Recently, bipolar dual-band photodetectors (BDPD) have been spotlighted for emerging applications such as optoelectronic logic gates and machine vision owing to their wavelength-dependent output signals. Compared to conventional unipolar photodetectors, BDPD devices provide clearly distinguishable spectral output signals based on opposite charge separation mechanism to verify the input optical information without further wavelength selection filters or multi-devices. This special ability of BDPDs offers higher device densities by reducing the number of unit components, and multi-functionality in a single optoelectronic device. However, challenges such as limited photo-active material combination or complicated device architecture to achieve opposite charge separation still limits the widespread use of BDPDs.
Herein, we present the wavelength-dependent bipolar photo-responsive organic/inorganic heterojunction photodiode based on dually stacked Schottky and pn junctions. The proposed BDPD was fabricated through a simple and cost-effective sequential spin-coating process. To generate oppositely charged two built-in electric fields, back-to-back diode system was demonstrated with only 4 stacked layers consisting of bottom ITO electrode, p-type fluorene copolymer (Poly(9,9-dioctylfluorene-alt-benzothiadiazole), F8BT), n-type tin-oxide (SnO_2) quantum dots (QDs) and transparent conductive polymer electrode (poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS)). Based on wavelength selective light absorption in Schottky and pn junctions, the proposed BDPD exhibited clearly distinguishable positive and negative photo responses in deep-ultraviolet (DUV) and visible blue wavelength. Finally, we demonstrated BDPD-based emerging applications including NOT, OR, and XOR optoelectronic logic gates, and true random number generation with arc discharge.

Organic Ligands Mediated Carrier Dynamics in Photochromic Nanoparticles AdamF. Gross, ShirellKlein, GregoryP. Rutkowski and ErikD. Crenshaw; HRL Laboratories LLC, United States

Photochromic materials are useful for glare reduction, optical switches, and laser dazzling protection. While many photochromics darken rapidly, their reversal to a clear state is governed by ambient temperature or a sequence of optical excitations. Slow detinting times limit their use in many applications where a rapid return to a clear state is needed for retaining visibility for safe operation or faster cycling rates. Photochromic Cu-doped ZnS nanoparticles were recently discovered where darkening occurs via the reversible oxidation of the dopant (J. Am. Chem. Soc. 2021, 143, 2239−2249; J. Phys. Chem. Lett. 2021, 12, 8129−8133). However, the detinting time depends on the concentration of environmental water and temperature to mediate the capture of a photoexcited hole. Instead of the environment regulating detinting times, ligand engineering can provide a more direct and controllable route to tune detinting. The nanoparticles' high surface area and small diameters enable placing hole traps on the surface that affect carrier dynamics; conjugated ligands trap photoexcited holes and return the material to a clear state. Control of the amount of conjugation in the ligand and proximity to the surface reduces the detinting time by up to 8 fold. Furthermore, while ZnS is a known photochromic material, we show that Cu-doped ZnS’ darkening mechanism applies more broadly to additional materials. We employed a fundamental computational pipeline to hunt for fingerprints of photochromicity, which enabled us to identify and validate novel visible and NIR photochromic material compositions.

Two in One: Ni-Doped CsPbBr3 Nanocrystals Enabling Photocatalytic Dehydrogenation of Diaryl Hydrazines HaipengLu; The Hong Kong University of Science and Technology, Hong Kong

Colloidal semiconductor nanocrystals, also known as quantum dots (QDs), have demonstrated remarkable abilities as photocatalytic systems for organic transformations, with efficiencies that can rival those of traditional molecular catalysts. However, the unique potential of QDs for photocatalysis, which stems from their large surface-volume ratio, tunable chemical composition, and quantum confinement, has yet to be fully explored. In this presentation, we will discuss our recent work on the design of colloidal CsPbBr3 QDs for acceptorless dehydrogenation of diaryl hydrazines under mild conditions. We achieved this by doping CsPbBr3 QDs with Ni2+, creating a dual-catalysis system. Specifically, our catalyst combines visible-light active CsPbBr3 as the photoredox catalyst and Ni2+ as the proton-reduction catalyst. This dual-catalytic strategy exhibits a broad substrate scope. Transient absorption spectroscopy indicates an ultrafast electron transfer step from the QD to Ni2+ dopants upon photoexcitation, which serves as the proton reduction centers. Our work demonstrates a new design strategy for challenging photocatalytic organic transformations using proton-coupled multiple electron transfer processes.

