$ (GST), which consists of germanium, antimony, and tellurium, is one of the representative PCM materials and is widely studied for a dynamic color display or phase change memory by utilizing its great tunability in both optical and electrical properties. Due to the nature of the refractive index variation depending on the phase of GST, there have been tremendous suggestions for reconfigurable photonic structures, including photonic memory, thermal radiation modulator, and tunable structural color [2]. Typically, optical coating of dielectric thin films is based on Fabry-Perot or thin film interference. Recently, high-absorption dielectric films have been studied as optical coatings, and when metals are combined with high-absorption dielectrics, strong optical interference can be obtained with a small phase change of the reflected wave, which can significantly reduce the thickness compared to conventional coating layers. Resonance behavior impacting the structural color can be observed in structures consisting of a metal-coated substrate with an ultra-thin absorbing layer. The high color purity and feasible tuning functions of structural coloration has attracted attention due to its promising applicability as a next generation color display. Despite its great potential application, low chromaticity and limited intermediate step over phase change have been treated as a barrier to the efficient operation as a color display [3].
In this study, we present an ultrathin tunable color filter comprising GST. We modulate the effective index of GST by applying porosity (P_r) with anisotropic geometry, resulting in color purity enhancement and enhanced controllability based on polarization-driven modulation. Specifically, we deposit GST on top of an Au film using glancing angle deposition (GLAD) to manufacture self-aligned porous nanocolumns (PNCs) with varying P_r (0% 40%, 75%). In the amorphous GST/Au reflection spectrum, dip intensity decreases as P_r increases, and we find that color purity can be enhanced by controlling the P_r and phase. Particularly, the amorphous phase of GST exhibits a higher color purity and a wider color range than the crystalline phase. Additionally, mitigate the risk of surface oxidation and potential damage when depositing GST on an Au film exposed to ambient air, we conducted simulations to explore the effect of incorporating an oxide layer as a film passivation strategy. This additional dielectric layer serves noticeable shift in the dip position of the reflectance spectrum and changes in the phase condition, the color response can be dynamically adjusted, offering a wide range of color variations depending on the thickness of the oxide layer. Furthermore, GLAD technique induces atomic shadowing and creates inclined columnar structures on the substrate, resulting in an increased porosity. Due to the shadowing effect, the slanting plane direction of the PNCs has a higher P_r and varies with the polarization angle, causing a structural color change.
We confirm that the color purity can be improved with the P_r, phase, thickness of GST, and polarization angle. And the incorporation of the additional dielectric layer provides both protective benefits and enhanced control over color changes, presenting exciting possibilities for diverse applications. Our suggestions can be used as a way to improve optical properties in applications such as optical coating, optoelectronic displays, and optical storage devices.

Infrared Thermal Management with Graphene-Ag Nanocubes Heterostructures IhsanUluturk[1], MichaelLeuenberger[2], PeterCapuzzi[1], MargaretPeters[3], Jin HoKim[1], MichaelJ. Manser[1] and RichardM. Osgood[1]; [1]U.S. Army, United States; [2]University of Central Florida, United States; [3]University of Massachusetts Lowell, United States

The main purpose of textiles throughout history is to regulate heat flow and provide warmth or decrease excessive heat for the wearer. In recent times, the textile industry has developed new materials that can ensure the wearer stays dry in hot environments and that repel moisture. The main downside of these new textiles, however, is that their electromagnetic response has not been fully optimized, allowing too much radiation to be absorbed and radiated back to the skin, causing the wearer to overheat. Our work is composed of two parts: simulation and experimentation. Simulations will first be conducted to better understand graphene chemistry, as graphene ink with Ag nanocubes, $FeCl_3$, and SU-8 are spin coated onto silicon wafers.

In this work, heterostructures made of Ag nanocubes-Graphene-$FeCl_3$-SU-8-Si wafer-Al mirror are considered. This system is a representative of a Fabry-Perot type of cavity, where incident infrared light interacts strongly with graphene and the Ag nanocubes. $FeCl_3$ is used to dope graphene to a Fermi energy of E_F=-0.6 eV. The thickness of SU-8 will be chosen to be a quarter of the infrared wavelength in order for the amplitude of the infrared light to be maximal at the position of the graphene sheet.
Finite-difference time domain (FDTD) simulations show narrow resonance peaks in the absorbance (=emittance) due to localized acoustic surface plasmons (AGPs) in the dielectric between graphene and the Ag nanocubes.
The positions of the resonance peaks can be tuned in the range between 3 mm and 12 mm by means of a gate voltage.
When the number of graphene layers is increased, the conductivity is multiplied by the number of layers, which results in a blueshift of the AGP peaks. By increasing the size of the Ag nanocubes and the period of the square lattice of Ag nanocubes, the AGP peaks are redshifted.
For highly doped graphene layers with a small layer of $FeCl_3$ of around 50 nm between graphene and the Ag mirror, the absorbance (emittance) between 3 mm and 12 mm is around 2%, independent of the number of graphene layers. Such heterostructures could be useful for thermal management systems.
Based on the simulation results, we will be fine tuning the graphene chemistry. Resultant graphene ink with Ag nanocubes will be spin coated onto Si wafers. The fabricated heterostructures made of Ag nanocubes-Graphene-$FeCl_3$-SU-8-Si wafer-Al mirror will be characterized using in-house developed Delta T measurement system. In this system, anodized Aluminum with an emissivity of 0.77 is used, which is smaller than the emissivity of human skin (95% to 98%). The anodized aluminum is placed on a hot plate and a thermocouple. The hot plate is heated up to 38 C to simulate the body temperature and standoff is created between heterostructures and the hot plate. Thermocouples will be used to measure the temperature difference between the heterostructures and plain Al mirrors to see if the heterostructures have a significant effect on the thermal management property.

8:00 PM EL08.14.17

Genetic Algorithm Optimization of Mid-Infrared Nonreciprocity in Weyl Semimetal Planar Photonic Structures HannahGold, SimoPajovic, AbhishekMukherjee and SvetlanaV. Boriskina; Massachusetts Institute of Technology, United States

Engineering thermal radiation from surfaces is usually limited by the constraints of Kirchhoff's law of radiation, which states that the spectral directional emissivity of a surface equals its spectral directional absorptivity at thermal equilibrium; This imposes fundamental limits on the efficiency of radiative- energy harvesting, as any absorber also acts as a thermal emitter in the same spectral and angular range. In turn, breaking this reciprocity enables breaking the barriers in thermal efficiency engineering [1,2]. In this work, we develop an algorithm to optimize the non-reciprocal infrared response and to enable breaking of the Kirchhoff's law in a one-dimensional (1D) planar photonic multi-layer stack composed of thin films of Weyl semimetals and dielectrics. The design space and parameters of this structure were traversed using a genetic algorithm to find a global optimal solution, and then the design was further refined with numerical gradient descent to find the local minimum thereafter. The resulting design achieves a large nonreciprocal absorption contrast in the near infrared wavelength range at positive and negative angles of incidence (55 and -55 degrees were used during the optimization). Differently from prior studies, our optimized design accounts for both s- and p- polarized reflection coefficients when calculating the non-reciprocal Figure of Merit (FOM), which is vital for applications in harnessing the thermal radiation from the structure. Because the non-reciprocity is governed by the excitation of the surface plasmon polariton modes at the interfaces between Weyl semimetal and dielectric layers, it is limited to the p-polarized optical response engineering. Thermal emission into the allowed s-polarized modes is still reciprocal and may degrade the overall figure of merit in the design of a non-reciprocal thermal emitter. Furthermore, our optimally designed 1D planar non-reciprocal absorber avoids the technical challenges of fabricating grating-based structures that require lithographic techniques. Finally, our optimum design offers the largest FOM while using much fewer layers in the heterostructure, which should significantly simplify its experimental realization. The use of the Weyl semimetals instead of the conventional magneto-optical materials in our design eliminates the need for an external magnetic field bias, thus allowing for a compact form factor and integrability. Applications of our work range from thermophotovoltaic cells to optical switches, circulators, and isolators.

Nanoimprinted Pyramid Scanning Probe for Nanoscale Optical Mapping JunzeZhou, AdamSchwartzberg and AlexanderWeber-Bargioni; Lawrence Berkeley National Laboratory, United States

Tip-enhanced Photoluminescence (TEPL) enables the simultaneous collection of emission spectra and topographic information with sub-diffraction spatial resolution, providing valuable insights into the correlation between local material properties, structure, and macroscopic functionality of a material. In this study, we focus on the development of a novel near-field probe using a cost-effective and efficient nanoimprinting technique for investigating the optical properties of low-dimensional quantum materials. Through extensive experimental demonstrations, we showcase the performance of the nanoimprinted probe in terms of high-precision height sensing and high-resolution optical mapping on a 2-dimensional (2D) semiconductor. Additionally, we introduce advanced plasmonic designs and nanofabrication strategies based on the pyramidal probe, which facilitate the observation of nanoscale dark states and plexciton emission in 2D materials.

Ellipsometric Detection of Bacteria using Dielectrophoresis FenjaSchröder[1], SorayaZangenehzadeh[1,2], EmilAgocs[1,2], MartenMusiol[1], NassimaAmroun[1], RebekkaBiedendieck[1], DieterJahn[1], Hans-HermannJohannes[1,2] and WolfgangKowalsky[1,2]; [1]Technische Universität Braunschweig, Germany; [2]Leibniz Universität Hannover, Germany

The aim of this research is to detect bacteria by ellipsometry and evaluate if dielectrophoresis (DEP) can be useful to improve the limit of detection of optical biosensors.

Spectroscopic ellipsometry allows the non-destructive and contactless analysis of thin films or biological samples in a time range of seconds. Ellipsometry is based on the investigation of the polarization state of reflected or transmitted light. The measured parameters are the amplitude ratio (Ψ) and the phase difference (Δ) of s- and p-polarized light. Our measurement set-up consists of a flowcell that guides bacteria in liquid environment to a sensing surface, which consists of a glass substrate coated with thin film gold electrodes. Measurements were performed in Kretschmann configuration utilizing a quartz prism and gold electrode substrates. The bacteria studied in our experiments is the well-known, Gram-negative *E. coli* K12 strain.

The irradiation of the electrodes under a certain angle of incidence at a certain wavelength of light allows the excitation of surface plasmons resonance (SPR). Under this condition p-polarized light is coupled to the mode of surface plasmons at the metal-liquid-interface. This phenomenon can be monitored in the spectra of the ellipsometric parameters Ψ and Δ in form of a sharp dip, that correlates to the intensity minimum of the reflected p-polarized light. The excitation of SPR is highly dependent on the refractive index at the metal-liquid-interface. The presence of bacteria in a liquid changes the refractive index near the gold surface and therefor also changes the excitation condition of the SPR. Due to the penetration depth (~300nm) of the evanescent wave associated with the excitation of SPR, SPR-based sensors can only provide information on the refractive index very close to the metal interface. Therefore, it is of high importance to increase the number of bacteria at the metal-liquid-interface. To reach our goal of a highly sensitive SPR sensor we utilize the effect of dielectrophoresis.

Dielectrophoresis (DEP) describes the movement of dielectric particles in suspension due to the presence of inhomogeneous electric fields. DEP is divided into positive and negative DEP, depending on the different movement of particles due to the outer electric field. For positive DEP (pDEP) particles, such as bacteria, are accelerated to regions of high field inhomogeneity, which occur at the electrode edges. Hence bacteria are collected directly on the electrodes, the change in the spectra of Ψ and Δ magnified.

To explore the efficiency of bacteria collection by pDEP and the behavior of different electrode geometries in ellipsometry, a variety of electrode structures were designed. The structures vary in complexity and symmetry. Furthermore, the dependence of dielectrophoretic bacteria collection and SPR excitation on the gold film thickness was investigated. The designed electrodes and measurement set-up were able to visualize the influence of DEP on an ellipsometry based biosensor.

Hardware and Sensor Optimization of a Nanotechnology Enabled Implantable Sensor for Hormones in Marine Animals XiaojiaJin, VolodymyrKoman, MankiSon and MichaelS Strano; Massachusetts Institute of Technology, United States

Biologging has yielded tremendous insights in ecological biology by enabling the collection of data in animals free-roaming in their environments. However, measurements have largely been limited to temperature, pressure, and movement. Physiological data of animals' biomarkers would create valuable orthogonal datasets and produce more nuanced understanding of organisms in the context of their environments and behaviors. Nevertheless, successes in collecting such biochemical information remain absent. In this work, we explore hardware and sensor optimization of nanotechnology-enabled implantable sensor for tracking hormone levels in marine animals. We have extensively studied the performance of nanosensors based on polymer-wrapped single-wall carbon nanotubes (SWNT) embedded within a biocompatible poly (ethylene glycol) diacrylate (PEGDA) hydrogel under various temperatures, illumination conditions, and sensor concentrations. We have further prototyped a miniaturized fluorescent system integrated into commercially available acoustic tags used in marine biology. An integrated nanosensor hydrogel reached 100 nM limit of progesterone detection as an example of important hormone in marine animals. The developed form-factor will complement the presently collected data by providing insights into the physiological state of the animals in the context of their behavior and environments. With these new data, biologging studies will reach a new level of sophistication and nuanced understanding.

Using Cell Lensing and Nanosensor Chemical Cytometry to Characterize the Efflux Heterogeneity of Immune Cell Populations XiaojiaJin[1], XunGong[1], VolodymyrKoman[1], Soo-YeonCho[2] and MichaelS Strano[1]; [1]Massachusetts Institute of Technology, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Cellular immune heterogeneities play a critical role in the progression and prevention of cardiovascular or neurodegenerative diseases. Thus, a tool that can profile the dynamic antigenic responses of different immune cell populations in terms of their chemical efflux and biophysical properties can enhance our understanding of past and future unknown microorganisms and diseases. Herein, we have developed a technique called Nanosensor Chemical Cytometry (NCC), that utilizes an optical nanosensor array embedded within microfluidics to interrogate chemical species efflux from individual cells in real-time. The NCC technique takes advantage of the cell itself as an informative Gaussian lens, projecting both the nIR emission of the single-walled carbon nanotube sensors as well as various cellular physical properties. Different nanosensor integration methods were investigated to optimize the signal readout.

Using the NCC technique, we have profiled both the heterogeneity of nitric oxide (NO) efflux from macrophage populations and hydrogen peroxide (H_2O_2) efflux from monocyte populations. The technique was able to profile immune heterogeneities at attomolar sensitivity in a completely non-destructive and real-time manner with a throughput rate of ~600 cells/hr. In addition, new phenotype correlations between real-time extracellular immune responses and multiple biophysical properties (cell size, eccentricity, RI) of cell populations were investigated with exact numerical values and distribution statistics. This work provides an efficient strategy for the chemical analysis of cell populations in manufacturing and biopharmaceutical engineering.

Core-Shell and Yolk-Shell Plasmonic Nanocrystals for Hydrogen Production Yung-JungHsu; National Yang Ming Chiao Tung University, Taiwan

With the inherently high degree of complexity, heterostructures composed of two or more materials joined in unique architectures may exhibit superior synergetic properties that are difficult or impossible to acquire from their individual constituents. For semiconductor heterostructures, the relative band alignment of the constituents promotes effective charge separation to bring them desirable properties for photocatalysis applications. Among the different types of heterostructures, core-shell and yolk-shell nanocrystals have received particular interest due to their fascinating properties. Several representative works from our lab will be introduced to demonstrate the promising potentials of core-shell and yolk-shell nanocrystals for hydrogen production applications, especially those involving localized surface plasmon resonance.

8:00 PM EL08.14.23
Optical Confinement in Silicon Nanowire: A Correlated Characteristics and Fabrication of Vertically Aligned Nanowire Mohammad KamalHossain[1] and AymanMukhaimar[2]; [1]King Fahd University of Petroleum & Minerals, Saudi Arabia; [2]RMIT University, Australia

Here in this work, finite-difference time-domain (FDTD) analysis has been carried out to extract the optical characteristics of a single silicon nanowire (Si-NW) on a c-Si slab. Correlated absorption depth profile, electromagnetic field distribution, energy distribution and generation rate distributions of the Si-NW model showed the possibility of efficient light trapping within the nanowire. An experimental attempt has been taken to fabricate catalyst-induced vertically aligned Si-NWs. High-resolution field emission scanning electron microscope (FESEM) revealed the coverage of ca. $6.5\times10^8/cm^2$ with a diameter in the range of 50-200 nm. Si-based nanostructures, particularly Si-NWs exhibit strong optical absorption with reference to those observed in conventional Si-based solar cells. Henceforth, Si-NW is a promising candidate in confining incident light and contributes in designing efficient and miniaturized solar cells.

The sputtering technique was used to deposit a gold ultrathin film on the Si wafer and the film was annealed at a high temperature to achieve metal nanoparticles. Thereafter, a CVD reactor was used to grow Si-NWs. The morphology of as-fabricated Si-NWs was confirmed by SEM and high-resolution SEM investigations. Exciton generation rate distributions of vertically aligned Si-NWs of 50 and 200 nm diameters at 700 and 1100 nm solar spectral wavelengths have been simulated. Excitation rate distribution was found to be localized near the edges in both scenarios. At 700 nm wavelength confined spots were observed in a repeated fashion along with lower intensities, whereas at 1100 nm wavelength such spots increased in intensity and lower in repetition. Unlike those observed for Si-NW of 50 nm diameter, excitation rate distribution was found to be localized near the center with higher intensity at 700 nm solar wavelength, whereas at 1100 nm wavelength such distribution disappeared.

During the fabrication process adopted here in this work, it was observed that metal nanoparticles acted as catalysts and were the main ingredient to define the diameter of the Si-NWs. FESEM observations confirmed the diameter of the as-grown Si-NWs to be in the range of 50 to 200 nm. In the simulation we have considered four different sizes of Si-NWs, such as 50, 100, 150 and 200 nm in diameters. Due to space constraints, further details are out of this context and will be elaborated in the event as well as in the full manuscript.

Nanoscale Imaging of Surface Plasmon Polaritons at Interface of Metal/Dielectric by UEM HaihuaLiu, Thomas E.Gage and IlkeArslan; Argonne National Laboratory, United States

Haihua Liu[1,*], Thomas E. Gage[1], Ilke Arslan[1]
[1] Center for Nanoscale Materials, Argonne National Laboratory, Lemont, IL, USA
[*]Corresponding email: haihua.liu@anl.gov

Surface plasmon polaritons (SPPs) are collective oscillation of surface charge-density waves at the interface between a metal and a dielectric material. The SPPs that propagate along the interface and exhibits exponential decays perpendicular to the interface into an adjacent dielectric medium. With the unique properties of evanescence and surface localization, SPP's are non-radiative and can be transversely localized and guided into subwavelength metallic structures as small as a few nanometers. A new branch of photonics called plasmonics, based on control and manipulation of light using SPPs at the nanoscale, has the potential to break diffraction limit of light and exhibit significant advantages in nanophotonics device development by replacing electronic signals with light as information carriers is a prime motivation behind research on photonic circuits.[1] Therefore, it is of great importance to image the SPPs at the nanometer scale to give one deeper understanding of the guide and localization of light below the diffraction limit for nanophotonics applications.

Ultrafast Electron Microcopy (UEM) has been used to study the ultrafast dynamics of light-matter interactions in physics, chemistry and materials science with temporal resolution of hundreds of femtoseconds,[2] which is 10 orders better than that of conventional electron microscopy limited by the camera read-out rate. Other than light-matter interaction observed in UEM, the investigation of photon-electron interaction has been enabled by one unique technique called Photon-Induced Near Field Electron Microscopy (PINEM) developed in UEM to capture the evanescent electromagnetic field on its intrinsic time scale and nanometer scale.[3] We recently established one state-of-art UEM scientific platform at the Center for Nanoscale Materials (CNM), Argonne National Laboratory. Besides the capabilities of imaging and diffraction, the UEM at the CNM is equipped with one GIF spectrometer, which enables it to work in energy filtering mode and record the PINEM image.[4] Here, we investigated the excitation and localization of extended two-dimensional surface plasmon polaritons waves at the interface of metal and dielectric material including metal/dielectric interface with simple irregular nano holes or nano slots, and metal/dielectric interface with nanofabrication of nano hole array under excitation by ultrashort laser pulses using PINEM. The dependence of the SPPs on surface roughness, propagation distance, laser wavelength, fluence, and polarization was studied at the nanometer spatial scale and femtoseconds time scale. The results reveal that UEM is one powerful tool to study the SPPs at high spatiotemporal resolution of nanometer scale and femtoseconds time scale for the development and applications of SPPs-based photonic circuits such as waveguides, near-field optics, date storage, solar cells biosensing and optical communication.

ZnO-ZnWO4 Eutectic Composites as Tunable Mid-IR Polaritonic Metamaterials MarcoCentini[1], EmilijaPetronijevic[1], AlessandroBile[1], DorotaA. Pawlak[2], ConcitaSibilia[1] and Maria CristinaLarciprete[1]; [1]University of Rome, Italy; [2]Ensemble3 sp. z o.o., Wolczynska, Poland

A wide branch of nanophotonics in the infrared (IR) range is based on the ability to excite surface plasmon polaritons (SPPs) at the interface between a metal and a dielectric. However, the use of metals restricts the SPP band to the visible/near IR, being the poor field confinement at longer wavelengths the main limitation. The development of a photonic platform in mid-IR range is crucial for applications like sensing the number of IR active vibrational fingerprints for the identification of trace levels of chemical and biological contaminants.
Recently proposed polarization sensitive applications in mid-IR relies on metamaterials and metasurfaces based on so called van der Waals (vdW) materials exhibiting strong anisotropy as well as natural hyperbolicity [1-2]. In the present work we investigated another interesting strategy, provided by the exploitation of self-assembled ZnO/ZnWO4 eutectic composites [3].
In the visible range, the optical linear properties of these eutectic structures were found to exhibit a natural narrowband strong polarization dependence of the transmitted signal at l=(397±3) nm [4]. This effect is due to the refractive index matching of the two constituents so that, for some specific wavelength and polarization state, the composite medium appears homogenous while it produces strong scattering losses under all other conditions.
In the present work, we demonstrate that a similar polarization sensitive behaviour can be obtained, in reflection mode, at much longer wavelengths (around 11.6 μm).
We characterized the polarization dependent reflectivity spectra in the 2-16 μm range from several eutectic ZnO/ZnWO4 samples [5]. The eutectic composites under investigation display a lamellar geometry with regions composed of ZnO alternating to regions of ZnWO4. Reflectivity spectra have been recorded using a Fourier Transformed infrared interferometric (FTIR) microscope (Bruker Hyperion). During data acquisition, knife edge apertures were set to designate selected sample portion so to get defined area where lamellas display similar orientation.
The obtained micro-FTIR spectra show that it is possible get a polarization sensitive reflection band by taking advantage of the optical phonon properties of ZnWO4 and excitation of surface phonon polaritons at ZnO/ZnWO4 interfaces.
Specifically, a high reflectivity band, corresponding to a phonon Reststrahlen band of the ZnWO4 is located around 850 cm-1 (11.6 mm). The reflectance signal, measured under different polarization state of the incoming light, reaches its maximum value when the incident field is polarized along the
direction of the lamellas. When the input field is polarized perpendicularly with respect to the lamellas direction, the corresponding reflectivity value is strongly attenuated. The strong reflectivity modulation of ZnO/ZnWO4 system with polarization direction leads to reflectivity dynamic range as high as DR=72%.
Furthermore, preliminary optical images also indicate that improved lamellas thickness as well as area with better definition of lamellas lead to higher polarization sensitivity of the reflected signal.
In conclusion the complex, self-assembling, geometry arising in eutectic composites unveals extremely interesting optical properties both in the visible [4] and in the IR ranges [5].
The obtained experimental findings will make a valuable contribution in surpassing the wavelength limitations imposed by plasmonics. This advancement holds promise for a wide range of applications in the IR spectrum, including modulators, thermal radiators, tunable radiative cooling, thermal emitters, and advanced sensing capabilities.

Nonlocality and Loss in Nonreciprocal Photonics Enabled by Weyl Semimetals MorganBlevins and SvetlanaV. Boriskina; Massachusetts Institute of Technology, United States

Engineering new nonreciprocal optical devices is an important initiative in current photonics research. There is a desire to engineer new, nonreciprocal integrated photonic devices to replace the current standard of magneto-optic materials, which require bulky external magnets incompatible with many chip-scale device architectures [1]. Much research has been dedicated to modeling and designing nonreciprocal devices made from Weyl semimetals (WSMs) for next generation isolators and enhanced near-field radiative heat transfer devices [2]. However, as has been recently discussed [3], the impacts of nonlocality and loss on the proposed nonreciprocal Weyl devices close the window of one-way transport and render the realistic structures less useful than those initially proposed in the lossless, local regime. While loss and nonlocality are inherent to plasmonic devices, nonreciprocal Weyl devices with large figures of merit can be engineered by judicious combinations of external symmetry-breaking stimuli. To date, the qualitative impacts of loss and nonlocality have been mostly investigated in intrinsic time reversal-breaking WSM [4]. Here, we expand this analysis to time reversal- and inversion symmetry-breaking WSMs under a variety of *in situ* and *ex situ* stimuli, which either induce or enhance nonreciprocity. These stimuli include inhomogeneous strain and Fizeau drag via DC current bias. By evaluating the effect of various external stimuli that induce nonreciprocity in WSMs – as well as their combinations – we aim to identify a breadth of useful regimes for nonreciprocal and tunable WSM devices operation when realistic loss and nonlocality are accounted for.

10:15 AM EL08.15.04
An Active Metasurface Single-Pixel Lensless Imaging Device JulieBelleville, PrachiThureja and HarryA. Atwater; California Institute of Technology, United States

We present a computational model that evaluates the performance of active metasurfaces as platforms for lensless imaging and find that an active metasurface with a 0.3 mm aperture size could capture images at >2 pixel/degree resolution across a wide field of view (FOV) of 120°. Our model optimizes the metasurface array configuration to obtain angular Hadamard and Fourier bases, and the results address the performance of an experimentally realized indium tin oxide (ITO)-based metasurface operating at telecom wavelengths.

Lens-coupled detector arrays are the basis for most of today's imaging systems but are not well suited to realized low-weight or small-footprint systems due to the weight and focal lengths of lenses. Lensless imaging—in which a modulator is coupled to a detector and modifies the detected light to enable computational image retrieval—offers an attractive alternative to lens-coupled detectors in applications requiring low SWaP (size, weight and power) devices or wide FOVs [1].

We investigate active metasurface elements to modulate light in a single-pixel imaging configuration. In contrast to passive metasurfaces that have set optical properties, the phases and amplitudes of active metasurface elements can be dynamically controlled via external stimuli which modulate their dielectric properties. In this study, we use the experimentally demonstrated performance of a field-effect tunable ITO-based metasurface at an operating wavelength of 1510 nm, with a phase tunability of 271°, covarying reflectance and phase, and modulation speeds exceeding 10 MHz [2][3]. The model and analysis, however, can be applied to various active metasurface platforms.

To determine the attainable performance of active metasurfaces in imaging, we use array-level inverse design, which was previously used to enhance beam steering performance [4]. We simulate the 1D far-field intensity of the metasurface using an array factor calculation and control the acceptance of light by optimizing the voltages applied at each element. Using a simulated aperture size of 0.3 mm (768 elements), we demonstrate a peak resolution of 4 pixel/degree and of 2 pixel/degree across a 120° FOV. We also show the suitability of active metasurfaces for compressed sensing, in which sparse images are recovered in fewer measurements than there are pixels. For this, we optimize the metasurface array configuration to obtain angular Hadamard and Fourier bases. In preliminary tests, our optimized Hadamard basis retrieves images with good agreement to the ground truth, with a power signal-to-noise ratio of 40 dB across 512 pixels. Additionally, we demonstrate the convolution of image processing filters across the FOV, which is desirable in classification applications. Our ability to produce grayscale filters distinguishes our platform from digital micromirror devices, which are often used in single-pixel imaging and support modulation speeds of ~20 kHz only for binary bases [5]. As resolution and FOV improve with metasurface size, we note that our current results are not an upper bound on performance.

As a next step, we will explore algorithms for 2D imaging and increase the realism of our model by modeling amplitude/phase errors, voltage discretization, and component reaction times. We will also report on an analysis of which imaging bases are best suited to active metasurfaces, and on the use of machine learning to correct for imperfections in basis construction. Finally, we will discuss the potential of active metasurfaces in multi-pixel lensless imaging applications.

Biomineral-Based Optical Metasurfaces and Cavities - Analysis and Sensing RichardM. Osgood, Jin HoKim, PeterCapuzzi, MargaretPeters, IhsanUluturk and RichardPang; CCDC-SC, United States

New optical biomaterials such as biopigments and biominerals enable fascinating optical properties, such as bright and structural color and advanced camouflage. Arrays of isoxanthopterin nanoparticles in reflectors within shrimp eyes cause significant photonic backscattering, optimizing the sensitivity and spectral coverage of shrimp eyes.[1] Biominerals such as silicate in diatoms, strontium sulfate in radiolarians, goethite in limpets, magnetite in magnetotactic bacteria, and calcium phosphate in bones provide mechanical structure, sense magnetic and gravitational fields, and can store and mobilize iron. Biominerals are primarily non-toxic and environmentally friendly materials, generally with very high indices of refraction, especially for organic compounds. Biominerals are good candidates for optically sensing materials, because of their high index of refraction and non-toxic, scalable, and manufacturable properties. They are expected to be unregulated in the future due to lack of toxicological concern, unlike metal oxide nanoparticles, which are facing increasing amounts of regulation in manufacturing settings, due to concerns about potential carcinogenic nature from chronic exposure to workers in a manufacturing plant. Biominerals should be supply-chain resilient as well because they are straightforward and relatively simple to fabricate.

We have chemically synthesized the biomineral goethite (a-FeOOH), using a mixture of iron nitrate and tetramethylammonium hydroxide with an initial pH around 13. The reactant has a pure yellowish color, forms spinel rods that have 10-30 nm diameters and lengths in the range of 100-300 nm as determined by Scanning Electron Microscopy (SEM), exhibits the correct elemental composition for goethite in Electron Dispersive Spectroscopy (EDS), and powder x-ray analysis matches reference data from x-ray crystallographic data. 2-D photonic crystals were formed using 508 nm PS beads and were very iridescent, producing different colors at different angles. These photonic crystals had a bandgap in the red and transmitted light therefore had a yellowish-green color. A film of goethite was dropcast onto this 2-D array and registered an interesting drop in signal intensity when exposed to ethanol vapor, the analysis of which will be reported in this presentation. 1-D photonic crystal arrays consisting of alternating 70 nm PVA and 100 nm goethite layers were fabricated, show the expected multilayer peaks in reflectivity (7 maxima between 800 nm and 2500 nm), and considerable backscattering above 1100 nm. For wavelengths less than 1100 nm, the silicon substrate attenuated the backscattered light. Exposing this multilayer to glucose liquid, ethanol vapor, and humidity all results in an attenuated signal and possibly a peak shift. This peak shift was modeled and the wavelength shift per refractive unit change at the surface estimated, for detecting molecules like ethanol, water, and glucose. Single Fabry-Perot cavity films of goethite were also fabricated, thickness and optical indices measured with profilometry, spectrophotometry, and ellipsometry, and sensing results from these F-P cavities will be reported. We will also explain how, in the future, to make the biomineral-based sensing more sensitive and selective, using an embedded specific receptor in the photonic crystal and in thin films. Potential optical systems and detection methods using biominerals will be discussed.

Pushing the Limit of Multiplexing Capacity in Photonic Metasurfaces YongminLiu; Northeastern University, United States

Over the past decades, we have witnessed tremendous progress and success of photonic metasurfaces. By tailoring the geometry of the building blocks of metasurfaces and engineering their spatial distribution, we can control the amplitude, polarization state, phase and trajectory of light in an almost arbitrary manner. For practical applications such as high-capacity optical display, information encryption, and data storage, it is crucial to encode distinct functionalities into a single meta-device and increase the information channels. In this talk, I will present our recent works that aim to push the multiplexing limit in photonic metasurfaces through both physics-guided and data-driven approaches. In the first part of my talk, I will show that we can break the fundamental limit of polarization multiplexing capacity of metasurfaces by introducing the engineered noise to the precise solution of Jones matrix elements [**Science** 379, 294 (2023)]. We experimentally demonstrate up to 11 independent holographic images using a single metasurface illuminated by visible light with different polarizations. To the best of our knowledge, it is the highest capacity reported for polarization multiplexing. Combining our noise engineering method with the position multiplexing scheme, we design and demonstrate another metasurface that can generate 36 distinct images, forming a holographic keyboard pattern. In the second part of my talk, I will show that machine learning enables us to accelerate the development of complex metasurfaces (and other photonic structures) with high efficiency, accuracy and fidelity [**Nature Photonics** 15, 77 (2021)]. The developed machine learning models, after training, can evaluate the optical responses of metasurfaces and inversely design them in less than seconds. We propose to embed machine learning models in both gradientbased and nongradient optimization loops for the automatic implementation of multifunctional metasurfaces [**Advanced Materials** 34, 2110022 (2022)]. Fundamentally different from the traditional two-step approach that separates phase retrieval and meta-atom structural design, the proposed end-to-end framework facilitates full exploitation of the prescribed design space and pushes the multifunctional design capacity to its physical limit. With a single-layer structure that can be readily fabricated, metasurface focusing lenses and holograms are experimentally demonstrated in the near-infrared region. They show up to eight controllable responses subjected to different combinations of working frequencies and linear polarization states.

Undoped Organic Semiconductors as a New SERS Platform AntonioFacchetti; Northwestern University/Flexterra Inc, United States

Nanostructured molecular organic semiconductor films are promising Surface-Enhanced Raman Spectroscopy (SERS) platforms for both fundamental and technological research. In this presentation we report that nanostructured films of oligothiophenes functionalized with different fluorinated alkyl or aryl groups demonstrate unprecedent Raman enhancement factor ($>10^5$) and a low limit of detection (10^{-9} M) for the methylene blue probe molecule. This data is comparable to those reported for the best inorganic semiconductors and even intrinsic plasmonic metal-based SERS platforms. Photoluminescence spectroscopy and computational analysis suggest that both charge-transfer energy and effective molecular interactions, leading to a small but non-zero oscillator strength in the charge-transfer state between the organic semiconductor film and the analyte molecule, are required to achieve large SERS enhancement factors and low molecular sensitivities in these systems. Our results provide not only a considerable experimental advance in organic SERS figure-of-merits but also guidance for the molecular design of more sensitive SERS platforms based on organic (macro)molecules.

Intelligent Meta-Imagers for Machine Vision JasonG. Valentine[1], HanyuZheng[1], BrandonSwartz[1], XiaomengZhang[1], GregForcherio[2] and YuankaiHuo[1]; [1]Vanderbilt University, United States; [2]Naval Surface Warfare Center Crane Division, United States

Rapid developments in machine vision have led to advances in a variety of industries, from medical image analysis to autonomous systems. These achievements, however, typically necessitate digital neural networks with heavy computational requirements, which are limited by high energy consumption and further hinder real-time decision-making when computation resources are not accessible. Here, we demonstrate an intelligent meta-imagers that are designed to work in concert with a digital back-end to off-load computationally expensive convolution operations into high-speed and low-power optics. The key to these architectures are the new freedoms afforded by metasurfaces such as optical edge isolation, polarization discrimination, and the ability to spatially multiplex, and demultiplex, information channels. I will discuss how these freedoms can be utilized for accelerating optical segmentation networks and objection classifiers, both based on incoherent illumination. This approach could enable compact, high-speed, and low-power image and information processing systems for a wide range of applications in machine-vision and artificial intelligence.

2:00 PM EL08.16.02
Inverse-Designed Metasurfaces with Oblique Helicoidal Cholesterics for Active Multicolor Holography JoohoonKim and JunsukRho; Pohang University of Science and Technology, Korea (the Republic of)

Metasurfaces are composed of arrays of subwavelength structures and can provide fine wavefront-shaping platform with a compact form factor, resulting in both capability of diverse functionality and drastic miniaturization of the optical device. However, due to their low information capacity and passive nature, extensive studies focusing on overcoming these limitations have been conducted to achieve high information capacity[Science 379, 294-299 (2023)], spatial (wavefront) tunability[Science 364, 1087-1090 (2019)], and spectral (wavelength) tunability[Nat. Nanotechnol 16, 795-801 (2021)]. However, previous approaches cannot simultaneously achieve all these features. This manuscript provides the first report of simultaneous spatial and spectral tunable metasurface with high information capacity and its applications in dynamic multicolor holography. To this end, we propose unique combination of an inverse designed metasurface and a layer of oblique helicoidal cholesteric liquid crystal (ChOH) layer. The inverse design method enables the single-phase map encoding of 10 independent holographic images at different wavelengths. To the best of our knowledge, this represents the highest capacity reported for a single-cell metasurface. ChOH provides precise and free modulation of the reflected wavelength with a wide spectral range (420 nm ~ 720 nm) and narrow bandwidth (13 ~ 32 nm). Therefore, both holographic image and its color can be varied by applying programmed stimuli (electric field and temperature). Further, we believe that it is a simple and generalizable approach for interactive metasurface with high information capacity, spatial and spectral modulation. Moreover, this work can also be applied to a wide range of novel applications, including secret-sharing platform, hyperspectral imaging, and full-color 3D display.

2:15 PM EL08.16.03
3D Plasmonic Nanoarchitecture on Paper-Based Strip for Deep Learning-Assisted Human Urine Sensing and Cancer Screening Ho SangJung; Korea Institute of Materials Science, Korea (the Republic of)

Practical human biofluid sensing device is required to screen the patient from the normal group with high sensitivity and specificity. Especially, urine metabolite detection of cancer patient provides insights for early diagnosis and finding of new biomarkers. Here, 3D coral-like plasmonic nanoarchitecture (3D-CPN) is fabricated on a paper substrate as a urine test strip via direct one-step gold reduction process, which is available for quick urine absorption and metabolite filtration. The coral-like nanoarchitecture was grown with multiple grain boundaries forming particle-like protrusions (PPs), which were characterized by scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD) and so on. The coral-like structure formation mechanism can be explained by successive primary particle-to-particle attachment process, such as oriented attachment and coalescence, following atomic diffusion. After preparation of the nano-structural model using conjugated gaussian random particle generation method, the optical characteristics of the 3D-CPN was investigated and compared with the experimental results. For clinical validation, the prepared 3D-CPN urine strip was used for label-free surface-enhanced Raman scattering (SERS) sensor to obtain metabolite signals from normal, prostate and pancreatic cancer urine. Statistical analysis was performed to verify the meaningful Raman peak positions related with cancer metabolites and then matched with metabolite candidates reported in previous literatures. Then, a typical deep learning method of convolutional neural network (CNN) was applied to classify the normal, prostate and pancreatic cancer after oversampling the train, validation and test sets. The confusion matrix showed the 95~97% accuracy for patient classification. This technology is expected to be applied for non-invasive multi-cancer analysis and also for other diseases after training the urinary signal.

2:30 PM EL08.16.04
Optical Fourier Surfaces for Holography YannikM. Glauser[1], PatrickBenito Eberhard[1], HannahNiese[1], JuriG. Crimmann[1], ValentinaG. De Rosa[1], NolanLassaline[1,2], DanielPetter[1] and DavidJ. Norris[1]; [1]ETH Zürich, Switzerland; [2]Technical University of Denmark, Denmark

Controlling light is crucial for modern technologies, such as solar cells, biosensors, and optical communication. A common approach involves the fabrication of nanostructured surfaces with sub-wavelength feature sizes to manipulate electromagnetic fields through diffraction. However, current lithographic methods are typically restricted to “binary” surface profiles with only two depth levels, limiting their optical performance. Here, we overcome this limitation by exploiting thermal scanning-probe lithography to fabricate grayscale diffractive surfaces, known as optical Fourier surfaces (OFSs) [1]. We utilize these OFSs as reflective phase-only holograms in silver to control the amplitude and phase of the diffracted wavefront in the far field. Due to the non-trivial relation between the surface profile and diffraction output [2], an adapted Gerchberg–Saxton algorithm [3] is applied to inversely design the OFS holograms. Furthermore, we extend the concept of OFS holograms to diffract bound electromagnetic modes, such as surface-plasmon polaritons [4] and waveguided photons [5], to free space. This approach may provide expanded possibilities for holography, beam shaping, and optical display technology.

Van der Waals Nanophotonics for Deeply Subwavelength Optics ArturDavoyan; University of California, Los Angeles, United States

Van der Waals materials are of great promise for photonics and optoelectronics. In this talk I will discuss use of bulk van der Waals materials for controlling visible and infrared radiation. I will show that strong light matter interaction within excitonic transition metal dichalcogenides, such as MoS2, allows deeply subwavelength light confinement and manipulation. I will demonstrate passive nanophotonic devices that can confine and guide light in structures that are more than 16 times smaller than the wavelength. I will further present a combined near and far field imaging and discuss device efficiency. I will then discuss use of hexagonal boron nitride for controlling mid-infrared radiation. Specifically, manifestations of strong light phonon coupling in hBN will be discussed and their use for creating deeply subwavelength resonators will be shown. I will then present first in a kind measurement of tunable hBN metasurface emitters which can cover over 2 micron band. Our studies suggest that smaller and more efficient devices may be created with the use of van der Waals materials.

3:45 PM EL08.16.06
Experimental Demonstration of Deep Learning enabled Ultra-Broadband Epsilon-Near-Zero Perfect Absorbers DavidDang, SudipGurung, Juan ManuelRaffo Calixto, XuguoZhou, AlekseiAnopchenko and Ho Wai (Howard)Lee; University of California, Irvine, United States

Epsilon near zero (ENZ) materials have gained interest in recent years due to their unique optical properties, such as their large optical nonlinearity, non-reciprocal magneto-optical effects, and specifically, perfect absorption of light. Transparent conducting oxides, in particular, hold promise as ideal ENZ material due to their tunable optical properties during the fabrication process. Broad perfect absorption of light can be achieved by creating a thin film stack of ENZ materials. However, the design of multilayer ENZ stacks is challenging due to the many

parameters involved, including the number of layers, thicknesses, ENZ wavelength, and optical losses.