4:00 PM EL10.10.08
Bifunctional Electron-Transporting Agent for Red Colloidal Quantum Dot Light-Emitting Diodes HaoyueWan[1], YakunWang[1], JianXu[1], YunZhong[1] and EdwardH. Sargent[1,2]; [1]University of Toronto, Canada; [2]Northwestern University, United States

Indium phosphide (InP) quantum dots have enabled light-emitting diodes (LEDs) that are heavy-metal-free, narrow in emission linewidth, and physically flexible. However, ZnO/ZnMgO, the electron-transporting layer (ETL) in high-performance red InP/ZnSe/ZnS LEDs, suffers from high defect densities, quenches luminescence when deposited on InP, and induces performance degradation that arises due to trap migration from the ETL to the InP emitting layer. We posited that the formation of Zn^{2+} traps on the outer ZnS shell, combined with sulfur and oxygen vacancy migration between ZnO/ZnMgO and InP, may account for this issue. We synthesized therefore a bifunctional ETL (CNT2T, 3′,3″,3‴,3⁗-(1,3,5-triazine-2,4,6-triyl)tris(([1,1′-biphenyl]-3-carbonitrile)) designed to passivate Zn^{2+} traps locally and *in situ* and to prevent vacancy migration between layers: the backbone of the small molecule ETL contains a triazine electron-withdrawing unit to ensure sufficient electron mobility (6×10^{-4} cm^2 V^{-1} s^{-1}), and the star-shaped structure with multiple cyano groups provides effective passivation of the ZnS surface. We report as a result red InP LEDs having an EQE of 15% and a luminance of over 12,000 cd m^{-2}; this represents a record among organic-ETL-based red LEDs.<quillbot-extension-portal></quillbot-extension-portal><quillbot-extension-portal></quillbot-extension-portal>

4:15 PM EL10.10.09
Development of Molten Salt Solvents for Synthesis of Ternary and Quaternary III-V Colloidal Nanocrystals via Cation Exchange JustinOndry[1], Jun HyukChang[1], AritrajitGupta[1], ZiruiZhou[1] and DmitriV. Talapin[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

For the most part, colloidal nanocrystals made of III-V materials (*e.g.*, GaAs, InP, GaSb, *etc.*) are less developed than their corresponding II-VI and IV-VI counterparts in terms of synthetic control and optoelectronic performance. Despite this, colloidal III-V nanocrystals are desirable since these materials have many impressive optoelectronic properties in bulk, they are less toxic than many II-VI and IV-VI phases, and they may have higher chemical and thermal stability. So far only the indium-based III-V materials (*e.g.*, InAs, InP, and InSb) have been prepared as

colloidal nanocrystals with high quality. Gallium- and aluminum-based III-V nanocrystals are difficult to synthesize via traditional colloidal synthesis due to the high temperatures needed to crystallize the more covalent III-V materials and the extreme reactivity of Ga^{3+} and Al^{3+} cations towards organic solvents at elevated temperatures. To address this, we have developed molten salt solvents as reaction media to synthesize several important alloy III-V nanocrystal phases via cation exchange from their corresponding indium pnictide colloidal nanocrystals. In this presentation we will discuss how colloidal In-pnictide nanocrystals can be transformed to their respective InGa-pnictide and InGaAl-pnictide alloy phases via processing in gallium and aluminum containing molten salts. Further we will discuss the importance of the molten salt composition, elucidated using *in-situ* high temperature UV-vis absorption and Raman spectroscopy, for ensuring chemical stability of III-V nanocrystals in molten salt solvents. From this, we identify Lewis neutral alkali tetrahalogallate ($MGaX_4$) molten salts are the key reactive phase which engender chemical stability of colloidal InAs nanocrystals and allows their subsequent transformation to InGaAs and InGaAlAs using Lewis neutral alkali tetrahaloaluminate ($MAlX_4$) molten salts. Additionally, we will describe how controlling the redox potential in the molten salt solvents by using reduced gallium halide molten salts is key to protecting InSb from decomposition and thus enabling the synthesis of InGaSb colloidal nanocrystals. Finally, we describe an atomically precise colloidal atomic layer deposition approach to grow wide band gap II-VI shell materials which precisely passivate surface traps enabling bright band edge photoluminescence from molten salt synthesized InP nanocrystals and quaternary InGaPAs nanocrystals. The materials synthesized by the molten salt methods provide access to continuously tunable light emission from the visible to mid IR suggesting these materials could have broad impact in many applications. Together our work provides key insights into strategies to prepare a diverse family of III-V alloy nanocrystals and will likely enable future development of all-III-V colloidal nanocrystals heterostructures via growth of wide band gap shell materials in molten salt solvents.