Our machine learning-based approach enables us to efficiently search through the vast design space and experimentally verify the performance of the resulting thin film stack. In particular, we use a physics inspired generative neural network to optimize the thickness and optical properties of the thin film stack. Once we obtained the optimized thickness and optical properties, we used atomic layer deposition and spectroscopy techniques to fabricate and measure the meta-material. The resulting 2-layered AZO ENZ thin film stack achieved perfect absorption of light (> 98%) in the near-infrared region from 1500 nm to 2500 nm, highlighting the potential of machine learning techniques in designing ENZ materials for various applications.

SESSION EL08.18: Quantum Photonics and Emission Control

9:30 AM EL08.18.01
Highly Confined Surface and Epsilon-Near-Zero Phonon Polaritons in $SrTiO_3$ Nanomembrane YinLiu[1], AlexeyKuzmenko[2], RuijuanXu[1], IrisCrassee[2] and HansBetchtel[3]; [1]North Carolina State University, United States; [2]Université de Genève, Switzerland; [3]Lawrence Berkeley National Laboratory, United States

Free-standing, wafer-scale, single-crystalline complex oxide membranes have enabled a new set of optical, electrical, and magnetic functionalities and structural and quantum phase transitions. Recent theoretical studies suggest that oxide perovskites nanomembranes support surface phonon polaritons with low-loss and strong confinement. In this work, we explore the $SrTiO_3$ nanomembrane as a photonic platform for phonon polaritons in the far-infrared regime. Our combined far-field and near-field infrared spectroscopic and nanoscopic studies reveal two types of phonon polaritons on a $SrTiO_3$ membranes transferred on gold and thermally oxidized silicon substrate, namely surface phonon polaritons and epsilon-near-zero(ENZ) polaritons. Radiative Berreman modes and bound ENZ polaritons confined within the nanomembrane are detected in the frequency window with epsilon zero, resulting from the deep subwavelength thickness of the membrane . Moreover, we reveal highly confined, propagating surface phonon polaritons through real-space hyperspectral nanoimaging. Surface polaritons with up to 7 times increased momenta as compared to surface polaritons of the same energy in bulk $SrTiO_3$ are detected. Our results suggest that perovskite oxide nanomembranes are promising two-dimensional polaritonic platforms within the terahertz regime.

9:45 AM EL08.18.02
Non-Local Effects in Epsilon Near-Zero Photonic Gap Antennas Boost Field Enhancement FelixThouin[1], DavidM. Myers[2], AshutoshPatri[2], BillBaloukas[2], AntonioI. Fernández-Domínguez[3], LudvikMartinu[2] and StephaneKena-Cohen[2]; [1]Photon etc, Canada; [2]Polytechnique Montréal, Canada; [3]Universidad Autónoma de Madrid, Spain

A material's non-local response to an electromagnetic field becomes important when its dimensions are comparable to the Fermi wavelength of electrons within. This regime is particularly relevant for optical antennas, where fields are confined to deep subwavelength regions of the device. Particularly, optical antenna devices based on epsilon-near zero (ENZ) materials are further susceptible to non-localities, given their long electronic Fermi wavelengths. Simulating the extent to which non-localities affect the performance of these devices is challenging as it requires a proper account of this complex phenomena along with conventional electromagnetics.
We observed the impact of non-localities on the far-field and near-field optical properties of epsilon near-zero photonic gap antennas (ENZ PGA). These devices consist of dielectric pillars (a-Si) within which a 10-nm thin slab of indium tin oxide (ITO) material is embedded. In these, hybrid dielectric-ENZ modes emerge from the strong coupling between the dielectric antenna modes and the thin film's ENZ mode. These hybrid modes efficiently couple to free space and strongly confine the incident electric field within the ITO slab over nearly an octave bandwidth. The far-field response of single ENZ PGAs is probed using hyperspectral dark field scattering spectroscopy (DFSS) and their near-field response using third-harmonic generation (THG). Sharp resonances invisible in DFSS are observed atop of a broad band in the THG efficiency spectra and shift when changing the dimensions of the antennas. Local simulations using conventional electromagnetics fail to reproduce this phenomenon and instead predict broad featureless THG efficiency spectra. However, in addition to yielding a better agreement with the experimental DFSS, non-local simulations using a local analogue model qualitatively capture the resonant character of THG efficiency spectra as well as their dependence on device geometry. This work opens up the possibility of leveraging non-local effects to further enhance electromagnetic field confinement in optical antennas. It shows how a proper theoretical account of non-localities in simulations is crucial to guide the design of these non-local devices.

Simultaneous Control of Spectral and Directional Emissivity with Gradient Epsilon-Near-Zero InAs Photonic Structures Jae SeungHwang, JinXu and AaswathP. Raman; University of California, Los Angeles, United States

Controlling the spatial distribution of broadband far-field radiation is a challenging, but a fundamentally enabling capability in a broad range of applications such as thermophotovoltaics, thermal imaging and IR sensing. Here, we discuss a III-V semiconductor-based broadband directional thermal emitter where the angular and spectral response of the nanophotonic structure can be decoupled, in contrast to conventional beliefs. We demonstrate this capability by using the concept of plasmonic gradient ENZ materials, where the epsilon-near-zero (ENZ) frequency of the constituent plasmonic thin films vary spatially along the depth dimension. To show that plasmonic thin film based gradient ENZ materials enable arbitrary and simultaneous tuning of the spectral peak and operation range of the thermal emitter by changing the doping concentration range of the gradient ENZ layer, we compare two plasmonic gradient ENZ structures with the same total thickness of 300nm but different doping profiles. We compare two structures, structure 1 with a doping concentration of the gradient ENZ thin film ranging from 1.010^{18} cm^{-3} to 1.910^{18} cm^{-3} and structure 2 ranging from 2.010^{18} $cm^{-3}$to 4.510^{18} cm^{-3}: the first structure demonstrating thermal beaming between 17.5 to 19.5 m and the second structure between 12.5 to 15m. Here, we also observe that it is possible to control the operational bandwidth of the thermal emitter by introducing a larger spatial gradient of the doping concentration of the gradient ENZ layer. This highlights the remarkable control over spectral emissivity bandwidth that plasmonic gradient ENZ structures can provide by controlling the doping concentration profile of the gradient ENZ layer. Furthermore, we demonstrate the directional tunability of plasmonic thin film based gradient ENZ materials by controlling the total thickness of the gradient ENZ layer, where a third structure with the same doping concentration range as structure 2 but larger thickness of 900nm is used as the test sample: the high emission angular range of the 300nm structure was centered at 74, whereas the 900nm structure was centered at 66. This response originates fundamentally from the spatial shift of the optical mode supported by the thicker gradient ENZ photonic structure relative to the thinner one. As the total thickness of the gradient ENZ layer increases, the dispersion curve of the broadband Berreman mode moves to the left and thus will couple to modes from angles of incidence that are closer to normal incidence. We emphasize that in our approach a directional emitter has emissivity that is highly directional to the *same* set of angles, across an arbitrary bandwidth. By constraining directional emission to particular angular ranges over arbitrary spectral ranges, improved performance may be possible for a range of applications, including thermophotovoltaics, radiative cooling, and waste heat recovery. It is noteworthy that the lithography/patterning free, chip-scale geometry suggests that the plasmonic gradient ENZ structure can be incorporated with conventional scattering structures, opening up exciting possibilities to observe new optical phenomena where the narrowband resonance condition is relaxed. Ultimately, since these plasmonic gradient ENZ materials exhibit extraordinary modulation of their complex refractive indices as their carrier concentrations can be controlled by orders of magnitude by applying external fields, we believe that this configuration provides an avenue for on-demand control of broadband directional thermal emission, beam steering, as well as broadband non-reciprocal thermal emission.

10:45 AM EL08.18.04
Dimensional Patterning of CdO Thin Films for Plasma Frequency Tunability in Mid-IR Plasmonic Metamaterials MaxwellTolchin[1], AngelaCleri[1], MingzeHe[2], KevinWynne[3], KhalidHattar[4,5], BhaveshkumarKamaliya[6], NabilBassim[6,6], JoshuaD. Caldwell[2,7] and Jon-PaulMaria[1]; [1]The Pennsylvania State University, United States; [2]Vanderbilt University, United States; [3]University at Albany, State University of New York, United States; [4]The University of Tennessee, Knoxville, United States; [5]Sandia National Laboratories, United States; [6]McMaster University, Canada; [7]Sensorium Technological Laboratories, United States

Dimensionally patterned monolithic cadmium oxide (CdO) thin films are accessible by high-power impulse magnetron sputtering (HiPIMS) coupled with donor defect doping via ion-beam modification. Although compositional platforms exist to dope grated structures in transparent conducting oxides (TCOs), they are conventionally complex and mostly limited in interface and structural competency. However, we demonstrate two ion-beam techniques of high energy ion bombardment (1-3 MeV) across micron-area grated masks and nanometer-scale ion implantation via focused ion beam (FIB) as facile approaches to spatially modulate CdO permittivity and effectively tune CdO plasma frequency in the mid-IR regime. High-energy bombardment generates donor dopant defects with exceptional transport properties: carrier densities of 2.5×10^{19} cm^{-3} to 2.5×10^{20} cm^{-3} and mobilities of up to 200 cm^2/Vs relative to the ion's displacement damage dose (DDD). Even upon pattern removal, well-defined optical and morphological interfaces are observed by far-field variable-angle reflectance spectroscopic dispersion maps. Near-field and atomic force microscopy supported by transfer matrix method (TMM) simulations. To further reduce grating feature size, preliminary FIB implantation indicates generated local and

controllable donor defects thermally activated with nanometer resolution between doped and undoped regions. These are indicated by Raman shifts and peak sharpness as carrier density and mobility are enhanced respectively. Also, we are currently systematically investigating mechanisms to CdO defect healing and donor activation based on temperature and environment. Overall, these ion-beam modification methods facilitate new dimensional patterning capabilities of CdO for tunable mid-IR plasmonic metamaterials.

11:00 AM EL08.18.05
Deterministic Positioning of Aqueous Quantum Dots for Single-Photon Emission DeepshikhaArora[1], MuhammadT. Pambudi[2,3], XiaoLiang[3], LuDing[2] and JoelYang[1]; [1]Singapore University of Technology and Design, Singapore; [2]A*STAR, Singapore; [3]Nanyang Technological University, Singapore

Colloidal semiconductor nanocrystals (NCs), commonly referred to as quantum dots (QDs), represent an innovative class of materials distinguished by their unique electrical and optical properties as well as notable antibunching behavior.[1] Consequently, colloidal QDs emerge as indispensable contenders for deployment in single photon devices, a crucial component facilitating various emerging applications in quantum information technology, quantum sensing, and quantum communication.[2] A pivotal advantage lies in their amenability to solution processing, offering substantial versatility and scalability for seamless integration across a diverse spectrum of material platforms and nanocavities.[3–5] A significant aspect of nanophotonics is the coupling of NCs and nanoantennas. Realizing their full potential requires that the emitter be deterministically placed in the nanoantenna hotspot. Thus, the controlled assembly of nanocrystals is imperative for the incorporation of these materials into solid-state devices. Numerous assembly techniques have been explored, aiming to achieve precise nanocrystal positioning, high process controllability, scalability, and universality. However, most existing methods fall short of simultaneously accomplishing all of these objectives. In this work, we present a facile and universally applicable, high-yield method for depositing core-shell CdSe/CdS/CdZnS/SiO_2 QDs. This method leverages capillary-assisted slow evaporation in a saturated vapor environment induced by Marangoni flow, for deposition. Herein, polymer cavities are fabricated through lithographic techniques on various substrates. Following this, QDs are deposited into these cavities, and a lift-off process is then utilized to attain a clean background. Therefore, this technique can be effortlessly implemented for photonic integration on various substrates, including silicon (Si), gold (Au), and silicon nitride (SiN). Noteworthy advantages of this method encompass minimal sample requirements and the preservation of the QDs' optical properties through the requisite processes. We demonstrate a high-yield deterministic deposition, with ~60% representing single particles. Furthermore, this approach not only enables precise single nanocrystal patterning but also opens avenues for deposition and optical studies on both individual and small nanocrystal clusters, holding great significance for various applications.

11:15 AM EL08.18.06
Near-Field Scanning Optical Spectroscopy of Known Gold Nanoaggregate Mohammad KamalHossain; King Fahd University of Petroleum & Minerals, Saudi Arabia

Nanoassembly of noble metal nanoparticles facilitates surface plasmon confinements and such localizations can coalesce and percolate due to a small variation in local nanogeometry. However, realizing such confinement by conventional microscopic and spectroscopic techniques has been challenging until now. We report near-field optical confinement observed by an aperture near-field scanning optical microscopy (a-NSOM). Three typical constructs of gold nanoparticles, viz., archetype dimer, nano-assembly of few nanoparticles and long-range two-dimensional (2D) nano-assembly were investigated. Surface-sensitive techniques such as near-field surface-enhanced Raman scattering (SERS) and near-field surface-enhanced two-photon-induced photoluminescence (TPI-PL) have been recorded using a-NSOM. Well-correlated optometrology was confirmed amongst SERS, TPI-PL and shear-force topography of the abovementioned constructs tapping simultaneously at the very same spot of interest.
Distinctive aggregates and 2D nano-assemblies of gold nanoparticles (~100 nm diameter) were fabricated by the “sandwich technique”, wherein the droplet on a silane treated cover-slip was sandwiched by another glass slide. Monomers, dimers and nano-assemblies of various sizes were confirmed by a field-emission scanning electron microscope. The specimens were spin-coated with Raman active dyes, Rhodamine 6G. A fs-Ti:sapphire laser (λ= 800nm, <100fs, 80MHz) and He-Ne laser (λ=632.8nm) were coupled to the a-NSOM to carry out TPI-PL and SERS measurements. Au-coated tapered optical fibre was used to carry the excitations and act as an apertured probe (aperture ~ 50-100 nm) to scan the specimen. The emitted signals were collected by an objective lens and transferred to an avalanche photodiode (for single-channel detection) and/or to a polychromator-CCD (for multichannel detection).
As expected, optical signals from SERS and TPI-PL were found to be confined and localized at the interstitials of dimers, whereas coalescence and hybridization of such nearby confinements for nan-assemblies were observed. For long-range 2D nano-assembly, optical confinements were more complex and homogenously distributed apart from the edge effect in this context. Finite-difference time-domain (FDTD) simulations were carried out to validate the results obtained in this investigation. FDTD models were designed in such a way that the geometries and parameters closely represent the constructs under investigation and the a-NSOM setup. Such a direct observation with high spatial resolution is required to comprehend the origin of the localized electromagnetic (EM) field at the "hot-site" and the EM amplification factor in surface-sensitive optical processes.

Polaritonic Metastructures AndreaAlu; City University of New York, United States

In this talk, I will discuss our recent progress in the area of polaritonics, and its role in advancing the field of metamaterials and metasurfaces. Tailored material resonances, based on excitons, phonons, magnons and electronic transitions, can be strongly coupled to light in engineered metastructures, unveiling new degrees of freedom for the control of light-matter interactions and enhancing optical nonlinearities. In particular, I will discuss our recent progress on metasurfaces strongly coupled to vibrational and excitonic modes of van der Waals crystals, and control of magnon-exciton polaritons through the magnetic bias in tailored metastructures.

SESSION EL08.20: Quantum Photonics and Emission Control

Friday Afternoon, December1, 2023
Hynes, Level 3, Room 312

2:00 PM EL08.20.01
***In silico* programming the atomic-scale metal gap junctions over wafer-scale substrates**KexinWang[1], YuhyeonJung[1], ZhaoxuanZhang[1], SuhuiZhang[2], Ling-DongSun[1], Chun-HuaYan[1] and WeiSun[1]; [1]Peking University, China; [2]Xiamen University, China

The ability of site-specific programming few atoms-spaced metal gap junctions on wafer enables the volume production of future atomic-scaled high-performance devices. Towards this projected milestone, bottom-up self-assembly of solution-synthesized nanoparticles exhibits unique capabilities in atomic-smooth interface and mesoscale programmable junction geometries, suggesting an alternative approach to conventional top-down lithography. Here, we report an effective strategy, i.e. deterministic assembly of nanoparticle arrays (DANA), to program the assembly of billion oriented nanoparticles on 2-inch wafer. Different from previous bottom-up approaches, DANA defines the geometries of diverse designer atomic-scale gap junctions and their positionongs without using directional molecular linkers.DANA is generalizable to wide material selections and complex asymmetric patterns. Assembled gap junctions exhibit average spacing down to sub-10 atoms, smaller than the 12-nm gap spacing in the projected 2 nm technology node. The atomic-spacing gap junctions facilitate efficient charge transport different from direct tunneling, with performance superior to lithography-defined or thin film-assembled analogs. Hence, DANA bridges the atomic-smooth solution synthesis/assembly into wafer-scale high-performance devices, and complements to the resolution limit of conventional lithography.

2:15 PM EL08.20.02
Active Exciton Resonance Tuning for Ultrathin Free-Space Optical Modulators TomHoekstra and Jorikvan de Groep; University of Amsterdam, Netherlands

Emergent optoelectronic technologies such as augmented reality and free-space optical communications call for ultracompact devices with dynamic control over their optical functionalities. This presents a problem, since conventional optoelectronics require bulky optical elements and filters to operate, thereby limiting the minimal device footprint. In recent years, optically resonant nanostructures and metasurfaces have enabled highly compact devices and optical coatings with tailored spectral, angular, and polarization responses. Nevertheless, active tuning of the optical response remains challenging, owing to the weak electro-absorptive and electro-refractive effects in traditional semiconductors and noble metals.

Here, we leverage highly tunable exciton resonances in 2D quantum materials to realize hybrid metasurfaces for active wavefront manipulation. We greatly enhance the excitonic light-matter interaction through coupling with guided mode resonances in dielectric metasurfaces. More specifically, we embed atomically thin WS_2 in an asymmetric Van der Waals heterostructure cavity and integrate it with a subwavelength grating. The resulting hybrid-2D metasurface exhibits highly tunable and near-unity excitonic light absorption at room temperature, which we leverage to realize an ultrathin free-space optical modulator.

We fabricate a heterostructure comprised of atomically thin WS_2 encapsulated by hBN on a Au back-reflector using an all-dry deterministic stamping technique. This method enables sequential stacking of the 2D layers onto the back-reflector, which we prepatterned on a SiO_2/Si substrate. As such, we circumvent direct lithography on the WS_2 flake, thereby largely preserving its pristine optical and electronic properties. Encapsulation of the monolayer with hBN also limits degradation caused by oxidation, environmental adsorbates, and nanofabrication of the grating.

Next, we integrate the heterostructure cavity with a nonlocal dielectric metasurface to maximize the excitonic light-matter interaction. We fabricate a subwavelength grating in the top hBN layer using electron-beam lithography and reactive-ion etching. The grating allows free-space radiation to couple efficiently to a guided mode resonance of the structure. The guided mode confines the field in the structure and therefore interacts strongly with the monolayer. By tailoring the modal dispersion to spectrally overlap with the exciton resonance, we greatly enhance the coupling efficiency at the operation wavelength. In fact, we achieve near-unity excitonic absorption at room temperature through critical coupling to the cavity mode.

Lastly, we employ electrostatic gating to actively manipulate the exciton resonance amplitude. In our device, the WS_2 monolayer is connected to ground, while the Au back-reflector is attached to a voltage source. By applying a gate voltage, we actively modulate the carrier density in the WS_2 via the field effect. By inducing strong n- or p-type doping in the monolayer, the Coulombic electron-hole interaction is effectively screened, and we observe a 90% reduction in excitonic emission at room temperature. We can actively and reversibly switch the device out of the critically coupled state by suppressing the exciton state, allowing for a large modulation depth in reflection. Altogether, our results demonstrate how exciton resonance tuning combined with strong light-matter interaction in hybrid-2D metasurfaces enables dynamically tunable and ultracompact optoelectronic devices.

Plasmonically Enhancing 2D WSe_2 Light Absorption for Photodetection SereneKamal[1], AndrewBennett-Jackson[2], RohitSrivastava[3], RobertBruce[2], EkinG. Ozaktas[1], ChrisKhoury[1], RameshBudhani[3], DavidShrekenhamer[2] and SusannaM. Thon[1]; [1]Johns Hopkins University, United States; [2]Johns Hopkins University Applied Physics Laboratory, United States; [3]Morgan State University, United States

2D material semiconductors, specifically transition metal dichalcogenides (TMDs), have gained attention in recent years due to their unique and tunable electronic and optical properties at the monolayer and few-layer thicknesses. Because these materials are thin, low loss, and lightweight, TMDs such as WSe_2 are good candidates for flexible photodetector technology. However, unlike traditional semiconductors, TMD films cannot simply be made thicker to increase their absorptivity because their spectral response is a function of their thickness. Surface plasmonics are a nanoscale, size-tunable solution for enhancing light absorption in certain materials. By incorporating a periodic pattern consisting of nanoplasmonic structures on top of WSe_2 and tuning its design parameters, the performance of a WSe_2 photodetector can be greatly improved at targeted wavelengths.
In this work, Finite Element Method (FEM) simulations are first performed in CST Microwave Studio to design gold nanoellipse arrays as enhancement structures for 2D WSe_2 photodetectors. We simulate the coupling between the WSe_2 layer and the localized surface plasmon resonances of the patterned metal layer, and we show that the WSe_2 thickness (number of WSe_2 monolayers) strongly affects the behavior of these plasmonic resonances. By varying the Au nanoellipse size and lattice spacing in the plasmonic layer, we optimize the WSe_2 absorption enhancement at a targeted wavelength of 690 nm. We demonstrate an absolute theoretical WSe_2 absorption of 26% in a 5-layer WSe_2 film, which is over 3 times greater than the WSe_2 absorption without the plasmonic structures.
In addition to investigating traditional nanoellipses in our simulations, we also investigate their inverses, elliptical nanohole arrays. At a wavelength of 690 nm, we show that inverted nanohole arrays achieve a theoretical WSe_2 absorption of 24%, which is comparable to the optical enhancement achieved by the inverse nanoellipse design. These designs can be directly incorporated into the interdigitated electrodes of WSe_2 photoconductive photodetectors. This multifunctional electrode strategy could allow for more efficient charge extraction due to the generation of hot carriers associated with plasmonic excitation precisely at the charge extraction point, causing increased photocurrent.
We use our simulated designs to fabricate WSe_2 photoconductive photodetectors enhanced by plasmonic nanoellipse and nanohole arrays, and we investigate the impact of these designs on the light absorption, photoresponsivity and sensitivity in the devices. We fabricate devices consisting of Au nanoplasmonic arrays on epitaxially-grown WSe_2 using electron-beam lithography, and we characterize the photodetectors' photocurrent response and polarization dependence at 690 nm.
We demonstrate designs for plasmonic Au nanoellipse and nanohole arrays and calculate theoretical enhancement factors of up to 3 for absorption in 2D WSe_2. We use electron beam lithography to fabricate plasmonically-enhanced 2D WSe_2 photoconductive photodetectors and investigate these designs experimentally. These results should advance the field of next-generation sensors for flexible and wearable applications, and could be further applied to optical communications, photovoltaic, and environmental sensing technologies.

3:15 PM EL08.20.04
Plasmonic SERS Biosensor for Rapid and Accurate Bacterial Identification JiwooKo and Yeon SikJung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In 2019, an estimated 7.7 million people died from bacterial infections, accounting for 13.6% of all global deaths. This means that more than 1 in 8 deaths were due to bacterial infections, making it the second leading cause of death worldwide. Deaths from pathogenic bacterial infections are predicted to reach 10 million per year by 2050 due to the emergence of superbugs. Identifying the correct type of bacteria is critical for proper prevention and treatment.
Bacteria are categorized into cocci, bacillus, vibrio, spirilla, and spirochaetes based on their shape. While most bacillus (rod-shaped) bacteria are harmless, some, like Bacillus anthracis (causing anthrax) and Bacillus cereus (causing food poisoning), are deadly to humans. Identifying Bacillus species accurately is challenging due to their structural and genetic similarities (99.2-99.6%). PCR analysis is the industry standard, but it is accurate yet time-consuming. Rapid and accurate identification is crucial for high-risk pathogens, prompting the need for a faster analysis method.
Surface-enhanced Raman spectroscopy (SERS) is emerging as an alternative to PCR analysis for the detection of biomaterials. SERS is a rapid, highly sensitive, accurate, and selective identification of extremely trace amounts of analytes by significantly enhancing the Raman signal from plasmon resonance on metal nanosurfaces. However, because the SERS effect is strongest at the metal nanosurface and decreases with distance, SERS-based measurements of bacteria can only utilize information about limited outer regions such as the cell wall, cell membrane, and membrane proteins. Therefore, SERS is not known to be a suitable method for the analysis of relatively large biomaterials such as cells or bacteria.
In this study, we propose a bacterial pretreatment process to apply the high-potential SERS technique to bacterial identification and analyze the obtained Raman spectra to discriminate

between structurally and genetically similar bacteria. The proposed pretreatment process suitable for SERS is a hybrid lysis process consisting of a mechanical lysis process and a chemical lysis process.
Bacillus, Gram-positive bacteria, have a relatively thick cell wall layer, so mechanical lysis is primarily used to reduce the size of the macromolecule bacteria while releasing intracellular components. Alkaline lysis is used to further reduce the size of the analyte, including the crushed cell wall and intracellular components, and in particular, to denature the released DNA into single strands, making it suitable for SERS analysis.
In parallel, for Raman signal enhancement, we fabricated a 20 nm three-dimensional nanowire network using nanotransfer printing technology to fabricate nanodevices with ultra-high density hotspot regions where electromagnetic fields are enhanced. The presence of numerous factors in the pretreated bacterial samples, including small crushed cell walls and intracellular components, which can be located in the ultra-high density hotspot regions formed on the fabricated nanodevices, resulted in new signal peak shapes or enhanced signal results.
Finally, principal component analysis, which is used to analyze high-dimensional data, was performed to verify that discrimination of five structurally and genetically similar Bacillus bacteria was possible, confirming its applicability as a next-generation biosensor.
The proposed mechanical/chemical hybrid lysis process, which is an appropriate pretreatment process for SERS analysis of macromolecules, is applicable to large biological materials such as cells as well as bacteria. In addition, as a rapid analysis method with high accuracy, it can be applied beyond the public health industry to the high-tech bioindustry, and high-tech defense industry and is expected to be used in the medical field, such as early diagnosis of diseases.

3:30 PM EL08.20.05
Lattice Kerker Effect and Out-Of-Plane Anisotropic Radiation of Photoluminescence from Nanoparticle Array of Titanium Oxide with Tuned Packing Volume MakotoHigashino, ShunsukeMurai, Tien-YangLo and KatsuhisaTanaka; Kyoto University, Japan

Surface lattice resonance (SLR) is a collective resonance induced by radiative coupling between localized resonances in periodically arranged nanoparticles. When the local scattering elements are Mie-resonators such as dielectric nanoparticles, Mie-SLRs are formed by coupling between local Mie resonances mediated via in-plane diffraction [1]. Because of the orthogonality of local magnetic and electric dipoles excited in each Mie resonator, their scattering fields extend to the orthogonal direction and couple to the diffraction modes that match the direction of field expansion. Especially, in rectangular lattice the spectral positions of magnetic and electric SLRs are tunable independently via periodicities along two axes.
The multipolarity of Mie resonances can cause an optical response known as the Kerker effect. In this effect, interference between the far fields deriving from electric and magnetic polarizations suppresses either forward or backward scattering. Rectangular lattices of Mie resonators are very suitable platforms for inducing the Kerker effect, i.e., lattice Kerker effect, because of the independent tunability of spectral position of magnetic and electric SLRs. Zero-backscattering has been reported numerically by carefully tuning the periodicity of one axis [2]. In this study, we focused on Photoluminescence control by utilizing the Lattice-Kerker effect in the square array of rectangle-shaped TiO_2 nanoparticles. We fixed the lattice periodicity while changing the length of one axis of TiO_2 nanoparticles in order to achieve mode crossing of electric and magnetic SLRs. We found asymmetric out-of-plane PL radiation from the light-emitting layer deposited on top of the array at the spectral and angular point where the lattice Kerker effect is achieved.

As a precursor of TiO_2, titanium nanoparticle array was fabricated on SiO_2 substrate by utilizing nanoimprint lithography. Then TiO_2 nanoparticle array was obtained by thermal oxidation of titanium nanoparticle array [3]. Excited resonances were attributed by measured and calculated optical extinction. PL enhancement of TiO_2 nanoparticle array was obtained by measured PL intensity of these arrays embedded in polymethyl methacrylate (PMMA) containing coumarin 153.

The optical extinction of TiO_2 nanoparticle array was measured through optical transmission at various incident angles. By using in-plane diffraction conditions that dominate SLR and calculated extinction through the finite element method, the peaks in the extinction spectra were attributed to electric and magnetic SLRs. In the angle-resolved extinction spectra, we confirmed the intersection of electric and magnetic SLR due to changes in the dispersion relation near $\theta_{in} = 0°$ with increased packing factor of nanoparticles.
The PL enhancement in the front and back of the array as a function of the emission angle was evaluated for each thickness of the emitter layer. Significant PL enhancement was observed at the intersection of electrical and magnetic SLR independent of film thickness. In addition, the PL enhancement at the front of the array was greater than at the back, given a certain film thickness. This result suggests a coupling of Lattice-Kerker effect and PL.

SESSION EL08.21: Virtual Session I
Tuesday Morning, December5, 2023
EL08-virtual

10:30 AM *EL08.21.01
Lasing Polarization Control and Imaging with Reflective Metasurfaces Pin ChiehWu; National Cheng Kung University, Taiwan

In this presentation, I will discuss two specific applications that utilize nanophotonic metasurfaces in reflection. Firstly, we propose the active modulation of the polarization state of a lasing emission at the source using a metasurface-engaged microcavity. This approach allows for generating highly circularly polarized, linearly polarized, or elliptically polarized lasing emissions. By leveraging the strong optical feedback produced by the Fabry-Perot optofluidic microcavity, we can enhance the interactions between light and metasurface atoms, resulting in polarized lasing emissions with high purity and controllability.
Secondly, we introduce and demonstrate a compact snapshot hyperspectral imaging system that incorporates the concept of meta-optics with small-data deep learning theory. Our snapshot hyperspectral imager utilizes a single multi-wavelength metasurface chip operating in the visible window of 500 to 650 nm, significantly reducing the device footprint. To showcase the high performance of our imaging system, we employ a multispectral imaging dataset as the input and through the deep learning-driven imaging system. We generate a hyperspectral data cube with exceptional fidelity through such an approach.
By elegantly integrating multi-resonant metasurfaces with other techniques, such as microcavities and computational imaging, we anticipate the development of low-profile advanced instruments for fundamental science studies and laser physics. This integration will bridge the gap between metasurfaces and microlasers, opening up new possibilities for practical applications.

11:00 AM *EL08.21.02
Exploring Light Absorption and Light Emission with Gold Microflakes GiuliaTagliabue; École Polytechnique Fédérale de Lausanne, Switzerland

In the last decade, optical nanoantennas have revolutionized light manipulation and control at the nanoscale. In particular, by engineering material and morphology it has become possible to shape light absorption and emission. While light absorption was initially considered a purely detrimental process in plasmonic nanostructures, the discovery of hot carriers has sparked great interest, leading to novel light-energy conversion pathways.
Monocrystalline gold microflakes offer interesting possibility for the study of light absorption and emission processes, seamlessly going from bulk metals to plasmonic nanostructures. We recently developed an advanced synthesis method that breaks the proportionality between lateral size and thickness of the gold microflakes [1]. As a result, it becomes possible to obtain on-substrate growth of large area (>100 um) and ultra-thin (<30nm) gold monocrystalline films, uniquely bridging bottom-up and top-down nanofabrication processes. I will thus discuss the distinct features of hot carrier generation in these monocrystalline films as well as their performance in plasmonic photoelectrochemical devices. I will also show comparison with cm-scale plasmonic photoanodes for solar-driven redox cells [2]. Finally, I will report interesting experimental observations on photoluminescence emission from the flakes as well as theoretical analysis of these results.

Tailored Spectro-Temporal Dynamics in Hot-Carrier Plasmonics WenshanCai; Georgia Institute of Technology, United States

Plasmonic metamaterials and metasurfaces can serve as a versatile arena for the investigation and utilization of optically excited, or plasmonically induced, energetic carriers. This is particularly intriguing when the decay pathways of hot carriers are rationally engineered with purposeful selections of the constituent materials and geometrical symmetries. The generation, transport, and relaxation of hot carriers also provide a novel route to active and nonlinear optical effects with ultrafast response rates.

Ultrafast optical switching in plasmonic platforms relies on the third-order Kerr nonlinearity, which is tightly linked to the dynamics of hot carriers in nanostructured metals. Although extensively utilized, a fundamental understanding on the dependence of the switching dynamics upon optical resonances has often been overlooked. Here we employ all-optical control of resonance bands in a hybrid photonic-plasmonic crystal as an empowering technique for probing the resonance-dependent switching dynamics upon hot carrier formation. Differential optical spectral measurements reveal an enhanced switching performance near the anti-crossing point arising from strong coupling between local and nonlocal resonance modes. Furthermore, entangled with hot-carrier dynamics, the nonlinear correspondence between optical resonances and refractive index change results in tailorable dispersion of recovery speeds which can notably deviate from the characteristic lifetime of hot carriers.

We further exploit hot-carrier dynamics to facilitate the creation of handedness-selectable transient chirality in achiral optical metasurfaces. As much as chiral metasurfaces are significant in stereochemistry and polarization control, tunable chiroptical response is important for their dynamic counterparts. A single metasurface device with invertible chiral states can selectively harness or manipulate both handedness of circularly polarized light upon demand, where in fact chiral inversion in molecules is an active research field. Tactics for chirality switching can be classified into geometry modification and refractive index tuning. However, these generally confront slow modulation speed or restrained refractive index tuning effects in the visible regime with forbidden ‘true’ inversion. Here, we reconfigure the ‘optical’ geometry through inhomogeneous spatiotemporal distribution of hot carriers as a breakthrough, transforming a plasmonic achiral metasurface into an ultrafast transient chiral medium with near-perfectly-invertible handedness in the visible. The photoinduced chirality relaxes through the fast spatial diffusion process of electron temperature compared to electron-phonon relaxation, empowering hot-carrier-based devices to be particularly suitable for ultrafast chiroptics.

Our comprehensive understanding provides new protocols for optically characterizing hot-carrier dynamics and optimizing all-optical light modulation and chirality manipulation for operations across the visible spectrum.

12:00 PM EL08.21.04
Large Magneto-Optic Response from Transparent Conducting Oxide Films near Their Epsilon-Near-Zero Frequency JonathonSchrecengost[1], AngelaCleri[1], MaxwellTolchin[1], RamyaMohan[2], JohnP. Murphy[1], SaraAdamkovic[1], AlexJ. Grede[1], MarioImperatore[1], PatrickE. Hopkins[2], Jon-PaulMaria[1] and NoelGiebink[1,3]; [1]The Pennsylvania State University, United States; [2]University of Virginia, United States; [3]University of Michigan–Ann Arbor, United States

Transparent conducting oxide (TCO) materials are promising for a variety of plasmonic and nanophotonic applications because their plasma frequency can be varied across the near- and mid-infrared spectrum via doping. In this work, cadmium oxide thin films doped with In or Gd ions are demonstrated as a promising magneto-optic (MO) material for integration of MO isolators, circulators, non-reciprocal linear to circular polarizers (“Faraday retarders”), and sensors in NIR-MIR Si photonics. Near the epsilon-near-zero (ENZ) condition, applied magnetic fields induce large differences between the refractive index of right and left-hand circularly polarized light, leading to correspondingly large Faraday rotations. Experimental data supported by theory show that doped CdO films have Verdet constants in the range of 10^5-10^6 deg T^{-1} m^{-1} that increase with wavelength up to the ENZ condition. The high optical mobility of CdO leads to >10x the Verdet constant and >100x MO figure of merit (rotation/loss) compared to other TCOs such as indium tin oxide (ITO). CdO films offer additional advantages over current state-of-the-art materials, such as high saturation fields (>3 T) that are achievable in photonic chip applications, an ENZ condition that is tunable over a broad range of mid-infrared wavelengths (2-10 microns), and the ability to sputter high quality films on Si.

12:15 PM EL08.21.06
Fabrication of Multi-Emissive Nanostructures using Two-photon Lithography for Photonics Applications GauravP. Singh[1], ArunJaiswal[1], SarikaJoshi[1,2], SwetaRani[1,2], AjinkyaPalwe[1], SumitSaxena[1,2] and ShobhaShukla[1,2]; [1]Indian Institute of Technology Bombay, India; [2]IITB-Monash Research Academy, India

Nanoscale structures enable unprecedented opportunities in innovating multifunctional devices, especially in nanophotonics, optoelectronics, and other related fields. It is desirable to tailor electromagnetic wave response by tuning size and morphology for niche photonics applications. The realization of such nanostructures depends on sophisticated, complex, time-consuming, serial, and conventional nanofabrication techniques like mask-based photolithography, electron beam deposition, and reactive ion etching. Additionally, precise fabrication of 3D nanostructures, especially control over z-axis features with the subwavelength resolution is challenging using above mentioned methods. There is a need to develop a facile three-dimensional fabrication protocol using new material formulations with embedded functionalization capabilities. In this context, we report the fabrication of multi-emissive nanostructures via two-photon lithography of multifunctional resin.

In this work, we present a multi-emissive polymeric resin comprising a commercially available acrylate-based resin and carbon nanomaterial (CNM). The formulated composite resin was exposed using a femtosecond (fs) laser to induce nonlinear absorption at the focal volume, which helps to create nanostructures with three-dimensional characteristics. The CNMs are multi-emissive with its optical activity retained in resin form as well as in polymerized micro/nanostructures under ultraviolet (UV) excitation. The fabricated structures, when examined under a fluorescence microscope at varying depths, exhibit uniform, bright emission, indicating uniform distribution of CNMs present in the composite resin. These multi-emissive micro/nanostructures are potential building blocks for photonics and can be applied in many areas, such as sensing, optoelectronics, and frequency-selective devices. These multi-emissive properties of the micro/nanostructures have a big impact on improving the field of photonics. Further, tailoring the dimensions of the micro/nanostructures pave the way towards the development of optically engineered next-generation photonic devices.

SESSION EL09.01: Quantum Platforms
Session Chairs: Anna Fontcuberta i Morral and Prineha Narang

1:30 PM *EL09.01.01
Layered Materials as a Platform for Quantum Technologies AndreaC. Ferrari; University of Cambridge, United Kingdom

Layered materials are taking centre stage in the ever-increasing research effort to develop material platforms for quantum technologies. We are at the dawn of the era of layered quantum materials. Their optical, electronic, magnetic, thermal and mechanical properties make them attractive for most aspects of this global pursuit. Layered materials have already shown potential as scalable components, including quantum light sources, photon detectors and nanoscale sensors, and have enabled research of new phases of matter within the broader field of quantum simulations. I will discuss opportunities and challenges faced by layered materials within the landscape of material platforms for quantum technologies, with focus on applications that rely on light–matter interfaces[1].

2:00 PM *EL09.01.02
Predicting Signatures of Unconventional Transport in Low Dimensional and Topological Quantum Materials PrinehaNarang; University of California, Los Angeles, United States

The re-invigorated field of electron hydrodynamics in quantum matter has recently garnered considerable scientific interest, both due to its technological promise of designing near dissipation-less nanoelectronics, as well as its fundamental importance as an experimental probe of strong electron-electron interactions. Investigating the capacity to which observations of electron hydrodynamic flows can inform the nature of electron-electron interactions is particularly important and timely with the advent of spatially-resolved transport measurements which, having demonstrated the hallmark spatial signature of electron hydrodynamic channel flow, must now turn their attention to studying more spatially-complex geometries, enabling the observation of intricate fluid phenomena such as vortices. Recently we have explored the effects of crystal symmetry on electron fluid behaviors starting from the most general viscosity tensors in two and three dimensions, constrained only by crystal symmetry and thermodynamics. In our work we demonstrate the anomalous landscape for electron hydrodynamics in systems beyond graphene, highlighting that previously-thought exotic fluid phenomena can exist in both two-dimensional and anisotropic three-dimensional materials with or without breaking time-reversal symmetry. In this context, the first part of my talk will discuss our recent predictions of hydrodynamics beyond graphene, especially the role of phonons in hydrodynamics in Weyl semimetals. We identify phonon-mediated electron-electron interactions, computed with techniques recently developed that I will discuss in this talk, as critical in a microscopic understanding of hydrodynamics. The second part of my talk will introduce a new theoretical and computational transport framework, the SpaRTaNS (Spatially Resolved Transport of Nonequilibrium Species) framework. I will discuss applications of this method in nonequilibrium electron and phonon transport in low dimensional and layered quantum matter.

2:30 PM *EL09.01.03
Hexagonal Boron Nitride—An Intriguing Platform for On Chip Quantum Technologies IgorAharonovich; University of Technology-Sydney, Australia

Engineering robust solid-state quantum systems is amongst the most pressing challenges to realize scalable quantum photonic circuitry. While several 3D systems (such as diamond or silicon carbide) have been thoroughly studied, solid state emitters in two dimensional (2D) materials are still in their infancy.
In this presentation I will discuss hexagonal boron nitride (hBN) as an emerging platform for integrated quantum photonics. In particular, I will focus on emerging ways to deterministically engineer quantum emitters in hBN and discuss their photophysical properties. I will also highlight scalable pathways for integration of these emitters with on chip optical and photonic resonators. I will conclude by discussing a new class of spin defects in hBN, that operate as quantum sensors and can be used at room temperature. Hosted by an atomically thin lattice, the new spin defects poised to revolutionise the field of quantum sensing, by enabling true atomic proximity between the sensor and the analyte.
I will summarize by outlining challenges and promising directions in the field of quantum nanophotonics with hBN and its integration with other van der Waals structures.