4:30 PM EL10.10.10
Short-Wave Infrared Quantum Dots with High Quantum Yield Through Mercury Cation Exchange WonseokLee and AndrewM. Smith; University of Illinois at Urbana-Champaign, United States

Colloidal semiconductor nanocrystals (NCs) are photonic materials with a combination of unique properties such as size-tunable electronic/optical energy levels, high absorption cross-section, high photoluminescence quantum yield (PLQY), long-term photochemical/photophysical stability, and versatile solution-based processability. NCs with optical transitions in the infrared are currently being developed to reduce the cost of infrared optoelectronic devices, which are currently limited to a few high-tech specialized areas, including defense and astronomy. Among the candidate NC materials, mercury chalcogenide (HgE) and mercury cadmium chalcogenide ($Hg_xCd_{1-x}E$) are leading candidates for infrared optics. In comparison with alternative infrared NCs (*e.g.*, InAs and lead chalcogenides), these materials provide extremely wide spectral tunability across the near, mid, and far infrared spectra. Nevertheless, challenges remain in their advancement due to the low reduction potential of mercury ions that limit the high-temperature solvothermal synthesis and difficulties in the precise selection of mercury-to-cadmium ratios in alloys.
The cation exchange (CE) reaction can create new functional NCs by replacing one type of cation with another. The product materials which often cannot be synthesized de novo, can inherit the structural integrities of the parent nanomaterials in terms of size, shape, crystal phase, and homogeneity. However, due to the diffusion-limited CE reaction mechanism, achieving fine control of the radial composition of host and guest cations has been challenging. In addition, for some material systems, the slow diffusivity of cations significantly impedes the CE reaction and requires a high reaction temperature, resulting in a loss of structural homogeneity. In this research work, we developed a new CE method that can bypass the diffusion-limited reaction pathways. In particular, we developed a CE conversion of CdSe NCs to HgSe NCs and evaluated the reaction mechanism. Through the improved reaction, $Hg_xCd_{1-x}Se$ NCs exhibit a homogeneous radial distribution of cation species and enhanced overlap of electron and hole wavefunctions, as well as improved PL properties tunable across the short-wave infrared spectrum (~1000–1700 nm wavelength). After shell overcoating, these $Hg_xCd_{1-x}Se$/CdS/ZnS NCs exhibited excellent optical properties: the PLQY was above 85% and photoluminescence full-width-at-half-maximum (FWHM) was below 110 meV, properties matching those of the parental CdSe-based core/shell NC emitters.

4:45 PM EL10.10.11
Stability Assessment of Binary Mixture of Small Colloidal Nanoparticles AzitaRezvani[1], OsamaAnwar[1] and DorisSegets[1,2]; [1]Institute for Energy and Materials Processes (EMPI), Germany; [2]Universität Duisburg-Essen, Germany

Over the past few decades, extensive research has been conducted on the stability and surface interactions of colloidal dispersions consisting of a single component. However, practical formulations in the real world often involve mixtures of colloidal nanoparticles with different components, such as binders and additives. Therefore, it is crucial to have precise control over the stability of these mixtures, as it plays a vital role in various applications like the self-assembly of nanoparticles into complex structures [1, 2] and the recycling or separation of nanoparticles after synthesis [3-4]. However, studies on handling and stability regulation are scarce in the literature, even for binary colloids. This lack is particularly evident for small nanoparticles (< 20 nm), which are highly interface-dominated. This can be attributed to significant challenges in characterizing and comprehending the surface interactions in such complex systems of small colloidal nanoparticles.
In this work, we studied the stability regulation of a mixture of colloidal Au nanoparticles (< 20 nm) and an aqueous dispersion of ZnS quantum dots (< 5 nm) as a binary colloid made of nanoparticles of different sizes and compositions. This is a practically relevant model system and of great interest in this context when we try to recycle the smallest nanostructures from complex mixtures, for instance during the recovery of metals from fuel cell or battery electrodes, in a true circular economy. Here, we investigated how the surface ligand and the purification process of Au nanoparticles affect the stability of the hetero-colloid. To do this, we investigated the stability of Au nanoparticles with three different ligands on the surface after mixing them with ZnS QDs, each before and after functionalization of the Au NPs by bis (p-sulfonatophenyl) phenyl phosphine (BSPP). To characterize the mixture, UV-visible spectroscopy as the main method was combined with dynamic light scattering and analytical centrifugation to assess and monitor the stability of both colloidal components over time. This enabled us to understand the stability-controlling parameters and tailor the surface interactions.
Our work presents a general strategy to understand and tailor the stability of a binary mixture of small colloidal nanoparticles which is a challenge. We successfully created a stable binary mixture of BSPP-capped Au nanoparticles with ZnS QDs as a representative model system. We consider this achievement to be a significant initial stride in the characterization and understanding of the surface interactions of real-world multicomponent formulations.