2D Meets 1 and 3D: Opportunities and Open Questions. AnnaFontcuberta i Morral; Ecole Polytechnique Federale de Lausanne, Switzerland

Since the discovery of graphene 2D materials have opened a new world of opportunities in a large variety of applications, ranging from electronics to energy harvesting. In this talk we walk through several examples in which 2D materials have enabled new functionality. We start by outlining the use of commercial graphene to integrate materials that otherwise would not exhibit any commercial latticematched epitaxial substrate. We then move by explaining how 2D materials can be integrated to 3D and 1D materials, forming heterostructures of hybrid dimensionality that involve highly heterogeneous materials. We explain how the functional properties of each part, strain and interface characteristics dictate the functionality of the whole and provide several examples.

4:00 PM *EL09.01.05
Control of Magneto-Optic Response in Van Der Waals Magnets via Strong Light-Matter Coupling VinodMenon[1,2]; [1]The City College of New York, United States; [2]Graduate Center, The City University of New York, United States

van der Waals (vdW) magnets that host electronic excitations (excitons) correlated to the magnetic order present a unique opportunity to realize strongly coupled magneto-exciton-polaritons and thereby manipulate electronic and spin degrees of freedom via light. Here we report our recent work on such strongly coupled polaritons that show signatures of the underlying magnetic order. Specifically, we will discuss the formation of polaritons in antiferromagnetic insulator NiPS3 and the use of polariton nonlinear spectroscopy to shed light on the nature of excitons in this system [1]. Following this, we will present our work on magnetic semiconductor, CrSBr where the excitons are naturally dressed by photons forming self-hybridized polaritons. We demonstrate the signature of coherent magnon oscillations on these polaritons and the potential to modify magneto-optical response by tuning the photon fraction of the polariton states [2].

8:30 AM *EL09.02.01
Dimensionally Hybrid Nanostructures by Van Der Waals Epitaxy ErnestoJoselevich, YardenDanieli, NoyaR. Itzhak, OlgaBrontvein, KatyaRechav, LotharHouben, IfatKaplan-Ashiri, IddoPinkas, HagaiCohen, IritRosenhek Goldian and SidneyCohen; Weizmann Institute, Israel

Mixed-dimensional heterostructures with unusual optoelectronic properties are created by placing two materials of different dimensionalities together, but often without control of their interface at the atomic level. Nanoribbons and nanofins combine in themselves the 2D character of their atomically thin constituents with the 1D character that arises from their elongated structure. They can have unique optoelectronic properties too, but are difficult to produce with well-defined geometries and to assemble into ordered arrays for integration into devices. Our group has developed a series of epitaxial approaches for the guided growth of 1D nanostructures like nanotubes and nanowires with exquisite control of their orientation on surfaces. Here we extend this approach to create a variety of epitaxial mixed-dimensional nanostructures, including nanoribbons, nanofins and nanoplatelet-2D material heterostructures with a high degree of control at the atomic, nanoscopic and macroscopic levels, which enable their integration into devices. Under certain conditions, MoS_2 grows epitaxially on sapphire forming oriented hybrid nanoribbon-nanofin structures, which possess an advantageous geometry for fast and efficient photodetectors. $CsPbBr_3$ perovskite grows on $ReSe_2$ forming aligned rectangular nanoplates. Despite the highly symmetric cubic structure of the $CsPbBr_3$ perovskite, the nanoplatelets are elongated in one principal direction due to the broken symmetry of the $ReSe_2$ substrate. The $CsPbBr_3$ nanoplatelets on $ReSe_2$ have highly anisotropy tribological properties: They easily slide along their long axis, but are firmly locked along their short axis. Cross-sectional TEM shows

that the $CsPbBr_3/ReSe_2$ interface is highly mismatched and incommensurate in the long axis direction, as typical of van der Waals epitaxy, but it is highly coherent with very low mismatch in the perpendicular direction. This explains the anisotropic growth and sliding of the $CsPbBr_3$ nanoplatelets on $ReSe_2$. The electronic and optoelectronic properties of the mixed-dimensional heterostructure are characterized by a series of methods. Our work underscores the potential and richness of van der Waals epitaxy for the creation of dimensionally hybrid nanostructures and heterostructures with controlled shapes and orientations and their integration into devices.

Enhanced Crystallinity of ZnO Columns Grown on Monolayer MoS_2 via Compliant Substrate and Combinatorial Epitaxy YeonjooLee[1,2], XuejingWang[1], KyungtaeKim[1], BenjaminDerby[1], TerrenceMcGuckin[3], GabrielCalderón[4], MichaelT. Pettes[1], JinwooHwang[4], YeonhooKim[5], JeongwonPark[6], AipingChen[1], KibumKang[6] and JinkyoungYoo[1]; [1]Los Alamos National Laboratory, United States; [2]University of Minnesota, United States; [3]Ephemeron-Labs, United States; [4]The Ohio State University, United States; [5]Korea Research Institute of Standards and Science, Korea (the Republic of); [6]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Numerous multi-dimensional architectures have been studied to realize reusable substrates using remote and van der Waals (vdW) epitaxy techniques. In order to prepare high-quality and transferrable semiconductor films, it is mandatory to understand behaviors of two-dimensional (2D) and three-dimensional (3D) materials in epitaxy techniques. We investigated growth behavior of a 3D material on a 2D material by growing ZnO on monolayer MoS_2 which is known that this 2D/3D heterogeneous integration is out of scope for remote and van der Waals epitaxy. We performed high-resolution transmission electron microscopy, grazing incidence wide-angle X-ray scattering, electron beam absorbed current microscopy, Raman microscopy, and photoluminescence measurements to correlate the microstructures and functional properties. This study revealed that random in-plane ordering was preserved while ZnO grew across the monolayer MoS_2 layers. By stacking multiple ZnO/MoS_2 layers, it was shown that inversion of crystallinity occurred; the crystallinity of the top ZnO layer was improved compared to that of the middle ZnO layer. This complex heterostructure can be explained by combinatorial epitaxy, grain alignment across atomically sharp interface, and a compliant substrate. The growth study enabled to form ZnO/MoS_2 heterostructure with type-I band alignment as the narrow band gap of monolayer MoS_2 serves as a charge carrier sink. Our findings provide insight to realize the 2D/3D heterostructure for highly functional device applications.

CMOS Compatible Single-Crystal 2D Material Growth by Geometric Confinement KiseokKim[1], DoyoonLee[1], SeunghwanSeo[1], JunyoungKwon[2], ChanghyunKim[2], MinsuSeol[2], Jin-HongPark[3] and JeehwanKim[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Samsung Advanced Institute of Technology, Korea (the Republic of); [3]Pohang University of Science and Technology, Korea (the Republic of)

The innovations in Si-based complementary metal–oxide–semiconductor (CMOS) technology have a fundamental limit, which precludes achieving ultimate scaling and thereby meeting consumers' demands in the era of data explosion. Thus, for innovation beyond Si-based CMOS scaling, back end of line (BEOL) compatible new materials and the development of next generation transistors are urgently required. Recently, 2D TMD materials are attracting attention as channel materials for next-generation CMOS logic semiconductor devices, as they can outperform Si-based counterparts in terms of the scaling length and carrier mobility. However, despite the excellent performance of 2D TMDs, major obstacles remain in the commercialization of 2D materials; i) Deterioration of channel performance due to polycrystalline growth, ii) Requirement of epitaxial high-temperature growth and transfer process to form single-crystal channels etc.
In this study, we demonstrated the growth of non-epitaxial single-crystal 2D TMD materials at low temperatures by fabricating trenches on amorphous HfO_2-coated Si wafers. This technology enables the direct growth of single-crystal 2D materials on a Si wafer without a separate transfer process. This advancement significantly enhances the potential for integrating 2D materials into commercial CMOS technology.

Remote Epitaxy-Assisted Mixed-Dimensional Integration of 3D Complex-Oxides and 2D Materials SanghoLee, Jung-ElRyu, KiseokKim, XinyuanZhang, CelestaS. Chang, Min-KyuSong and JeehwanKim; Massachusetts Institute of Technology, United States

A new method for growing and releasing three-dimensional (3D) complex-oxide layers in a single crystal form through an atomically thin graphene interlayer, known as remote epitaxy, has revolutionized the heterogeneous integration strategies, which were previously limited due to stringent lattice and processing restrictions. However, the transfer of graphene, which is a typical process for forming graphene on growth substrates, inevitably introduces a significant number of unwanted defects such as wrinkles, holes, process residues, and interfacial contamination. Such defects can disturb the remote interaction between the substrate and epitaxial layer through graphene, reducing the crystal quality and exfoliation yield of membranes. Recently, we developed a direct synthesis method for growing alternative two-dimensional (2D) materials, such as transition metal dichalcogenides (TMDs), on epitaxial substrates, which enables the creation of wafer-scale, defect-free 2D interlayers for reliable remote epitaxy of spinel $CoFe_2O_4$ (CFO) and garnet $Y_3Fe_5O_{12}$ (YIG) thin films of high-quality. The atomically clean van der Waals interfaces formed by direct growth of TMDs onto epitaxial substrates offer an ideal platform for high-throughput production of single-crystalline, freestanding complex-oxide membranes that can be released from substrates, but also for facile fabrication of a new class of mixed-dimensional heterogeneous systems that exhibit emergent physical phenomena at well-defined 3D/2D heterointerfaces. Based on this unique approach to integrating mixed-dimensional heterostructures in a scalable and controlled manner, we demonstrate new device concepts that take advantage of unusual physical coupling or decoupling at exotic 3D/2D interfaces, which are both fundamentally intriguing and practically useful.

2D Materials-Based Remote & Van Der Waals Epitaxy for Heterogeneous Vertical Integration of RGB LEDs and Flexible LEDs Young JoonHong; Sejong University, Korea (the Republic of)

Epitaxy, a process to grow single-crystalline overlayers on wafers of diverse materials, has facilitated the commercial deployment of superior heterostructured electronic and optoelectronic devices. Increasing demand for multifunctional, high-performance devices on a single chip has led to a technological transition from miniaturization to high-density hetero-integration. This shift has catalyzed the development of stamping-printing and transfer-assembly techniques [1]. One approach to heterogeneous integration employs transfer-based assembly methods, requiring the delamination of epi-layers fabricated through different batches and procedures. This process encounters two significant technical obstacles when aiming for high-density integration of high-performance devices. Firstly, traditional epitaxial growth methods produce epi-layer devices strongly bonded to the substrate, making their separation challenging without resorting to high-power laser irradiation or chemical etchants. These separation techniques are known to cause damage to both the substrate and epi-layers, and their strict requirements restrict improved device performance and productivity [2]. Secondly, during the transfer and assembly process, diverse functional devices need to be divided into tiny chips before their precise transfer and assembly onto the target surface (or substrate). Even slight misalignment during chip bonding to backplane circuits can disrupt device interconnects with underlying layouts, thereby increasing the manufacturing costs of micro-LED displays. Additionally, fabricating higher-density vertical stack devices presents a formidable challenge, not only for high-resolution display production (such as augmented reality (AR) and metaverse devices) but also for hetero-integrated electronics. In this presentation, we examine an emerging epitaxy technique that eliminates chemical bonds between the epi-layer and wafer [3-5]. This method offers a potential solution via simple delamination of epi-layers and subsequent stacking of these layers, supplemented with precise photolithographic patterning procedures [4]. We will showcase our recent work on high-density heterogeneously integrated vertical R/G/B micro-LEDs and flexible devices utilizing this innovative epitaxy approach, highlighting potential applications in AR [6]. The remote epitaxy of spatially isolated micro-crystal LEDs has enabled the fabrication of deformable lighting devices [7]. The emerging epitaxy without chemical bonds could be readily employed to broaden the scope of the semiconductor manufacture, potentially leading to a heterogeneous system on a chip for all-in-one electronic and optoelectronics.

Wafer-Free Monolithic 3D Integration Enabled by Mixed Dimensional Heterostructure JeehwanKim; Massachusetts Institute of Technology, United States

Reduction in the size of devices is no longer an option for enhancing the performance of next-generation electronic products. Vertical stacking of wafers containing electronic devices, known as 3D heterogeneous integration, is being considered as the most promising strategy for further performance enhancement. However, this technique requires the following complex processes: i) drilling holes through the wafer (TSV), filling the holes with Cu, and bonding the wafers through bumps. Omitting wafers during such a complicated 3D stacking process would greatly simplify the process and minimize device loss. However, there are almost no options available to transfer active devices detached from the wafer and restack them together. The direct growth of device layers on top of finished circuitry is even more challenging. In this talk, I will discuss the unique strategies to transfer active device layers from the substrate and ultimately direct grow single-crystalline films on BEOL-processed wafer based on our signature 2D material-based layer transfer technique.

11:15 AM EL09.02.07
Area-Selective Deposition of Germanium on Patterned Graphene/Molybdenum Disulfide Stacks JinkyoungYoo[1], TowfiqAhmed[2], XuejingWang[1], MichaelT. Pettes[1], YeonhooKim[3], YeonjooLee[1,4], JeongwonPark[5], Woo SeokYang[6], KibumKang[5] and Young JoonHong[7]; [1]Los Alamos National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States; [3]Korea Research Institute of Standards and Science, Korea (the Republic of); [4]University of Minnesota, United States; [5]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [6]Korea Electronics Technology Institute, Korea (the Republic of); [7]Sejong University, Korea (the Republic of)

Advances in multi-dimensional structures via epitaxy techniques have revealed that two-dimensional (2D) materials can be substrates of the conventional semiconductors, called as three-dimensional (3D) materials, for economical manufacturing and delivering novel functionalities. Integration of 2D materials into the existing device architectures is a key approach for ‘More Moore’ and ‘Beyond Moore’. However, transfer of 2D materials onto the device architectures has been hindered by unintentional formation of wrinkles and absence of a way to remove the support media for the transfer. Therefore, direct growth of 2D materials on conventional materials and vice versa is a scalable and promising way to integrate 2D and 3D materials in an architecture. Growth of 3D materials on 2D materials has been hindered by low nucleation efficiency due to low density of surface dangling bonds on a 2D material. Here, we present area-selective deposition of germanium (Ge) on patterned graphene/MoS_2 stacks. Stacking graphene onto monolayer MoS_2 induces out-of-plane dipole moment due to charge transfer between the 2D materials. The out-of-plane dipole moment results in higher adsorption of germanium precursors. We performed density functional theory calculations of the out-of-plane dipole moment in the graphene/MoS_2 stack, chemical vapor deposition of Ge, and processing-dependent Ge nucleation behaviors on the graphene/MoS_2 stack.

Remote Epitaxial Growth of GaN Thin Films on Graphene Buffer Layer on SiC Substrates using Metalorganic Vapor-Phase Epitaxy SeokjeLee[1], HanikKim[1], Bo-InPark[2], JekyungKim[2], HyunseokKim[2], Gyu-ChulYi[1], KyusangLee[3] and JeehwanKim[2]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States; [3]University of Virginia, United States

High-quality inorganic thin films on flexible substrates are crucial for advancing the field of flexible devices such as wearable sensors, flexible displays, and electronic devices. Remote epitaxy on graphene-coated substrates has emerged as a promising methodology for creating these thin films, offering the potential for mass production of superior material platforms. However, the remote epitaxy of GaN thin films using the widely favored metalorganic vapor-phase epitaxy (MOVPE) has been challenging, mainly due to the degradation of the graphene by the harsh MOVPE growth environment and poor nucleation of GaN on graphene.
In this study, we demonstrate the successful remote epitaxial growth of GaN thin films on graphene buffer layer (GBL) on SiC substrates using MOVPE. The unique properties of GBL, including its strong adhesion to the SiC substrate and the quasi-2D surface that allows for epilayer release, make it a suitable candidate for enduring the harsh growth conditions of MOVPE and remote epitaxy. Moreover, the step edges of GBL, naturally formed by the SiC substrate during the graphitization process, provide numerous nucleation sites for GaN.
To identify the optimum conditions for GaN film growth on GBL, we investigated the nucleation and lateral growth of GaN, with an emphasis on varying growth parameters such as temperature, pressure, and precursor flow rates. Notably, we found that the step edges of GBL served as effective nucleation sites for GaN. The resultant films exhibited smooth surface morphology, and their high crystalline quality was confirmed through XRD and EBSD analyses. Additionally, we successfully exfoliated and transferred these films onto different substrates, fully preserving their properties.
This study opens new horizons for the large-scale production of high-quality, freestanding GaN membranes by overcoming previous challenges related to the remote epitaxy of GaN in the harsh MOVPE environment.

Engineering Defects in III-V Semiconductors Grown by Remote Epitaxy on Thin Amorphous Carbon Ne MyoHan, KuangyeLu, HyunseokKim, Seong HoCho and JeehwanKim; Massachusetts Institute of Technology, United States

Remote epitaxy has emerged as a facile technique for producing freestanding, wafer-scale membranes of single-crystalline semiconductors. However, it still encounters challenges but also presents other benefits when compared to direct epitaxy. In the case of growing epitaxial layers on the same or lattice-matched substrates, remote epitaxy results in lower material quality and higher defect density due to the attenuated atomic registry from the substrate. To address this issue, we propose the incorporation of thermal cycle annealing (TCA) and strained layer superlattice (SLS) into the growth process, which effectively reduces the threading dislocation density by a few orders of magnitude.

Conversely, when the substrate and epitaxial layer have a high lattice mismatch, remote epitaxy offers an advantage through the van der Waals interface, which provides an additional pathway to relax the strain developed in heteroepitaxial layers. This spontaneous relaxation mechanism significantly reduces the occurrence of misfit dislocations that are commonly observed in direct heteroepitaxy. By directly growing thin amorphous carbon (TAC) on GaAs, bypassing the need for a 2D layer transfer process, we can create an ultra-thin van der Waals interface that enhances the atomic registry of the epitaxial layer to the substrate while facilitating strain relaxation. In this study, we investigate the impact of TAC growth time on the material quality of remote heteroepitaxial InGaAs layers grown on GaAs substrates. The inherent strain relaxation capabilities offered by remote epitaxy enable the heteroepitaxy of high-quality membranes on lattice-mismatched substrates, paving the way for the fabrication of diverse electronic and optoelectronic devices.

SESSION EL09.03: Excitonic Platforms

Energy and Charge Transfer in Novel Hybrid Transition Metal Dichalcogenides/2D Perovskite Heterostructures MichalBaranowski; Wroclaw University of Science and Technology, Poland

Van der Waals heterostructures are currently the focus of intense investigation, this is essentially due to the unprecedented flexibility offered by the total relaxation of lattice matching requirements, and their new and exotic properties compared to the individual layers. In this study, we present experimental and theoretical findings on hybrid transition metal dichalcogenide (TMD)/2D perovskite heterostructures. Our density functional theory (DFT) calculations reveal distinctive band alignment in these structures. Specifically, we observe that direct electron transfer between layers is hindered by the presence of the organic spacer in the 2D perovskite. However, the valence band forms a cascade from the TMD monolayer through the organic spacer to the PbI_4 octahedral layer, facilitating hole transfer. Optical spectroscopy studies further support these predictions, providing compelling evidence for both charge transfer and energy transfer between the layers.
Moreover, we demonstrate the presence of long-lived interlayer excitons in these structures, which inherits unique valley properties of WSe_2. By successfully achieving circular polarization of interlayer excitons, we highlight the efficient spin injection from WSe_2 into the 2D perovskite layer. These findings underscore the ability of TMD/2D perovskite heterostructures to engineer the band alignment for diverse excitation transfer processes, as well as spin injection and manipulation.

2:00 PM EL09.03.02
Magnetic Exciton-Polariton with Strongly Coupled Atomic and Photonic Anisotropies QiuyangLi[1], XinXie[1], AdamAlfrey[1], YangLu[1], JiaqiHu[1], WenhaoLiu[2], BingLv[2], LiuyanZhao[1], KaiSun[1] and HuiDeng[1]; [1]University of Michigan, United States; [2]The University of Texas at Dallas, United States

Anisotropy plays a key role in science and engineering. However, the interplay between the material and engineered photonic anisotropies has hardly been explored due to the vastly different

length scales. Here we demonstrate a matter-light hybrid system, exciton-polaritons in a 2D antiferromagnet, CrSBr, coupled with an anisotropic photonic crystal (PC) cavity, where the spin, atomic lattice, and photonic lattices anisotropies are strongly correlated, giving rise to unusual properties of the hybrid system and new possibilities of tuning. We show exceptionally strong coupling between engineered anisotropic optical modes and anisotropic excitons in CrSBr, which is stable against excitation densities a few orders of magnitude higher than polaritons in isotropic materials. Moreover, the polaritons feature a highly anisotropic polarization tunable by tens of degrees by controlling the matter-light coupling via, for instance, spatial alignment between the material and photonic lattices, magnetic field, temperature, cavity detuning and cavity quality-factors. The demonstrated system provides a prototype where atomic- and photonic-scale orders strongly couple, opening opportunities for photonic engineering of quantum materials and novel photonic devices, such as compact, on-chip polarized light sources and polariton lasers.

2:15 PM EL09.03.03
Bandgap Tunable Metal Oxynitride Nanosheets and Functions of Oxynitride/Oxide Superlattices-Like Hybrids ShintaroIda and KazutoHatakeyama; Kumamoto University, Japan

Nanosheets have been studied as multi-functional nanomaterials for a wide range of applications. Controlling the bandgap of nanosheets remains a major challenge. Herein, we report bandgap tunable lanthanum niobium oxynitride nanosheets, which was prepared by exfoliation of layered perovskite oxynitride ($K_{1+x}LaNb_2O_{7-x}N_x$) via ion-exchange and two-step intercalation processes. The resulting $[LaNb_2O_{7-x}N_x]^{(1+x)-}$ nanosheets had homogeneous thickness (1.6 nm) and exhibited a variety of chromatic colors depend on the nitridation temperature including yellow, orange, and brown. The band gap energy of the nanosheet was tunable from 2.03 to 2.63 eV, and their band structures were determined by UPS, Mott–Schottky and photoelectrochemical measurement. In addition, well-organized superlattices are successfully prepared by a layer-by-layer assembly using two different oxynitride/oxide perovskite nanosheets ($LaNb_2O_{7-x}N_x/Ca_2Nb_3O_{10}$). Moreover, the superlattices-like restacked $Ca_2Nb_3O_{10}/LaNb_2O_6N$ hybrid showed proton conductivity and dielectric properties strongly influenced by the oxynitride nanosheets, and enhanced photocatalytic activity under visible light irradiation.

2:30 PMBREAK

3:00 PM *EL09.03.04
Interlayer Excitons in 2D Perovskite/Transition Metal Dichalcogenide Heteostructures DehuiLi; Huazhong University of Science and Technology, China

The emergence of two-dimensional (2D) materials has intrigued a great deal of research on novel physical phenomena and various functional applications due to their particular crystal structures and reduced dimensionality. Chemical bonds between two layers of 2D materials are replaced by van der Waals forces, which are weak and do not require lattice match. Therefore, unlike 3D materials, bulks of 2D materials can be easily thinned to atomic thickness by mechanical exfoliation and atomically thin 2D materials can be arbitrarily stacked to form vertical van der Waals (vdW) heterostructures, which could inherit the unique characteristics of the constituent layers and even exhibit new properties not possessed by them. Particularly, when type-II vdW heterostructures are excited, the positive and the negative charges would reside in the different layers after the charge transfer but be limited within a short distance due to the strong quantum confinement effect of 2D materials, leading to strong Coulomb interaction and the formation of interlayer excitons (IXs). IXs are generally equipped with orientated dipole moment and long lifetime. Currently, studies on IXs are mainly focused on the vdW heterostructures formed by monolayers of transition-metal dichalcogenides (TMDs). Here, I will first talk about an alternate system, vdW heterostructures formed by 2D perovskites and TMDs, for studying IXs. Stacking different kinds of 2D perovskites and TMDs, formation of IXs is confirmed by excitation-power-, temperature-, electric-field-dependent and time-resolved photoluminescence (PL) studies. Notably, robust IX emission can be observed regardless of the stacking sequence and geometric alignment of the constituent layers, showing great advantages over the TMD/TMD vdW heterostructures, which require special twist-angle and thermal annealing. Then, I would like to give a brief introduction on widely tuning the IX emission energy by changing the layer number of the 2D perovskite or the TMD, which shed light on the application of 2D perovskite/TMD vdW heterostructures in broad-spectrum optoelectronics. Besides the layer number, I would like to next talk about how the selection of organic chains in 2D perovskites influences the properties of the IXs. By using chiral 2D perovskites, the IX emission shows substantial circular polarization and the polarization direction is only related to the chirality of the molecules regardless of the excitation scheme or any other external field, which could open up new passages for controlling valley- or spin-polarization of IXs. By introducing molecules with different dielectric constants, the dielectric screening strength in the vdW heterostructure is changed and hence the binding energy of the IXs is also modified, which offers great opportunities for exploiting tunable excitonic devices. Finally, I will also introduce IX as a non-destructive tool for probing the local phase transition at the surface of the 2D perovskite $(BA)_2PbI_4$ flakes. By spatially PL mapping of the $(BA)_2PbI_4/WSe_2$ heterostructure, two different IX species can be observed to distinguish the low-temperature and the high-temperature phase respectively, which offer a new route to regulate the phase transition of $(BA)_2PbI_4$.

3:30 PM EL09.03.05
Hybrid Charge Transfer Exciton at WS_2-Rubrene Interface YuchenKan, ZhengyangLyu and ParagDeotare; University of Michigan, United States

The low dimensionality and van der Waals nature of organics and transition metal dichalcogenides (TMDs) provide a unique opportunity to combine two disparate excitonic systems. This can lead to hybrid interfaces with photophysical properties that do not normally coexist in the individual material systems.
In this work, we investigate a hybrid type-II heterointerface formed between monolayer tungsten disulfide (WS_2) and single crystal Rubrene using optical spectroscopy at cryogenic temperature. We find that hybrid charge transfer excitons (HCTEs) are formed only when WS_2 monolayer is transferred onto the *bc* facet of orthorhombic Rubrene thin film single crystal. In addition, we observe that HCTE formation efficiency and energy is dependent on the twist angle between the monolayer and Rubrene crystal axes. Finally, polarization measurements reveal that HCTEs preserve spin-valley polarization of the WS_2 monolayer.

8:00 PM EL09.04.01
Van Der Waals Epitaxy and Thin Film Transfer using Sputter-Grown Two-Dimensional α-MoO_3SanghoHan[1], SanghoLee[2], XinyuanZhang[2], DohyunKo[1], DeokyeonLee[1], SehyunOh[1], JeehwanKim[2], CarolineA. Ross[2] and Dong HunKim[1]; [1]Myongji University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

The manipulation of electronic, optoelectronic, and magnetic properties of oxide thin films by applying strain provides powerful functionality for future electronic devices. Strain originated from lattice or thermal expansion mismatches changes the physical properties of epitaxial thin films. But external strain by mechanical deformation of rigid substrates has been prohibited due to the low mechanical stability of single crystalline substrates, which limited the application of the epitaxial layers to flexible electronics. The low thermal stability of polymer-based flexible substates has been motivated the development of advanced lift-off technique of van der Waals or remote epitaxy using two dimensional layers.
We present the epitaxial growth of α-MoO_3 layers using sputtering for low cost and large area devices. The films grown at lower temperature and oxygen-free atmosphere showed randomly oriented growth while, they grew epitaxially on $SrTiO_3$ (001) substrates due to the coherent lattice constant along the in-plane at optimized deposition conditions. We detailed microstructure was investigated using an electron backscatter diffraction mapping and high-resolution transmission electron microscopy.
We also report the transfer of high temperature grown thin films using sputter-grown α-MoO_3 layers consisting of MoO6 sheets with normal along the [010] direction bonded by weak van der Waals forces while the bonds within each layer are covalent and ionic. The metallic Au films on α-MoO_3 layer can be easily transferred to flexible supports by cracking the weak interface between the sheets using tapes or by dissolving the α-MoO_3 layer in heated water. We demonstrate that spinel-structured $CoFe_2O_4$ thin films with high crystallinity can be grown on α-MoO_3 layers and can be separated from substrates via mechanical exfoliation, which allows for the modulation of magnetic anisotropy of freestanding $CoFe_2O_4$ films by bending.

8:00 PM EL09.04.02
Collective States in 2D Molecular Monolayers SabrinaJuergensen[1], MoritzKessens[1], CharlotteBerrezueta-Palacios[1], NikolaiSeverin[2], SumayaIfland[2], JürgenRabe[2], NiclasS. Mueller[3] and StephanieReich[1]; [1]Freie Universität Berlin, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]University of Cambridge, United Kingdom

Molecules (0D) have long been known to interact through the dipole moments of their excited states, which may be exploited to create complex opticaa excitations. In recent years, great interest arose in combining them with 2D materials to design hybrid heterostructures with greatly tunable optical properties. Of particular interest are lattices of molecular monolayers that mimic 2D systems through ordered arrangment of 0D monomers. They can be thought of as a new material platform to replace and expand existing optically active 2D monolayers such as transition metal dichalcogenides (TMDs). Most organic monolayer are grown out of planer dye molecules that tend to form J-aggregates. In J-aggregates the transition dipole moments of the molecules are aligned resulting in a strong coupling of the molecules, forming a collective state. The photonic excitation of the collective states to higher electronic levels will result in a very

narrow and strong emission peak.

Theoretically and experimentally, we show how robust the collective state is against spatial disorder excited state quenching, and inhomogeneous broadening of the molecular transitions. Therefore, we grew monolayers of N,N′-Dimethyl-3,4,9,10-Perylentetracarboxylic diimide (MePTCDI), a perylene derivative, on two different van der Waals materials, few-layer hexagonal boron nitride and graphene. Both materials have a flat surface promoting the growth of dye monolayers providing a perfect platform to study the fundamental mechanism of collective states. High resolution AFM was used to determine the lattice structure that the molecules form in a monolayer. Showing a dense packed and highly ordered molecular structure. Optical spectroscopy and light scattering were used to characterize the collective state of the grown 2D material. We were able to measure the characteristic fluorescence for closely packed molecules, further we observed the vanishing Stokes shift between absorption and emission spectrum which is another characteristic for the presence of a collective dipole state. These findings make the molecular monolayers exciting platforms to implement designs of quantum optics in scalable devices.

8:00 PM EL09.04.03
Amorphous 2D Materials – A Novel Platform for Remote Epitaxy and Nanopatterned Epitaxy of III-V Semiconductors with Low Decomposition Temperatures KuangyeLu, HyunseokKim, Ne MyoHan, SanghoLee, YunpengLiu and JeehwanKim; Massachusetts Institute of Technology, United States

III-V semiconductor materials such as indium phosphide (InP) offer outstanding photonic properties that outperform silicon. However, the cost of InP wafers is considerably higher compared to commonly used semiconductor wafers like gallium arsenide (GaAs). While reusing original wafers can effectively reduce costs, traditional techniques for wafer recycling, such as chemical or mechanical lift-off, introduce significant expenses during fabrication, negating the cost savings achieved through wafer reuse. Besides, unlike other III-V materials such as GaAs, the epitaxial lift-off method for wafer recycling has not been extensively investigated for InP due to the lack of lattice-matched sacrificial layers with sufficient etching selectivity. Consequently, the reuse of InP wafers becomes more challenging.
Remote epitaxy and nanopatterned epitaxy have emerged as novel methods capable of facilitating the growth of III-V semiconductor membranes with single-crystal quality, as well as enabling easy exfoliation of these films. These breakthroughs offer a promising avenue for cost-effective wafer reuse. However, traditional approaches for transferring two-dimensional (2D) materials, utilizing polymethyl methacrylate (PMMA) or metal stressor layers to transfer materials grown on foreign substrates like copper (Cu) or silicon carbide (SiC), have been found to introduce defects and damages to both the 2D layer and the substrates during the transfer process. As a result, remote epitaxial and nanopatterned epitaxial films grown on these damaged 2D layers or substrates exhibit lower crystal quality and imperfect exfoliation, hampering wafer reusability and device performance. Additionally, the method of using grown thin amorphous carbon (TAC) for AlGaAs/GaAs is not suitable for InP, since the decomposition temperature of InP (< 600°C) is significantly lower than the growth temperature of TAC (700°C).
Here we report the MBE growth of amorphous boron nitride (a-BN) on InP wafers at low temperature that enabled improved quality of remote epitaxial and nanopatterned epitaxial films and their perfect exfoliation. We show fully covered a-BN on InP substrates despite their low decomposition temperatures. The surface of a-BN coated InP substrate remains smooth with a RMS roughness of around 3Å. We also demonstrate 100% coverage of single-crystal InP thin films grown on a-BN, with the film's quality significantly improved compared to the case of transferred 2D materials. In addition, the growth and exfoliation were successfully repeated multiple times, proving the feasibility for InP wafer recycling. Through this low temperature MBE growth approach with remote epitaxy and nanopatterned epitaxy, we successfully demonstrate large-scale flexible thin film exfoliation and recycling of InP substrates, which will lead to new opportunities in InP thin film-based photonics and novel heterostructures with significantly reduced cost.

8:00 PM EL09.04.04
Remote Epitaxy of III-N Membranes on Amorphous Boron Nitride YunpengLiu[1], KuanQiao[2], WeiKong[3], Bo-InPark[1], JekyungKim[1] and JeehwanKim[1]; [1]Massachusetts Institute of Technology, United States; [2]Intel Corporation, United States; [3]Westlake University, China

Gallium Nitride (GaN) is a wide bandgap binary semiconductor material, which can be fabricated by epitaxy crystal growth such as MBE. GaN owns may physical properties such as wide bandgap and high breakdown electric field. These merits make GaN a promising material for devices such as Light-Emitting diode (LED) and High-Electron-Mobility Transistor (HEMT). Knowing the merits of GaN compared with other semiconductor materials, remote epitaxy appears as a new way to manufacture free-standing GaN films recently. Compared with other methods of fabricating free-standing film such as Laser Lift Off (LLO), Controlled Spalling and Epitaxial Lift Off (ELO), remote epitaxy has smoother lift-off interface, higher substrate reusability, thinner membranes and faster process.
So far, both graphene and Hexagonal Boron Nitride (hBN) have been shown in previous papers as promising 2D materials for remote epitaxy growth. Graphene can be transferred to the substrate from Copper (Cu) foil or SiC substrate or directly grown on the substrate by Chemical Vapor Deposition (CVD). Graphene transferred by PMMA (wet transfer) always results in polymer residuals on the graphene surface, which leads to bad epitaxial film quality. Although less residuals appear during dry transfer process (transferred by Nickle), the process results in the holes on the graphene, which can finally lead to the spall of the substrate during exfoliation. CVD grown graphene shows better graphene quality compared with transferred graphene. However, contaminations generated during sample transferring process between chambers, and graphene leads to high Carbon doping concentration. Besides graphene, hBN is also reported as the platform for remote epitaxy. However, unlike graphene, hBN is a polar material, which means epilayer is guided by the ionic field of the substrate as well as the hBN interlayer. Depending on the thickness of the transferred hBN, the epitaxial layer can be dominated by either of the two phases.
Aiming to solve the problems mentioned above, in situ MBE grown amorphous Boron Nitride (aBN) is developed as the 2D material for remote epitaxy. aBN is grown in MBE chamber with the help of high temperature effusion Boron cell and plasma assisted nitrogen source. aBN is a more transparent 2D material with no ionic field compared with hBN. Epilayer is purely seeded by the substrate in the remote epitaxy process. This MBE in situ grown aBN fully eliminates the contaminations generated during 2D material transferring process and sample reloading process. This technique enables the growth of ultrathin free-standing single crystalline GaN films. This high-quality free-standing film enables the high sensitivity Surface Acoustic Wave (SAW) sensor which can make a conformal contact on human skin. By transferring the GaN on a substrate with higher heat conductivity, GaN based device heat dissipation can be improved. Multiple GaN/aBN layers can be stacked together with single MBE growth to enhance the fabrication rate of the free-standing films. Furthermore, unlike normal epitaxy methods, the epilayer of remote epitaxy spontaneously relaxes due to the slippery surface of the 2D material. The Van der Waal force on the 2D material doesn't limit the relaxation like the covalent bond. Therefore, high quality relaxed InGaN can be obtained with this method.
The synthesis temperature of MBE grown aBN can go as low as 300 °C, which broadens the application field of aBN based remote epitaxy. In the future, this technique has the potential to be applied to more semiconductor materials.

Transfer-Free Graphene for High-Quality Wafer-Scale Free-Standing GaN Membrane by Remote Epitaxy JekyungKim, Bo-InPark, YunpengLiu, HyunseokKim, SeokjeLee and JeehwanKim; Massachusetts Institute of Technology, United States

To fabricate universal platforms for electronic and photonic devices with significantly reduced material costs, it is highly essential to realize free-standing membranes with successful separation of active materials from substrates. However, conventional techniques have their own drawbacks considering poor interface quality, difficulty in stack-up, or materials limitations. Recently, remote epitaxy has posed a remarkable potential that can ultimately overcome the existing challenges and produce high crystalline quality even with the simplicity in choosing the materials. 2D material (e.g. graphene) enables remote interaction between two materials and results in the "remote" epitaxial growth of the material (III-N, III-V, or complex oxides). In this study, we demonstrated an ultra-stable and transfer-free 2D platform using pseudo-graphene(pGr)/SiC in remote epitaxy of GaN. Our approach removed the process for fabricating conventional pGr by exfoliation and achieved wafer-scale high-quality free-standing GaN membrane. This can pave the way for realizing multiple wafer-scale GaN free-standing membranes with high-quality using a single SiC.

III-N Remote Epitaxy on Epitaxial 2D Materials Bo-InPark, JekyungKim, YunpengLiu, HyunseokKim and JeehwanKim; Massachusetts Institute of Technology, United States

The demand for semiconductor technology is rapidly increasing alongside the significant growth of industries such as communication, military, aviation, automobile, and high electric power. GaN and SiC-based compound semiconductors, known for their cutting-edge optical and power devices, are being recognized as the next-generation semiconductors with the potential to revolutionize the world. These compound semiconductors are already extensively utilized in various industries. Recently, the principle of "Remote epitaxy" technology has been discovered, capturing the attention of researchers in different epitaxy-related fields. Remote epitaxy, developed specifically for the epitaxial growth of high-quality compound semiconductor materials, takes advantage of the unique surface and physical characteristics exhibited by certain two-dimensional (2D) materials. Unlike existing epitaxy techniques, remote epitaxy stands out by enabling the production of freestanding membranes through easy separation and transfer from the substrate. Over the past few years, we have successfully demonstrated the viability of this technology and acquired scientific knowledge in fabricating diverse high-quality compound semiconductor materials.
In this research, we introduce the implementation of remote epitaxy for producing freestanding, high-quality single crystalline GaN membranes. We present the manufacturing process involving optimized 2D materials obtained through various epitaxy methods and thoroughly analyze their characteristics. The development of defect-free 2D materials through remote epitaxy has facilitated the fabrication of high-quality single crystalline membranes on a wafer scale.

Generalising Murray's Law for Materials BinghanZhou[1], QianCheng[1], ZhuoChen[1], ZeshengChen[1], DongfangLiang[1], EricA. Munro[1], GuolinYun[1], YoshikiKawaii[2], JinruiChen[1],

HidetoshiMatsumoto[2] and TawfiqueHasan[1]; [1]University of Cambridge, United Kingdom; [2]Tokyo Institute of Technology, Japan

Hierarchically porous materials benefit from their multi-level and interconnected pore networks by combining the advantages of efficient mass transfer and high specific surface area. Recently, Murray's law has garnered significant research interest as a promising tool for optimising hierarchy in porous materials.[1] This biomechanics principle describes optimal biological networks for transport.[2] The bio-inspired synthetic porous materials following this law, Murray materials, have been reported to excel in applications involving mass transfer processes. However, Murray's law is based on branching tubular networks found in biological systems, whereas synthetic pores in materials often exhibit complex geometries. This discrepancy in architecture undermines the strict application of Murray's law to synthetic materials.

Here we expand Murray's law for hierarchically porous materials. We extend Murray's law into a universal form and demonstrate its use in other hierarchical structure and transfer type. We further discuss the structural optimisation of several typical hierarchical networks and transfer types in porous materials, demonstrating this law's remarkable applicability and universality. We verify the optimal laminar flow predicted by Universal Murray's law in freeze-casted graphene oxide aerogel through experiments and simulations. Additionally, we demonstrate the practical value of this principle in gas sensors, where simply adjusting the macroscopic shape according to Murray's law improves response and recovery time. Our study therefore establishes a solid theoretical foundation for future Murray material development.

Shape-Driven Variation of Photon Emission in Dimensionally Hybrid ML-TMDs/III-V NWs Heterostructures ClaireBlaga[1], MicheleZendrini[1], OsmanBalci[2], SachinShinde[2], SohamJoshi[1], VictorBugnion[1], AndreaC. Ferrari[2], AnnaFontcuberta i Morral[1,3] and ValerioPiazza[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]University of Cambridge, United Kingdom; [3]École Polytechnique Fédérale de Lausanne, Switzerland

Transition metal dichalcogenides (TMDs) have high spin-orbit coupling (spin splitting energies between 0.1 and 0.5 eV [1]), exciton funneling [2] and strain modulation [3] which may allow them to be core semiconductors in a wide variety of devices. The ability to tune their properties by applying localized strain is appealing in fields ranging from electronics [4] to photonics [5], from spintronics [6] to optoelectronics [7]. The combination with 1D nanostructures could be used to control the strain distribution in monolayers (1Ls) as the morphological reshaping of the TMDs on nanowires (NWs) results in a localized strain [5,6]. III-V NWs can enable control over charge and exciton injection into 1L-TMDs. Heterostructures made of 1L-TMDs on horizontal III-V NWs exhibit interesting optical properties in view the design of quantum emitter arrays [8]. However, the impact of material stacking, geometry and NW size on the strain distribution and the consequent effect on the optical properties must be clarified.
Here, we report on hybrid heterostructures made of 1L-WSe_2 on horizontal GaAs NWs. The 1L-WSe_2 is grown on sapphire by water-assisted chemical vapor deposition (CVD) using WSe_2 bulk as the presursor. Selective area epitaxy molecular beam epitaxy (SAE-MBE) is used to grow ordered arrays of faceted III-V NWs, differing by width and height and NW-to-NW distance. After GaAs surface passivation with ammonium sulphide, 1L-WSe_2 is placed on the horizontal NWs via wet transfer using polymethyl methacrylate as the support layer. Micro-photoluminescence and Raman mapping are performed at room and low temperature to outline the variation of optical features with the NW array parameters. Numerical simulations support the strain distribution description, consistently with the experimental optical maps.