Passivation and Stabilization of InP Nanocrysals with Organic Halide Ion Salts RodolpheValleix, AbrhamJordan, WilliamZhang and JonathanS. Owen; Columbia University, United States

The surface coordination chemistry of InP nanocrystals prepared from oleylamine, indlum chloride and aminophosphines was investigated following synthesis, purification, and ligand exchange. ^{1}H, ^{31}P, and ^{19}F nuclear magnetic resonance and Fuorier transform infrared absorption spectroscopy were used to quantify the surface ligand coverages and to monitor the ligand reaction with ammonium halides, diethyl zinc, phosphine, and chlorotrimethyl silane reagents. The coverage of tetralkylaminophosphonium chloride, alkylammonium fluoride, metal halide surface ligands were determined. The findings will be discussed in light of the metal rich stoichiometry and the steric constraints of packing surface passivating ligands.

9:00 AM EL10.11.02
Low-Cost Synthesis of Silicon Quantum Dots and Their Applications on Luminescent Solar Concentrators JingjianZhou; Uppsala University, Sweden

Here, we developed a cost-effective batch synthesis method for silicon quantum dots (Si QDs) with large Stokes shift and high quantum yield (>50% in polymer nanocomposite) for efficient light conversion. These Si QDs were fabricated from an inexpensive commercial precursor (triethoxysilane, TES), using optimized annealing and etching processes. The optical properties of such QDs are similar to those prepared from state-of-the-art precursors (hydrogen silsesquioxane, HSQ) yet featuring an order of magnitude lower cost. FTIR revealed that the surface oxide on Si QD was closely related to its light conversion efficiency. Based on this mass production method, we are able to investigate many factors when applying Si QDs as fluorophores in luminescent solar concentrators (LSCs), such as the thickness of polymer interlayer, the appropriate UV dose for curing polymer to avoid haze etc. Eventually, we are aiming at transparent

large-area light-harvesting devices serving as "solar windows".

9:15 AM EL10.11.03
Composition-Defined Optical Properties and the Direct to Indirect Transition in Core-Shell $In_{1-x}Ga_xP$/ZnS Colloidal Quantum Dots JustinOndry[1], AritrajitGupta[1], KailaiLin[2], RichardSchaller[3], EranRabani[2,4] and DmitriV. Talapin[1,3]; [1]The University of Chicago, United States; [2]University of California, Berkeley, United States; [3]Argonne National Laboratory, United States; [4]Lawrence Berkeley National Laboratory, United States

Semiconductors are commonly divided into materials with direct or indirect band gaps based on the relative positions of the top of the valence band and the bottom of the conduction band in crystal momentum (**k**) space. It has, however, been debated if **k** is a useful quantum number to describe band structure in strongly quantum-confined nanocrystalline systems, which blur the distinction between direct and indirect gap semiconductors. In bulk III-V semiconductor alloys like $In_{1-x}Ga_xP$, the band structure can be tuned continuously from direct to indirect gap by changing the value of *x*, where for $x>0.75$, the material behaves as an indirect gap semiconductor. The effect of strong quantum confinement on the direct-to-indirect transition in this system has yet to be established because high-quality colloidal nanocrystal samples have remained inaccessible. Herein we report one of the first systematic studies of ternary III-V nanocrystals by utilizing an optimized molten salt In-to-Ga cation exchange protocol to yield highly emissive $In_{1-x}Ga_xP$/ZnS core-shell particles with photoluminescence quantum yields exceeding 80%. As the gallium content is increased in these systems, we observe the quantum yield decreases and the PL lifetime *increases* indicating the radiative lifetime increases with increased gallium content. This indicates the oscillator strength of the excitonic transition decreases as gallium is incorporated, consistent with increased indirect-like character of the band edge states. Transient absorption spectroscopy on $In_{1-x}Ga_xP$/ZnS nanocrystals enables direct identification of the direct-like or indirect-like character of the band edge in $In_{1-x}Ga_xP$/ZnS nanocrystals based on the presence or absence of a band edge bleach feature respectively. Further we study the biexciton lifetimes of $In_{1-x}Ga_xP$/ZnS nanocrystals across as broad size and composition range. We identify that biexciton dynamics are dominated by volume scaling explanations, rather than composition effects, which is consistent with what is observed for many strongly quantum confined binary semiconductor systems. Finally, atomistic electronic structure calculations based on the semi-empirical pseudopotential model are used to calculate absorption spectra, radiative lifetimes, and evaluate band edge degeneracy. The resulting calculated electronic properties are consistent with experimental observations and provide considerable insight into the underlying band character of the excitonic transitions in these systems. Altogether our results provide a detailed picture of the electronic structure of strongly confined alloy III-V nanocrystals which point to key design principles for optimizing optoelectronic properties of strongly confined semiconductor emitters.

9:30 AM *EL10.11.04
Unlocking the Potential of Metal Borides Nanocrystals—A Journey Through Synthesis and Surface Modification LoredanaProtesescu; University of Groningen, Netherlands

Metal borides, a versatile class of materials used in various industrial applications such as superconductors, magnetic materials, and hot cathodes, remain under-explored at the nanoscale due to the challenges in synthesizing single-phase nanocrystals (NCs). Their small size, high surface area-to-volume ratio, and well-defined surfaces exhibit unique physical and chemical properties, making them appealing for various applications, including catalysis, energy storage, electronics, and biomedical imaging. While metal-rich borides, like Ni_3B, are mainly used in electrocatalysis, boron-rich metal borides (metal hexaborides, MB_6) are highly valued for their broad range of physical properties that vary based on the metal ion present in their structure. For example, CeB_6 and LaB_6 have low work functions, while CaB_6 and SrB_6 exhibit high potential for high-temperature thermoelectric applications. Additionally, they are known for their high hardness, making them suitable for ultra-hard protective coatings.

In this presentation, we will showcase a novel method for synthesizing boron-rich M_1B_6 (M_1=Sr, Ca, Ba, La, Ce) and metal-rich $M_{2x}B$ (M_2=Ni, Co, Fe, x=2,3) [1] NCs through solid-state synthesis at low temperatures (380-440°C), as well as a strategy for stabilizing these crystals for use in solution-based mass production processes. Our discussion will highlight the reaction mechanisms in both classes of nanomaterials, demonstrating the versatility of boron chemistry. By using specific surface modifications, including inorganic and organic ligands, we have achieved stable suspensions of these nanocrystals in both polar and non-polar solvents, with the potential for implementation in cutting-edge technologies.

Organic-Inorganic Supramolecular Photosynthesis: The Quantasome Vision MarcellaBonchio[1,2]; [1]University of Padova, Italy; [2]INSTM unit of Padova, Italy

The use of solar-activated H_2O/CO_2 routines as a feed-stock for photosynthetic processes is nowadays a breakthrough concept for sustainable energy, solar fuels, green chemistry and food security. [1-2] The enormous potential of this vital cycle is far from being adequately exploited. An extraordinary research effort has been dedicated to elucidate the structural and mechanistic prerogatives of the natural oxygen evolving complex embedded within the photosystem II enzyme (PSII-OEC). [2] In the early studies, on Oxygenic Photosynthesis, the “quantasome hypothesis” led to seminal discoveries correlating the structure of natural photosystems with their complementary photo-redox functions.[1] Indeed, and despite the vast bio-diversity footprint, just one protein complex is used by Nature as the H_2O-photolyzer: photosystem II (PSII). Man-made systems are still far from replicating the complexity of PSII, showing the ideal co-localization of Light Harvesting antennas with the functional Reaction Center (LH-RC). A recent breakthrough in the field of artificial photosynthesis is the discovery of totally inorganic multi-redox clusters, as analogs of the PSII-OEC, with a common functional-motif, i.e. a redox-active, tetranuclear, metal-oxo core boosting H_2O oxidation to O_2 with unprecedented efficiency. Our vision points to a careful choice/design of the catalytic core, of its ligand set and of the surrounding nano-environment. We report herein a synthetic, spectroscopic and mechanistic study on the use multi-metal catalysts for water oxidation and their combined use with visible light sensitizers and carbon-based nanostructures (CNS). [3-4] In particular we will report on the design of multi-perylenebisimide (PBI) networks shaped to function by interaction with a polyoxometalate water oxidation catalyst (Ru_4POM). [5-7] Our results point to overcome the classical “photo-dyad” model, based on a donor-acceptor binary combination, with integrated artificial “quantasomes” formed both in solution and on photoelectrodes, showing a: (i) red-shifted, light harvesting efficiency (LHE>40%), (ii) favorable exciton accumulation and negligible excimeric loss; (iii) a robust amphiphilic structure; (iv) dynamic aggregation into large 2D-paracrystalline domains. Photoexcitation of the PBI-quantasome triggers one of the highest driving force for photo-induced electron transfer applied so far. The outcome is a hybrid organic-inorganic nanomaterial,showing a hierarchical supramolecular structure with a striking resemblance to the natural plasmid membranes, enabling water splitting using low energy green photons at overpotentials as low as the natural protein. [5-7]