Low-Barrier Heterojunction of Layered Sb_2Te_3 on Si for Low Resistance n-Type Contacts NaoyaOkada, ShogoHatayama, Wen HsinChang, YutaSaito and ToshifumiIrisawa; National Institute of Advanced Industrial Science and Technology, Japan

In advanced CMOS, the transistor performance is becoming highly dependent on the contact resistance at the source/drain with recent extreme scaling. To reduce the specific contact resistivity, a low Schottky barrier height at the metal/semiconductor interface is required; however, it is well known that most metal/Si junctions always show a high electron Schottky barrier height to n-Si owing to the Fermi-level pinning in the range between the mid gap and the valence band edge. This fact imposes a fundamental difficulty in obtaining low contact resistance and further high performance in Si n-FET.
We have recently demonstrated van der Waals stacking of Sb_2Te_3 on MoS_2, and additionally achieved significant device performance enhancement of MoS_2 n-FET using the Sb_2Te_3 contact at source/drain thanks to the significant reduction of the contact resistance [1]. These findings motivated us to investigate the junction properties of Sb_2Te_3 on Si. In this work, we demonstrate the low barrier height of the Sb_2Te_3/n-Si junction. To evaluate potentials of Sb_2Te_3 as the source/drain contacts in n-FET and p-FET, we prepared the W/Sb_2Te_3/Si junctions. Here, the Sb_2Te_3 with a thickness of 20 nm was prepared by magnetron sputtering in pure Ar onto the n- and p-type Si substrates (~1-10 Ωcm), and then the W electrode with a thickness of 30 nm was successively formed onto Sb_2Te_3 in the same deposition system. The formed Sb_2Te_3 films have a layered structure on Si, and they are stable against annealing up to 400 °C. Control samples of W/Si direct junctions showed a high electron barrier height of 0.65 eV and hole barrier height of 0.41 eV, owing to the Fermi-level pinning at the Si surface. These resulted in rectifying behavior both for n- and p-Si. In contrast, the current-voltage characteristics of Sb_2Te_3/n-Si junction was found to become ohmic, while the only Sb_2Te_3/p-Si junction was rectifying with the hole barrier height of 0.81 eV. These results suggest that the Fermi level in the Sb_2Te_3/Si junction is close to the conduction band edge of Si.
In conclusion, a clear reduction in an electron barrier height was obtained by the insertion of Sb_2Te_3 between W electrodes and n-Si substrates. This low electron barrier height will be useful in the n-FET. Thus, the Sb_2Te_3 film is a promising contact material for the source/drain in the advanced Si CMOS transistors.

Composition Control of Two-Dimensional $Cu_{2-x}S$/CdS Heterostructured Nanoplates via Cation Exchange Reaction for Photocatalytic Hydrogen Generation under Visible Light KodongBang, BumjinPark and HyunjoonSong; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Solar-to-fuel conversion using semiconductor materials has long been studied as a promising sustainable and clean energy solution. Among various reactions, photocatalytic hydrogen generation holds significant potential for the development of clean and renewable energy sources. To enhance the efficiency of photocatalytic activity, heterostructures has been explored to reduce electron-hole recombination and promote increased charge separation efficiency. In this study, we present the controlled metal ratio of two-dimensional $Cu_{2-x}S$/CdS heterostructured nanoplate achieved through a cation exchange reaction. By adjusting the composition ratio, we investigated the photocatalytic activity and focused on the optical and photochemical properties. Notably, a 65% of Cd content of $Cu_{2-x}S$/CdS heterostructured nanoplate exhibited the highest photocatalytic activity, surpassing that of a similar one-dimensional $Cu_{2-x}S$/CdS system. Our observation provides a guideline to the rational design of semiconductor-semiconductor heterojunctions in two-dimensional nanostructures for enhanced photocatalytic activity.

8:00 PM EL09.04.11
Synthesis and Characterization of TiO_2-GO Hybrid via Femtosecond Laser Irradiation in Liquid for Enhanced Photocatalytic Applications under Visible-Light BersuBastug Azer, AhmetGulsaran, RezaKarimi, JosephSanderson, MichaelPope and MustafaYavuz; University of Waterloo, Canada

In the pursuit of efficient photocatalytic materials, the integration of titanium dioxide (TiO_2) with graphene oxide (GO) has emerged as a promising strategy. Herein, we present a novel and environmentally friendly method for synthesizing a TiO_2-GO hybrid through laser irradiation in liquid. This technique offers simplicity, greenness, and remarkable control over the heterostructure's properties depending on the laser parameters.

The TiO_2-GO hybrid was fabricated by ultrasonication of TiO_2 nanoparticles and GO in a liquid medium, followed by femtosecond laser irradiation. The resulting heterostructure was

characterized using various techniques. The structural properties were investigated through X-ray diffraction (XRD), Raman spectroscopy, and BET analysis. The XRD patterns confirmed the successful integration of TiO_2 and GO, while Raman spectroscopy revealed a strong interface formation between the two materials. BET analysis demonstrated increased surface area in the hybrid structure. To evaluate the optical properties, UV-Vis spectroscopy was employed. The absorption spectra exhibited enhanced light absorption in the visible range, indicating efficient utilization of visible light for photocatalytic processes. The band gap energy of the TiO_2-GO hybrid was estimated using the Kubelka-Munk function, revealing a reduced band gap compared to pure TiO_2. This band gap narrowing enables the hybrid to harness a broader spectrum of light, enhancing its photocatalytic activity under visible light illumination. Moreover, the morphology of the TiO_2-GO hybrid was examined using scanning electron microscopy (SEM). The SEM images showcased a well-dispersed and interconnected structure with intimate contact between TiO_2 nanoparticles and GO sheets.

In summary, our laser irradiation in liquid synthesis approach enables the fabrication of a TiO_2-GO hybrid with outstanding properties for photocatalytic applications. This green and straightforward technique results in a heterostructure that exhibits enhanced photocatalytic performance under visible light, surpassing the capabilities of TiO_2 and GO individually. The comprehensive characterization of the hybrid's optical, structural, and morphological properties validates its potential for highly efficient photocatalytic applications.

Artificially Intelligent Formaldehyde Sensing using Printed Graphene-Based Aerogels ZhuoChen, BinghanZhou, TyneeBhowmick and TawfiqueHasan; University of Cambridge, United Kingdom

The identification and analysis of formaldehyde as a hazardous air pollutant in indoor environments present an immediate and critical concern. The endeavour to achieve real-time recognition of formaldehyde in the presence of interfering gases represents a formidable challenge, particularly for room temperature sensors that are susceptible to noise and baseline drift. Exploring the unique properties of dimensionally hybrid systems based on graphene and leveraging artificial intelligence (AI) offer promising pathways.
In this study, we tackle these challenges by utilising the 3D-printed porous structure of graphene-based aerogels as interconnected frameworks for rapid gas diffusion and sensitising the aerogels with tin oxide quantum dots (QDs) for high-performance chemical sensing at room temperature. Through reaction-coupled diffusion modelling of both filament-structured and film-like aerogels, we explain and experimentally demonstrate the superior gas-sensing capabilities of thinner filaments with higher surface porosity. With optimised morphology and doping of the printed structures, we achieve an outstanding response of 15.23% towards 1 ppm formaldehyde at room temperature.
Furthermore, we explore the versatility of different structures and chemical doping to construct gas sensor arrays capable of distinguishing formaldehyde from ammonia and nitrogen dioxide. To enable real-time gas species classification, we develop gas recognition algorithms based on dynamic response features that are independent of steady-state response or testing sequences. These algorithms demonstrate remarkable accuracies, even in the presence of significant noise and baseline drift. Our findings present a novel artificially intelligent solution for the detection and real-time identification of formaldehyde at room temperature, offering promising prospects of graphene-based aerogels for addressing this pressing environmental issue.

8:00 PM EL09.04.13
Introduction of Low Dimensional Charge-Boosters into Graphene Oxide Nanochannels for Energy Harvesting Ki HyunLee, HyeonhooLee, WoojaeJeong and Tae HeeHan; Hanyang University, Korea (the Republic of)

Osmotic energy, a potential source of electricity from salinity differences in water, relies on ion-exchange membranes to convert salt gradient energy into electric power. However, these membranes encounter challenges, including inadequate charge densities and resistance to mass transfer. Recent efforts have focused on enhancing ion-selective membranes using materials like polymers, metal oxides, and frameworks. Two-dimensional (2D) nanosheets, such as graphene and boron nitride, have shown promise, featuring nanochannels with controlled thickness. These structures exhibit an electrical double layer that enhances ion transport. Utilizing reverse electrodialysis (RED), 2D nanochannel membranes demonstrate high ion conductance and osmotic power extraction. However, the challenges also arise from the intrinsic limitations of 2D nanomaterials, including relatively low surface charge densities and mass-transfer resistance, which hinder their effective integration into RED systems. In this study, we used negatively charged graphene quantum dots (GQDs) and polyelectrolyte nanorods to boost the charge density of graphene oxide (GO) nanochannels. Charged GQDs and polyelectrolyte nanorods can be integrated into GO fibers and films to increase the charge density and improve energy harvesting performances. Moreover, by aligning nanoscale charge boosters onto GO nanochannels through a blade-coating technique, the charge density can be precisely directed to optimize ion transport. Our study introduces an innovative and efficient approach to refining ion transport characteristics of 2D GO nanochannels, ultimately enhancing ion selectivity for proficient osmotic energy generation.

Phonons and Thermal Transport in Two-Dimensional Systems IlariaZardo[1,2]; [1]University of Basel, Netherlands; [2]Universität Basel, Switzerland

Phonon engineering leads to a controlled modification of phonon dispersion, phonon interactions, and transport. However, engineering and probing phonons and phonon transport at the nanoscale is a non-trivial problem. In this talk, we discuss how phononic properties and thermal transport can be engineered and measured in low dimensional systems.
In particular, a fundamental difference in the phononic properties of 2D and 3D polar materials is predicted to be the long-wavelength dispersion of longitudinal (LO) and transverse (TO) optical phonon modes [1]: in 2D systems these modes become degenerate at the zone center, at variance with the well-known splitting they exhibit in bulk 3D materials. Besides the fundamental importance of understanding how the phonon modes of polar materials change when dimensionality is reduced, we stress two applicative reasons for this investigation: *i)* the peculiar characteristics of the phonon modes have an impact on thermal and electrical transport and optical coupling of 2D materials; *ii)* Raman spectroscopy is one of the most important non-destructive tools used to determine the thickness of the flakes [2], and thus it is essential to interpret correctly the experimental measurements by identifying all the observed phonon modes. We provide the experimental proof of the collapse of the TO-LO splitting in polar 2D materials [3], predicted by ref. [1]. We also investigate the effect of the parity of the number of layers and the role of inversion symmetry. Once all the proper theoretical tools required to fully account for all the experimental features of the Raman spectra of 2D materials are assessed, we exploit them to unveil the lattice dynamics of WSe_2 [4], which is, among the most diffused transition metal dichalcogenides, the one having the most controversial phononic properties, due to a very small thickness-dependence of the main phonon modes (A_{1g} and E^1_{2g}). We show that conventional first order Raman spectroscopy has a limited validity in the determination of the number of layers in WSe_2 and we propose an alternative, more general approach, based on multi-phonon bands, which enables to distinguish between 1L, 2L, and 3L [4].
Finally, we present a method to investigate thermal transport in two-dimensional systems using multi-terminal suspended SiN_x membranes with resistive elements. These devices enable us to probe thermal transport along different directions as a function of thermal bias.

Generating and Exploring the Effects of Ultrastrong Electric Field in 2D Material/molecule Heterostructures KirillBolotin; Freie University Berlin, Germany

We consider a new type of heterostructure: a 2D material with donor molecules on one side and acceptor molecules on the other. The charge transfer between the molecules generates an electrical field inside the 2D material. We experimentally measure the field produced by this “molecular gating” and show that it reaches >4V/m, the highest field measured in a solid-state device. We then explore the effect of this intense field. First, we demonstrate that the field suffices to modify and eventually completely close the bandgap in bilayer 2D semiconductors driving a semiconductor-to-metal transition. Second, we show that the field lifts degeneracies between excitons in semiconductor 2D bilayer and brings different excitons into resonance. Finally, we demonstrate new types of excitonic states that arise because of that.

9:30 AM EL09.05.03
Role of the Anion in an Ionic Liquid-Gated MoS_2 Transistor AnoirHamdi[1], Iréné Bérenger AmieheEssomba[2], KanaIshisone[2], RaminKarimi[3], TianLan[3], ClaraSantato[3], MauroBoero[2],

GuidoOri[2] and EmanueleOrgiu[1]; [1]Institut National de la Recherche Scientifique- Centre Énergie, Matériaux et Télécommunications (EMT), Canada; [2]Institut de Physique et Chimie des Matériaux de Strasbourg, CNRS, Université de Strasbourg, France; [3]Polytechnique Montréal, campus de l'Université de Montréal, Canada

Electrical double layer gating is employed to achieve ultra-high charge carrier accumulation in a semiconductor material operating as the active layer in a transistor. Such strategy allows to overcome the problem of low carrier density and high operating voltage in field-effect transistors (FETs) due to low capacitance and electrical breakdown of the gate dielectric. In the present work, electrical double-layer transistors based on molybdenum disulfide (EDLT- MoS_2) and an ionic liquid (IL) were fabricated to achieve a higher carrier density and lower operating voltage than those in the FET-MoS_2 transistor. EDLT-MoS_2 were obtained by combining a three-terminal back-gated MoS_2 FET with an ionic liquid while disabling the back-gate effect and using the ionic liquid as a top-gate dielectric. A heavily p doped silicon layer Si^{++} with thermally grown 285 nm thick SiO_2 was used as substrate, while gold (Au) with chromium (adhesion layer) were used to fabricate the source and drain electrodes of the EDLT-MoS_2. Activated carbon was chosen as the gate electrode. Two different ionic liquids [EMIM][anion1] and [EMIM][anion2] were used as gate dielectrics in order to: obtain high performance transistors, study the IL/MoS_2 interface and identify the anion/cation pair most capable of injecting a high density of charge carriers on the surface of the molybdenum disulfide channel. The results of electrical characterizations showed that both [EMIM][anion1] and [EMIM][anion2] allow us to achieve a higher carrier density in the MoS_2 channel than what usually achieved by means of conventional gating with insulating oxides such as SiO_2. This allows to use our transistors at lower operating voltage. Comparing the results obtained by the two ILs, it was found that although the gating occurs through the [EMIM] cation, [anion1] achieves the highest electric double layer capacitance over [EMIM][anion2]. Surprisingly, we found that the anion plays a role in the gating efficiency of our devices in spite of the fact that it is the cation that actually recalls charge carriers (electrons in this case) within the FET channel. This is in agreement with theoretical predictions and modeling carried out by using classical and first-principles molecular dynamics simulations. Furthermore, the performances of FET gated by [EMIM][anion1] were found to be stable over time. This work explored from a theoretical and an experimental point of view the role of the anion in an ionic liquid. This paves the way for the choice of suitable pairs of ILs for applications in electronics or superconductivity.

9:45 AM EL09.05.04
Electrostatic Self-Assembly of GO-CNT Nano-Hybrid Structures LokeshSoni, Kamendra PSharma and Ajay SinghPanwar; Indian Institute of Technology Bombay, India

Carbon-based hybrid nanostructures consisting of graphene oxide (GO) and carbon nanotubes (CNT) could potentially provide superior properties relative to their individual components. However, the fabrication of such nanostructures at this length scale is found to be an arduous task, due to restacking of GO sheets and aggregation of CNTs. By using CNTs as anchoring material to prevent restacking of GO sheets, a hybrid nanostructure can be synthesized which can show synergistic properties from both materials[1], [2]. In this study, we report a scalable approach to develop highly ordered CNT intercalated GO hybrid nanostructures in an aqueous medium with an electrostatic self-assembly process. The GO-CNT hybrids were synthesized by first modifying the GO and CNT with polyelectrolytes such as Poly(diallyldimethylammonium chloride) (PDDA) and Poly(styrene sulfonate) (PSS) via non-covalent interactions, resulting in highly stable dispersions of mGO, and mCNT respectively. The hybrid nanostructures were synthesized by homogeneous mixing of mGO and mCNT constituents with varying volumetric ratios with ultrasonication. The hybrid nanostructures were characterized by zeta potential, dynamic light scattering, scanning electron microscopy (SEM), and transmission electron microscopy (TEM). From SEM the hybrid nanostructure with 1:0.5 mGO:mCNT (v/v) ratio was found with highly organised stacking of CNT intercalated GO sheets , owning to the charge neutralization point of the dispersion as studied with zeta potential study. TEM micrographs also show homogeneous distribution of CNTs on the exfoliated GO sheets. Strengthened electrostatic interaction on the GO and CNT with adsorbed polyelectrolytes prevents restacking and aggregation of GO sheets and CNTs and further facilitates the self-assembly of oppositely charged nanoparticles into the formation of layered hybrid nanostructures. The mobility of polyelectrolyte chains also facilitates the ordered arrangement of CNTs with their anisotropic shapes and extends the electrostatic interaction to a much greater length scale to produce a compact yet strengthened nanostructure. The proposed process provides a highly cost-effective method against processes such as CVD, and large-scale production of a highly ordered arrangement of CNTs than the conventional Layer-by-layer assembly method to produce GO-CNT hybrid nanostructures for membrane and high surface area application in aqueous media.

Nanoscale Optoelectronic Characterisation of Hybrid Heterostructures via Scattering-Type Scanning-Near-Field Optical Microscopy JessicaL. Boland[1,2]; [1]University of Manchester, United Kingdom; [2]National Physical Laboratory, United Kingdom

Dimensionally hybrid semiconductor heterostructures and 2D heterostructures have enormous promise for a range of functional technologies. Indeed, heterostructures of planar 2D materials have already found applications in photonics, optoelectronics, straintronics, valleytronics and twistronics; where pushing towards 2D/1D and 2D/0D systems have shown exciting optoelectronic phenomena [1,2]. To understand the effect of this hybridisation, characterisation techniques with high spatial resolution, temporal resolution and depth selectivity are required in order to examine the optoelectronic and chemical properties of individual layers and components of the heterostructure.
In this talk, we present scattering-type scanning near-field optical microscopy (s-SNOM) as a powerful tool for non-destructive optoelectronic characterisation of hybrid heterostructures [3,4]. By coupling radiation to the apex of an atomic force tip, we achieve spatial resolutions way beyond the diffraction limit of light down to 10 nm across wavelengths from the visible to the terahertz range. We perform both imaging and spectroscopy to extract the local material dielectric function on nanometre length scales. By oscillating the tip and changing the tapping amplitude, we can also alter the probing depth to perform nanotomography, enabling us to observe differences in optoelectronic properties in different layers of a material. Here, we present s-SNOM on a range of example heterostructures, including: interlayer charge transfer between 2D TMDC heterostructures [5]; identification of surface layer in InN nanoparticles; nanoscale 3D mapping of dielectric function in topological insulator thin films and nanowires [6].

New Optical Features of Designer 2D Materials and Machine-Learning Assisted Characterization ShengxiHuang; Rice University, United States

2D materials offer enormous opportunities to build designer structures with widely tunable properties. The precise atomic engineering and quick characterization approach are critical to advance the application of designer 2D materials. This talk will introduce new optical features of designer 2D materials [1-4] with a focus on atomic substitution in monolayer WS_2 [1]. The engineering of 2D materials presents unique opportunities for optoelectronic device and quantum information platform. When designing optoelectronic devices of 2D materials, spectroscopic permittivity of 2D material is a key parameter. While ellipsometry has been used to measure permittivity, it requires simple device structure, non-trivial parameter fitting, and special setup. This talk will also present a new machine-learning assisted approach to measure permittivity of 2D materials embedded in complex device structures without model fitting, which can facilitate a quick, accurate, and in-situ characterization of 2D and other thin film materials [5].

Tailored Epitaxial Growth and Morphology of 1D/2D Heterostructures KateReidy[1], NoyaR. Itzhak[2], MayaLevy-Greenberg[2], PaulMiller[1], YasenHou[1], FedericoPanciera[3], JagadeeshMoodera[1], ErnestoJoselevich[2] and FrancesM. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Weizmann Institute of Science, Israel; [3]Université Paris-Saclay, France

Controlling emergent phenomena at the nanometer regime requires unprecedented precision, resolution, and uniformity not readily feasible through conventional top-down fabrication techniques. This is particularly true in the growth and design of van der Waals (vdW) bonded 'mixed dimensional' heterostrucutres, where two-dimensional (2D) and nD (where n is 0, 1 or 3) materials adhered primarily through non-covalent interactions are highly dependent on local structure.[1] Direct visualization of atomic-scale structures and interfaces allows the determination of growth mechanisms and routes towards tailoring morphology.

Here, we explore how vdW-bonded 2D substrates influence complex epitaxial growth modes of 1D tellurium (Te) nanostructures using a combination of *in-situ* growth and *ex-situ* analysis via atomic resolution scanning transmission electron microscopy (STEM). Te is a p-doped semiconductor that can exhibit a chiral atomic structure and is emerging for application in next-generation electronic, optoelectronic, and piezoelectric applications. First, we utilize vdW epitaxy to tailor Te nanostructure growth on a variety of 2D substrates, exhibiting both hexagonal symmetry and more asymmetric surface structures. We then elucidate the role of temperature in the resulting nanostructure morphology, moving towards facetted islands at higher temperature with well-defined interfaces and morphologies. We compare the growth morphologies of chiral Te with the case of higher symmetry crystal structures, such as Au, Ti, and Hf, examining the role of symmetry on nanostructure morphology. Such understanding of tailored growth mode allows versatile design of heterostructures for next generation nanoscale devices, and we discuss mechanisms by which optimizing this 1D/2D interface is crucial for improving existing devices as well as generating novel mixed-dimensional heterostructures.

Epitaxial MoS_2 Nanofins and Nanoribbons for Optoelectronics YardenDanieli, LotharHouben, KatyaRechav and ErnestoJoselevich; Weizmann Institute of Science, Israel

2D materials are a versatile platform for optoelectronics, memory and energy-harvesting devices owing to their high-carrier mobility and strong light-matter interaction. Scientific efforts were invested during the last decade to tailor the physical properties of these materials by gaining control over their dimensionality. The synthesis of new structures with mixed dimensionalities, such as nanoribbons or nanofins, with controlled orientations, can give rise to a change of physical behavior and has many potential applications in electronics and optoelectronics. However, efficient synthetic methods for the bottom-up creation of aligned single-crystal nanoribbons and nanofins are still lacking.
Our group gained substantial knowledge regarding the aligned growth of 1D nanowires of different semiconductors, guided by different crystalline substrates, as part of the general guided-growth approach. This work aims to implement the guided growth approach to induce 1D growth of MoS_2 nanofins-nanoribbons with controlled orientations. Synthesized in a CVD system by epitaxy on sapphire, the formation of these unique hybrid structures is discussed in terms of crystal structure and morphology. Optical properties such as photoluminescence and Raman spectroscopy are also presented. The MoS_2 nanoribbons-nanofins were integrated into arrays of visible-light photodetectors, showing high responsivity and short response times with respect to previously reported MoS_2-based photodetectors. Such growth of nanofins-nanoribbons can be generalized to other 2D materials, suggesting new structures that enable various device architectures with improved performance.

Controlling Valley-Selective Absorption and Emission from Monolayer Materials with High-Q Metasurfaces JenniferA. Dionne, FengPan, YinLiu, Sze CheungLau, FangLiu, MarkL. Brongersma and TonyF. Heinz; Stanford University, United States

Atomically thin two-dimensional (2D) materials, transition metal dichalcogenides (TMDCs), graphene, and hexagonal boron nitride as well as their heterostructures, have recently found wide applications in optoelectronic devices, condensed matter physics, and quantum information science (QIS). Among these 2D materials, excitons in atomically-thin TMDCs have large exciton binding energies (>500 meV) and provide bright and sharp photoluminescence (PL) emission. More importantly, the presence of spin-orbit coupling and broken inversion symmetry renders the spin/valley polarization addressable through optically-circular polarization control. The valley-polarized PL can be observed and characterized by the degree of circular polarization, defined as DOP = $[I(\sigma+) - I(\sigma-)]/[I(\sigma+) + I(\sigma-)]$, where $I(\sigma+/-)$ are right and left circularly polarized PL intensities. Achieving high DOP is important for high-fidelity quantum information processing and generating high-quality chiral light sources. However, their short spin coherence time due to intervalley scattering, i.e. a few ps even at low temperatures (4 K or 100 K), prevents them from being employed as on-chip valley-selective devices for wide applications in valleytronics.

Here, we integrate the TMDC MoS_2 with high-quality-factor silicon metasurfaces to enhance and control valley-specific absorption and emission. By varying the metasurface disk diameter, we tune the frequencies of Mie scattering modes to match the exciton frequency in MoS_2. When the electric and magnetic Mie modes overlap (a Kerker-like condition), the photoluminescence (PL) intensity of MoS_2 is enhanced by over 30 times on the metasurface in contrast to that on flat sapphire substrate. The MoS_2 emission spectra are also markedly modified via the coupling of neutral excitons, trions and defect bound excitonic states with the metasurface Mie modes. At the Kerker condition, we also demonstrate the symmetric enhancement of the degree-of-polarization (DOP) of neutral exciton and trions via valley-resolved PL measurements, and find that the DOP can be as high as 24% for exciton emission and 34% for trion emission at 100K. These results can be understood by analyzing the near-field impact of metasurface resonators on both the chiral absorption of MoS2 emitters as well as the enhanced emission from the Purcell effect. Combining Si-compatible photonic design with large-scale (mm-scale) 2D materials integration, our work makes an important step towards on-chip valleytronic and QIS applications approaching room-temperature operation.

Interfacing 2D Transition-Metal Dichalcogenides with III-V Substrates and Nanostructures MicheleZendrini, MichelePonso, ClaireBlaga, JinJiang, MitaliBanerjee, ValerioPiazza and AnnaFontcuberta i Morral; Ecole Polytechnique Federale de Lausanne (EPFL), Switzerland

Two-dimensional transition metal dichalcogenides (2D-TMDs) figure as promising candidates for new generation optoelectronics, ranging from flexible electronics to single-photon emitters and strain-tunable devices. Their functionalization through the integration with a suitable substrate is a key factor as 2D materials are strongly influenced by both the substrate morphology and the dielectric environment. The heterostructures of 2D-TMDs and III-V materials have shown to induce sharper and more stable emission with respect to their counterparts on oxides [1]. A clear understanding of the band alignment between the 2D material and the specific III-V material is still needed to outline the most suitable material coupling for functional devices. In this context, one must also consider the impact of the strain on the band structure of the 2D-TMDs and thus on the heterojunction. The substrate morphology is therefore of primary importance as it can be engineered to induce various strain configurations [2].
In our work, we transfer MoS_2 and WSe_2 monolayers (ML) on different III-V substrates such as GaAs and related ternary alloys. We grow the III-V semiconductors by molecular beam epitaxy in form of a thin film or an ordered array of 1D nanostructures such as horizontal nanowires. Selective area epitaxy allows obtaining arrays with precise morphology and size. In the case of thin films, the TMD/III-V stacking is explored to evaluate the effective band alignment. In the latter case of nanostructures, the extent of strain-induced modification is investigated. The heterojunction properties are defined both optically and electrically. On the one hand, micro-photoluminescence and Raman spectroscopy are utilized to evaluate the evolution of emissions and vibrational modes respectively when transitioning from unstrained to strained MLs. On the other hand, conductive atomic force microscopy and electrical contacts patterned by electron-beam lithography provide comprehension of the electrical response of the different heterojunctions.

Laser Induced Incorporation of CNTs in Graphene Electrodes Improves Flexibility and Conductivity AsmitaDutta; Ariel University, Israel

Laser processing of nanocarbon films emerges as the preferred technique to prepare carbon-based electrodes. A great effort focuses on exploiting this fast, sustainable, and cost-effective method on a broader range of nanomaterials. This study describes the laser-induced production of reduced graphene oxide with carbon nanotube (rGO/CNT) composites and their application as flexible electrodes. Conductive carbonized films were imprinted on a flexible substrate by laser-carbonization. The composites formation is supported by a detailed microstructural and

chemical analysis, which confirms the structural integration of rGO with CNTs. Electrodes containing CNTs exhibit 7.5-fold increase in conductivity compared to only rGO electrodes. Importantly, when the electrodes are bent, the conductivity retention of the composite is significantly superior compared to the only rGO electrodes. Upon bending, the change in conductivity is lowered from 0.62 to 0.19. Furthermore, when used as electrodes in flexible supercapacitor devices, the composites with CNTs show 98.45 % retention in specific capacitance while maintaining structural integrity. In contrast, rGO electrodes without CNT addition deform upon bending and retain only 63.88 % of the relaxed specific capacitance.

8:30 AM *EL09.06.01
Heterostructuring in Mechanically Deformed Van Der Waals Crystals AntonioPolimeni[1], ElenaBlundo[1], SalvatoreCianci[1,2], MarziaCuccu[1,2], FedericoTuzi[1], GiorgioPettinari[3] and MarcoFelici[1]; [1]Sapienza Università di Roma, Italy; [2]TU Dresden, Germany; [3]Italian National Research Council (CNR), Italy

Heterostructures (HSs) of van der Waals (vdW) crystals are created by stacking atomically thin layers with different compositions and relative angular alignment thus prompting an endless number of combinations and novel physical phenomena. Another key feature of vdW HSs, and of their constituent layers, is their highly sensitive response to mechanical deformations stemming from their virtually two-dimensional (2D) structure. Strain indeed has been demonstrated to be a most powerful tool to modify controllably the electronic properties of 2D materials [1].
Here, we report two exemplary cases, where the interplay between heterostructuring and strain add new functionalities to and improve the optoelectronic characteristics of 2D crystals and their HSs.
In the first instance, we consider HSs formed by strained transition metal dichalcogenide (TMD) monolayers (MLs) and hexagonal boron nitride (h-BN). Strain is achieved by proton irradiation of TMD bulk flakes, in which protons lead to a local blistering of the crystal just beneath the topmost plane and hence to the formation of highly strained ML micro/nano-domes filled with H_2 [2]. The capping with h-BN promotes an elastic energy transfer from the domes to h-BN that eventually prevents the dome deflation at the liquefaction temperature of H_2 (~33 K). In turn, this preserves the dome strain field and enables the fabrication of spatially controlled quantum emitters [3].
In the second case, InSe/TMD dome HSs are presented. InSe features excellent transport properties but poor emission efficiency in the few layer limit. We exploit the strain-induced transition of the valence band maximum from K to Γ in MS_2 (M=Mo,W) ML domes [4] to create a type-I HS with InSe. Therein, a direct transfer of holes from the Γ point of the ML dome to that of the InSe occurs, while electrons undergo a defect-assisted tunnelling from the conduction band of the strained ML to that of InSe. As a result of these processes an increase by up to two orders of magnitude in the emission efficiency of InSe is observed.

Engineering Hybrid Nanowire/2D Systems for (Opto)Electronics HannahJ. Joyce, TomAlbrow-Owen, OliverBurton and JackAlexander-Webber; University of Cambridge, United Kingdom

The combination of nanowires with two-dimensional (2D) systems is an exciting one enabling new growth approaches, new (opto)electronic device functions and new systems. Here we present two such examples, firstly a nanowire-graphene spectrometer, and secondly an array of single nanowires addressed through a two-dimensional electron gas.

Semiconductor nanowires of graded composition are prime candidates for miniaturised spectrometers [1]. In these devices, the nanowire's bandgap varies with position along the nanowire's axis, and photons of sufficient energy will selectively excite particular regions depending on the local bandgap. Multiple electrode pairs placed laterally at intervals along the nanowire axis are used to detect local changes in conductivity induced by photoexcitation, with the graded bandgap giving a means to discriminate incoming wavelengths. This concept is powerful, but complicated by the diffusion of photoexcited charge carriers into lower bandgap regions. To overcome this problem, we instead use graphene channels at intervals in contact with the graded bandgap nanowire, and measure the conduction through the graphene. Efficient transfer of photoexcited carriers from the nanowire into the graphene alters its chemical potential and conductivity, which provides a measure of the wavelength-dependent intensity of incident light.

Multiplexed arrays of single InAs nanowires were achieved using a quantum multiplexer chip [2] with individual InAs nanowires transfer printed onto each of the chip's channels. The quantum multiplexer itself consists of a two-dimensional electron gas (2DEG) patterned into a cascaded structure with arms that can be depleted by the application of a gate bias. Depletion prevents conduction through the associated channels. Using the multiplexer, measurements of conductance and quantum transport through 16 individual nanowire channels were achieved with just 9 electrodes. The multiplexer permits a reduction in the number of electrodes needed, with the number of devices scaling as 2^((n-1)/2) with n being the number of electrodes. This multiplexer is particularly beneficial for experiments at cryogenic temperatures in which the number of leads entering a cryostat is limited, and for large statistical studies of nanowires.

Hybrid Carbon Materials: Synthesis, Properties and Electrochemical Sensor Potential CarolinaRojas Michea[1,2], NeidaSantacruz[3], FrankMendoza- Centeno[3], GerardoMorell[3,2], BradWeiner[1,2] and AnaR. Guadalupe[1,2]; [1]University of Puerto Rico at Río Piedras Campus, United States; [2]Molecular Science Research Center, University of Puerto Rico, United States; [3]University of Puerto Rico at Río Piedras, United States

This research presents a hybrid carbon material foam developed by chemical vapor deposition technique, with acetone as a carbon source and Ni as scaffolds. Carbon poses some interesting allotropes, and this material exhibits some of them. Graphene and graphene oxide are valuables in the sensors field due to their electrical and conductive properties. However, there are essential applications in gas and liquid media that can benefit from the unique properties of graphene but require a 3D structure able to interact thoroughly with the medium. We studied how the structural properties of the graphene hybrids foams depend on the growth parameters, such as temperature, precursor concentration, and Ni foams thickness. This material will be used as an electrode in sensing some enzymes or other biological molecules which are at low concentrations.
The high purity and yield of the material fabrication would enable further applications for research and industrial processes, such as catalysis and environmental remediation.

10:15 AM EL09.07.04
Multi-Walled Carbon Nanotubes and Graphene Oxide Decorated Pitch-Derived Carbon Foam Composites for Enhanced Structural and Catalytic Performances MuhammadKhan and HusnuE. Unalan; Middle East Technical University, Turkey

Various amounts of multi-walled carbon nanotubes (MWCNTs) and graphene oxide (GO) were synergistically dispersed into the pitch-derived carbon foam (CF) matrix via direct pyrolysis. The structural and catalytic behaviors of prepared CF composites were investigated. Results showed porous morphology with compressive strength and Young's modulus of 19.3 MPa and 57.4 MPa, respectively, after an additive loading of 2%. Excellent thermal and electrical conductivities of 30.92 W/m. K and 27.4 $\times 10^3$ S/m were obtained from the CF sample with an additive loading of 2%. Furthermore, the catalytic decolorization performance of the CF samples against methyl orange (MO) dye was investigated and reported. Results revealed that the CF sample with an additive loading of 4% decolorized about 76% MO dye under exposure to UV light within 60 min. The decolorization of MO dye increases by increasing additive loading in the nanocomposite while dye decolorization decreases with increasing the initial dye concentration.

Understanding and Enhancing the Color Center Emission in hBN Coupled to Photonic Circuits HenryRoberts[1], ScottWicker, Jr.[1], apratimKhandelwal[2] and XiulingLi[1]; [1]The University of Texas at Austin, United States; [2]University of Illinois at Urbana-Champaign, United States

Defects embedded in solids or thin films function as attractive quantum sensors. For example, negatively charged nitrogen vacancies NV^- in diamond films can be used for detecting electric, magnetic, and strain fields with promising sensitivity and resolutions. Here we explore the color center emission in van der Waals (vdW) materials, particularly hexagonal boron nitride (hBN), and in silicon carbide nanostructures, coupled to photonic circuits. We will discuss the design, photonic structure fabrication, deterministic spin defect generation, and characterization.

11:00 AM *EL09.07.06
(Clarifying) A Few Alternative Facts about 2D Materials EricPop; Stanford University, United States

Great interest in the science and engineering of two-dimensional (2D) materials has led to a great rush of publications, some stating or propagating a number of “alternative facts” about 2D material and device properties (with thanks to Kellyanne Conway for coining this term). An “alternative fact” (AF) is a statement, a number, or a belief that is presented as “fact”, despite reasonable uncertainty or evidence to the contrary. Common examples include the 0.65 nm thickness and 1.8 eV band gap of monolayer MoS_2, or various exaggerated mobility values. Unfortunately, such AFs have propagated in the 2D literature perhaps by accident, perhaps because some form a compelling story, or perhaps due to convenience. Here we try to address and hopefully clarify a few AFs, especially as they pertain to basic 2D material parameters or simple device applications. The presentation will be incomplete, yet will hopefully provide some useful guidance for researchers working with 2D materials. The audience will be encouraged to participate and contribute their favorite AFs (and corrections), which will be published online for the benefit of new students and others entering the broad and exciting field of 2D materials.

Enhanced Interactions of Interlayer Excitons in Free-Standing Hetero-Bilayers YueruiLu; Australian National University, Australia

Strong, long-range dipole-dipole interactions between interlayer excitons (IXs) can lead to novel multi-particle correlation regimes that drive the system into distinct quantum and classical phases[1] including dipolar liquids, crystals, and superfluids. Both repulsive and attractive dipole-dipole interactions have been theoretically predicted between IXs in a semiconductor bilayer[2,3], but only repulsive interactions have been experimentally reported so far[4,5]. This study[6] investigated free-standing, twisted (51°, 53°, 45°), tungsten diselenide/tungsten disulfide (WSe_2/WS_2) hetero-bilayers, where we observed a transition in the nature of dipolar interactions among IXs from repulsive to attractive. This was caused by quantum-exchange-correlation effects, leading to the appearance of a robust interlayer biexciton (formed by two IXs) phase that was theoretically predicted[7] but never observed in experiments before. The reduced dielectric screening in a free-standing hetero-bilayer not only resulted in a much higher formation efficiency of IXs, but also led to strongly enhanced dipole-dipole interactions, which allowed us to observe the many-body correlations of pristine IXs at the two-dimensional (2D) quantum limit. In addition, we first observed multiple emission peaks from moiré-trapped IXs at room temperature in a well-aligned, free-standing WSe_2/WS_2 hetero-bilayer. Our findings can open avenues for exploring new quantum phases with potential for application in nonlinear optics.<!--![endif]---->

Two-Dimensional Materials for Next-Generation Electronics and Optoelectronics Technologies—From Fundamentals to Applied Industrial Solutions SumeetWalia; RMIT University, Australia

Atomically-thin materials possess unique intrinsic properties and are amenable to a range of tuning techniques. We harness these properties underpinned by application demand and work with industry to translate into end-user products.
Firstly, we synthesise a variety of atomically-thin metal oxides, mono/dichalcogenides and elemental 2D materials using solid, liquid and vapour phase techniques guided by application. Our fundamental advances have been uncovering the origins of oxidative degradation in few-layer black phosphorus (BP) and subsequently proposing an ionic liquid-based approach to prevent ambient degradation of BP. Using defect engineering, we have demonstrated light operated artificial- synaptic and logic devices and neural networks that can recognise numbers and patterns. We have explored the use of hybrids of dissimilar materials to enhance electronic and optical performance. Ultra-thin layers have been used to develop one of the world’s thinnest photodetectors that can sense all shades of light from UV-infrared. We further study strain-tunability in low-dimensional structures via integrating them onto elastomeric platforms and engineer optoelectronic functionalities.
Using a cross-disciplinary approach, we deploy multifunctionality of these new material systems into solving technological challenges for a range of industry partners.

9:00 AM EL01/EL09/EL12.03
Correlated KPFM and TERS Imaging to Elucidate Defect-Induced Inhomogeneities in Oxygen Plasma Treated 2D-MoS_2 Layers SanjuGupta; Penn State University, United States

Modulating physical and chemical properties of two-dimensional (2D) transition metal dichalcogenides (TMDC) by defect-engineering induced by oxygen plasma is actively pursued. In this work, exfoliated 2D MoS_2 layers treated by medium power oxygen plasma for different times (0, 10, 20, 40, and 60 s) are investigated using Kelvin Probe Force microscopy and tip-enhanced Raman spectroscopy (TERS) besides micro-Raman and photoluminescence (PL) spectroscopy. Under oxygen plasma, defects (mono- and di-sulfur vacancies) and chemical oxidation is predominant from 0s (native defects) up to 40s, while etching becomes dominant beyond 40 s, for mono- (1L), bi- (2L), and tri- (3L) layer MoS_2 with optimal defect density for four- (4L) and more layers. While Raman spectra exhibited lattice distortion (broadening of phonon bands) and surface oxidation by the presence of sub-stoichiometric molytrioxide MoO_3 (*i.e.*, MoO_{3-x} or MoS_xO_{2-x}) the increased spectral weight of trions and quenching in PL spectra are observed with treatment time. The localized nanodomains (~20-40 nm) and aggregated vacancies as nanovoids and intermixed MoS_2/MoO_{3-x} alloy are identified in near-field Raman spectra. The atomic force microscopy also showed defects aggregation and Kelvin probe force microscopy revealed the work function (WF) increase from 4.98 eV to 5.56 eV, corroborating the existence of MoO_{3-x} phase which enables doping and shift Fermi level. We also highlight the unique interaction between the gold substrate and the formed MoO_{3-x} facilitating Mo^{6+} cation reduction to lower oxidation (*i.e.*, Mo^{4+}) thereby yielding intermediate oxidation states responsible for lower WF (*ca.* theoretical 6.3 eV for stoichiometric MoO_3). Strong correlations among the work function, vibrational and optical responses are established while exploring the oxygen plasma-induced defects and changing the landscape on oxygen doping at the nanoscale with varying MoS_2 layers, which are useful for heterogeneous electrocatalysis and applicable to other 2D TMDCs.