Alignment of Colloidal Metal-Oxide Based Nanoparticles Embedded in Polymer-Based Nanofibers via Electrospinning for Electrochemical Biosensing of Microbial Pathogens BiancaSeufert, ArashTakshi and NirmitaRoy; University of South Florida, United States

The aeronautics industry continues to evolve its approach to deep space exploration and therefore the growing need for rapid accurate biosensing is becoming more and more relevant. Along with size, weight, and various technology constraints making a nano-scale biosensor is critical to furthering this exploratory venture. Furthermore, to expand this endeavor the proposed research chiefly investigates the viability of the design of an electrochemical biosensor to detect microbial pathogens. Through embedding colloidal metal oxide-based nanoparticles (MOxs) in electrospun polymer-based nanofibers one can further investigate the interfacial passivation between the biomolecule under study and the MOx embedded nanofibers. The unique characteristics of these adjoined nanomaterials such as large surface areas can provide many opportunities for manipulating their shape, size, and other properties. Which is why the use of several different metal oxide (MOX) based electrodes aptly placed as a bio-field effect transistors (bioFET) are used in this study as electrochemical sensors for a specific antigen/antibody detection. This study utilizes the testing methods of Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) using the VersaStat 4 Potentiostat to measure the sensors’ responses. It will be necessary to analyze and identify the effect on sensitivity, response time, and LOD of each sensor.

Zinc Chalcogenide Based Colloidal Nanoplatelets MuhammedS. Es, CagatayH. Aldemir, EbrarColak, NehirErgezer and YusufKelestemur; Middle East Technical University, Turkey

Two-dimensional colloidal nanoplatelets have become an attractive class of colloidal nanocrystals. With their thickness dependent excitonic properties, they exhibit exciting performance in optoelectronic devices. However, the most widely studied family of colloidal nanoplatelets are based on cadmium chalcogenides, which are considered as toxic materials and their optical properties cover very limited range of the electromagnetic spectrum. To overcome these limitations, we studied the synthesis of zinc chalcogenide based nanoplatelets with two different approaches: cation exchange and direct synthesis. For the cation exchange experiments, we firstly synthesized CdSe/ZnS core/shell NPLs and then performed cation exchange. With this approach, we can achieve core/shell nanoplatelets emitting in the blue spectral region (450 – 480 nm) by preserving their narrower emission linewidth (< 30 nm). In the second approach, we tried direct synthesis of zinc chalcogenide based nanoplatelets. We demonstrated that it is also possible to synthesize ZnSe nanoplatelets having zinc-blende crystal structure with direct synthesis approach. With our optimized synthesis conditions, we synthesized two different population of ZnSe nanoplatelets having absorption peaks at 347 and 369 nm.

Exploring Interplay of Engineered Materials with the Living by Label-Free Analytical Imaging IngeK. Herrmann; ETH Zurich, Switzerland

The well-controlled synthesis of nanoscale materials is arguably one of the most important achievements of material science in the past decades. Nanoscale materials find growing applications also in biomedicine. Fascinating therapeutic performances have been achieved by employing metal, metal oxide, and metal organic framework nanoparticles as drug delivery vehicles, radio-enhancers, and antimicrobial agents. Although recent studies have recognized the limited stability of nanomaterials in biological environments, analytical techniques have not yet been harnessed to their full potential to assess the biological fate engineered nanomaterials in complex biological environments. Despite fascinating achievements, the current limited understanding of the molecular interplay between engineered materials and the surrounding tissue remains a major obstacle in the rational development of medical materials, which is reflected in their modest clinical approval rate.
In this presentation, I will present a multiscale multimodal analytical imaging approach for the label-free assessment of nanomaterial fate and alterations to tissue. I will, in a first example, demonstrate that cerium oxide-based nanozymes preferentially accumulate in tissue macrophages after topical application to the subcutis and partially biotransform into catalytically inactive cerium phosphate over time. In a second example, I will present a methodological approach for the analysis of iron-based nanoparticles after systemic administration and reveal accumulation of iron paticles in splenic macrophage subpopulations co-accumulating endogenous iron. Finally, I will showcase the application of multimodal analytical imaging in the assessment of the stability and fate of a diverse set of metal organic framework nanoparticles. Taken together, this presentation discusses how modern analytical methodologies can be harnessed for the label-free tracking of nanomaterials in complex biological environments with single particle sensitvity. Comprehensive assessment of material alterations and changes in the local tissue surrounding at unprecedented sensitivity decisively contributes to a rational and safer nanomaterial design and development for health applications.

11:00 AM EL10.12.02
Cathodoluminescent Rare-Earth-Doped Nanoprobes as Bright Labels in Electron Microscopy SebastianHabermann[1,2], MathieuKociak[3], AlexanderGogos[1,2], LukasGerken[1,2], ChristianMonachon[4], KerdaKeevend[1,2] and IngeK. Herrmann[1,2]; [1]Swiss Federal Laboratories for Materials Science and Technology (Empa), Switzerland; [2]ETH Zurich, Switzerland; [3]Université Paris-Saclay, CNRS, France; [4]Attolight AG, Switzerland

Progress and achievements in the natural sciences are fundamentally linked to appropriate analytical tools. By unlocking previously unattainable scales, microscopy laid the foundation for many future-shaping discoveries and enabled the emergence of whole scientific fields. Due to its widespread usage in biological and medical laboratories, (fluorescence-)microscopy significantly contributed to our today's understanding of the fundamental processes in living systems. Intensive work with and on the improvement of microscopy techniques allowed ever-new milestones, primarily by enhancing contrast and resolution by exploitation of optical labels and physical phenomena. However, understanding the interactions of biomolecules at the nanoscale and put them in a cellular context remains a major challenge. Electron microscopy (EM) as a non-Abbe limited technique gives access to the cellular ultrastructure yet results in low-contrast grey-scale images and is not able to (co-)localize biomolecules without electron-dense labels or correlative microscopy approaches.
In this work, we demonstrate the feasibility of nanoparticle-based immunolabels for correlative cathodoluminescence electron microscopy (CCLEM). By introducing rare-earth-doped labels, the challenging sample preparation and resolution mismatch of correlative (light-)microscopy methods is addressed. Further, incorrect assignment of electron-dense labels due to their low-contrast and similarity with cell features is prevented. Hereby, we exploit the single-particle cathodoluminescence (CL) of sub-20 nm nanoparticles as a unique spectral fingerprint to identify their precise location and enable the separation from second labels and cell components without additional investigations. To maximize the nanoparticle's emission intensity, the dopant was incorporated in a sodium gadolinium fluoride host lattice and separated from the environment using a passivating shell. Both folic acid and caffeic acid decorated nanoparticles were prepared using terbium and europium as their characteristic signature dopants. Their potential for immunolabeling in CCLEM and easy (co-)localization was successfully demonstrated using HeLa cells, as both embedded particle populations demonstrated strong single-particle emission and therefore added a color contrast to the previously grey-scale EM image. Taken together, these results open a route to color immunolabelling based on cathodoluminescence electron microscopy.

Selective On-Off-On Polymer Bonded Quantum Dot-Nitroxide Radical Fluorescent Sensor to Detect Cd^{2+} Ion in Aqueous Media MerveKarabiyik and OzgencEbil; Izmir Institute of Technology, Turkey