9:15 AM *EL01/EL09/EL12.04
Manufacturing of Meta Optics by Nanoimprint Lithography NiklasHansson; NIL Technology, Denmark

Metalenses have gained significant attention in various fields such as augmented reality (AR), automotive technology, and consumer electronics. Their unique properties, including high thermal stability, fewer lens components, and focal lengths that closely match design values in production. These aspects lead to simplified camera modules, and make meta lenses highly desirable for these applications.

The efficiency of metalenses is crucial, as low-efficiency metalenses result in undesirable diffraction of light. To achieve high efficiency, it is important that the fabricated meta atoms, typically in the form of pillars, closely match the intended design. Even small deviations in the order of a few nanometers can lead to noticeable decreases in efficiency. Nanoimprint lithography (NIL) is a manufacturing technique employed for mass producing metalenses. We have investigated how closely the fabricated pillar diameters align with the design specifications. In the case of a focusing lens designed for 940 nm, the deviations in pillar diameters were found to be within the range of +/-10 nm for repeated fabrication on a single wafer and between consecutive manufactured wafers.

The corresponding focusing efficiencies of these metalenses were measured to be between 85% and 90%. This indicates that NIL is a valid manufacturing method for producing metalenses suitable for the aforementioned applications. The high efficiency of the manufactured metalenses suggests that they effectively mitigate the issue of light diffraction into unwanted orders, making them a promising choice for AR, automotive, and consumer electronics.

Effect of Ligands on the Structure and Mechanical Properties of Three-Dimensional Nanoparticles Superlattices ElenaShevchenko[1,2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States

Extensive research has been conducted on the self-organization of uniform nanoparticles, leading to the formation of various types of periodic structures. Numerous instances of both single and multicomponent periodic assemblies have been successfully demonstrated. It has been established that the self-assembly process of nanoparticles is highly intricate, involving a wide range of attractive and repulsive interactions between particles and their ligands.
In this study, we will explore the influence of nanoparticle purification, ligand solvation, and the type of ligands on the self-assembly of nanoparticles and their impact on the structure and properties of the resulting structures. Furthermore, we will discuss the effect of size distribution on the structure of periodic superlattices.
We will present combined quasi-hydrostatic high-pressure small-angle X-ray scattering (SAXS) and X-ray diffraction (XRD) studies on faceted 3D supercrystals self-assembled from colloidal nanoparticles. To investigate the overall mechanical characteristics of the assembled structures, we employed the diamond anvil cell technique, allowing us to examine the contributions of solvated ligands and inorganic ligands. Additionally, we will discuss the role of ligand solvation in the mechanical properties of periodic structures, as well as the structural transformations that occur upon compression for supercrystals obtained using different nonsolvents and ligands.

How General are Changes in Excited State Surface Chemistry of Colloidal Quantum Dots for Photocatalysis?JohnB. Asbury; Pennsylvania State University, United States

The ligand-nanocrystal boundaries of colloidal quantum dots (QDs) mediate the primary energy and electron transfer processes that underpin photochemical and photocatalytic transformations at their surfaces. These boundaries also protect nanocrystal surfaces from photochemical degradation and maintain their colloidal stability. In recent work, we demonstrated using time-resolved infrared (TRIR) spectroscopy that certain types ligand-nanocrystal interactions on PbS QDs exhibit marked reduction in surface bonding strength in the excited states of the nanocrystals, which may provide a pathway to modulate ligand bonding during photocatalytic reactions. In this work, we examined changes in the excited state surface chemistry of CdSe QDs passivated with stearic acid ligands to test the generality of this phenomenon. Transient absorption and photoluminescence spectroscopies were used to characterize the vibrational spectra of the ligands in the excited states of the QDs and to compare their time-dependence to the dynamics of the electronics states. The transient vibrational spectra of the symmetric and antisymmetric stretch modes of the carboxylate anchoring groups of the ligands indicated a net reduction of their higher frequency antisymmetric stretch and an enhancement of the lower frequency symmetric stretch modes. These changes were consistent with the influence that image dipoles created by the polarizable excited excitonic states of the QDs have on the transition dipole moments of the carboxylate anchoring groups. Importantly, a lower frequency transient vibrational feature around 1330 cm^{-1} appeared in the TRIR spectra that was not present in the ground state infrared absorption (FTIR) spectrum of the QDs. This feature corresponded to the C–O single bond of more weakly bonded carboxylate groups in the monodentate bonding geometry. The shorter excited state lifetime of CdSe in comparison to PbS QDs allowed us to directly observe the reattachment of ligands to their original bonding geometries on much longer time scales. These findings suggest that changes in excited state surface chemistry may be general to metal chalcogenide QDs and motivates continued work to elucidate the origins and means to control the phenomenon for photocatalytic applications.

Density Functional Theory Investigation of Trap States in III-V Quantum Dots EzraA. Alexander[1], MatthiasKick[1], AlexandraMcIsaac[2] and TroyVan Voorhis[1]; [1]Massachusetts Institute of Technology, United States; [2]University of California, Berkeley, United States

Cadmium selenide, one of the premier quantum dot (QD) materials for light emission, solar cells, and biomedical imaging, is highly toxic to both humans and the environment. Alternative nontoxic III-V QDs are held back by a high density of surface-localized mid-gap states, which trap photoexcited charge carriers and reduce device efficiency. Despite the prevalence of density functional theory (DFT) in past research on surface trapping in the II-VI family of QDs, very few studies have applied DFT to the substantially different III-V family of QDs. In this work, we survey a broad range of realistic, carefully selected InP and GaP QDs of different sizes, shapes, and surface terminations. By utilizing orbital localization techniques to deconvolute the dense manifold of states at the band edges, we create a framework for understanding the complex surface trapping in these III-V QDs. Not only can trap states form from under-coordinated surface atoms as in II-VI QDs, but we also identify localized midgap states that originate from atomic dimers and distorted four-coordinate surface atoms. We discuss several factors that influence the depth of both electron and hole traps in these materials, including potential avenues for removing such localized states from the band gap. Finally, we identify key differences between the surface reconstruction and electronic structure of InP and GaP QDs.

Surface Chemistry, Optoelectronic Properties and Methods for Enhancing the Photoluminescence Quantum Efficiency of InP-based Core/Shell Quantum Dots PieterSchiettecatte, BenCruyssaert, LucaGiordano, HannesVan Avermaet and ZegerHens; Ghent University, Belgium

Colloidal quantum dots (QDs) possess spectrally narrow and tunable emission lines, making them highly attractive for applications in displays, light sources, and energy devices. However, to meet the stringent demands of efficient and sustainable devices, it is essential for QDs to exhibit high photoluminescence quantum efficiencies (PLQY) that are close to unity. In this study, we, therefore, focus on enhancing the PLQY of InP-based core/shell QDs by investigating the relationship between their surface chemistry and their optoelectronic properties.

Our approach involves saturating the surface of InP-based QDs using a zinc acetate complex. This surface passivation step can be carried out either during QD synthesis or after synthesis. We have successfully applied this method to over 25 QD samples with diverse compositions synthesized by different collaborators, demonstrating its robustness and versatility. Additionally, we develop a ligand exchange technique that enables the transfer of InP-based QDs from apolar to polar media while preserving their high PLQY. This method opens up new possibilities for utilizing QDs in both polar and apolar environments without sacrificing their photoluminescence efficiency.

By significantly enhancing the PLQY of InP-based QDs, our findings offer promising prospects for their application in optoelectronics and photonics. These advancements can contribute to the development of more efficient and high-performance devices in different fields.

Solid-State Synthesis and Solution-Processable MB_6 Nanocrystals SuhasMutalik; University of Groningen, Netherlands

Metal hexaborides (MB_6) are of high technological interest as they show a wide range of bulk physical properties depending on the metal ion in the structure. Boron-rich compounds like CeB_6 and LaB_6 possesses low work functions (2.5-2.7 eV), while CaB_6 and SrB_6 possess high-temperature thermoelectric properties. [1] The MB_6 is reported to have very high hardness (9.5 on the Mohs hardness scale) with nanoindentation hardness of 16-18 GPa. [2] The existing literature reports the solid-state synthesis of MB_6 nanocrystals below 500 °C, but so far, no studies have been reported on solution-processable MB_6 hexaborides. Herein we report a solid-state synthesis of LaB_6 and SrB_6 nanocrystals performed at 440 °C and a novel post-processing technique of treating the nanopowders obtained from solid-state reaction to form a colloidally stable ink. Through the surface modification of the nanocrystals, we can exchange the surface ligands from inorganic short-chain ligands to organic long-chain ligands, making them solution processable in both polar and non-polar solvents. The colloidally stable MB6 nanocrystals have great potential to be used as thermoelectric devices or ultra-hard protective coatings, which can be fabricated at low cost by solution-based mass production processes.

Ligands on Nanocrystal Surfaces - What Ligand Stripping Can Tell Us ZegerHens; Ghent University, Belgium

Colloidal semiconductor nanocrystals are in most cases synthesized as hybrid inorganic/organic objects where organic ligands passivate the surface of the inorganic crystallite. This organic ligand shell helps controlling the growth of nanocrystals during synthesis, stabilizes nanocrystal dispersions by steric hindrance, contributes to the electronic passivation of surface-localized electronic states and determines the mobility of charge carries in nanocrystal films. Hence, the importance of understanding the binding and packing of ligands to nanocrystal surfaces in nanocrystal science.
In this contribution, we focus on the binding of metal salts such as cadmium oleate, zinc oleate or zinc halides to semiconductor nanocrystals surfaces. We first discuss how the displacement of such Lewis acids through the addition of Lewis bases can be used to probe the binding energy of these metal salts to the nanocrystal surface. By gradually increasing the concentration of the Lewis base, displacement isotherms can be recorded and analyzed using surface-adsorption models. Using this approach on core nanocrystals, such as CdSe, CdS and ZnSe, we show that Z-type ligands can be ranked according to their binding strength. In a second step, we use the method to probe the distribution of binding energies accross the nanocrystal surface, where in the case of 2D colloidal nanoplatelets, the weakest ligands could be localized at the nanoplatelet edges. Finally, we extend the method to InP/ZnSe core/shell nanocrystals, where we relate the progressive displacement of zinc halides from the shell outer surface to the creation of a non-radiative recombination channel that can still compete with the radiative recombination of electron-hole pairs to quench the photoluminescence. This result contrasts starkly with colloidal CdSe nanoplatelets, where the passivation of edge states by a CdS crown suffices to eliminate non-radiative recombination related to ligand desorption.
We conclude by highlighting the relation between progressive ligand stripping and photoluminescence quenching as a most useful stresstest to evaluate the emission characteristics of colloidal semiconductor nanocrystals.

Designer Zwitterionic Phospholipid Capping Ligands for Structurally Soft Metal Halide Nanocrystals ViktoriiaMorad[1,2], AndriyStelmakh[1,2], MariiaSvyrydenko[1,2], LeonG. Feld[1,2], MarcelAebli[1,2], JoelAffolter[1], ChristopJ. Kaul[1], NadineJ. Schrenker[3], SaraBals[3], IhorCherniukh[1,2], GabrieleRaino[1,2], AndrijBaumketner[4] and MaksymV. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]University of Antwerp, Belgium; [4]National Academy of Sciences of Ukraine, Ukraine

The success of colloidal semiconductor nanocrystals (NCs) in science and commercial optoelectronic devices is inextricable from their surfaces. A versatile and robust surface functionalization of lead halide perovskite (LHP) NCs and NCs of other structurally soft metal chlorides, bromides, and iodides poses a formidable challenge. Compared to conventional semiconductors, surface capping ligands bind in a non-covalent, rather ionic manner; furthermore, they may readily engage in adverse solubilization equilibria with the ions constituting the labile inorganic cores of these NCs. We posited that the vast and facile molecular engineering of phospholipids as zwitterionic surfactants make for an attractive platform to deliver highly customized surface chemistries for diverse metal halide NCs. Molecular dynamics simulations inferred that ligand-NC surface affinity is primarily governed by the structure of the zwitterionic head group, particularly by the geometric fitness of the anionic and cationic moieties into the surface lattice sites, as corroborated by the solid-state nuclear magnetic resonance (NMR) spectroscopy. Lattice-matched primary ammonium phospholipids enhance the structural and colloidal integrity of hybrid organic-inorganic LHPs – $FAPbBr_3$ and $MAPbBr_3$ (FA-formamidinium; MA-methylammonium), as well as a range of other functional metal halides. The molecular structure of the organic ligand tail instead governs the long-term colloidal stability and compatibility with solvents of diverse polarity, from hydrocarbons to acetone and alcohols. These NCs exhibit photoluminescence quantum yield (PL QY) above 96% in solution and solids, retained after repetitive purification steps, and minimal PL emission intermittency at the single particle level with an average ON fraction as high as 94%, as well as bright and high-purity (ca. 95%) single-photon emission.

2:15 PM EL10.02.03
Conformational Entropy Mediated Orientation of Ligated Nanocrystals ElizaPrice and WilliamTisdale; Massachusetts Institute of Technology, United States

Colloidal nanocrystals (NCs) are often assembled into ordered superlattices (SLs) for incorporation into optoelectronic devices. For some NCs, self-assembly is dominated by the inorganic core, depending on NC size and shape. However, when NCs are coated in a soft ligand layer, self-assembly behavior can become unpredictable due to the competing interactions of the inorganic and organic components. To address this knowledge gap, we investigated how the conformational entropy of organic ligands mediates the orientation of non-spherical NCs in self-assembled SLs.

With a framework combining numerically derived ligand density distributions and analytical expressions for the freely jointed chain model, we predict NC orientation for several polyhedral shapes, self-assembled structures, and ligand lengths. Additionally, we compare rotationally ordered and disordered NC SLs to estimate the driving force for nanocrystal orientation, finding a strong dependence on both NC shape and ligand length. We test the predictive ability of this framework by comparing model results to the experimentally observed orientation of truncated octahedral PbS NCs in BCC and FCC superlattices. Our work offers a tractable starting point for the thermodynamic understanding of polyhedral NCs with competing core-ligand interactions and may inform experimental efforts to achieve the self-assembly of coherently oriented NCs for high-quality devices.

2:30 PM EL10.02.04
Selective Agglomeration for 2D-Separation: Insights into the Surface Interaction in Colloids AzitaRezvani[1], ZhuangWang[1] and DorisSegets[1,2]; [1]Institute for Energy and Materials Processes (EMPI), Germany; [2]Universität Duisburg-Essen, Germany

Small semiconductor nanoparticles (NPs), known as quantum dots (QDs), have a wide range of applications in various fields, including electronics, optoelectronics, photovoltaics, biotechnology, and medicine. The unique properties of QDs, such as size-tunable emission, high photostability, and high quantum yield are intricately linked to their size, shape, composition, and surface chemistry [1]. Hence, the dispersity of a sample in all these dimensions becomes one of the most crucial factors to tailor the final product properties. Although the synthesis of colloidal QDs has seen impressive progress in the past two decades, even with sophisticated synthetic techniques, the obtained sample always exhibits a certain dispersity [2]. It can be assumed that this will be even more dominant in large-scale productions which makes it essential to narrow down the dispersity in different dimensions by post-processing approaches. However, there is a clear lack of scalable post-synthetic separation strategies for such small colloids, even in terms of size. In recent studies, selective agglomeration has shown promise as an effective approach with the potential to be scaled up in continuous setups for size-classification of ZnS QDs smaller than 5 nm [3, 4]. It is based on the titration of an already existing dispersion by a poor solvent to selectively flocculate one colloidal component.
A highly relevant case in this context is the post-synthetic classification after the larger-scale synthesis of core-shell QDs, where the shell thickness directly influences the final performance of the product. Therefore, we studied a mixture of InP QDs (first colloidal component) and InP/ZnS (core-shell) QDs (second colloidal component), both having oleylamine on the surface [5]. Considering the small size of QDs, the main challenge in such a binary system is the characterization of the coarse and the fine fraction after separation regarding the mixture composition and particle size distribution of each individual component, in each fraction. To achieve this, we developed a combination of UV-Visible spectroscopy, X-ray photoelectron spectroscopy, analytical ultracentrifugation, and inductively coupled plasma optical emission spectroscopy. Their combination resulted in a toolbox for the characterization of such a complex system which is applicable to similar and potentially even more complex multinary colloids. Finally, the toolbox enables a systematic study of important parameters including the type of good and poor solvents and their volume ratios, and to establish a stability map for the binary mixture.
In conclusion, we developed a strategy to characterize binary colloids of ultrasmall QDs during their selective separation. We successfully established a stability map that provides a fundamental understanding of surface interactions and driving forces in binary colloids in solvent mixtures. This is so far not addressed but it is the main step towards the design of multidimensional classification processes reliant on selective agglomeration. Finally, based on these findings we reported the results of the 2D-separation of ultrasmall QDs in terms of size and composition.

Expeditious Nanoparticle Transfer via Combinatorial Electrostatic Engineering DoeunKim, Ji YeongMa, JuhyeongLee, GyurinKim, Jang-HwanHan, Hyun MinKim and Hyeon-HoJeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

The versatility of solution chemistry offers exceptional flexibility in synthesizing functional nanoparticles with tailored materials, shapes, and surface properties. However, the translation of these colloidal nanoparticles into the industrial domain remains a significant challenge due to the lack of a rapid and uniform transfer technique for achieving 2D-like monolayered coating – an essential requirement for various applications, particularly photonic devices for plasmonics (metals), down- and up-conversion luminescence (semiconductors), and Mie resonance (dielectrics).
We here present a significant advancement in scalable nanoparticle transfer techniques, enabling the efficient transport of nanoparticles from liquid to a 2-inch wafer remarkably within10 seconds to reach over 40% surface coverage in a 2D monolayered fashion. This transfer rate, to the best of our knowledge, represents the record, reaching 2.03 cm^2/s with 30% nanoparticle coverage – an order of magnitude faster than the currently reported results in the literature. Our success lies in the refinement of the well-established electrostatic coating method, where we combinatorially engineer electrostatic features of both the nanoparticles and the surface. This electrostatic engineering leads to enhanced potential differences and thus generates strong electrostatic attraction forces between the nanoparticle and the substrate. Notably, electrostatic repulsion also plays a crucial role, self-limiting the coating process to a single layer due to repulsive interactions between nanoparticles. This charge-sensitive dynamic further offers ‘one-shot’ nanoparticle patterning when the surface is patterned with two opposite charges, i.e. the nanoparticles are selectively coated only on the oppositely charged area. Furthermore, our approach can be seamlessly extended to various surface materials, including dielectrics, conducting metal oxides and polymers, and 3D-printed polymers, without requiring conventional surface functionalization and treatment processes specific to individual materials.
In this presentation, we will discuss the nanoparticle coating method in which the electrostatic features are engineered, highlighting its key features such as rapid coating speed, large-area uniformity, charge-sensitive selectivity, and flexibility in surface materials and geometries. We will indeed demonstrate how this coating technique enables the realization of novel functional plasmonic metasurfaces, exhibiting consistent resonating colors across diverse material and geometrical platforms.

Ligand Exchange Equilibrium at Quantum Dot Surfaces in Polar and Aqueous Solvent Environments AndrewB. Greytak; University of South Carolina, United States

Our group and many others have contributed to an increasingly detailed understanding of the surface chemistry of representative compound semiconductor quantum dots, including metal chalcogenides, pnictides, and halide perovskites with effective bandgaps spanning much of the visible and infrared spectrum. Such particles are frequently stabilized by organic molecules with nucleophilic or anionic headgroups that coordinate surface atoms. To date, the greatest understanding has been achieved in non-polar or less polar solvents in which charge balance helps to simplify the range of surface reactions that must be considered. Techniques such as NMR and infrared spectroscopy, mass spectrometry, and isothermal titration calorimetry have helped to reveal the chemistry at such surfaces, including the importance of ligand interactions that can govern the composition and local organization of the surface monolayer.

It is critically important to extend the understanding of such nanocrystal surfaces to polar solvents, including aqueous solution required for biological applications and polar organic mixtures favored for storable nanocrystal inks for electronic devices. However, polar solvents and buffers introduce additional challenges for fundamentals studies due to charge stabilization, acid-base equilibria, protic buffer components, oxidation, and the need for core/shell structures to achieve good photoluminescence quantum yield.

I will describe our group’s efforts to quantify ligand association and exchange reactions on nanocrystal surfaces in polar and aqueous solutions, including coordination of quantum dots by imidazoles, thiolates, and polymeric ligands, and prospects for extending these studies to additional classes of materials including magnetic oxides and halide perovskites. I will also emphasize the advantages and limitations of isothermal titration calorimetry as a tool to study the surfaces of colloidal nanostructures and compare the binding of different ligand architectures in polar environments.

4:00 PM EL10.02.07
Non-Einsteinian Viscosity Reduction in Water-Based Nanofluids of Boron Nitride Nanotubes, Graphene Nanoflakes and Carbon Nanotubes AndreGuerra, MilanMaric, AlejandroD. Rey and PhillipServio; McGill University, Canada

Introduction: Nanoparticles have multiple applications, including drug delivery systems, biosensing, and carbon capture. Non-Einstein-like viscosity reduction has been reported in

nanoparticle-polymer blends at low nanoparticle concentrations. More recently, a similar non-Einsteinian viscosity reduction effect has been observed in aqueous ultra-low concentration carbon-based nanofluids of graphene nanoflakes (GNF) and multi-wall carbon nanotubes (MWCNT)[1,2]. The use of nanoparticles as promoters of the growth of gas hydrates has been an active research field in the past decade[3–6]. This study aimed to explore the viscosity of ultra-low concentration boron nitride nanotube (BNNT) nanofluids in the presence of air and methane.
Methods: We use a boron nitride nanotube functionalized with hydrophilic groups in rheological experiments to investigate the viscosity reduction in ultra-low concentration nanofluids (0.1-10 ppm). We measure the dynamic viscosity in an air atmosphere and methane (0-5 MPag) at low temperatures (0-10 C).
Results: A negligible effect on the temperature dependence of viscosity was found. Ultra-low concentrations of BNNT reduced the viscosity of the nanofluid by up to 29% at 10 ppm in the presence of methane. The results presented here were compared to similar studies on O-GNF and O-MWCNT nanofluids, which also reported significant viscosity reductions. The non-Einsteinian viscosity reduction measured in BNNT nanofluids in the present work was higher than the effect measured for O-GNF and O-MWCNT nanofluids.
Conclusions: This work identified a non-Einsteinian viscosity reduction in BNNT nanofluids, exacerbated by methane dissolved in the nanofluid. In a previous study, we suggested the role of nanoparticles in viscosity reduction by disrupting hydrogen bond networks and facilitating energy dissipation through enhanced density fluctuations. At ultra-low concentrations, these effects may dominate over conventional drag and viscous forces present higher-concentration nanofluids and colloidal suspensions, which lead to increased viscosity with particle loading (Einsteinian behavior). The effects measured for the three different nanoparticles studied so far indicate the role of nanoparticle geometry and surface chemistry on the disturbance of hydrogen bond networks in water leading to the reduction in dynamic viscosity. We suggest computational modeling to investigate molecular scale interactions to elucidate the non-Einsteinian viscosity reduction.

Engineering the III-V/II-VI Interface in Core-Shell Heterostructures in Colloidal Nanocrystals Yields Bluer Emission AritrajitGupta, Jun HyukChang, JustinOndry, ZiruiZhou and DmitriV. Talapin; University of Chicago, United States

A persistent red shift and broadening of the emission peak during the shelling step renders obtaining blue emission from III-V colloidal nanocrystals difficult, despite significant efforts invested in improving synthetic protocols. Previous studies of the type-I core-shell III-V/II-VI interface have ascribed this red shift to factors such as the thickness and shape of the II-VI shell, the band energy alignment of the core-shell, surface dangling defects, surface oxidation, and structural disorder associated with lattice defects. In particular, in-depth studies of the InP/ZnS interface have established that Zn^{2+} ions incorporated at substitutional or interstitial sites introduce internal disorder, observed via broadened Raman lines that are accompanied by a pronounced increase in Stokes shift of the emission. In contrast, when the long-chain organic ligands on as-synthesized InP QDs are exchanged for S^{2-} ligands, the sulfide-capped nanocrystals show little change in the Raman spectrum even after high-temperature annealing. We hereby employ the knowledge from the InP system to ternary alloyed $In_{1-x}Ga_xP$ nanocrystals that are synthesized in a molten halide salt reaction medium. We optimize the III-V/II-VI interface in bright $In_{1-x}Ga_xP$/ZnS core-shell nanocrystals at the shelling step, allowing us to yield bluer emissions from systems that are otherwise very similar in size and composition.

4:30 PM EL10.02.09
Multilayer Diffraction: A New Tool for Probing the Interparticle Region in Nanocrystal Superlattices StefanoToso[1], DmitryBaranov[2,1], UmbertoFilippi[1], CinziaGiannini[3] and LiberatoManna[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Lund University, Sweden; [3]Consiglio Nazionale delle Ricerche, Italy

Owing to their hybrid nature, the properties of nanocrystals are determined by both their inorganic core and their organic shell. This is particularly true when nanocrystals are packed into superlattices, where the ligands surrounding each particle stop being just a surface coating and become an actual component of a more complex nanostructured material. Thanks to these organic spacers, each nanocrystal can retain its non-bulk characteristics while also interacting with neighbors through a variety of coupling mechanisms.

Since these phenomena take place at short distances (electronic coupling = neighboring particles; optical coupling = dozens of nanometers), quantifying parameters like the interparticle distance and the degree of disorder at very local scales is crucial for understanding the superlattice properties. This, however, is far from trivial: the grazing-incidence diffraction techniques usually employed for such studies provide an average response over a much wider volume of the sample, and the diffracted signal comes mainly from the inorganic core, overshadowing the contribution of the inter-nanocrystal region.

In our research, we propose a novel approach to answer such questions. Our method is based on Multilayer Diffraction, an intriguing collective interference effect known for epitaxial thin films but never reported for colloidal nanocrystals before.[1] This phenomenon occurs when X-rays are diffracted by nanocrystals stacked vertically: the radiation scattered by each particle interferes with that diffracted by neighbors, creating fringes of constructive interference. Since the interfering radiation comes from nanocrystals, the fringes are convoluted by their Bragg peak profile, thus retaining information on the nanocrystals structure, size, and orientation. However, the position of the fringes depends on the overall stacking periodicity, which includes the inter-nanocrystal spacing, while their broadening provides a direct quantification of the stacking disorder.

We will retrace our journey into the understanding of Multilayer Diffraction, from its serendipitous discovery in $CsPbBr_3$ nanocubes superlattices,[2] to the development of open-source pattern fitting algorithms,[3] and their application to films of colloidal nanoplatelets,[4] where the unique advantages of Multilayer Diffraction can be appreciated at their best. Finally, with the help of literature and simulations we will show that Multilayer Diffraction is a much more common phenomenon than one might think, and is routinely observed without being recognized in a variety of appealing nanomaterials behind the borders of halide perovskites.

Combing Organic or Inorganic Dyes with Lanthanide Nanoparticles to Overcome the Weak Absorption of Lanthanide Ions ZhongzhengYu; University of Cambridge, United Kingdom

Lanthanide-based nanoconstructs have gained increasing attention in recent decades due to their unique optical and magnetic properties. The design of lanthanide-based nanosystems is expected to contribute to various applications including biomedical applications, data storage, optical communications, remote sensing, super-resolution fluorescence microscopy, and night vision etc., due to their advantageous properties such as excellent photostability, non-photobleaching, low cytotoxicity, large Stokes/anti-Stokes shift, narrow and tunable emission peaks. There are two major limitations for lanthanide ions, including weak absorption and low photon conversion efficiency. Developing novel lanthanide-based nanoconstructs and uncovering new insights of the energy conversion pathways are key to the advancement of the field. Combing organic or inorganic dyes with lanthanide nanoparticles to form nanohybrids is highly possible to overcome the weak absorption of lanthanide ions. In this talk, I will introduce our recent work about a) dye-sensitized lanthanide-doped nanoparticles, b) novel nanocomposites as photothermal agents and their corresponding applications in light-controlled release, light-activated photomedicines, sensing, multiplexing imaging, photoacoustic imaging and photothermal therapy. I hope the strategies and studies presented in this talk could further enhance the attractiveness of lanthanide-based nanoconstructs towards clinical translation and applications influencing our daily life.

Semiconductor Nanocrystals and Copper Clusters for Radiotherapy: The Importance of the Coating and Composition for the Radio Incorporation of Cu*64*, Their Photo-and Colloidal- StabilityTeresaPellegrino; Italian Institute of Technology, Italy

Cation exchange (CE) reactions on nanocrystals consists of the replacement of cations in the nanocrystalline structure with different metal ions while maintaining in place the anion framework. This technique has been extensively used for the synthesis of nanocrystals at different compositions. Here, we exploit CE reactions to radiolabel cadmium-free semiconductor NCs of ZnS, ZnSe and chalcopyrite (CuFeS*2*) NCs with Cu-64 radioisotope. [1] To make it possible a one-step CE protocol that is straightforward and highly efficient while maintaining good NC colloidal stability, the type of ligand coating to be chosen as water soluble stabilizer agents and the amount of Copper-64 to be exchanged were the key factors. This enabled to obtaining *64*Cu:CuFeS*2* in very high yields which did not require any further work out for the purification thus speeding up the radiolabeled NCs preparation. This unique approach of CE reaction enables to tune the specific activity in a wide range (from 2 to 100 TBq/g) with an unprecedentedly record value of specific activity up to 100 TBq/g. In addition, among the NCs explored, CuFeS*2* NCs [2] even after partial-CE reaction with Copper-64 were promising heat mediators for photo-thermal therapy (PPT). The synergic toxicity of photo-ablation and *64*Cu mediated radiotherapy ionization is here used to eliminate the glioblastoma and epidermoid carcinoma tumor cells. Further, as demonstrated with preliminary and unpublished results, the dual therapy is evaluated on xenograft mice models bearing epidermoid carcinoma tumor, resulting in elimination of solid tumor mass in mice. A modified version of this protocol was also established to obtain copper-64 radio-clusters of sub nanometer size and having also radio and photoluminescent properties. The optical stability of the copper clusters was tuned by controlling the size, coating and composition of the clusters and it will be also discussed.

Conjugation of Quaternary Zn-Cu-In-S/ZnS Quantum Dots to Porphyrins and Their Photodynamic Therapy and Antibacterial Activities SamuelO. Oluwafemi; University of Johannesburg, South Africa

Photodynamic therapy (PDT) is a non-invasive treatment modality that uses photosensitizing drugs (PS) to generate reactive oxygen species for the destruction of abnormally growing cells or microorganisms. Porphyrins are the most widely used PS in PDT, their clinical application is limited by poor water solubility, which often results in aggregation and their low quantum yield of ROS generation after light absorption in the near infra-red region (NIR. To overcome these limitations and improve PDT efficacy, we herein report the conjugation of Zn-Cu-In-S/ZnS (ZCIS/ZnS) quantum dots (QDs) to porphyrins and evaluated their PDT efficiency and antibacterial potency. The ZCIS/ZnS QDs and porphrins were evaluated to determine the optimized reaction conditions for the formation of QDs-porphyrin conjugates. The PDT efficiency of ZCIS/ZnS QDs, porphyrin and NIR emitting QDs- Porphyrin conjugates was evaluated against murine metastatic melanoma (B16 F10 Nex 2) cell line in the absence of light and under LED irradiation. B16 F10 Nex 2 exhibited the highest reduction in cell viabilities following exposure to the conjugate under LED light irradiation compared to the bare QDs and porphyrins (1%). The antimicrobial therapy studies were tested by exposing Escherichia coli (ATCC 25922) to ZCIS/ZnS QDs, porphyrin and the conjugate. The conjugate showed greater antibacterial effects compared to the bare ZCIS/ZnS QDs even in the absence of light. The results of this study show that the as-synthesized conjugate is a suitable and promising class of material for dual anticancer and antimicrobial PDT.

Multimodal Nanoparticle Bioengineering for X-Ray Fluorescence Imaging Giovanni MarcoSaladino[1], BerthaBrodin[1], CarmenVogt[1], KianShaker[1], Nuzhet InciKilic[1], YuyangLi[1], KenthAndersson[1], IdrisYazgan[2], MarieArsenian-Henriksson[3], MuhammetS. Toprak[1] and HansM. Hertz[1]; [1]KTH Royal Institute of Technology, Sweden; [2]Kastamonu University, Turkey; [3]Karolinska Institutet, Sweden

Multimodal nanoparticles (NPs) are promising contrast agents for multiscale and complementary bioimaging. It is essential to study the interactions between the cellular environment and NPs in order to evaluate their functional and toxic properties. Here, we present a methodology for complementary imaging to evaluate the biocompatibility and biodistribution of dual-mode hybrid NPs *in vitro* and *in vivo*. These inorganic NPs are composed of an X-ray fluorescent (XRF) active element, complemented with dye-doped silica coating, conjugated carbon quantum dots, or decorated superparamagnetic iron oxide NPs. We investigated the advantages of whole-animal XRF imaging and local XRF computed tomography (XFCT), characterized by high specificity and sensitivity. The complementary properties enabled the multiscale visualization of the NPs *in vitro* and in tissues from excised organs via optical fluorescence microscopy and correlative imaging with *in vivo* magnetic resonance imaging (MRI). The optimization of the hybrid NP surface chemistry and colloidal stability led to biocompatible contrast agents for XRF molecular imaging.

Zwitterionic Polymer Coatings for Stable and Stealthy Nanocrystals in Bioimaging and Micromanipulation ThomasPons; LPEM ESPCI/CNRS/SU, France

Inorganic nanocrystals such as gold, iron oxide and semiconductor nanocrystals have unique optical or magnetic properties that make them very promising for cancer detection, imaging and therapeutic applications. The surface ligands of these nanoparticles play a critical role in their application and control the nanoparticle interaction with biomolecules and cells. I will present the development of zwitterionic copolymer ligands containing a multidentate anchoring block, adaptable to the type of nanoparticle, and that provide a stable binding to the surface of different inorganic nanocrystals, enabling prolonged biological applications. The nature of the zwitterion group has a strong influence on antifouling properties, ranging from specific interactions with some biomolecules to a complete suppression of interactions with serum biomolecules, cytosolic components and macrophage cells. This enables various applications including intracellular targeting of fluorescent quantum dots, in vivo tracking of individual circulating cells, or micromanipulation in the nucleus of living cells using magnetic nanoparticles.

Peptidic Bioactivable Au Nanoclusters for Extracellular Vesicles and Cellular Labelling and Biosensing ValerieMarchi-Artzner[1], ReginaCheichio[1], SoleneDucarre[1], EsterButera[1], PascaleEven-Hernandez[1] and CeliaRavel[2]; [1]University Rennes, France; [2]CHU Rennes, France

We present an overview of the interaction between ultrasmall luminescent gold nanoclusters and lipidic or biological membranes, showing that it is possible to induce a large change in membrane structures or not. The synthesis of original aqueous bioactivatable and PEGylated AuNC suspensions of various charges were performed by using synthetic short peptides. This chemical plateform provides various charged AuNC with potential sensitivity to the environment for biosensing applications.
Extracellular vesicles (EVs) are well-known membrane-limited particles that are secreted by healthy and cancerous cells. EVs are heterogeneous in size and three subtypes are described depending on the location of secretion: microvesicles, myelinosomes and exosomes. EVs are identified in human follicular fluid as a mode of communication in the ovarian follicle (Neyroud A. S. et al. Int. J. Molecular Sci. **2022**). In addition EVs involved in cell-cell communication are considered as biomarkers for early cancer diagnosis. The analysis of their content and their labeling with easily detectable nanoparticles could enable the development of a powerful tool for the early diagnosis of specific diseases.
In this view, Gold nanoclusters (AuNCs) appear as a recent class of non-toxic fluorophores. Their brightness, their ultrasmall size (< 2 nm) and large window of fluorescence lifetime (1ns – 1ms) and their good biocompatibility make them an attractive alternative as fluorescent probes for biological labeling and bioimaging.
Following incubation of the AuNCs with oppositely charged vesicles, either liposomes or EVs, the strong electrostatic attraction resulting in the adsorption of AuNCs to the membranes was evidenced by complementary techniques such as zetametry, fluorescence optical microscopy, SAXS, and cryo-TEM. In the presence of an excess of oppositely charged AuNCs, the liposomes strongly adhere to each other without disrupting their membrane whereas the EVs extracted from human follicular fluid rearrange into a hybrid lamellar phase. Instead, in the presence of a membrane surface excess, AuNCs do not change the size of the membrane thickness, so they are positioned between the polar headgroups of the membrane phospholipids. As opposed to larger gold nanoparticles, the smaller size of AuNCs not only prevents the deformation of biological membranes but also allows labeling with higher spatial resolution (R. Cheichio et al. J. Phys. Chem. Lett **2022**).
By adjusting the surface ligands, these probes are easily internalized into cells and in vivo organisms such as Arabidopsis plant or cancerous cell lines. We demonstrated their in vivo targeting ability because of specific recognition groups (R. Cheichio et al. ACS Nano materials **2023**) and biosensing by fluorescence because of their sensitivity to microenvironment.
In addition their small size make them attractive to encapsulate them into liposomes without damaging the compartment integrity and then to be delivered into the extracellular vesicles. We demonstrated first the possible encapsulation of the AuNC into liposomes for drug delivery. Cell-like-sized vesicles (GUVs) encapsulating red or blue Au NCs were successfully obtained by

an innovative method using emulsion phase transfer. Finally, exosome-like-sized vesicles (LUVs) containing Au NCs were obtained with an encapsulation yield of 40%, as estimated from ICP-MS (R. Chiechio et al. Nanomaterials **2022**). Finally the lipidic membranes composition was optiized with ionizable lipids so that the mixture of the liposomes and EVs results in efficient fusion and delivery of AuNC into the lumen of EVs. The lipid exchange was demonstrated by FRET experiments and fusion was revealed by the increased size and the fluorescent labelling of the fused EVs. The fused EVs encapsulating the AuNC were successfully separated by size exclusion chromatography. Such nanostructures offer promising candidates for fluorescent in vivo biosensing and biolabeling.

11:00 AM EL10.03.06
Lithographic Synthesis of Anisotropic Nanomagnetic Bars for *In-Vivo* Magnetic Particle Imaging and SpectroscopyNoahKent[1], EliMattingly[2], KeisukeNagao[1] and PolinaAnikeeva[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard University, United States

Magnetic Particle Imaging (MPI) is an imaging modality where a field free point is scanned over magnetic nanoparticle (MNP) tracers generating a temporally resolved spatial map of particle distribution, and velocity [1]. MPI tracers are designed to be biocompatible enabling in-vivo MPI. Additionally, by analyzing the spectral frequency response of MPI tracers as their magnetization reverses, information about their local environment can be extracted (e.g. temperature, viscosity). This approach, termed magnetic particle spectroscopy (MPS), leverages the changes in the Neel and Brownian behavior of a tracer as a function of the external parameter being measured [2].
In MPS the resolution (the spectral information available) is highly dependent on the magnetic properties of the magnetic tracer. To achieve high spatial resolution, the magnetic field range over which a particle reverses its magnetization should be small. For a strong MPS signal, the particle should be physically anisotropic (to have a more pronounced Brownian rotation) and the dynamics of magnetic switching behavior should be independent of drive field frequency.

Guided by nanomagnetic simulations in MuMax3, we lithographically fabricated Permalloy (PY, Ni80Fe20) nanomagnetic bars of varying sizes with a length to width ratio of 5:1 and layered structure that is Ti 5nm/ PY 30nm/ Ti 5nm. Due to shape anisotropy PY structures of these dimensions are strongly uniaxial ferromagnetic with the magnetic hard axis along the length of the bars. These bars were released into solution via dissolution of a sacrificial layer. To enhance colloidal stability and enable biocompatibily, the bars were chemically coated with silica using the modified Stöber method. The silica coating also allowed the bars to be passivated with poly(ethylene glycol) via ester-carbodiimide chemistry. The resultant mixture is colloidally stable, biocompatible lithographically fabricated magnetic nanoparticles.

Initial MPS measurements show that due to the uniaxial ferromagnetic switching behavior demonstrated in the bars, the magnetic field range over which MPI signal is measured is a factor of 5 smaller than the current state of the art particles (Synomag®). This is directly correlated with the particle's spatial resolution as a tracer. For MPS, comparison between a large number of spectral harmonics gives information about the local environment. State of the art MPI tracers lose harmonic signal around the 15th harmonic, but anisotropic magnetic bars retain strong harmonic signal until the 24th harmonic. Additionally, harmonic strength relative to overall magnetic signal is stronger in bar particles when compared to Synomag®. Current work is focused on further optimizing the bar particles for their future applications in vivo.

Subak: A Novel Color-Switching Reporter for Nuclease Activity and Nucleic Acid Detection SoonwooHong, JadaWalker, AaronLuong, Yu-AnKuo, Yuan-IChen, Trung DucNguyen, YujieHe, Anh ThuNguyen, JenniferS. Brodbelt and TimYeh; The University of Texas at Austin, United States

The COVID-19 pandemic has underscored the importance of nucleic acid amplification tests for reliable and sensitive detection of pathogens. While recent advancements have eliminated the need for specialized equipment, the fluorescence readout remains crucial in highly accurate nucleic acid assays. However, existing fluorescent reporters, such as TaqMan and DNaseAlert, which soely rely on fluorescence resonance energy transfer (FRET), have limitations in terms of cost, quantitative sensing, and dual labeling requirements. We introduce Subak, a novel DNA-templated silver nanocluster (DNA/AgNC) probe to address these challenges. Subak exhibits green fluorescence emission when intact but undergoes a remarkable color-switching to bright red upon fragmentation by nuclease activities, distinct from other fluorescent nanomaterials.

Compared to conventional FRET reporters, Subak offers significant advantages, including a cost reduction of over 60-fold ($1 vs. $62 per nanomole) and the ability to support ratiometric sensing of nuclease activities. Subak reporters are synthesized using a 37-nt long hairpin DNA strand, silver salt ($AgNO_3$), and a reducing agent ($NaBH_4$). As none of the starting materials are inherently fluorescent, purification steps to remove excess products are unnecessary. Addition of a DNase I to Subak results in a discernible color change within 20 minutes, visible to the naked eye under a UV lamp due to the effective excitation of DNA/AgNCs by UV light.

Subak reporters enable both single-color detection and ratiometric sensing. In single-channel detection, fluorescence enhancement ratios of up to 20-fold are achieved upon Subak reporter digestion (using Subak and DNase I). For ratiometric sensing, Subak and Cas12a demonstrate a remarkably low limit of detection (~1.19 pM) for SARS-CoV-2 strands in a DETECTR assay without the need for pre-amplification steps. Notably, this performance is comparable to DNaseAlert under the same conditions, exhibiting 15 times higher fold changes (221-fold vs. 14-fold).

The color-switching mechanism of Subak reporters arises from a combination of altered base-cluster coordination geometry and the modified size/shape of the fragmented AgNC. Electrospray ionization mass spectrometry (ESI-MS) analysis identifies preferred cleavage sites on Subak reporters and determines silver stoichiometries before and after fragmentation. The intact Subak reporters emit green fluorescence due to an Ag_{13} cluster, while fragmented Subak reporters emit red fluorescence attributed to an Ag_{10} cluster. This color-switching property results from the breakdown of Ag_{13} into Ag_{10} and Ag_3. Traditional nucleation-and-reduction methods that yield Ag_{10} clusters only exhibit low fluorescence or green emission, necessitating postprocessing steps such as complementary strand hybridization and nuclease fragmentation. These steps alter the AgNC stoichiometry and transform the AgNC into a new geometry within the DNA host, previously unachievable using traditional methods. The combined altered base-cluster coordination geometry and changed size/shape of the fragmented AgNC ultimately contribute to the color-switching phenomenon in Subak reporters.

While some AgNC reporters have been reported for nuclease activity detection, they either operate as turn-off sensors based on fluorescence quenching or require multiple steps in detection, involving digestion by nucleases followed by AgNC nucleation. Our findings demonstrate that DNA/AgNC probes, such as Subak, can be simple and versatile reporters for detecting nuclease activities in nucleic acid detection assays. Moreover, this study presents a promising strategy to create novel AgNC fluorophores that were previously unattainable using traditional nucleation-and-reduction processes.

Ultrafast Dense DNA Functionalization of Quantum Dots and Rods for Scalable 2D Array Fabrication on DNA Origami with Nanoscale Precision ChiChen, XinLuo, AlexanderE. Kaplan, MoungiG. Bawendi, RobertJ. Macfarlane and MarkBathe; Massachusetts Institute of Technology, United States

Quantum dots (QDs) and quantum rods (QRs) have attracted extensive interest in next-generation display systems due to their bright and tunable narrowband photoluminescence (PL). Moreover, QDs are also key candidates for quantum computing, quantum sensing, and quantum metrology through integrated quantum photonics. Scalable fabrication of QD/QR arrays possessing controlled spacing and orientation with nanometer precision on a device substrate is essential to the advancement of such research and applications. DNA origami technology has offered a scalable bottom-up strategy to organize nanoparticles at the nanoscale with unparalleled programmability and versatility. However, multiplexing QDs and QRs with DNA origami structures has been challenging, primarily due to the low DNA conjugation density to QDs/QRs from existing methods, which often leads to poor colloidal stability and low binding efficiency. Here, we developed an ultrafast strategy to prepare high-density DNA functionalized QDs/QRs (0.17–0.21 DNA per nm^2) directly from their organic solution using a dehydration and rehydration process that reduces the fabrication time from hours to a few minutes. As prepared QDs/QRs were stable in a range of buffer conditions and able to hybridize to DNA origami structures with excellent efficiency and precision. To fabricate QD/QR arrays, we further developed a Surface-Assisted Large-Scale Assembly (SALSA) method to construct 2D origami lattices directly on a solid substrate for QD/QR temptation, which circumvents problems in transferring solution-assembled soft 2D materials to a device surface. We designed a 6-helix-bundle (6HB) rhombic-shaped wireframe origami structure with high structural fidelity, planarity, and rigidity. With unique anisotropic crossover designs between neighboring origami structures, 2D origami lattices up to micrometer scale were produced by tuning origami surface diffusion, hybridization error correction and landing face selection. QDs and QRs were then assembled to the origami lattices with precisely controlled positions, inter-particle distances and orientations, with a loading yield over 90%. We further fabricated a monolayer QR array with aligned QR orientations, which can function as a polarized light source due to the PL emission anisotropy along the long axis of QRs and their alignment on surface. Our approaches can enable scalable fabrication of DNA-programmed QD and QR devices with nanoscale orientation and positioning accuracy for advanced applications in display, sensing and photonics.

Evaluating the Catalytic Activity of the Enzyme Matrix Metalloproteinase (MMP-14, a Cancer Marker) using AuNP−Peptide Conjugates ZhichengJin, NarjesDridi, Qing-XiangA.

Sang and HediM. Mattoussi; Florida State University, United States

Proximity-driven interactions between plasmonic nanostructures and fluorescent dyes yield efficient quenching of the dye photoluminescence (PL). This has provided researchers with an effective strategy to develop analytical biosensors.
We report on the use of polyethylene glycol-stabilized gold nanoparticles (AuNPs) covalently coupled to several dye-labelled peptides, as sensitive optically-addressable sensors for determining the catalytic efficiency of the human matrix metalloproteinase-14 (MMP-14), a known molecular marker of select metastatic cancers. We exploit the time-dependent recovery of the dye emission triggered by hydrolysis of the AuNP-tethered peptide-dye by added MMP-14, to extract quantitative analysis of the proteolysis kinetics. Sub-nanomolar limit of detections for the target enzyme has been achieved using these constructs. In addition, we have used conceptual rationales that consider the effects of the AuNP size, reduced Brownian diffusion combined with surface crowdedness of the AuNP-peptide conjugates, compared to peptide only system, to gain additional insights into the kinetic of the PL recovery. We derive enzyme substrate hydrolysis equations and evaluate the catalytic efficiency ([endif]-->) for these platforms. This allowed us to describe the complexity of enzyme activity interacting with nanosurface-bound substrates. Our findings offer a great strategy for the development of highly sensitive and stable biosensors for cancer detection and imaging.

SESSION EL10.04: Semiconductor QDs, Strucure and Photophysics

Electrically Pumped Colloidal-Quantum-Dot Sources of Amplified Spontaneous Emission NamyoungAhn, ClémentLivache and VictorI. Klimov; Los Alamos National Laboratory, United States

Electrically pumped lasers employing solution-processable optical gain media will be a game changer in numerous technological areas including on-chips photonics and electronics, optical communications, lab-on-a-chip devices, displays, and projectors. Colloidal quantum dots (QDs) are a promising class of materials for realizing laser diodes. In addition to being compatible with standard solution-based processing techniques, they feature size-controlled emission energies, low optical-gain thresholds, and high temperature stability of lasing characteristics originating from atomic-like character of electronic states.
Despite their promising characteristics, QDs are difficult lasing materials, especially in the case of electrical pumping. One challenge is fast nonradiative Auger recombination of multicarrier states needed to achieve optical gain. Other challenges include poor stability of QD solids under high current densities required for lasing and unfavorable balance between modal gain produced by a thin electroluminescence (EL) active QD layer and large optical losses in charge injection/transport layers.
Recently, the problem of Auger recombination has been alleviated using continuously-graded QDs (cg-QDs) that exhibit strong suppression of Auger decay.[1] Here we resolve the remaining challenges on a path to a QD laser diode. In particular, we develop “current-focusing” EL devices capable to sustain without damage current densities (j) of more than 1 kA cm^{-2}.[2,3] Next, we integrate an ultra-high-j charge-injection architecture with a low-loss Bragg-reflection photonic waveguide which allows us to improve optical field distribution within the device and thereby realize the regime when net optical gain is positive.[4] Finally, we develop devices that exhibit strong edge emitted amplified spontaneous emission (ASE) under electrical pumping. The next important milestone – the demonstration of a QD laser oscillator – can be accomplished by supplementing the developed structures with an optical resonator implemented, for example, as an in-plane distributed feedback grating.

1:45 PM EL10.04.02
Inter-Shell Structure-Dependent Optimization of Electroluminescence and Driving Performance of Colloidal Quantum Dots Geun WooBaek[1], SeungG. Seo[2], DonghyoHahm[3], Wan KiBae[3], Sung HunJin[2] and JeonghunKwak[1]; [1]Seoul National University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Colloidal quantum dots (QDs) have attracted attention as promising emitters owing to their excellent optical properties, such as broad absorption, narrow emission bandwidth with near-unity photoluminescence quantum yield, size-dependent tunable bandgap, and high stability. Due to these advantages, QD-based light-emitting diodes (QLEDs) have been investigated as the next-generation display devices. In this work, we investigated the effects of the inter-shell structure on the device performance of QLEDs by comparing two different giant QDs, i.e., $CdSe/Cd_xZn_{1-x}Se/ZnS$ QDs (Se-QDs) and $CdSe/CdZn_yS_{1-y}/ZnS$ QDs (S-QDs). Through the systematic analysis of Se-QDs and S-QDs, we found that the modification of the inter-shell structure can improve the device efficiency and operational stability. In particular, the QLEDs with Se-QDs exhibited a maximum external quantum efficiency and an operational half-lifetime (at 100 cd/m^2) of 21.2% and 38,100,000 h. We further investigated the optimal configuration of QLEDs by changing the device structure and circuit geometry for practical display application.

2:00 PM EL10.04.03
A Generalized Approach for Colloidal Synthesis of Chalcogenide Perovskites and Related Materials as Emerging Photoabsorbers for Optoelectronic Applications DanielC. Hayes, ShubhanshuAgarwal, IzoduwaAimiuwu, MadeleineC. Uible, ApurvaPradhan, RyanN. Swope, SuzanneBart and RakeshAgrawal; Purdue University, United States

Among thin-film technologies, the perovskite crystal family (of the form ABX_3), most of which has been dominated by the lead-halide perovskites (where typically A = $CH_3NH_3^+$, B = Pb^{2+}, and X = I^-), has seen an unprecedented growth both in the sheer number of contributions from the research community, but also in improvements to the power conversion efficiencies (PCEs). From a modest 3.8% to an impressive 26.0% for a single-junction device, lead-halide perovskites have achieved, in just over a decade, what has taken silicon technologies over six decades. While lead-halide perovskites are incredibly high performing, they suffer from one crucial flaw: they are incredibly air and moisture sensitive. This vital flaw severely limits their commercial applicability where multiple decades of service are required.
Because of this, a different class of perovskites has gained interest, namely the chalcogenide perovskites (A = Ca^{2+}, Sr^{2+}, Ba^{2+}…, B = Ti^{4+}, Zr^{4+}, Hf^{4+}…, and X = S^{2-} or Se^{2-}). Of these, $BaZrS_3$ has been the most widely studied chalcogenide perovskite to date due to its favorable bandgap, experimentally reported between ~1.7-1.9 eV, for photoabsorbing applications. Traditionally, chalcogenide perovskites, $BaZrS_3$ included, have required rigorous synthesis conditions, both in high temperature (>1000 °C) and/or significant residence times (>2 weeks). These demanding conditions consequently would prevent this material from being used with traditional conductive substrates such as gold or molybdenum. More recently, work has been done to synthesize these materials at less extreme conditions. Over just the past two years, procedures have been developed to synthesize the material well below 1000 °C, and in some cases via solution-deposited methods below 600 °C, and through a bottom-up, colloidal nanoparticle approach at temperatures from 330-365 °C. As a result, the possibility of using these materials in thin-film devices is on the horizon.
In this work, we report a generalized approach to synthesize an array of chalcogenide perovskites and related ternary materials as colloidal nanocrystals. Colloidal syntheses provide us the unique advantage of relatively easy size- and shape-control which allows us to optimize these nanomaterials for downstream fabrication methods, such as in use for thin-film devices. Like previous reports, we show that $BaZrS_3$ can be synthesized at similar conditions ranging from 340 °C to below 300 °C. These comparatively mild conditions make the use and scale-up of such a process more attractive for other researchers as the field of chalcogenide perovskites continues to grow. In addition to $BaZrS_3$, we also show that the synthesis approach can be translated to other materials like $BaHfS_3$, $BaTiS_3$, and $SrZrS_3$ nanomaterials, owing to the versatility of the approach.

2:15 PM EL10.04.04
Biexciton Auger Recombination in Strongly Confined Perovskite Quantum Dots and its Correlation to Photoluminescence Blinking YitongDong, ChenjiaMi, GavinGee and MatthewAtteberry; The University of Oklahoma, United States

Lead halide perovskite quantum dots (QDs) are promising single photon emitters owing to their high room temperature luminescence efficiency and solution processibility. Moreover, strongly confined perovskite QDs (SCPQDs), whose physical sizes are much smaller than their Bohr diameters, are predicted to have high single photon emission purity due to their ultra-fast biexciton Auger recombination rates. Recent advances have demonstrated that reducing the sizes of perovskite QDs leads to higher single photon emission purities. It is also known that biexciton emission quantum yield can be estimated by the $g_2(0)$ values from the second-order photon correlation measurements. However, studies on single perovskite QDs have witnessed unexpectedly low single photon emission purities with $g^2(0)$ values varying dramatically. Additionally, perovskite QDs often show severe fluorescence intensity fluctuations. Recently, we have developed a

QD-in-matrix method that can successfully passivate and disperse SCPQDs with improved photostability. By controlling the surface passivation conditions, we have studied over 1000 single SCPQDs and correlated their fluorescence blinking behaviors with their $g^2(0)$ values. We found that perovskite QDs with high "ON" time fraction show significantly lower biexciton emission efficiency. The biexciton emissions from perovskite QDs with high "OFF" fraction are more efficient. Such a positive correlation between QD "OFF" time fractions and biexciton emission quantum yields is opposite to what has been revealed in CdSe core-shell QDs, and it suggests that the Auger recombination rate can change with respect to the surface conditions of the perovskite QDs. We propose a model that combines both exciton trapping and exciton-surface lattice interaction for different biexciton emission quantum yields observed in SCPQDs.

Colloidal Quantum dots as Single Photon Quantum Emitters MoungiG. Bawendi; Massachusetts Institute of Technology, United States

The spectroscopic riddles of quantum confined colloidal quantum dots (CQDs) initially fueled synthetic advances following their birth at the end of the last millennium. As the 1990's turned into the 2000's, the synthesis had developed rapidly and commercial applications of CQDs emerged, first as bright and robust emitters for biological imaging, and later as the source of saturated green and red light in displays widely sold around the world. From the beginning the fluorescent properties of CQDs has been central to both their academic study as well as to their commercial success. As the tools to probe the photo-physics of individual CQDs have become more sophisticated, an appreciation of their properties as nano-emitters has grown. CQDs are now showing potential as quantum emitters, sources of single indistinguishable photons. It is this new direction that will be the focus of my presentation. Cesium lead halide perovskite CQDs, an emergent nano-material with unique optical properites, have now shown potential as colloidal sources of coherent single photons at cryogenic temperatures. We report that large CsPbBr3 CQDs (~20nm in size) show direct evidence of interference between indistinguishable single photons sequentially emitted from a single nanocrystal through Hong-Ou-Mandel interference in the absence of any radiative enhancement or photonic architecture.

Synthesis and Applications of Two-Dimensional $Cs_2AgM(III)X_6$ Double Perovskite Nanoplatelets OuChen; Brown University, United States

Lead-free double perovskite nanocrystals have emerged as a promising class of materials with potential to be integrated into a wide range of optical and optoelectronic applications. In this regard, composition engineering and morphology control are the two effective means to tune and optimize their properties. In this talk, I will discuss about the synthesis of high-quality $Cs_2AgM(III)X_6$ (M(III) = In, Bi, and X = Cl, Br, I) two-dimensional nanoplatelets through our newly developed synthetic method. By analyzing the optical, morphological, and structural evolutions of the samples during synthesis, we elucidated that the growth mechanism of lead-free double perovskite nanoplatelets followed a lateral growth process from mono-octahedral-layer cluster-based nanosheets to multilayer nanoplatelets. Through controlling composition, the optical properties of double perovskite nanoplatelets can be tuned and optimized with the highest photoluminescence quantum yield reaching over 40%. Importantly, the synthesized double perovskite nanoplatelets possess large surface areas, and high colloidal and solid-phase stabilities, which allow them to be applied for photocatalytic CO_2 reduction and light emitting diode applications.

4:00 PM EL10.04.07
Post-Synthetic Doping and Surface Ligand Engineering of Lead-Free Perovskite Nanocrystals: Tuning the Composition, Dimensionality and Dopant Characteristics LacieConnelli and OuChen; Brown University, United States

Doping in perovskite nanocrystals (NCs) offers effective means to alter and improve the magnetic, optical and optoelectronic properties of the perovskite NCs. Unlike traditional direct-synthetic doping methods, post-synthetic perovskite NCs doping reactions provide a facile doping method with the possibility of providing insights into intermediate states and reaction mechanisms through highly controllable reaction kinetics and minimum side products. As such, the previous development of post-synthetic doping reactions focused on the phase (i.e. solid or liquid) dependence of both the precursor and NC to determine dopant incorporation and diffusion kinetics. Herein, I will show a detailed study of post-synthetic doping of perovskite NCs within three distinct aspects: NCs composition, dopant interactions and the perovskite crystal dimensionality. More specifically, diffusion dynamics of Mn^{2+} dopants were interpolated and compared between lead-based and lead-free perovskite NCs. Furthermore, post-synthetic ligand engineering characterized by 1D and 2D NMR techniques was applied to enhance both the particle stability and optical properties of the doped perovskite NCs.

Multicomponent Functional Superlattices Co-Assembled from Shape Anisotropic Lead Halide Perovskite Nanocrystals TarasSekh[1,2], GabrieleRaino[1,2], IhorCherniukh[1,2], EtsukiKobiyama[1,3], ModestosAthanasiou[4], AndreasManoli[4], ThomasSheehan[5], WilliamTisdale[5], ThiloStoeferle[3], RolfErni[2], GrigoriosItskos[4], MarynaBodnarchuk[2,1] and MaksymV. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]IBM Research-Zurich, Switzerland; [4]University of Cyprus, Cyprus; [5]Massachusetts Institute of Technology, United States

With the development of new approaches in synthetic chemistry over the last few decades, various colloidal nanocrystals were obtained in the monodisperse form, which, in turn, fostered the extensive research and application possibilities of novel nanomaterials. To this end, self-assembly of colloidal nanocrystals via a bottom-up approach holds great promise for creating metamaterials with programmable functionalities which originate from not only ensemble-average properties but also from diverse synergistic and collective effects, including conductivity enhancement, dipolar interactions, plasmonic couplings as well as collective light emission–superfluorescence [1]. The last was recently shown on the single-component perovskite nanocrystal superlattices [2]. Such peculiar optical properties, together with a high degree of monodispersity, size tunability, and shape anisotropy of perovskite nanocrystals, stimulated research in exploring multicomponent superlattices [3]. Thus, a whole plethora of superlattice types has become accessible, encompassing the superlattices comprised of perovskite nanocubes and spherical, truncated cuboid, or disc-shaped nanocrystals acting as spacers between fluorescent nanocrystals [4]. The superlattices can be fabricated as films on different flat substrates, including at the liquid-air interface, or as spherically confined 3-dimensional supraparticles [5]. A particular interest lies in studying superlattices containing a few light emitter types, wherein promising collective phenomena are expected to emerge. For such systems exemplified on lead perovskite nanocrystal superlattices, we observed the Foster-like energy transfer with accelerated exciton diffusion.

4:30 PM EL10.04.09
Accurate TDDFT Absorption Spectra of Molecules on Surfaces over Full Spectral Range MatthiasKick, EzraA. Alexander and TroyVan Voorhis; Massachusetts Institute of Technology, United States

Theoretically, electronic excitations can be obtained by analysing the frequency components of the time-dependent dipole moment obtained from real-time time-dependent density functional theory (RT-TDDFT) simulations. Yet, an exact treatment of electronic excitations in large systems with TDDFT is computational prohibitive. Super-resolution techniques such as compressed sensing typically fail due to the presence of a quasi-continuum of electronic excitations. We present a new approach where we combine exact short time dynamics with approximate frequency space methods. As a prototypical test system, we use an organic dye-molecule adsorbed on a semi-conductor quantum-dot surface. We calculate the entire electronic absorption spectrum of this system and find that our approach can accurately capture narrow features and a quasi-continuum of states at the same time. We see a reduction of the required amount of data points up to a factor of 40 compared to standard Fourier analysis. By doing so, our method allows us to study electronic properties of large systems in ways that are not currently possible.

4:45 PM EL10.04.10
Lanthanide Doping into All-Inorganic Heterometallic Halide Layered Double Perovskite Nanocrystals for Multimodal Visible and Near-Infrared Emission TongCai[1,2] and OuChen[1]; [1]Brown University, United States; [2]Northwestern University, United States

The introduction of rare earth lanthanide ion (Ln^{3+}) impurities into all-inorganic lead-free halide perovskites has captured significant research attention and exhibited great promise in a range of optoelectronic applications. Nevertheless, the successful achievement of Ln^{3+} doping within heterometallic layered double perovskite (LDP) nanocrystals (NCs) remains as an unexplored frontier, accompanied by a lack of understanding. Herein, we report the first colloidal synthesis of Ln^{3+} (Yb^{3+}, Er^{3+}) doped LDP NCs utilizing a modified hot-injection method. The resulting NCs exhibited proficient NIR PL profiles encompassing both the NIR-I and NIR-II regions, achieved *via* energy transfer down-conversion mechanisms. Density function theory (DFT) calculations reveal that Ln^{3+} dopants exhibit a preference for substituting Sb^{3+} cations, occupying within the LDP crystal lattice while maintaining its structural stability. By leveraging sensitizations of intermediate energy levels, we delved into the mechanisms of energy transfer between the host and dopants, and between different types of dopants, across a series of

designed Ln^{3+} doped $Cs_4CdSb_2Cl_{12}$ or $Cs_4MnSb_2Cl_{12}$ LDP NCs. Interestingly, doping Er^{3+} ions into $Cs_4MnSb_2Cl_{12}$ LDP NCs yielded distinct photophysical responses, *i.e.*, brightening the pre-dark states of Er^{3+} dopants, owing to the role of Mn component played as an intermediate energy bridge. This study not only presents a novel model system that advances our understanding of sensitization-induced energy transfer mechanisms in doped semiconductor NCs, but also propels the potential applications of all-inorganic lead-free LDP NCs across a wide array of optoelectronic domains, such as optical data encryption, optical telecommunication, multiplexed NIR detection and imaging.

SESSION EL10.05: Poster Session I

All-Solution Processed Green Quantum-Dot Lighting Device with PEDOT:PSS:PMA P-Type Conducting Layer GuanningShao[1,2] and Young JoonHong[1,2]; [1]GRI–TPC International Research Center, Korea (the Republic of); [2]Sejong University, China

Quantum dot light-emitting diodes (QLEDs) have drawn substantial interest over the past few decades as potential large-area display devices, thanks to their remarkable quantum efficiency, pure and highly saturated RGB color expression, and broad process adaptability. Typically, the colloidal quantum dots (QDs) are spin-coated to form an emissive layer (EML) sandwiched between the hole and electron transport layers (HTLs and ETLs), essential for crafting p–n junction lighting devices. Despite their simple solution casting process, QLEDs show high efficiency and long lifetime, qualifying them for practical devices and displays. However, the overall efficiency of QLEDs is determined not just by the internal quantum efficiency of QDs, but also significantly by the carrier transport and injection capabilities of the HTLs and ETLs. Particularly, the electron mobility and concentration often surpass those of holes by orders of magnitude . This carrier imbalance leads to the accumulation of excess electrons at the interfaces around light EML, causing exciton quenching and leakage current overflow in the devices. Additionally, surplus electrons intensify the Auger recombination of quantum dots, resulting in further fluorescence quenching, which is a principal factor behind the reduced efficiency of QLED devices. Thus, the carrier imbalance poses a significant challenge in the fabrication of high efficiency devices.
In this presentation, we highlight the improved p-type conductivity in solution-processed green QLEDs, achieved through the use of mixed solution of poly(3,4-ethylenedioxythiophene):poly(styrene-sulfonate) (PEDOT:PSS) and phosphomolybdic acid (PMA) as an HTL. The mixing ratio of PEDOT:PSS to PMA was progressively adjusted from 1:0 to 1:0.5 to determine the optimal mixing ratio for maximizing p-type conductivity and QLED lighting efficiency. Ultraviolet photoelectron spectroscopy (UPS) and x-ray photoelectron spectroscopy (XPS) were used to investigate the actual energy level shift of hole transport layers in the junction device structure. Moreover, the redox of Mo in various valence states in the mixed solution was explored concerning work function and energy level via UPS, suggesting the modulation of hole injection and electron blocking abilities. The work function of PEDOT:PSS:PMA was evaluated as well. The optimized energy level mitigates the hole transport barrier, leading to a decrease in driving voltage and an enhancement in electroluminescent efficiency. The p-type conductivity of the mixture was further validated by assessing the electrical properties of hole-only devices. This approach to enhance the hole conduction can be extended to the fabrication of many other solution-processed QLEDs, thereby advancing practical display applications.

8:00 PM EL10.05.02
Intense Pulsed Light Annealing of All Printed Thin Film Transistors using Solution-Based Indium-Gallium-Zinc-Oxide Semiconductor and Printed Silver Electrodes. Jong-WhiPark[1], Chang-JinMoon[1] and Hak SungKim[1,2]; [1]Hanyang University, Korea (the Republic of); [2]Institute of Nano Science and Technology, Korea (the Republic of)

In this study, intense pulsed light (IPL) annealing process for printed multi-layered Indium-Gallium-Zinc-Oxide (IGZO) and silver (Ag) electrode structure was developed for high performance all printed inorganic thin film transistor (TFT). Through solution-process using IGZO precursor and Ag ink, the bottom gate structure TFT was fabricated. The spin coating method was used for the forming IGZO semiconductor layer on heavily-doped silicon wafer covered with thermally grown silicon dioxide. The annealing process of IGZO layer was proceeded using optimized IPL irradiation process. The Ag inks were printed on the IGZO layer by screen printing, so the source and drain (S/D) pattern was formed. This S/D pattern was dried by near infrared radiation (NIR), and the dried S/D pattern was sintered with the intense pulsed light varying the irradiation energy. The performances of all-printed TFT such as field effect mobility and on-off ratio electrical transfer properties were measured by parameter analyzer. The interfacial analysis such as contact resistance and the cross-sectional microstructure analysis was essential, because the diffusion phenomenon can occur during annealing and sintering process. Consequently, this TFT device shows noteworthy performance, it was similar performance compared to conventional TFT, which is expected to open a new path in the printed metal oxide based TFT field.

Nature-Inspired Superhydrophobic/Water-Repellent Surface on PCB/Semiconductor Based on Automatic Coating Process using Functional Nanoparticles SeungchulPark, Seon JuYeo and Bo-YeonLee; Korea Institute of Machinery and Materials, Korea (the Republic of)

We demonstrate a simple generic principle of constructing superhydrophobic and water-repellent surfaces, which is the biomimic of Lotus-leaf, based on automatic spray coating on PCB substrate. Using the low surface energy nanoparticles such as fluorinated silicon dioxide nanoparticles, atomized spray equipment can help to generate superhydrophobic and water-repellent surface with in large area and high-uniformity. The coating pathway can be controlled by the 3D image of the target substrate, PCB substrate in our case, and the nanoparticle coated PCB substrate can show the water-repellency without additional process such as thermal treatment due to the functional of our fluorinated silicon dioxide nanoparticle. We expect that our coating process with functional nanoparticles can increase the stability of electronic devices.

8:00 PM EL10.05.04
Functionalization Platform of Magnetic Nanoparticles Through Silica Shell Formation KatherineLei, KeisukeNagao, RobertJ. Macfarlane and PolinaAnikeeva; Massachusetts Institute of Technology, United States

Magnetic nanomaterials enable transduction of weak magnetic fields into biological signals including force, heat, and force or heat-mediated chemical release. However, biochemically benign ferrites, including iron oxide, pose challenges to surface modification offering limited surface functionalization options for cell targeting. We hypothesized that functionalization of magnetic nanomaterials with silica, for which numerous surface chemistries are established, would offer a versatile and robust route to their surface engineering. Although prior work suggested the use of the Stöber and reverse microemulsion methods to functionalize magnetic nanomaterials with silica, formation of thin uniform shells necessary to preserve the particles' functional properties remained challenging. Furthermore, during functionalization reactions multiple nanoparticles are readily encapsulated in a single silica shell, which similarly compromises performance. To overcome these challenges, we develop a novel, robust protocol for a reverse microemulsion method to create uniform shells with tunable thickness on magnetic nanoparticle cores. Our protocol uses oleic acid as a secondary surfactant to prevent the formation of multi-core particles and control the rate of silica shell growth. We demonstrate that our protocol is adaptable to a wide range of particles of different shapes/sizes and compositions such as spherical nanoparticles with high heat-dissipation rates in magnetic fields, hexagonal ferrite nanodiscs (>200 nm in diameter), and semiconductor quantum dots. Additionally, the surface chemistry of our coated nanoparticles can be readily modified with desired functional groups. Our protocol can be used to form uniformly coated core-shell nanoparticles of a desired thickness as a platform for applications in materials research, chemistry, and biomedicine.

Photoelectrochemical Behavior of Gold Nanocluster–Sensitized TiO_2 Electrodes Modulated by Interfacial Engineering MinwookJeon and Jin HoBang; Hanyang University, Korea (the Republic of)

Metal nanoclusters (NCs) are a newly emerging photosensitizer in light–conversion devices due to their unique physicochemical properties. While many aspects of NC-sensitized photoelectrodes have not fully been elucidated to date, recent reports uncovered exotic photoelectrochemical (PEC) behavior that has not been observed in conventional photosensitizers, thus attracting great interest in this newly devised system. Susceptibility of the PEC behavior of NC–sensitized photoelectrodes to surface states of the photoelectrodes is subtle; hence a systematic investigation is urgently required to obtain a better understanding of charge separation and charge recombination events occuring at the interface. In this work, we revealed that a simple pH change during the sensitization of NCs to TiO_2 can have a significant effect on charge injection and charge recombination kinetics. In–depth–time–resolved spectroscopy combined with

potential–dependent electrochemical impedance spectroscopy shed new light on these interfacial events. We envision that the newly acquired insight from our investigation would be crucial for the development of the NC–TiO_2 system because its PEC behavior is intimately altered by even a subtle change in the interface.

8:00 PM EL10.05.06
Direct Patterning of Colloidal Quantum Dots Through Blending with a Photo-Cross-Linkable Functional Polymers JaeyeopLee[1], Seon LeeKwak[1], Woon HoJung[2], ChaegwangLim[1], JaehoonLim[2], Do-HoonHwang[1] and JeongkyunRoh[1]; [1]Pusan National University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Colloidal quantum dots (QDs) have been spotlighted in advanced display technologies due to their unique ability to adjust emission colors based on their core size, along with their excellent color reproducibility*(Advanced Materials **n/a**, 2212220, **2023**).* Numerous researchers have made significant strides in developing high-performance quantum dot light-emitting diodes (QD-LEDs) by optimizing the device structure *(Organic Electronics **108**, 106593, **2022**),* achieving charge balance *(ACS Photonics **10**, 500-507, **2023**),* and refining emissive mechanisms *(Small **15**, 1905162, **2019**).* However, despite these impressive advancements, the commercialization of QD-LEDs still lags behind, primarily due to the absence of suitable patterning technologies for QDs (*The Journal of Physical Chemistry Letters **12**, 3522-3527, **2021**).* Optical lithography has often been employed to produce high-resolution QD arrays, but direct exposure to UV light often leads to the degradation of QDs by surface oxidation *Advanced Materials **31**, 1804294, **2019**).*
In this study, we addressed this challenge by blending QDs with a photo-cross-linkable functional polymer to mitigate oxidation during the patterning process. By adopting this method, we successfully achieved patterned QD films with a minimum line width of 2 *μm*. Furthermore, we demonstrated high-resolution RGB full-color QD pixels, surpassing 1,000 pixels per inch (*ppi*). Importantly, the pixelated QD-LEDs exhibited negligible degradation during the patterning process thanks to the protective presence of functional polymers surrounding the QDs. This result presents a readily accessible solution for QD patterning, effectively overcoming the challenges associated with the oxidation of QDs under UV exposure. This significant advancement in patterning technology holds tremendous potential for the development and commercialization of high-resolution RGB full-color QD-LEDs.

8:00 PM EL10.05.07
The Synthesis of Colloidal Au Nanocrystals with Unconventional Crystal Phase and Their Optical Applications ChenMa and YeChen; The Chinese University of Hong Kong, China

Gold nanocrystals have attracted considerable research attention due to their potential applications in energy conversion, catalysis, electronics, and biomedicine. However, previous studies mainly focused on tuning the morphology, facet, size, and dimensionality of Au nanomaterials. Recently, research in phase engineering of nanomaterials has highlighted the significance of the crystal phase in modulating the physicochemical properties of nanomaterials. Interestingly, most of the reported Au nanomaterials with unconventional crystal phases were prepared starting from [Au(I)-oleylamine] system because oleylamine exhibits unique adsorption behaviors with Au nanocrystals. Based on the [Au(I)-oleylamine] system, we developed a facile colloidal method to synthesize Au nanocrystals with unconventional crystal phases in high phase purity, high yield, and high shape uniformity. The crystal phase of as-synthesized Au nanocrystals was evidently revealed by selected area electron diffraction, X-ray diffraction, and high-resolution transmission electron microscopy. In addition, Au nanocrystals with different morphology were obtained via a simple ligand exchange method. More importantly, it is found that Au nanomaterials with unusual crystal phases possess unique optoelectronic properties compared with their thermodynamically stable face-centered cubic phase. Our work not only can pave a new avenue to the colloidal synthesis of nanocrystals with unconventional crystal phases but also promote the fundamental understanding of crystal phase-dependent optical properties of noble metal nanomaterials.

8:00 PM EL10.05.08
Stoichiometric Engineering of Ag_2S Nanocrystals to Realize High-Performance Organic-Inorganic Hybrid Photomultiplication-Type Photodiode JisuKwon, Kyu MinSim, DaesungChung and SungjeeKim; POSTECH, Korea (the Republic of)

Heavy metal-free Ag_2S nanocrystals (NCs) were synthesized for a novel class of sensitizing center of photomultiplication (PM)-type photodiodes in which polymeric semiconductor poly(3-hexylthiophene) (P3HT) was co-used. The key role of PM sensitizing center is considered as efficient charge separation and trapping, which requires prolonged capturing of minority carriers and advantageous band-bending at the cathode interface for continuous tunneling injection of majority carriers. To this end, the surface stoichiometry of Ag_2S NCs was strategically tuned as Ag-rich, stoichiometric, or S-rich. The Ag_2S NCs are designed to have more acceptor-like states when the stoichiometry is dominated by Ag atoms. Conversely, they have more donor-like states when S atoms prevail. In addition to the elemental analyses, the surface stoichiometry of NCs was further characterized by time-resolved photoluminescence and space-charge limited current analyses. An optimal PM-type photodiode was demonstrated by the structure of ITO/PEDOT:PSS/P3HT:Ag_2S NCs/Al with the holes as the majority carriers, Ag-rich Ag_2S NCs as the sensitizing centers. The Ag-rich Ag_2S NCs showed enhanced electron trapping and minimized hole trapping rate due to the high density of acceptor-like states. We showcased that fine-tuning the surface stoichiometry of Ag_2S nanocrystal enables high external quantum efficiency (EQE) of the PM-type photodiode. The optimized hybrid PM-type photodiode exhibited a high peak EQE of 170,000%, responsivity of 580 A/W, and specific detectivity of 3 X 10^{13} Jones. Sophisticated control of NC stoichiometry is important for the photophysical properties of sensitizing centers which guarantees successful applications to optoelectronic devices such as photodiodes.

8:00 PM EL10.05.09
Nanoparticle Accelerants for Liquid-Liquid Phase Separation (LLPS) of Intrinsically Disordered Proteins RyanM. Doherty, XiaotingGuo and VickiL. Colvin; Brown University, United States

Biomolecular condensates, also known as membraneless organelles, play a critical role in cellular organization, and their dysregulation has been linked to multiple disorders including neurodegenerative diseases and cancers. They form through a liquid-liquid phase separation process (LLPS) that occurs when LLPS-forming proteins demix into higher concentration and lower concentration phases within a cellular environment. Understanding what triggers LLPS formation and the role that protein structure may play remains an active area of research. Previous studies have shown that some small molecules and polymers may promote LLPS paving the way for generating druggable targets for this important class of biomolecules. This study evaluates whether nanoparticles can serve as accelerants for this important biological process ex-situ.

Gold nanoparticles coated with polyethylene glycol (PEG) have previously been shown to be crowding agents able to accelerate protein-protein interactions during crystallization processes. Given that crystallization requires a liquid-liquid phase separation (LLPS) step, we expected that these same materials would also accelerate the LLPS of candidate proteins. Au-PEG nanoparticle conjugates (AuNP-PEG) also can expand the set of conditions that allow for protein-protein interactions to occur.

This study looks to understand how the inorganic core diameter of AuNP-PEG and the PEG chain length — both important variables in designing agents that are efficient accelerants — can change the rate of liquid-liquid phase separation (LLPS) and the properties of condensates. Such design and modulation of this organic-inorganic interface allow us to create better tools to promote LLPS ex-situ. AuNP-PEG of various core diameters was prepared and functionalized with varying chain lengths of polymers from 1,000 to 40,000 molecular weight. The polymer coating has different properties; short-chain PEG is tightly packed and has a high grafting density whereas long-chain PEG adopts mushroom configurations and is less dense. Previous work with protein crystallization showed that nanoparticle core diameter did not play a significant role in the nucleation rate, a finding expected for the rate of LLPS. But, protein crystallization occurred faster at high PEG-chain lengths, so we expected AuNP-PEG to accelerate LLPS. Longer PEG length would increase the LLPS rate due to the more crowded environment, hydrophobicity, and multivalency, which are key LLPS-promoting factors associated with longer polymer chains. Optical microscopy was used to evaluate the kinetics of LLPS in addition to other spectroscopic tools. We also analyzed biomolecular condensate diameter, density, and other material properties.

Materials that accelerate the liquid-liquid phase separation (LLPS) should also promote LLPS under less extreme solution phase conditions. Typically, LLPS is brought about ex-situ by placing intrinsically disordered proteins into solutions of high ionic strength and/or low pH and then mixing with a low-salt buffer, producing a limited phase space. In the presence of accelerants, this phase space should be expanded. A screening procedure was performed at various protein and salt concentrations to determine if the presence of AuNP-PEG would induce LLPS in a larger set of conditions. From this, a phase map was developed to understand the expanded range of phase separation.

8:00 PM EL10.05.10
Reversibly Controlling Assembly/Disassembly of Plasmonic Nanoparticles by Electrochemical Redox of Copper-Coordinated Surface Ligands TaeyongHa[1], SanghwaJeong[2] and SungjeeKim[1]; [1]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

Plasmonic nanoparticles (NPs) show dramatically different scattering properties by the assembly/disassembly of the NPs due to the notable change between the collective and individual plasmonic modes. Reversible and on-demand control of such assembly and disassembly states of plasmonic modes is of great importance for potential optoelectronic and display applications. Control of assembly/disassembly of plasmonic NPs have been demonstrated by changing the pH, light exposure, or temperature. However, such cues are not very practical for device applications because of the limited reversibility and necessity of extended time. We report reversible and electrotunable control of assembly/disassembly of metal NPs by electrochemical redox reactions of copper complexes. The copper complex moiety is tethered to the surface ligands of metal NPs. The reversible control of assembly/disassembly of metal NPs was attained by switching the oxidation states between Cu(I) and Cu(II). Cu(I) state prefers tetrahedrally-coordinated complexes which form inter-NP sandwich structures and induces the assembled NP state. Whereas Cu(II) takes octahedral ligand geometry which results in individually and freely dispersed NP state. Our control does not need external chemical reagents, and the reversible change can be made quite rapidly. The electrochemical control was also demonstrated by using a low operating voltage less than a couple of volts. We believe our design can be useful in

optoelectronic display applications such as smart windows because it provides reversible bistability between transmittance and reflectance.

8:00 PM EL10.05.11
Trap-Induced Excitation "Memory" Enable High-Speed Modulation of Quantum-Dot Light-Emitting Diodes YunzhouDeng[1,2], XiuyuanLu[2] and YizhengJin[2]; [1]University of Cambridge, United Kingdom; [2]Zhejiang University, China

Quantum-dot light-emitting diodes (QLEDs), a class of solution-processed EL devices based on organic-inorganic hybrid structures, show great potential in next-generation optoelectronics. Understanding their transient response dynamics is essential for developing high-speed devices for EL display, light communications [1] and potentially electrically-pumped lasing [2].