One of the most important problems of recent years is heavy metal pollution, which has great harm to the environment and human health. Especially, Cd^{2+} ion selectivity of quantum dot (QD)-nitroxide radical nanoprobe developed in this study was found as higher than the other heavy metal ions (Al^{3+}, Co^{2+}, Cu^{2+}, Mn^{2+}, Ag^{+}, Fe^{3+}, Ni^{2+}, Pb^{2+}, Cr^{3+}, Hg^{2+}, Mg^{2+}, Zn^{2+}). Cadmium is widely used in industry, agriculture and many other fields. Recently, serious environmental and health problems caused by Cd^{2+} ion have made it a great need to develop methods for detecting and monitoring cadmium levels. Due to the simplicity and high sensitivity features, fluorescent methods have become powerful tools to monitor target heavy metal ions in different sources. The main aim of this study is to develop cross-linked copolymer-based fluorescent sensor with high mechanical strength, sensitivity and selectivity that can detect Cd^{2+} ion in aqueous media. In the literature studies, different types of fluorophores have shown selective properties against different heavy metal ions, and in general, only turn-off and turn-on sensors have been developed. Compared to the studies in the literature, in this study, it is planned to go one step further than the liquid-phase and disposable sensors that have been made so far, and develop a fluorescent sensor with a more functional and high mechanical strength and on-off-on feature. Today, solventless vapor phase deposition methods are most commonly used techniques for production of polymeric thin film coatings. Initiated chemical vapor deposition (iCVD) is a suitable method for the fabrication of crosslinked copolymer thin film coatings and it has many advantages such as low production cost, low temperature, 3D geometry coating performance and high deposition rate. Therefore, production of crosslinked copolymer thin films of glycidyl methacrylate (GMA) and 2,4,6,8-tetramethyl-2,4,6,8-tetravinylcyclotetrasiloxane (V4D4) via iCVD system was performed in this study. Also, experimental studies for investigations of quantum dot-nitroxide radical nanoprobe formation, attachment of this nanoprobe on iCVD deposited crosslinked copolymer film, interaction between the nanoprobe and target heavy metal ion and some parameter effects on the Cd^{2+} ion detection with developed fluorescent sensor were carried out. Fluorescence Spectroscopy, Fluorescence Microscopy, UV-Vis Spectroscopy, Fourier Transform Infrared Spectroscopy (FTIR) and Electron Paramagnetic Resonance Spectroscopy (EPR) analyses were performed to examine the formation of QD and nitroxide radical nanoprobe due to electron transfer between them, QD-nitroxide radical nanoprobe attachment to the thin polymeric film surfaces and interaction between polymer bonded nanoprobe and target heavy metal ion. Under optimal conditions, a good linear relationship between the fluorescence response and concentration of Cd^{2+} ion was obtained in the range from 0.5 to 15 μM. The detection limit (LOD) of Cd^{2+} ion with QD-nitroxide radical nanoprobe was found as 0.223 μM showed that sensor nanoprobe developed in this study can be comparable with the other Cd^{2+} ion detection studies made so far in literature. Cd^{2+} ion detection study was performed with nanoprobe connected to the developed cross-linked copolymer film and according to the results, Cd^{2+} ion detection was successfully performed with the novel polymer-bonded fluorescent sensor nanoprobe because the desired fluorescence recovery (~ 88%) was obtained from analysis results.

Design of Dendritic Promesogenic Ligands for Liquid Crystal-Nanoparticle Hybrid Systems YifanNing, ZheLiu, ShengsongYang, YumaMorimitsu, ChinedumOsuji and Christopher B.Murray; University of Pennsylvania, United States

Liquid crystal-nanoparticle (LC-NP) hybrid systems allow synergistic interactions between LC matrixes with anisotropic alignment and NP dopants with versatile functionalities. A uniform, well-dispersed, and highly stable thermotropic LC-NP mixture paves the way for further applications. In this work, a linear promesogenic ligand and two types of dendritic promesogenic ligands with alkyl or oligo ethylene glycol (OEG) chains are designed and synthesized to facilitate incorporating NPs into the thermotropic 4-cyano-4′-pentylbiphenyl (5CB) LC matrix. A comparison study between the linear and the dendritic ligands on the capability to promote miscibility and stability of NPs in LCs is conducted. Miscibility test results show that the linear

ligand and the OEG-chained dendrimer both perform well in uniformly dispersing NPs in LCs. Dynamic assemblies of NPs assisted by dendritic ligands and driven by aligning and equilibrating of mesogens are captured, showing the potential of manipulating the assembly of NPs through external thermal stimuli. The stability test shows that both types of dendrimers can significantly enhance the shelf-life time and thermal stability of NPs compared to the linear ligand. In particular, Au NPs capped with OEG-chained dendrimers are stable in 5CB for 6 months at room temperature and over 10 h at 50 °C. The synthesis of dendritic ligands is highly modulated and can be generalized onto NPs with different dimensions and properties. Tied by the dendritic promesogenic ligands, this LC-NP hybrid system with good uniformity and stability could be further applied to tunable optical displays, responsive materials, etc.

SYMPOSIUM EL11

Ultra-Wide Bandgap Materials, Devices and Applications

Lifetime Limiting Degradation Mechanisms of State-Of-The-Art UVC LEDs EnricoZanoni[1], FrancescoPiva[1], MatteoBuffolo[1], NicolaTrivellin[1], CarloDe Santi[1], NicolaRoccato[1], NormanSusilo[2], DavidHauer Vidal[2], AntoniMuhin[2], LucaSulmoni[2], TimWernicke[2], MichaelKneissl[2], GaudenzioMeneghesso[1] and MatteoMeneghini[1]; [1]University of Padova, Italy; [2]Technische