Here, we report that the transient responses of the QLED can be accelerated by the "memory" of its excitation history, distinguishing QLEDs from conventional inorganic LEDs. We elucidate that this transient behavior originates from the interplay between transient EL processes and deep-level fast traps in the organic hole-transport layer, which generates a new fast-response EL channel that occurs in high-frequency operations. Finally, we harness this transient response pathway on a micro-QLED, demonstrating high-speed modulations up to 100 MHz at a moderate excitation level of ~200 mA cm^{-2}.

This work highlights a universal transient EL behavior dominated by trap-related processes in the organic charge-transport materials, which is found to generally exist in solution-processed LEDs employing organic hole-transport materials, including perovskite LEDs and polymer LEDs. We except that the excitation-memory induced fast-response dynamics could facilitate the realization of solution-processed, low-power, and fast-response EL devices.

8:00 PM EL10.05.12
Aqueous Synthesis of Copper Plates Based on Anisotropic Growth of Copper Crystals with Bromide Ions YusakuNoda, ShunYokoyama and HideyukiTakahashi; Tohoku University, Japan

Copper micro/nanoplates (Cu MNPs) have been studied intensively for potential applications in optical devices and electronic wiring due to their low cost, unique optical properties, and high conductivity. Aqueous chemical reduction from Cu complexes to Cu crystals is used to produce Cu MNPs with halogen ions and surfactants as capping agents[1]. During the chemical reduction, halogen ions are predicted to adsorb on (111) facets of Cu crystals and the surfactants work as stabilizer for the halogen adsorption and consequently Cu crystals grow anisotropically, leading to plate-shaped particles. While the capping agents also adsorb on (100) facets depending on the synthesis conditions, leading to wire-shaped particles. It is unclear what triggers the wire and plate-shaped particle syntheses. Although we previously developed an environmental-friendly synthesis method of Cu nanowires with chloride ions and polymers as the capping agents, plate-shaped particles are never synthesized in the method. While reduction speed of the chemical reduction and types of capping agents are reported to greatly affected the anisotropic growth. In this study, we controlled types of capping agents and the reaction speed in the environmental-friendly synthesis method for selectively synthesizing Cu plate particles and revealing their formation mechanism. We selected bromide (Br) ions as the capping agent and no other capping agents are used. We used ascorbic acid and lactic acid (LA) as the reducing and complexing agent, respectively. We changed the reduction pass from Cu-LA complexes to Cu and the reduction rate by controlling pH and concentrations of Br and LA based on pH-potential diagrams. The synthesized particles were analyzed by SEM for particle morphologies and XPS for surface conditions.
In the calculated pH-potential diagrams, Cu-LA complexes are expected to be stable at wide pH region and then reduced to Cu through CuBr below pH 6 and through Cu_2O above pH 6.0 Micro-sized wire and plate particles were mainly synthesized at pH 3.5 and between pH 4.5 and 5.5, respectively. Above pH 6.0, polyhedral particles were mainly synthesized. From XPS results of particle surfaces obtained at various pH values, the amount of Br ions on particle surfaces obtained below pH 6.0 is larger than that above pH 6.0. These results indicate that low pH values facilitate adlayer formations of Br ions on Cu crystal surfaces because CuBr is more stable than Cu_2O, resulting in syntheses of wire and plate particles. Br ions could be adsorbed on (100) facets for wire particle formations and (111) facets for plate particle formations. To examine why this difference arose between pH 3.5 and pH 4.5 to 5.5, the reduction rate of Cu complexes at 3.5 and 5.5 was evaluated. The reduction rate at pH 3.5 was much slower than that at pH 5.5 due to changes in redox potentials of ascorbic acid with pH, indicating the reduction rate affected the adsorption of Br ions on Cu crystal facets. The details about the growth mechanism of wire and plate particles will be introduced.

New Syntheses for Aqueous and Processable Nanocrystals SureshSarkar, OpeyemiArogundade and AndrewM. Smith; University of Illinois Urbana-Champaign, United States

Many classes of nanocrystals are synthesized by reactions in solvents composed of aliphatic hydrocarbons, resulting in products dispersible only in nonpolar media. To disperse these nanocrystals in aqueous and other polar solvents, secondary processing steps are used to exchange ligands or encapsulate the particles within amphiphilic polymers. This report will focus on new processes to increase the efficiency, scalability, and environmental waste profile for the production of hydrophilic nanocrystals. In particular, new types of coordinating ligands and processing steps will be described that may increase access to diverse nanocrystals stable in biological media for diverse applications in imaging and sensing.

Chloride Ligands on DNA-Stabilized Silver Nanoclusters AnnaGonzalez Rosell[1], SamiMalola[2], RweetuparnaGuha[1], NeryArevalos[1], María FranciscaMatus[2], MeghenGoulet[1], EsaHaapaniemi[2], BenjaminKatz[1], TomVosch[3], JiroKondo[4], HannuHäkkinen[2] and StacyCopp[1]; [1]University of California, Irvine, United States; [2]University of Jyväskylä, Finland; [3]University of Copenhagen, Denmark; [4]Sophia University, Japan

DNA-stabilized silver nanoclusters (Ag_N-DNAs) are magic-sized nanoclusters of 10-30 silver atoms stabilized by one to three short DNA oligomers. The stabilizing DNA ligand's sequence sculpts the size and shape of the tiny nanocluster, thereby selecting its shape-tuned fluorescence excitation and emission peaks. The combinatorially large space of DNA sequence enables DNA ligands to stabilize a wide range of nanocluster structures with sequence-tuned optical properties. These emitters are promising for sensing and biomedical imaging applications, but until recently, the inorganic-organic interface of Ag_N-DNAs was not well-understood. Here, we report our recent work on characterizing the surface chemistry of a new class of Ag_N-DNAs with hybrid ligands and superior optical properties.
We investigate a set of five atomically precise Ag_N-DNA species with near infrared emission and previously reported X-ray crystal structures. Using high-resolution mass spectrometry, we determine the molecular formula of these nanoclusters to be $(DNA)_2[Ag_{16}Cl_2]^{8+}$. This is the first time that chloride ligands have been ever reported for Ag_N-DNAs. [1] Chloride ligands can be exchanged for bromide ligands, leading to a redshift in the optical spectra of the emitters. DFT calculations confirm the stability of chloride ligands on the Ag_{16} nanocluster core, yield qualitative agreement between computed and measured UV-vis absorption spectra, and provide interpretation of the ^{35}Cl-nuclear magnetic resonance spectrum of the $(DNA)_2[Ag_{16}Cl_2]^{8+}$. A reanalysis of the X-ray crystal structure confirms that two previously assigned low-occupancy silvers are, in fact, the two chloride ligands. Finally, using the unusual stability of $(DNA)_2[Ag_{16}Cl_2]^{8+}$ in biologically relevant saline solutions as an indicator of chloride ligands on Ag_N-DNAs, we use high-throughput screening to identify an additional new Ag_N-DNA with mixed DNA/chloride ligand chemistry. Inclusion of chlorides on Ag_N-DNAs presents a promising new route to expand the diversity of Ag_N-DNA structure-property relationships and to imbue these emitters with significantly enhanced stabilities for *in vivo* biomedical imaging applications. This work also demonstrates the power of combining high-resolution mass spectrometry, optical spectroscopy, nuclear magnetic resonance, and DFT to characterize the ligand interface of metal nanoclusters and to understand how this interface influences optical properties of these novel emitters.

Polydopamine Coated Gold Nanorods: Photothermal and Photocatalytic Mechanism Study DanielAguilar Ferrer[1,2], EmersonCoy[1], MikhaelBechelany[2,3], ThomasVasileiadis[1],

IgorIatsunskyi[1], MarcinZiolek[1], SergioMoya[4], KlaudiaZebrowska[1], OlenaIvashchenko[1], RaquelPazos[5], BartoszGrzeskowiak[1] and PaulinaBlaszkiewicz[6]; [1]Adam Mickiewicz University, Poland; [2]Université de Montpellier, France; [3]Gulf University for Science and Technology, Kuwait; [4]Soft Matter Nanotechnology, Centre for Cooperative Research in Biomaterials (CIC biomaGUNE), Basque Research and Technology Alliance (BRTA), Spain; [5]Chromatography & Mass Spectrometry Platform, CIC biomaGUNE, Spain; [6]Poznan University of Technology, Poland

The strong photothermal effect made by the combination of localized surface plasmon resonance (LSPR) presented by gold nanorods (AuNRs) with polydopamine (PDA) makes them appeal nanomaterials for biomedical applications. Here, by seed-mediated growth and a further self-polymerization of dopamine (DA), a reproducible hybrid nanoplatform combining these two materials have been synthesized (AuNRs/PDA). PDA shell thickness was controlled as well as LSPR, besides, their effect on temperature and the photocatalytic response was examined towards Rhodamine 6G (Rh6G) degradation showing a final depletion of 51% during 60 minutes of irradiation and a catalyst concentration of 7.4 μg mL^{-1}. Moreover, the kinetics of the reaction were studied through the Langmuir-Hinshelwood model which in combination with time-resolved spectroscopy, and finite-element method simulations of plasmons unveiled low thermalization and enhanced charge carrier at the composite resulted from the combination of AuNRs plasmons and low thermal conductivity presented by PDA [1].

Role of the Ligand Structure Around Nanomaterials for Chemical Reactions WolfgangParak and FlorianSchulz; Universität Hamburg, Germany

Ligands at the surface of nanomaterials can influence chemical reactions, as will be discussed for 3 different examples. 1) In case ion-responsive ligands are attached to nanomaterial surfaces, the binding properties and such working point can shift. As example, when pH-responsive fluorophores are attached with negatively charged ligands to a surface, then there is a local attraction of H^+, i.e. the pH at the surface is lower than in bulk. 2) Ligands may restrict the available space for reactions. 3) Ligands may change the adsorption properties of molecules to surfaces. One interesting example here is the formation of a protein corona. With different coating different proteins can be "fished" from the environment.

Engineering the Inorganic-Living Interface BruceE. Cohen[1], CassioPedroso[1], VictorMann[1], EmmaXu[2], ChanghwanLee[2], P. JamesSchuck[2] and EmoryChan[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Columbia University, United States

Surface functionalization of nanocrystals is essential for their practical application in living systems, but introducing biocompatibility can come at the cost of diminished nanoparticle optics, diminished colloidal stability, or massive increases in probe size. In addition, the cell presents a remarkably complex chemical environment, rich in metal ions, amines, thiols, and other compounds that can disrupt nanoparticle complexes that are perfectly stable *in vitro*. Inorganic nanocrystals such as quantum dots (QDs),[1,2] upconverting nanoparticles (UCNPs),[3] and avalanching nanoparticles (ANPs)[4,5] are uniquely suited for quantitative live-cell imaging and are typically functionalized with ligands to study specific receptors or cellular targets. Antibodies are among the most useful targeting reagents owing to their high affinities and specificities, but common nanocrystal labeling methods may orient antibodies incorrectly, be reversible or denaturing, or lead to antibody-nanoparticle complexes too large for some applications. We have shown that SpyCatcher proteins, which bind and spontaneously form covalent isopeptide bonds with cognate SpyTag peptides, can conjugate engineered antibodies to nanoparticle surfaces with control over stability, orientation, and stoichiometry.[6] Compact SpyCatcher-functionalized QDs and UCNPs may be labeled with short-chain variable fragment antibody (scFv) engineered to bind urokinase-type plasminogen activator receptors (uPAR) that are overexpressed in many human cancers. Confocal imaging of anti-uPAR scFv-QD conjugates shows the antibody mediates specific binding and internalization by breast cancer cells expressing uPAR. Time-lapse imaging of photostable scFv-UCNP conjugates shows that antibody binding causes uPAR internalization with a ~20 min half-life on the cell surface, and uPAR is internalized to endolysosomal compartments distinct from general membrane stains and without significant recycling to the cell surface. With Tm^{3+}-doped upconverting ANPs functionalized with these scFv antibodies, the extreme nonlinearly of ANP emission leads to sub-100 nm spatial resolution using only simple scanning confocal microscopy and before any computational analysis. Quantification of ANP spot intensity across multiple *z* planes then yields a high-resolution 3D map of uPAR distribution on the cell surface. The controlled and stable conjugation of engineered antibodies to nanoparticles enables targeting of diverse receptors for quantitative live-cell study of their distribution, trafficking, and physiology

Unravelling the Relationship Between Degradation and Toxicity of Copper Chalcogenide Nanocrystals via Ligand Control and Compositional Changes XingjianZhong[1,2] and AllisonM. Dennis[2]; [1]Boston University, United States; [2]Northeastern University, United States

Copper chalcogenide nanocrystals with a doped composition of $Cu_xM_yS_z$ (M = doping element), are promising agents for biomedical imaging and therapeutic applications. These nanocrystals include direct bandgap semiconductors such as copper indium sulfide (CIS) and stoichiometric Cu_2S quantum dots (QDs) exhibiting photoluminescence and indirect bandgap materials like vacancy-doped copper sulfide ($Cu_{2-x}S$) and iron-doped copper iron sulfide ($CuFeS_2$) that exhibit plasmonic features. Compositionally, copper chalcogenide nanomaterials like CIS were thought to have better translational potential than the prototypical QDs that contain the heavy metals cadmium and lead. However, we found that CIS QDs are only biostable and biocompatible when coated with a protective zinc sulfide (ZnS) outer shell; bare CIS QDs degrade rapidly causing acute toxicity *in vivo*. These findings link the nanotoxicity of CIS nanocrystals to their degradation; expanding on these results will provide a framework for the concerted design of biocompatible and optically active copper chalcogenides by controlling the degradation products and rate.

In this study, we quantitatively analyze the toxicity and biodegradation of similarly sized copper chalcogenide nanocrystals with compositional differences (CIS, $Cu_{2-x}S$, $CuFeS_2$) as well as the impact of coating and ligand differences (lipid-PEG micelle, poly-*iso*-maleic anhydride polymer, etc.) on CIS. We first observe the degradation of different chalcogenide species coated with the same DSPE-PEG_{2k} micelle encapsulation in biological media to examine the impact of composition on degradation rate. The rate of copper release into the solution is gradual and comparable between compositions. Release of indium and iron mimics that of copper in neutral and chelator-free biological media, but both indium and iron rapidly dissociate from the particles at very early time points upon exposure to the artificial lysosomal fluid containing citric acid, which is prevalent in the lysosomal compartment of cells. When testing the cellular toxicity of these particles on a $HepG_2$ cell line following 24-hour incubation, CIS exhibits severe toxicity with an estimated IC50 of 124.1 mg/mL total cation concentration. $Cu_{2-x}S$ shows moderate toxicity with IC50 cation concentration of 401.3 mg/mL, and $CuFeS_2$ demonstrates the least cytotoxicity with over 75% cell viability at 1 mg/mL cation concentration. We hypothesize that the chelation effect of citric acid in the artificial lysosomal fluid rapidly leaches the indium and iron from the particles. This high local concentration of indium ions appears to be detrimental to the cells, while the strong homeostasis mechanisms used to buffer iron bioavailability may prove protective even in the face of burst release. We found that the surface coating (lipid-PEG micelle encapsulation vs polymer wrapping) alters the rate of oxidation of the surface and particle degradation, inspiring further study into the effect of ligand coating on the degradation and toxicity of CIS QDs. We hypothesize that a covalently bonded ligand will slow the rate of CIS degradation in biological environments and will therefore lead to reduced acute nanotoxicity. This study informs the design of biocompatible nanocrystals by elucidating the relationship between nanoparticle surface ligands, particle degradation, and cytotoxicity for copper chalcogenide nanomaterials.

Multidentate Hybrid Ligand for Efficient and Robust Hydrophilic Quantum Dots JisuHan[1,1], YeonghoChoi[1,1], HyeonjunLee[2,2] and JaehoonLim[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Colloidal quantum dots (QDs) are promising nanomaterials in various fields thanks to high photoluminescence quantum yield (PLQY), band gap tunability and spectrally pure emission profile. To utilize QDs to various applications, surface functionalization, exchanging original surface ligands with functional moieties, is typically demanded for solvent exchange, orthogonal

processing capability, long-term colloidal stability, morphology control, and so on. However, typical ligand exchange protocols are likely to deteriorate innate properties of QDs owing to surface etching by excessive use of introducing ligands, for instance, a reduction in PLQY and colloidal stability during/after the fabrication of aqueous QDs. Adopting multidentate bindings in the functional molecules are one of promising approaches for resolving such troubles as an increased binding affinity allows for effective ligand exchange with minimal amount of ligands. However, the limited number of multidentate ligands and complex synthesis routes for granting multidentate nature obstruct their pervasive use.
Herein, we propose the facile synthesis of multidentate hybrid composed of zinc thiolate backbone and functional hydrocarbon branches. For demonstration, zinc chloride ($ZnCl_2$) and 3-mercaptopropionic acid (MPA) were chosen for preparing hydrophilic hybrid ligands. ^{1}H nuclear magnetic resonance spectroscopy and Fourier transformed infrared spectroscopy revealed two different configurations of linear and toroidal structure. Their multidentate binding on QDs was confirmed in two-dimensional ^{1}H nuclear Overhauser effect spectroscopy displaying clear negative cross peaks from propionate branches bound on surface. Titration of CdSe QDs using the hybrid ligands revealed enhanced binding affinity of the hybrid ligands, enabling effective aqueous phase transfer with ~70-fold fewer binding groups compared to MPA. The aqueous QDs using the hybrid ligands featured sustained PLQY and photochemical stability; the hybrid-capped InP/ZnSe/ZnS QDs displayed ~90% of PLQY that is the record efficient to our best knowledge. Prolonged shelf-life and resistance to ultraviolet irradiation were also achieved. We attribute these enhancements to the robust, thick hybrid ligand shell prohibiting invasion of oxygen and water molecules. We believe that our hybrid ligands are expected to serve as useful building blocks for nanocrystal functionalization.

11:30 AM EL10.06.08
How Giant ZnSe-Alloyed Shell Realizes Nearly Unity Quantum Yield Byong JaeKim[1,1], HyeongjunKim[1,1], YeonghoChoi[1,1], Woon HoJung[1,1], HyeonjunLee[2], Ji-SangPark[3] and JaehoonLim[1,1]; [1]Sung Kyun Kwan University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

Core/shell heterostructure has become one of essential formulae in various applications of colloidal quantum dots (QDs). Heteroepitaxy of wide band gap materials passivates mid-gap states derived from the surface dangling bonds of cores and confines carrier wavefunctions to the inside, allowing for realizing near unity photoluminescence (PL) quantum yield (QY). In addition, the extended shell thickness (typically, 4–10 nm), so-called giant QDs, enables us to manipulate ultrafast carrier dynamics in QDs such as nonradiative Auger recombination or energy transfer in densely packed QD films. In the early stages of giant QDs, CdSe/CdS heterostructures have been exclusively spotlighted as the only suitable pair capable of extended shell thickness due to their minimal lattice mismatch. However, recent research has successfully demonstrated giant ZnSe or its alloyed shells for CdSe cores despite the large lattice mismatch that generally deteriorates PL QY as a shell thickness increases. Unfortunately, there are no reasonable explanation for how such new giant QDs are possible.
Here, we scrutinize the origin of unexpectedly high PL QY observed in giant CdSe QDs with ZnSe-alloyed shells. In the synthesis of QDs growing the graded thick $Cd_xZn_{1-x}Se$ (average x = 0.3) or ZnSe shell up to ~10 nm, careful heteroepitaxy reaction accomplished nearly unity PL QY at moderate shell thickness (H ~ 4 nm) followed by the gradual reduction, understood as defect formation by compressive lattice strain of shell. However, it was found that more intense strain provided by ZnSeS or ZnS shell recovered the PL QY of giant QDs. To understand such counter-intuitive phenomenon, we investigate the development of strain in the heterostructure and consequent derivation of electronic states. Along the accumulation of compressive strain applied to CdSe core, probed from the CdSe phonon mode shift and altered exciton dynamics, we observed the emergence of low-energy tail in cryo-PL spectra regardless of shell thickness. Retarded decay dynamics at this tail states and Ab-initio calculation suggest that Zn vacancy in ZnSe shell (V_{Zn}) introduced during the shell growth forms shallow hole traps that is 0.05–0.1 eV higher than the $1S_h$ state of CdSe core. The formation of V_{Zn} and partial strain relaxation seems to prevent the excessive strain accumulation and consequent misfit dislocation. As long as the catastrophic strain is avoided, additional hydrostatic compressive strain lifts the $1S_h$ state of CdSe core and the shallow traps in the shell become deactivated. Our study proposes the bright side of defects that they can mitigate the lattice strain in the growth of thick ZnSe-based shells to prevent the destruction of QDs by the excessive stress.

Effect of Surface Chemistry in Cation Exchange of NPLs SandrineIthurria; Sorbonne Université, France

II-VI semiconductor nanoplatelets have attracted lot of interest due to their narrow optical properties controlled by the thickness of these 2D particles. Working with Cadmium chalcogenide semiconductor enables to cover the visible range both with homostructures and heterostructures. In order to extend the optical properties, it is required to use semiconductors with narrow band gaps. However, controlling the shape of the nanoparticles remains challenging and one option that has been explored for a number of years is cation exchange. One more time preserving the anisotropic shape may be challenging in the case one of the dimensions is very small. Here, we will show that ligands in NPLs, not only control the lateral dimensions of NPLs during a growth, but also the shape of the NPLs and the cation exchange rate such that NPLs with narrow band gap semiconductors with optical properties in the NIR may be obtained.

2:00 PM EL10.07.02
Controlling Electronic Coupling of Acene Chromophores on QD Surfaces Through Variable Concentration Ligand Exchange MarissaMartinez[1], MichelleNolen[1,2], NicholasPompetti[3,1], LeeRichter[4], CarrieFarberow[1], JustinJohnson[1] and MatthewC. Beard[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States; [3]University of Colorado Boulder, United States; [4]National Institute of Standards and Technology, United States

Controlling the binding of functional organic molecules on quantum dot (QD) surfaces and the resulting ligand/QD interfacial structure determines the resulting organic-inorganic hybrid behavior. In this study, we vary the binding of tetracene di-carboxylate ligands bound to PbS QDs cast in thin films by performing solid-state ligand exchange of as-produced bound oleate ligands. We employ comprehensive FTIR analysis coupled with UV-Vis spectrophotometric measurements, transient absorption and DFT simulations to study the QD/ligand surface structure and resulting optoelectronic properties. We find that there are three primary QD/diacid structures, each with a unique binding mode dictated by the QD-ligand and ligand-ligand intermolecular and steric interactions. They can be accessed nearly independently from one another via different input ligand concentrations. Low concentrations produce mixed oleate/tetracene ligand structures where the tetracene carboxylates tilt towards QD surfaces. Intermediate concentrations produce mixed oleate/tetracene ligand structures with ligand-ligand interactions through intramolecular hydrogen bonding with the ligands perpendicular to the QD surface and weaker QD/ligand electronic interactions. High concentrations result in full ligand exchange, and the ligands tilt towards the surface while the QD film compacts. When the tetracene ligands tilt or lie flat on the QD surface the benzene ring pi-system interacts strongly with the p-orbitals at the PbS surface and produces strong QD-ligand interactions evidenced through QD/ligand state mixing, with a coupling energy of » 700 meV.

Charge-and Energy-Transfer Processes in Two-Dimensional Supramolecular Materials RuggeroEmmanuele[1], HiroakiSai[2], DarienMorrow[1], SawHla[1,3], SamuelI. Stupp[2] and XuedanMa[1,4,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States; [3]Ohio University, United States; [4]The University of Chicago, United States

Synthetic soft materials could overcome the limitation of biological structures in terms of robustness, making them appealing for practical applications related to photovoltaics and photocatalysis.[1] Understanding of charge- and energy-transfer mechanisms is often required to build efficient devices from such synthetic soft materials. In this work, we self-assemble 2D supramolecular systems into 2D ribbons and investigate both Frenkel and charge-transfer excitons (FEs and CTEs, respectively) using optical spectroscopy. We discover that the presence of defects intentionally inserted into these nanoribbons leads to variations in the CTEs / FEs emission ratio. Moreover, we find that propagations of the CTEs and FEs are closely related to the compositions and lattice structures of the 2D ribbons. These results were well reproduced by our numerical simulations based on a charge-transfer model. Our findings have important implications for utilizing soft materials in photovoltaics and photocatalytic applications.

CdSe Nanoplatelet Sensitized Upconversion—(Lateral) Size Matters LeaNienhaus; Florida State University, United States

In photon upconversion, the energy of two photons is combined to generate a higher energy state. A popular pathway for upconversion is triplet-triplet annihilation as it can become efficient at low solar-relevant powers. Here, two triplets are combined to form the desired high energy singlet state. However, since triplet states are 'spin-forbidden', sensitizers are required to indirectly populate the triplet state.
Here, we investigate the effect of material dimensionality on the triplet generation mechanism at the interface of two-dimensional CdSe nanoplatelet sensitizers and surface-bound anthracene carboxylic acid and the resulting effect on triplet-triplet annihilation in the annihilator diphenylanthracene.
We find an unexpected anti-correlation between the upconversion quantum yield and power threshold I_{th} as the NPL lateral size increases. This result is attributed to differences in the triplet-triplet annihilation mechanism: one is mediated by molecular diffusion and the other by triplet energy diffusion.[1,2]

4:00 PM EL10.07.05
Fluorescence Energy Transfer Processes Involving $CsPbBr_3$ PQD-Dye Assemblies SelinDonmez[1], SisiWang[1,2] and HediM. Mattoussi[1]; [1]Florida State University, United States; [2]ASM International, United States

Fluorescence resonance energy transfer (FRET) is a well-known technique that exploits the non-radiative transfer of excitation energy from an excited donor fluorophore to a proximal ground-state acceptor molecule. FRET is highly sensitive to small changes in the separation distance between the donor and acceptor molecules which offers the use of FRET as a platform for a range of applications such as protein conformation studies and biological assays.
Colloidal lead halide perovskite quantum dots (PQDs) have gained interest, over the past few decades, owing to their unique photophysical properties, including tunable and narrow photoluminescence (PL) profiles, high PL quantum yields (PLQY), high tolerance for structural defects, along with relatively easy to implement synthesis. Energy transfer interactions using these colloidal materials is a highly important, yet underexplored process, for practical applications relying on energy harvesting as well as for addressing fundamental questions. Questions of whether resonance energy transfer interactions relying on the dipole-dipole approximation apply to colloidal QDs (including conventional nanocrystals) have persisted. Another serious challenge that has impeded a better understanding of energy transfer processes with PQDs is the implementation of controlled conjugation of acceptor molecules.
We hereby exploit the ionic nature of CsPbBr3 QDs to achieve controlled coupling, through electrostatic interactions, of sulfo-cyanine dyes bearing zwitterionic moieties. This has allowed us to control among others the spectral overlap function between PQD emission. We combined steady-state and time-resolved photoluminescence experiments using these assemblies to measure highly efficient energy transfer interactions. This manifested in pronounced losses in PQD emission along with shortening of the PQD PL lifetime. Energy transfer rates were also strongly dependent on the spectral overlap. We will detail our synthetic approach, compare our findings to available theories on energy transfer process, and address potential contributions from charge transfer-induced quenching.

4:15 PM EL10.07.06
Enhancing SWIR Emission: Gradient Alloying and Auger Recombination Suppression in High-Performance Heavy-Metal-Free Colloidal Quantum Dots HyunjinCho and DohChangLee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The short-wave infrared (SWIR) region, which indicates light in the 1.4 to 3 um wavelength range, is utilized in various fields such as bio-imaging, telecommunication, and surveillance. However, there has been limited research on the light emission characteristics in the SWIR region using heavy-metal-free colloidal quantum dots. Light Detection and Ranging (LiDAR) is a method that utilizes lasers to determine ranges by measuring the time it takes for the reflected light to return to the receiver. The use of colloidal quantum dots as light emitters in LiDAR can significantly reduce costs and enhance detection capabilities by leveraging the long wavelengths in the SWIR region.
Here, we successfully synthesized InAs/In(Zn)P/ZnSe quantum dots using a one-batch method, suppressing the vulnerability to oxidation, which is a common issue with III-V quantum dots. We controlled various parameters such as initial volume, injection rate, ligand, and temperature to create quantum dots that emit light in the SWIR region. The resulting quantum dots exhibited emission at 1550 nm in the SWIR region. Notably, these quantum dots achieved a photoluminescence quantum yield (PLQY) of 3% at a wavelength of 1400 nm, which represents the highest reported value thus far. To gain insights into the carrier dynamics, we conducted ultrafast time-resolved photoluminescence and transient absorption spectroscopy experiments. These investigations revealed energy variations attributed to the mid-shell gradient alloy and suppressed Auger recombination within the quantum dots. Moreover, the formation of an outer shell on the InAs quantum dots confirmed the passivation of interfacial traps.
Overall, these findings contribute to the development of heavy-metal-free colloidal quantum dots with excellent performance, particularly in the SWIR region at 1550 nm, where the Auger recombination is effectively suppressed. This research provides valuable insights into SWIR region emissions using colloidal quantum dots, furthering the understanding and application of these materials.

Tuning the Energy Flow in Halide Perovskite-Molecular Hybrids AkshayaChemmangat, JishnuChakkamalayath, JeffreyDuBose and PrashantKamat; University of Notre Dame, United States

The flow of energy and electron transfer processes in semiconductor nanocrystal based light harvesting assemblies is governed by the nature of the excited state interactions. Surface interaction of chromophore or redox active molecule with semiconductor nanocrystals dictate the efficiency of photoinduced energy/electron transfer processes. Metal halide perovskite nanocrystals are interesting in the sense that they can either transfer singlet or triplet energy, or selectively transfer electrons or holes to the adsorbed molecules. The presentation will show how one can direct the flow of energy to achieve desired results in a semiconductor-molecular hybrid assembly. The presentation will focus on two specific scenarios of the flow of energy and electron processes in $CsPbBr_3$ nanocrystal-molecular hybrids. The energy transfer is probed through three moleculr acceptors – rhodamine B (RhB), rhodamine isothiocyanate (RhB-NCS), and rose Bengal (RoseB), which contain an increasing degree of heavy atom pendant groups. When interacting with $CsPbBr_3$ as an energy donor, photoluminescence excitation spectroscopy reveals that singlet energy transfer occurs with all three acceptors. The acceptor functionalization directly influences several key parameters that dictate the excited state interactiCsPbI3) is employed as a sensitizer we observe triplet energy transfer to RoseB and other rhodamine dyes. A basic understanding of the fundamental differences between the two excited deactivation processes (energy and charge transfer) and ways to modulate them should enable design of more efficient light harvesting assemblies with semiconductor and molecular systems.

SESSION EL10.08: Poster Session II

8:00 PM EL10.08.01
Heat-Up-Assisted Precursor-Conversion Synthesis of Ultra-Monodisperse Perovskite Colloidal Nanocrystals JigeonKim[1], YounghoonKim[2] and Min JaeKo[1]; [1]Hanyang University, Korea (the Republic of); [2]Kookmin University, Korea (the Republic of)

Colloidal quantum-confined semiconducting nanocrystals are extraordinarily unique photo-active materials, with electronic energy structures, such as optical bandgap energy, that can be tailored by altering their size and dimensionality. Among them, lead halide perovskite nanocrystals (PNCs) have exhibited superior light-harvesting and emitting features, owing to their exceptional optical, photophysical, and optoelectronic properties. Therefore, the PNCs have been extensively studied for their optoelectronic applications such as solar cells, photo-detectors, and light-emitting diodes. Traditionally, the PNCs have been easily prepared at laboratory scale through precursor-injection synthetic methods such as hot-injection methods and ligand-assisted reprecipitation methods. However, the precursor-injection synthetic methods, using highly reactive ionic-salt-type precursor solutions, induce various synthetic variables such as temperature and precursor concentration gradients, leading to the inseparable and unmanageable nucleation and growth process. In this study, we design a precursor-conversion synthetic approaches to homogeneously control the nucleation and growth mechanism of $CsPbX_3$ PNC crystallizations by using the heat-up methods. In this approach, the highly monodisperse $CsPbX_3$ (X = Cl, Br, I) PNCs can be successfully synthesized by supplying halide reactants through S_N2 reactions of various haloalkanes in homogeneously blended precursor solutions(denoted as heat-up PNCs). The heat-up synthetic approaches accelerate the halide conversion rates by promoting the S_N2 reactions, and thereby lead to the crystallizations of photo-active $CsPbX_3$ crystal phases, suppressing the undesired production of photo-inactive and halide-deficient Cs_4PbX_6 phases. During the heat-up process, we monitored the production yield of

halide reactants and the nucleation and growth mechanism along with the increasing reaction temperature. Through this observation, we found that the nucleation and growth stages could be separated in the heat-up process and the heat-up $CsPbX_3$ PNCs are size-focused into highly narrow size distribution during diffusion-controlled growth. The size and dimensionality of the heat-up PNCs can be easily tuned by precisely adjusting the precursor feeding ratios. Furthermore, the heat-up approaches enable the synthesis of $CsPbX_3$ PNCs with diverse halide compositions by promoting the S_N2 reactions of various haloalkanes. As a result, ultra-monodisperse heat-up $CsPbX_3$ PNCs are obtained through the S_N2-based heat-up synthetic approaches, and their high monodispersity and optical features are maintained even in large-scale synthesis.

Gate Tunable High-Performance Broadband Phototransistor Based on Organic-Inorganic Vertical Heterojunctions SourabhPal, RajinderS. Deol, ReemAlshanbari, MeganNoga, OliverA. Durnan, VikrantKumar and IoannisKymissis; Columbia University, United States

In recent times broadband photodetectors find widespread applications in environmental surveillance, optical imaging, spectroscopy, and sensing. A remarkable photodetection performance over a broadband spectral range can be successfully achieved through two primary methods. The first approach involves the utilization of semiconductor materials with broad detection ranges. However, the selection of suitable broadband photoabsorbing materials, especially inorganic ones, is often limited. The second commonly adopted method is the development of hybrid systems by combining nanomaterials with distinct photoabsorption bands, thereby achieving a heterostructured system with a broad photodetection range. Amorphous Indium Gallium Zinc Oxide (a-IGZO) is one of the most widely researched oxide semiconductors owing to its high carrier mobility, good uniformity, and facile synthesis process.[1] However, as an active photosensitive material, a-IGZO also has its own limitation such as the large bandgap (~ 3.3 eV) leading to its limited light absorption capability and response to long-wavelength light.[2] On the other hand, organic semiconductor materials have garnered significant attention in the field of optoelectronics due to their favourable intrinsic properties, together with the simple and easy synthesis processes, making them cost-effective for large-scale fabrication. One promising area of exploration involves the utilization of organic-inorganic heterostructures, which combine the optoelectronic attributes of both constituent materials. This novel device structure allows for synergistic advantages, enabling extensive applications in the fields of electronics as well as optoelectronics.[3] Herein, we report a high-performance broadband phototransistor exploiting the concept of organic-inorganic heterostructure, in which conjugated polymer J71:ITIC with narrow band gap is used as a visible photosensitizer, whereas a-IGZO with high mobility acts as conducting channel as well as active UV sensing material. The favourable energy band alignment between J71:ITIC and a-IGZO effectively contributes to the high-efficiency separation of photogenerated carriers across the interface, resulting in ultrahigh photoresponsivity of $\sim 10^4$ A/W and specific detectivity of $\sim 10^{14}$ Jones at an applied gate bias of ~ -7.5 V for incident light illumination of ~ 680 nm together with an adequate UV photoresponse owing to the UV light sensitivity of active channel layer. These results validate that the fabricated J71:ITIC/a-IGZO heterostructure based phototransistor can be an ideal prototype for the next-generation broadband photodetection applications.

Triplet Energy Transfer from CdS QDs Enhances Organometallic Eu(III) Emission TingtingHuang[1], ShengHe[2], TianquanLian[2] and MingLeeTang[1]; [1]The University of Utah, United States; [2]Emory University, United States

Europium (III) complexes are of interest for bioimaging because of their long-lived, narrow emission in the visible and near-IR wavelengths. Since the direct absorption of light by Eu^{3+} ions is intrinsically poor, the photoluminescence (PL) intensity for Europium (III) complexes are usually low. Their PL quantum yield is improved by coordinating ligands that absorb photons. These coordination ligands are usually excited to their singlet state. Intersystem crossing to the ligand triplet state allows for energy transfer to the central Eu^{3+} ions. Therefore, excitation of the ligands requires high-energy photons and only UV light can be used. Here, we show for the first time that quantum dots (QDs) can serve as triplet photosensitizers for Europium (III) complexes. We make use of the high extinction coefficients of CdS QDs for excitation after 400nm. Energy transfer occurs through a dark triplet state, eliminating the need for high-energy photon excitation. 1-Napthoic acid (1-NCA) is used to enhance energy transfer because its triplet state is higher than $^5D_0$ state of Eu^{3+}(2.16eV) and lower than QDs' band edge. 1-NCA is critical in mediating the energy transfer between QDs and the Europium (III) complex. Transient absorption spectroscopy confirms triplet energy transfer between QDs, mediator, and Eu{(+)-facam}$_3$. The Eu(III) photoluminescence quantum yield is enhanced up to 21.4 times, the highest value reported in literature.

Surface Passivation of Blue-Emitting Perovskite Nanoplatelets using Polysalt Ligand Complexes UnaisahVorajee, SelinDonmez, SisiWang and HediM. Mattoussi; Florida State University, United States

Colloidal $CsPbBr_3$ nanoplatelets (NPLs) exhibit blue and narrow photoluminescence emission, which makes them highly promising for use in applications such as light-emitting diodes. However, these materials tend to be colloidally and structurally unstable under normal storage conditions. In addition, the presence of surface defects increases the exciton nonradiative recombination rates for as-grown nanocrystals, resulting in modest to small photoluminescence quantum yields (PLQYs).
In this presentation, we detail the use of a set of Br-based polysalt-complexes as stabilizing ligand-complexes that enhance the PLQY while preserving the morphology and the crystal structures of these NPLs. More precisely, we find that while application of the polysalts (made of imidazolium or ammonium bromide motifs and solubilizing alkyl chains) alone can improve the PL, it also tends to progressively etch the NPL surfaces and damages their structural integrity. In contrast, mixing bromide-based salts, namely $PbBr_2$, $SnBr_2$, $CoBr_2$, $MnBr_2$, and $ZnBr_2$, with the polymer prior to ligand substitution forms polymer-complexes, which promote electronic passivation and simultaneously impart morphological stability to the NPLs. Optical and spectroscopic results show a PL enhancement of about one order of magnitude measured compared to as-grown NPLs, with high color purity profiles at 460 nm. Furthermore, structural characterization and monitoring of NPL dispersions over time have proved long-lasting colloidal stability together with preserved structural integrity of these materials.

Engineered Hybrid Organic-Inorganic Perovskite/Ag Contact for Preventing Ag Diffusion using Buffer Barriers Ji MyeongYu, YunhwaHong, SeokgiKim, SungkyuKim and KwangHeo; Sejong University, Korea (the Republic of)

CH_3NHPbI_3($MAPbI_3$), one of the organic-inorganic halide perovskite materials, has attracted strong interest in various optoelectronic devices due to its high absorption coefficient, tunable band gap, and fast charge transport. [1] However, halide perovskite not only causes reliability issues in temperature and humidity environments but also is decomposed into $CH_3NH_3^+$ and PbI_3 by an electron-induced reduction reaction at the metal/$MAPbI_3$ interface. [2] Although various candidates such as oxide thin films, 2D perovskites, and polymers were proposed as protective layers to prevent the deformation of $MAPbI_3$, [3] the effects of diffused metal ions on structural deformation and phase transition in the metal/$MAPbI_3$ contact have not been clearly understood yet.
Here, we directly confirmed the diffusion of metal ions and phase deformation in Ag/$MAPbI_3$ contact using transmission electron microscopy and energy dispersive x-ray spectroscopy. The PbI_3 phase is formed in the $MAPbI_3$ matrix contacted with metal and gradually transformed into PbI_2 and I^- due to Gibbs free energy, which is confirmed by diffracted peaks of the PbI_2 phase at 12.6°, 28.2°, and 29.4°. Furthermore, thermodynamically stable Ag-I bonding is generated by energy barrier, forming an AgI interfacial layer at the Ag/$MAPbI_3$. Because non-protective $MAPbI_3$ with the damaged surface shows reduced grain size by 20% and the formation of deep pinholes, we inserted various protective layers to passivate the surface and maintain the $MAPbI_3$ matrix. In order to prevent penetration of Ag, SnO_2 thin films with a thickness of 30 nm were deposited onto $MAPbI_3$ by atomic layer deposition. Because anions of the SnO_2 precursor are bonded with the most reactive MA^+ at the early stage, only hexagonal and orthorhombic PbI_2 phases were identified in the as-deposited structure. The physically deposited C_{60} layer with a 30 nm thickness damages the $MAPbI_3$ matrix, resulting in the formation of PbI_2 phases and a 15% reduction in the grain size of $MAPbI_3$. PMMA of the 30 nm thickness was coated on the $MAPbI_3$ layer for surface protection and prevention of diffused Ag ions. The penetrated Ag ions through the PMMA layer generate AgI phase inside the $MAPbI_3$ matrix though the $MAPbI_3$ was effectively protected for 30 days without the formation of PbI_2 phase. Two types of structures composed of C_{60} and PMMA are suggested for the anti-diffusion barrier and passivation layer, respectively. Although the C_{60}/PMMA bilayer structure effectively prevents the formation of PbI_2 and AgI phases for 50 days, the grain size of $MAPbI_3$ decreased by 5%. Compared to the bilayer structure, $MAPbI_3$ matrix protected by C_{60}-PMMA complex is well maintained in its original structure even after 60 days without phase deformation and grain shrinking. Because the uniform and cohesive hydrophobic PMMA film not only effectively protects the $MAPbI_3$ structure but also the diffusion of Ag ions is controlled by the C_{60} layer, our findings suggest advanced buffer layers to protect the surface of $MAPbI_3$ and prevent structural deformation caused by metal diffusion in various metal/$MAPbI_3$ contact.

Self-Healable Quantum Dot/Polymer Composite Film for Quantum Dot Light-Emitting Diodes Ji SuKim and Dae-HyeongKim; Seoul National University, Korea (the Republic of)

Highly stretchable, self-healable material engineering is key for next-generation stretchable light-emitting devices. Despite recent progress in intrinsically stretchable materials for light-

emitting layer (EML), the formation and propagation of irreversible cracks on the EML remain a significant challenge, leading to rapid device failure. Here we report material design of self-healable and stretchable quantum dot (QD) based EML for stable and stretchable quantum dot light-emitting diodes (QLEDs). We fabricated a homogeneous ternary composite film by blending QDs, self-healable elastomer, and a semiconducting polymer. Upon optimization of the composition, the composite film exhibited autonomous self-healing ability at room temperature, and high stretchability while the optical properties of QDs remained intact. The resulting intrinsically stretchable QLED with self-healable EML demonstrated enhanced stability under repeated deformations.

8:00 PM EL10.08.07
Bright Visible Luminescence of Dimethylformamide-Stabilized Niobium Oxide Nanoparticles ShoheiMurotani, AkitoMizobata, MoegiNomura, HonamiIguchi, MahitoYamamoto, YasushiObora and MitsuruInada; Kansai University, Japan

Inorganic metal oxides are expected to be candidates for new functional materials because they exhibit a wide variety of physical properties. For transition metal oxides, slight differences in structure, composition, and oxidation state can cause completely different physical properties, due to the flexibility of their crystal structures and the diversity of their electronic structures. While it is well known that nanostructures exhibit different physical properties than bulk materials due to quantum size and surface effects. Therefore, metal oxide nanoparticles are suitable for novel functional materials. However, it has been difficult to synthesize nano-sized particles of niobium because of its easy oxidation and aggregation.
Recently, we have succeeded in synthesizing niobium oxide nanoparticles (Nb NPs) with a particle size of less than 4 nm by DMF reduction method. The surface of the Nb NPs is terminated with DMF molecules, which is extremely stable and has excellent re-dispersibility in water and alcohol solvents. We have modified the surface of the nanoparticles by adding chlorides. We compared the physical properties of the nanoparticles with and without the addition of chlorides: XPS and XANES analyses showed that the addition of chlorides resulted in a lower average oxidation state of niobium. The both Nb NPs with and without chloride additive showed bluish-white luminescence in the visible light range, but the nanoparticles with chloride additive showed a larger luminescence intensity. The broad emission spectrum could be divided into about four emission origins. As the concentration of nanoparticles in solution was increased, the peak emission wavelength was red-shifted. This shift was due to Förster-type resonant energy transfer. A light emitting device was fabricated by using Nb NPs. The EL devices showed different emission colors depending on the materials in contact with the nanoparticles: red emission was obtained for the Al/p-Si/Nb NPs/ITO structure and blue emission was obtained for the ITO/PEDOT:PSS/Poly-TPD/Nb NPs/TPBi/Al structure. These results suggest that the EL mechanism and origin can be controlled by the interface conditions between Nb NPs and the electron (hole) transport layer.

Development of Highly Fluorescent Copper and Silver Chalcogenides for SWIR Imaging via Surface Control YidanSun[1], XingjianZhong[2,1] and AllisonM. Dennis[1]; [1]Northeastern University, United States; [2]Boston University, United States

Ag_2S nanoparticles are promising candidates as short-wave infrared (SWIR) imaging agents due to their low toxicity, high photostability, small size, and tunable fluorescent properties in the second near infrared biological window (NIR-II). They have been widely studied for preclinical imaging with high resolution and signal-to-noise ratio. However, Ag_2S nanoparticles suffer from potential heavy-metal toxicity as well as poor fluorescence efficiency due to surface defects. To overcome these limitations, we are optimizing Ag_2S surface treatments while also investigating alternative heavy-metal-free compositions like Cu-based nanocrystals. While copper sulfide nanocrystals are more commonly known for their localized surface plasmon resonance behavior, recent research shows that stoichiometric Cu_2S nanocrystals fluoresce with a peak between 900 to 1100 nm; more effort is needed to optimize their fluorescence properties and stability. A common factor influencing the photophysical behavior of nanoparticles is their surface properties, including the presence of surface defects and the ligands at the interface between the nanoparticle and the surrounding media. Energy transition processes are highly correlated with these interfacial interactions, impacting both radiative and non-radiative recombination and thus photoluminescence. By modifying the ligand coating and shelling, nanoparticles can be protected from defect-derived nonradiative relaxation and energy loss during interaction with the environment.
In this study, we synthesize fluorescent Ag_2S and Cu_2S nanoparticles and manipulate their optical properties through surface treatment. We explore the impact of different shelling and ligands on surface traps, stability, and optical properties. Enhanced fluorescence intensity of Ag_2S demonstrates the removal of surface defects, while surface treatment of Cu_2S reduces surface oxidation, preventing the shift from fluorescent to plasmonic nanocrystals. By acknowledging the impact of surface conditions on nanoparticle behavior, we can pursue the deliberate design of high-quality contrast agents for SWIR imaging.

Photocatalytic Properties of Perovskite Quantum Dots and Their Role in the Degradation of Alkyl Halide Molecules SelinDonmez, SisiWang and HediM. Mattoussi; Florida State University, United States

Since the first successful implementation of solution phase growth of colloidal cesium lead halide perovskite nanocrystals (PNCs), interest in these materials has steadily grown. This has been driven by their unique photophysical properties and the ionic nature of the semiconducting cores. One of the most interesting properties of PNCs is the ability to forego anion exchange reactions with the surrounding medium, which offers an alternative route for tuning the photophysical properties of these materials.
We present a detailed study on the photo catalytically assisted anion exchange reaction of $CsPbBr_3$ PQDs dispersed in alkyl chloride solutions. We found that electron transfer from photoexcited PNCs to the surrounding alkyl chloride molecules triggers their electrochemical degradation which produces alkyl radicals and reactive Cl^- anions in the medium. The resulting reactive chlorides engage in halide exchange reaction with the PNC cores, resulting in blue shift in the absorption and PL emission properties of the samples. We probe the efficiency of the reaction by varying the nature of the photoexcitation source (e.g., laser source vs UV reactor or sunlight) and the relative reduction potential of the alkyl halide molecules used. We supplement our findings with thorough characterization of the nanocrystal intermediates to track changes in the crystal structure and stoichiometry during irradiation, using optical and fluorescence spectroscopy, powder X-ray diffraction and x-ray fluorescence spectroscopy. These findings bode well for testing the photocatalytic properties of PNCs in general and may have implications in the degradation of chlorinated molecules.

8:00 PM EL10.08.10
Doping Colloidal Quantum Dots MarissaMartinez and MatthewC. Beard; National Renewable Energy Laboratory, United States

Doping has been an important method for tuning semiconductor electronic and optical properites, yet doping quantum dots (QDs) still presents a challenge. Herein, we report a facile method to dope PbS, CdSe, and $CsPbBr_3$ quantum dots with Ag, Na and Bi using ligand chemistry. Adding a solution of the metal oleates to a QD solution produces a bleach in the QD exciton absorption in the UV-VIS spectrum, and a intraband absorption in the FTIR. We found a higher free-carrier conductivity in solution-doped coupled QD films, compared to as-synthesized, using sheet resistance measurements. This study demonstrates the ability to dope QDs in solution while maintaining colloidal stability and increasing conductivity of the QD solids.

8:00 PM EL10.08.11
Spatial Composition Tuning of Colloidal NiMgO Hole Transport Materials for All-Inorganic Quantum Dot Light-Emitting Diodes Woon HoJung[1,1], Byong JaeKim[1,1], JisuHan[1,1], JaehoonLim[1,1], YeonghoChoi[1,1], Yong WooKwon[1,1] and HyeonjunLee[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Rapid progress in the device performance of colloidal quantum dot (QD) based light-emitting diodes (QD-LEDs) proposed the new technical opportunity for next-generation displays. Beyond the premise of QD-LEDs in displays, scientists in this field are now looking forward to realizing brighter and robust lighting sources based on QDs, previously achieved solely by inorganic LEDs and lasing technologies. Unfortunately, the state-of-the-art QD-LEDs employing the hybrid device architectures, organic hole transport layers (HTLs) and inorganic electron transport layers (ETLs), seem to be incapable of the direction toward high power devices due to limited hole conductivity and thermal instability of organic HTLs. This intrinsic demerit of organic HTLs naturally calls for the development of inorganic HTLs featuring enhanced hole conductivity and stability. Among various candidates, nickel oxide (NiO_x, $x < 1$) has gained attention due to its wide band gap and p-type conductivity granted by Ni vacancy (V_{Ni}). However, prior attempts to implant NiO_x in QD-LEDs have exhibited suboptimal performance due to the large hole injection barrier and difficulty to match electrical property of ETL counterparts.
To address the disparity of valence band maximum (VBM) and conductivity of NiO_x to typical ETLs, herein, we propose the colloidal NiMgO nanocrystals (NCs) with spatially controlled Mg content. The NiMgO NPs was synthesized by co-condensation of $Ni(OH)_2$ and $Mg(OH)_2$ at elevated temperature. X-ray photoelectron spectroscopy (XPS) and photoemission yield spectroscopy (PYS) confirmed that the incorporation of Mg to the Ni–O lattice increased the amount of V_{Ni} *within and on* the NCs, and lowered VBM position. We verified that the internal Mg content was limited to ~2% and residual $Mg(OH)_2$ coordinated to V_{Ni} sites on NCs. Interestingly, V_{Ni} on NCs' surface had a marginal effect on the hole concentration but significantly suppressed hole mobility by an order of magnitude. Maneuvering the spatial Mg content, we successfully optimized NiMgO NCs to minimize the energy offset between the VBM of NiMgO and the $1S_h$ state of QDs, and to achieve suitable hole mobility similar to that of ZnMgO ETLs. This optimization was also beneficial to reduce photo-induced hole transfer from QDs to NiMgO that was identified as a serious efficiency-limiting process at NiO_x–QD junctions. All-inorganic QD-LEDs employing our NiMgO HTLs exhibited a record peak efficiency of 16.3% and T_{50} of 382,239 hr (at 100 nit), surpassing previous benchmarks. Our achievement highlights the potential of inorganic HTLs in paving the way for high power QD-LEDs in the future.

8:00 PM EL10.08.12

Effect of Charge Transfer to Quantum Dots on Electroluminescence HyeonjunLee[1], Yong WooKwon[2], HyunjinCho[1], Doh C.Lee[1] and JaehoonLim[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Recently, quantum dot light-emitting diodes (QLEDs) have extensively utilized electron transport layers (ETLs) based on the metal oxides such as ZnO, which stands out for their high performance in QLEDs. Despite the successful implementation of metal oxide-based ETLs, there is still a puzzle surrounding how they effectively drive QLEDs. Previous studies have primarily attributed this advancement to the modification of energy levels within the ETLs. However, despite the energetic considerations, several reports on metal oxide-based QLEDs have shown driving voltages lower than the optical bandgap of quantum dots (QDs). Additionally, the efficiencies of QLEDs often surpass the theoretical limit dictated by the emissive probability of neutral QDs. This intriguing finding suggests the existence of a concealed mechanism behind the performance improvement of QLEDs.
In this study, we demonstrate that the charge transfer between ZnO-based ETLs and QDs not only affects the energy alignment of QDs in QLEDs but also influences their optical properties. The study for ultraviolet photoelectron spectroscopy represents the overall energy landscape of QLEDs being rearranged centered on the surface states of QDs. The consequence of charge transfer from ZnO-based ETL to the QD surface increases the work function of QDs, providing electrostatic potential gain for hole injection. The spectrally-resolved photoluminescence and electroluminescence results show that carriers injected into individual QDs regulate the injection rate of opposite carriers through Coulombic interaction. By carefully assessing the carrier occupation in QDs, we are able to quantify the emissive probability of QDs on metal oxides. The transfer of electrons from the metal oxides to QDs electrically passivates the surface trap states on QDs, thereby increasing the emissive probability of QDs. The electrobrightening of QDs by metal oxide ETLs pushes the efficiency envelopment of QDs by surface defects.
Our series of analyses indicate an oversimplification in considering the QD ensemble as a single emitter and the ligand-passivated surface as a mere insulator within QLEDs. From a practical perspective, we emphasize the importance of considering individual QDs as discrete emitters and the optoelectronic changes resulting from charge exchange. We believe this consideration would pave the way for the design of efficient QLEDs.

8:00 PM EL10.08.13
Characterization and Optimization of Gold Nanoparticles Synthesized via Environmentally Benign Electrochemical Synthesis on Chitosan Layers HarjaisalS. Brar[1,2], DanielL. Lu[1,3], ClaireKang[1,4], JacobZerykier[1,5] and MichaelCuiffo[1]; [1]Stony Brook University, The State University of New York, United States; [2]Stockdale High School, United States; [3]Westview High School, United States; [4]Canyon Crest Academy, United States; [5]Massachusetts Institute of Technology, United States

Previously, palladium and other noble metal nanoparticles have been synthesized on chitosan-coated stainless steel [1][2]. These metal nanoparticles have been shown to have both antibacterial and catalytic properties. Finding ways to synthesize potentially catalytic noble nanoparticles (gold, palladium, and silver) while maintaining their stability under atmospheric conditions is an important goal of materials research. Electrochemically deposited chitosan layers on steel are used as an environmentally benign nucleation support structure for the creation of stable metal nanoparticles. Utilizing electrochemistry to create an abundance of activation sites on the chitosan structure, we have synthesized pure metal nanoparticles of gold.
1µm mirror finish 304 stainless steel purchased from McMaster-Carr was cut into 1 square inch samples (6.45 cm^2). The steel samples were ultrasonicated in deionized (DI) water for 10 minutes, briefly rinsed, and ultrasonicated for another 10 minutes in isopropyl alcohol to remove greases and other contaminants. The steel samples were then allowed to air dry and prepared for electrochemical deposition.
A chitosan solution with a concentration of 1.00 to 3.00 grams of chitosan per 120 mL DI water was prepared, and the pH was lowered to less than 5 by adding HCl dropwise to the solution. The solution was stirred overnight so that the chitosan could fully dissolve. A potassium gold (III) chloride solution with a concentration of 0.01 M was prepared in a volumetric flask using high purity (>18mΩ/cm) DI water.
Electrochemically deposited chitosan layers on steel are used as an environmentally benign nucleation support structure for the creation of stable metal nanoparticles. The steel samples were electrochemically coated with a layer of chitosan using controlled potential coulometry. A constant potential of -3.0 V was applied for 60-120 seconds. Each sample was air dried overnight. The chitosan-coated steel samples were used for electrochemical reduction of the gold (III) ions to synthesize nanoparticles on the chitosan layer at voltages ranging from -1.5 V to +1.5 V for 60-120 seconds in order to determine the optimized parameters for gold nanoparticle synthesis, as electrochemistry creates an abundance of activation sites on the chitosan structure. Once the process was complete, the samples were air dried overnight or placed in a vacuum chamber for several hours.
Various methods of analysis were employed to image and quantify the nanoparticles including Optical Microscopy, Scanning Electron Microscopy (SEM), Fourier Transform Infrared (FTIR) spectroscopy, X-Ray Fluorescence (XRF), Energy Dispersive Analysis by X-rays (EDAX), and cyclic voltammetry. It was also discovered that the nanoparticles created were protected by a thin film or coating of chitosan which prevented oxidation while maintaining viability for catalytic reactions and possibly antimicrobial and antibacterial applications [3]. Exposure to ultraviolet (UV) light following electrochemical deposition was found to enhance abundance and dispersion of nanoparticles formed. However, the amount of pure metal nanoparticles was found to decrease with exposure to UV light due to an increase in the formation of metal oxide nanoparticles. The elimination of trapped hydrogen gas bubbles formed during the cathodic polarization via heating was found to eliminate nucleation sites and lead to the formation of micron-sized clusters, oxides, and little to no pure gold metal. The surface of these mixed nanoparticles was found to be highly chemically reactive.
Future work will include X-Ray Photoelectron Spectroscopy (XPS) to determine the oxidation states of the nanoparticles and more experimentation with concentrations and voltages to optimize the parameters for electrochemistry.

8:00 PM EL10.08.14
Nearly 100% Radiative Lifetime Enhancement Through Polymer-Blend-Assisted Defect Passivation and Morphology Regulation in Inorganic Halide Peroskite LEDs ParvezAkhtar, RamanAggarwal, NidhiDua, HenamS. Devi, Md.S. Hassan and MadhusudanSingh; Indian Institute of Technology Delhi, India

All-inorganic halide perovskite light-emitting diodes (LEDs) exhibit color purity comparable to organic LEDs with significantly greater operational stability. However, owing to the rheological properties of inks of $CsPbBr_3$ with commonly used solvents such as dimethyl sulfoxide (DMSO) deposited on hole injection layers such as poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), formation of pinhole-free thin films is a challenge. Further, in the perovskite structures (ABX_3)[1], surface and grain-boundary defects play a critical role in determining transport and the degree of non-radiative energy loss. In this work, we report on the impact of the use of inexpensive polymers (poly(ethylene) glycol (PEG) and polyvinyl-pyrrolidone (PVP)) on passivating defect states in nanocrystalline $CsPbBr_3$. Precursors cesium bromide (CsBr) and lead bromide ($PbBr_2$) (in DMSO) were heated under vigorous stirring, and then optionally combined with the blend PEG:PVP in DMSO and dimethyl formamide (DMF) in a 1:1 ratio to form an ink[2]. X-ray diffraction (Rigaku, Cu-Kα 1.54Å) reveals an orthorhombic phase (ICDD 96-153-3063) with the stoichiometric composition confirmed using energy dispersive X-ray (EDX) analysis. Thin films of control ($CsPbBr_3$) and test ($CsPbBr_3$:PEG:PVP) formed with spin-coating exhibit different nanocrystallite sizes using field-emission scanning electron microscopy (FESEM, JEOL): ~204 nm (control) vs ~101 nm (test). The polymers are seen to assist in regulation of grain sizes, resulting in a narrower size distribution for the test film, and lead to a lower pinhole density (>99% coverage) in the test film vs control (<80% coverage) estimated using image processing techniques on FESEM scan data. However, owing to the increase of surface to volume ratio for the test film, we should expect an increased defect density, leading to a deterioration of the radiative efficiency. To investigate the impact on carrier lifetimes, we carried out time-resolved photoluminescence (TRPL) using time-correlated single-photon counting (TCSPC) with a pulsed laser (377 nm) (Edinburgh Instruments FLSP920). Interestingly, measurements and analysis using a bi-exponential model on the test thin film show a higher radiative lifetime (17.82 ns) vs control (9.10 ns). There is a nearly four-fold reduction in the relative strength of the nonradiative tail for the test sample when compared to control, with a ~4.5-fold enhancement in the relative intensities of measured photoluminescence. These results strongly suggest effective passivation of dangling bonds, grain boundaries, etc, which suggests potential Lewis acid-base interactions between Pb^{2+} and π-bonds in the polymer chains. This interaction was confirmed using a Fourier Transform Infrared (FTIR, Thermo-Fischer) spectrophotometer. Finally, LED devices (PEDOT:PSS/$CsPbBr_3$:PEG:PVP/2,2',2"-(1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole (TPBi)/LiF/Al) were fabricated using a combination of spin coating and thermal evaporation at a pressure 2.3 x 10^{-6} Torr (Angstrom Engineering, Evovac). Device characterization yields significant enhancement in electroluminescence (EL, green:518 nm, FWHM: 17nm) of test devices vs control in a manner consistent with the observed enhancement in PL. Briefly: peak brightness (7204 vs 2371 Cd/m^2), current efficiency (4.19 vs 0.54 cd/A) and efficacy (2.32 vs 0.29 lm/W), with a slight reduction in the turn-on voltage (2.9 vs 3.3 V), etc. can be attributed to effective defect-passivation despite a seemingly adverse increase in surface to volume ratio. Future work will involve quantification of any device lifetime changes arising from passivation of defects as we expect that the increase of current efficiency is likely to limit degradation of LEDs in demanding applications such as lighting, and high brightness displays.

Enhanced Interfaces for Higher Efficiency and Lifetime of Quantum Dot Light-Emitting Diodes JeonghunKwak, Geun WooBaek and TaesooLee; Seoul National University, Korea (the Republic of)

Owing to the superior optical properties of quantum dots (QDs), QD-based light-emitting diodes (QLEDs) are becoming established as the next generation of displays and light sources. In recent years, device performance has been steadily enhanced by improving the charge balance within the device as well as increasing the photoluminescence quantum yield of QDs. However, the light-emitting mechanism of QLEDs, the mechanism of carrier injection into QDs, and the factors affecting their operational lifetime are still not clearly understood. Research on these issues is crucial for the practical application of QLEDs. In this work, we show our recent research results on the influence of various interfaces on the efficiency and lifetime of the QLEDs, including the core/shell interfaces of QDs and the charge transport layer/QD interfaces.

Hydrodynamically-Modulated Dewetting of Colloidal Solution for Physical Unclonable Functions YeonginCho, JeongsuPyeon, HyoungsooKim and Yeon SikJung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Traditional methods of blocking counterfeiting are prone to detection by potential attackers. In response, Physical Unclonable Function (PUF) has emerged as an alternative security measure. PUF is a specialized function that leverages the inherent unpredictability of physical processes to yield unique responses to specific challenges. PUF offers hardware-based security, mitigating vulnerabilities inherent in software-based systems susceptible to hacking and signal jamming. Recent efforts have aimed to develop optical PUF labels using various randomness sources. These PUF's non-deterministic fabrication process ensures a substantial encoding capacity for robust data security. However, excessively disorderly PUF codes disseminated across the information space might exhibit a deficiency in possessing a distinguishing fingerprint key. Using random optical features for security keys mandates statistical image processing for digitization and key generation. Unfortunately, the processing of analog signals to digitized codes may compromise authentication accuracy resulting from an arbitrary threshold during an image analysis.
We tackle this by utilizing the geometric multi-bit patterning technique, manipulating dewetting of colloidal solution for advanced optical PUFs that exhibit both high randomness and determinism. By placing agglomerated dots of colloidal particles at a specific vertex within geometrically confined polygons, these two contrasting features can be provided to the PUF system through the hydrodynamic modulation of the dots as visual cues. Exploiting binary solvent flow unpredictability in confined spaces during dewetting, we fabricate sophisticated PUF labels in periodic pixel arrays. The fundamental principle stems from instability arising from imbalanced solutal-Marangoni flows in evaporating polygonal droplets. Importantly, the dynamic coating procedures have the capability to induce unforeseeable fluctuations in contact angles at every vertex during each coating iteration. These fluctuations perturbed the radial symmetry of the solutal-Marangoni flows within polygonal-shaped droplet, introducing randomness to the final PUF pattern—a phenomenon supported by statistical parameters. This pattern achieves an entropy of 0.977, a uniqueness value of 0.759, and a correlation coefficient of 0.009, all of which are close to the ideal values. It successfully passes the statistical test for random number generators conducted by NIST (National Institute of Standards and Technology), confirming its true randomness, unpredictability, and unclonability. These random PUF labels with quantized signals at deterministic sites enable efficient, accurate, and swift authentication in both encoding and decoding. They also offer reconfigurability, transferability to diverse surfaces, and the potential for enhanced security through fluorescent molecule dyeing.

8:00 PM EL10.08.18
Silica-Encapsulated Quantum Dots with Thiol Ligand Exchange for High Thermal and Photo-Stability Against Moisture Yoon-JeongChoi, Jeong-YeolYoo and Byung DooChin; Dankook University, Korea (the Republic of)

Colloidal quantum dots (QDs) have attracted attention in various fields including light emitters for the next-generation display due to their high photoluminescence quantum yield (PLQY) and excellent color purity.[1] However, their low stability under harsh conditions, such as exposure to heat and oxygen, limits their wide-scale applications. Barrier films for QD-sheet are widely used but are expensive and dimensionally less effective. Encapsulation of QDs with silica is regarded as one of the reasonable surface modification methods, which has many advantages such as optical transparency, excellent chemical/mechanical stability, and ease of making chemical modifications.[2] The encapsulation of QDs with silica is based on the use of a silane precursor in a solution containing water, ethanol, ammonia, and amines. However, general QDs are extremely sensitive to their surrounding environment and undergo quenching at these solution conditions. As a result, the development of a waterless silica coating method has become a new strategy.[3,4] Using the waterless method, the thickness of the silica shell can be controlled by the catalyzed hydrolysis and condensation of silane precursors and requires initial surface modification of the QDs with a silane source followed by condensation on the QD surface. However, the QDs often exhibit decreased quantum efficiencies. To address this issue, a reverse microemulsion method has been applied to facilitate the formation of silica-encapsulated QDs.
In this study, red-emitting QDs were coated with silica to enhance their thermal and photo-stability via a two-step involving ligand exchange and a reverse microemulsion method. Especially, native oleic-acid-capped hydrophobic QDs were substituted with strongly binding thiol-functionalized ligands, namely, (3-mercaptopropyl) methyldimethoxysillane (MPMDMS). Then, partially-MPMDMS ligand-exchanged-QDs (MQDs) were coated with silica ,and additional ligand substitution reaction with hydrophilic properties ligands such as 3-mercaptopropionic acid were conducted to enhance the incorporation of the QDs in the reverse microemulsion system. The final silica-coated QDs obtained using these two steps showed only a 6-13% reduction in their PLQYs after UV irradiation and upon high-temperature exposure for 7 days, compared to that of the untreated QDs showing a huge drop of 72-80%. Through this research, we see the great potential of our work that QDs with high stability can be used in the color-conversion layer in various ways such as spin coating, inkjet printing, and film manufacturing, expecting significant enhancement of lifetime compared with pristine QDs.

Spinel Plasmonic Metal Oxide Nanocrystals, The Role of Antisite Occupation and Faceting on the Observed Plasmon Properties GeoffreyF. Strouse; Florida State University, United States

Plasmonic metals have been a rich area of research for over two decades, exhibiting shape and size dependent extinction spectra. In n-doped wide band gap metal oxide semiconductors, a plasmon feature (w_p) is observed due to the introduction of carriers. In these plasmonic semiconducotr nanocrystals (PSNC), the plasmon frequency and spectral shape are correlated with the number of free carriers (n) at the Fermi level, the carrier effective mass (m*), and the faceting of the metal oxide nanocrystal. The stability of the free carrier in these materials is impacted by the nature of the surface passivation. Solid state NMR, high field EPR , and optical techniques allow the free carrier to be probed, the carrier mass measured, and the impact of faceting and surface interfaces to be evaluated. In the presentation, the role of surface, shape, faceting magneto-optical and synthetic approaches to address fundamental questions in classical oxygen vaccancy PSNCs WO_{3-x} , and spinel antisite PSNCs $CdSn_2O_4$ will be explored.

9:00 AM EL10.09.02
Thermal-Response of Promesogenic-Ligands Functionalized Nanocrystals ShengsongYang[1], YifanNing[1], Yi-YuCai[1], RuipengLi[2], YugangZhang[2], CherieR. Kagan[1] and Christopher B.Murray[1]; [1]University of Pennsylvania, United States; [2]Brookhaven National Laboratory, United States

Limited by the mobility of building units, assembled superstructures often lack dynamics, narrowing the potential for applications in smart materials. Here we introduce a novel approach using a specially designed dendritic ligand that exhibits liquid crystal-like behavior at the interface to enable the realization of dynamic superlattices. The ligands act as a thermally triggered lubricant between nanocrystals. It allows the substrate-bounded (dried) nanocrystal solids to transform from poorly ordered aggregates to superlattices with high crystallinity and preferred orientation simultaneously when subjected to thermal activation. With the help from *in situ* X-ray scattering, the process of the reorientation of the superlattices are revealed and the bottom-to top transition was observed. The superlattice also prefer to expose the most stable facet at the interface to the substrate.

Hydrosilylation on Hydrogen-Terminated Silicon Surfaces using Pt(dvs): From Efficient Grafting of Olefins to Platinum-Coated Silicon Nanoparticles for Catalysis PooriaGolvari, KhaledAlkameh, AzinaRahmani, TitelJurca and StephenM. Kuebler; University of Central Florida, United States

Hydrosilylation is an effective method for functionalizing the surface of hydrogen terminated Si substrates and Si nanoparticles (H-SiNPs). We report on the efficiency of Pt-catalyzed hydrosilylation using Karstedt's catalyst on H-SiNPs and H-Si(100) surfaces. In contrast to the well-established catalytic cycle for the hydrosilylation of olefins using tertiary silanes, we observe that the addition of Pt(0) onto H-SiNPs through oxidative addition is irreversible at room temperature. Optimal reaction conditions are reported for effective hydrosilylation of 1-octene. Higher temperature enable hydrosilylation of 1-octene on the surface of H-SiNPs by favoring reductive elimination of the catalyst. Trapping the catalyst at low temperatures opens a route for the synthesis of Pt(II)-loaded SiNPs that can undergo ligand exchange. Pt-on-Si ensembles were analyzed using Fourier-transform infrared spectroscopy, X-ray photoelectron spectroscopy, transmission electron microscopy, energy-dispersive X-ray spectroscopy, and atomic force microscopy. Calcination renders Pt-on-Si nanostructures catalytically active towards hydrogenation of phenyl acetylene. These robust Pt nanocatalysts are anchored on SiNPs which enables their facile recovery and reuse through centrifugation or filtration.

9:30 AM *EL10.09.04
Polymers on Metal Nanoparticles—Deficient Ligand Exchange and Site-Specific Grafting JieHe; University of Connecticut, United States

Symmetry-breaking nanoparticles (NPs) are important building blocks showing directional interparticle interaction as a key that enable precise macroscopic organization of NPs. We demonstrate a facile post-synthetic approach to prepare symmetry-breaking plasmonic NPs through deficient ligand modification. Our research highlights the patterning of isotropic gold spherical NPs (AuNPs) or anisotropic nanorods (AuNRs) with controlled surface coverage by polymer domains. The concentration of thiol-terminated polystyrene (PS-SH) ligands plays a dominant role in tunning the surface patterns through hydrophobicity-driven phase segregation. Through a gradual reduction in the concentration of polymer ligands, a distinct morphological transition from core-shell structures to site-specific grafting of AuNPs and/or AuNRs is observed. This transition arises from the interplay between the conformational entropy of PS-SH ligands and the interfacial energy between polymer ligands and the solvent. The method we have developed shows high yield, high quality, and remarkable selectivity in a one-step process for modifying NPs with polymer domains at precise locations. These polymer-patched NPs, serving as fundamental building blocks, exhibit controlled supracolloidal self-assembly as guided by polymer ligands.

Advancements in Synthesis and Multicomponent Superlattices of Highly Luminescent Lead Halide Perovskite Nanocrystals MarynaBodnarchuk[1,2], IhorCherniukh[1,2], TarasSekh[1,2], AlexTravesset[3], RainerMahrt[4], ThiloStoeferle[4], GabrieleRaino[2,1], RolfErni[1] and MaksymV. Kovalenko[2,1]; [1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland; [3]Iowa State University of Science and Technology, United States; [4]IBM Zurich, Switzerland

Colloidal lead halide perovskite nanocrystals (LHP NCs, $APbX3$, where A=Cs^+, FA^+, FA=formamidinium; X=Cl, Br, I) have become a research spotlight owing to their spectrally narrow (~100 meV) fluorescence, tunable over the entire visible spectral region of 400-800 nm, as well as facile colloidal synthesis. These NCs are attractive single-photon emitters and building blocks for creating controlled, aggregated states exhibiting collective luminescence phenomena. Attaining such states through the spontaneous self-assembly into long-range ordered superlattices (SLs) is a particularly attractive avenue. The atomically flat, sharp cubic shape of LHP NCs is also of interest because the vast majority of prior work had invoked NCs of spherical shape. Long-range ordered SLs with the simple cubic packing of cubic perovskite NCs exhibit sharp red-shifted lines in their emission spectra and superfluorescence (a fast collective emission resulting from coherent multi-NCs excited states).
When $CsPbBr_3$ NCs are combined with spherical dielectric NCs, perovskite-type ABO_3 binary NC SLs form, wherein $CsPbBr_3$ nanocubes occupy B- and/or O-sites, while spherical dielectric Fe_3O_4 or $NaGdF_4$ NCs reside on A-sites. When truncated-cuboid PbS NCs are added to these systems, ternary ABO_3-phase form (PbS NCs occupy B-sites). Such ABO_3 SLs, as well as other newly obtained SL structures (binary NaCl, AlB_2- and ABO_6 types, columnar assemblies with disks, *etc.*), exhibit a high degree of orientational ordering of $CsPbBr_3$ nanocubes. These mesostructures also exhibit superfluorescence, characterized, at high excitation density, by emission pulses with ultrafast (22 ps) radiative decay and Burnham-Chiao ringing behavior with a strongly accelerated build-up time. Co-assembly of steric-stabilized $CsPbBr_3$ nanocubes with disk-shaped LaF_3 NCs yields six columnar structures with AB, AB_2, AB_4, and AB_6 stoichiometry, not observed before with NC systems comprising spheres and disks. Combining $CsPbBr_3$ nanocubes with large and thick $NaGdF_4$ nanodisks results in the orthorhombic SL resembling CaC_2 structure with pairs of $CsPbBr_3$ NCs on one lattice site. Additionally, we have also implemented two substrate-free methods of SL formation. The first method involves oil-in-oil templated assembly that leads to the formation of binary supraparticles, while the second method utilizes self-assembly at the liquid-air interface.

11:00 AM EL10.09.06
Type-I CdS/ZnS Core/Shell Quantum Dot-Gold Heterostructural Nanocrystals for Enhanced Photocatalytic Hydrogen Generation NaJin[1], YongleiSun[2], WenwuShi[3], PingWang[4], YasutakaNagaoka[1], TongCai[1], RongzhenWu[1], YuziLiu[5], TomoyasuMani[2], XinzhongWang[6], JingZhao[2] and OuChen[1]; [1]Brown University, United States; [2]University of Connecticut, United States; [3]Southwest University, China; [4]Jilin Normal University, China; [5]Argonne National Laboratory, United States; [6]Shenzhen Institute of Information Technology, China

The rapid industrialization has led to serious problems of environmental pollution and energy shortages, necessitating the need for exploring renewable energy sources that can be produced ecologically without further releasing pollutants, such as molecular hydrogen (H_2). Type-I core/shell quantum dot (QD) systems have been long recognized and utilized as efficient, stable, and sustainable light harvesting and emitting materials. Nevertheless, the application of Type-I core/shell QDs in photocatalysis has been restricted due to the strongly confined photogenerated charges within the core, making them catalytically “inert”. In this project, we found that through the decoration of Au satellite-type domains on the surface of Type-I CdS/ZnS core/shell quantum dots, the energy barrier introduced by the wide-bandgap shell material can be effectively overcome and an over-four-hundred-fold enhancement of the photocatalytic H_2 evolution rate was achieved compared to bare CdS/ZnS quantum dots. Transient absorption spectroscopic studies indicated that the charges can be effectively extracted and subsequently transferred to surrounding molecular substrates in a sub-picosecond timescale in such hybrid nanocrystals. Based on density functional theory calculations, the ultrafast charge separation rates were ascribed to the formation of an intermediate Au_2S layer at the semiconductor-metal interface, which can successfully offset the energy confinement introduced by the ZnS shell. Our findings not only provide insightful understandings of charge carrier dynamics in semiconductor-metal heterostructural materials but also pave the way for the future design of quantum dot-based hybrid photocatalytic systems.

PbS Nanocrystal Surfaces and Their Assemblies WilliamTisdale; Massachusetts Institute of Technology, United States

PbS quantum dots (QDs) have been widely pursued in applications ranging from solar cells to IR LEDs to photon up/down conversion systems and thermoelectrics. Despite their rich history we continue to learn new things about PbS QD chemistry, photophysics, and self-organization into ordered solids. In this talk, I will highlight recent work from my lab at MIT on the structure of PbS QD surfaces. In particular, I will demonstrate neutron scattering as a powerful emerging tool for the characterization of colloidal QDs and the detailed information that small-angle neutron scattering (SANS) can provide about the ligand layers surrounding QDs. Additionally, I will demonstrate the underappreciated role of unbound – or “free” – ligand in mediating the structure of self-assembled QD superlattices.

2:00 PM EL10.10.02
Extended Size-Tunable Synthesis of Gold Nanorods and its Application in Catalyst JunZhu and R.B. Lennox; McGill University, Canada

The role of silver ions in silver-aided seed-mediated gold nanorod (AuNR) syntheses has been investigated and the key silver intermediate which controls the AuNR aspect ratio (AR) was identified to be a CTA-Ag-Br complex. The CTA-Ag-Br complex has a characteristic UV absorption peak which enables an *in situ* spectroscopy study of the roles the silver has in AuNR formation. Previous assumptions have held that silver is only involved in the symmetry breaking of the seed growth step. However, this is the case only a small fraction of the silver present is involved in the process, whereas the AuNR aspect ratio (AR) can be controlled by varying the Ag:Au ratio. The current work however provides direct experimental evidence for the first time that the silver intermediate is consumed at the same rate as gold nanorod growth. The silver intermediate also plays an important role during the AuNR growth step and becomes a size-limiting reagent due to its limited solubility. However, addition of a limited quantity of acetonitrile (2% v/v) leads to a significant increase in the solubility of the silver intermediate, leading to AuNR with a greater range of characteristic AR values. The LSPR of the resulting AuNR can be increased from 880 nm (AR = 4.5) to 1200 nm (AR = 8). The catalytical property of the resulting AuNRs for nitrophenol reduction was tested and this reduction reaction showed AR dependant. This work provides new insight into the mechanism of seed-mediated growth of AuNRs as well as the synthesis of AuNRs having a greater AR range (1.5 - 8) using the same seed-mediated growth method. The catalytic property of AuNRs was also tested and gave insight for the catalytical active site on AuNRs.

2:15 PM EL10.10.03
Harvesting of Photons in a Broad Spectrum via Quantum Dot Integration in a Polymer Based Solar Cells IdrisCandan; Kocaeli University, Turkey

The narrow absorption range and the energy loss associated with the spectral mismatch of materials are among the main challenges in conventional solar cells. To use solar energy effectively, solar cells must absorb photons across a broad spectrum, from UV to IR. New approaches are required to enhance the power conversion efficiency (PCE) of solar devices. The main goal of this work is to increase efficiency by extending the absorption range and absorbing photons throughout a broad spectrum. We added a quantum dot (QD) thin film layer within the inverted polymer solar cell (IPSC) structure as a novel approach to accomplish broadband absorption and gather photons specifically toward the IR region for effective use of solar energy. The efficiency of the solar cell devices was much improved by sandwiching a thin layer of lead sulfide quantum dots (PbS QDs) between the photoactive polymer layer and the metal oxide

electron transport layer. The optical, structural, and morphological measurements were carried out using the transmission, absorbance, photoluminescence (PL), XRD, Raman spectroscopy, SEM and TEM measurements to characterize the PbS QDs thin film layer. Measurements of photoconductivity, Hall effect, external quantum efficiency (EQE), current-voltage (I-V), capacitance-voltage (C-V), and impedance spectroscopy were performed to ascertain the contribution of the PbS QDs thin film layer to the device parameters. The quantum dot thin film has greatly enhanced the parameters of solar cells, resulting in increases in power conversion efficiency (PCE). The PCE improvements were found to be largely dependent on the QD thin film thickness. Additionally, an increase in external quantum efficiency (EQE) was seen as carrier concentration and mobility increased. Our findings provide a novel approach for enhancing IPSC device parameters and the PCE by adding a QD thin layer to the solar cell architecture.

2:30 PM EL10.10.04
Solution-Processed Flexible Broadband Photodetectors XiongGong and TaoZhu; University of Akron, United States

Broadband photodetectors (PDs) with high detectivities are widely utilized in telecommunications, day/night surveillance, thermal imaging, interconnects, and medical instruments. Today, separate sensors or materials are required for different sub-bands within the ultraviolet (UV) to infrared (IR) wavelength (λ) range. To obtain the desired sensitivities, IR PDs must be operated at low temperatures (for example, at 4.2 K). Moreover, the PDs with different spectral response are required to be integrated together to cover the spectral range from 250 to 2600 nm. Therefore, it would be advantageous to have a solution-processed low-cost multicolor PDs with high sensitivity and highspeed response over the broad spectral range from the UV to IR and the PDs do not require cooling to obtain high detectivity. In this presentation, I will report room-temperature solution-processed photodetectors with spectral response from 300 to 2600 nm based on the solution-processed polymeric thin film electrodes, which is with transparency ranging from 300 to 7000 nm and superior electrical conductivity. Solution processed flexible broadband photodetectors with a “vertical” device structure incorporating a perovskite/PbSe quantum dot bilayer thin film based on the above solution-processed transparent polymeric electrode are demonstrated. The utilization of perovskite/PbSe quantum dot bilayer thin film as the photoactive layer extends spectral response to infrared region and boosts photocurrent densities in both visible and infrared regions through the trap-assisted photomultiplication effect. Operated at room temperature and under an external bias of -1 V, the solution-processed flexible photodetectors exhibit over 230 mA W-1 responsivity, over 10^{11} cm $Hz^{1/2}$/W photodetectivity from 300 to 2600 nm and ≈70 dB linear dynamic ranges. It is also found that the solution-processed flexible broadband photodetectors exhibit fast response time and excellent flexibility. All these results demonstrate that this work develop a facile approach to realize room temperature operated ultrasensitive solution-processed flexible broadband photodetectors with “vertical” device structure through solution-processed transparent polymeric electrode.
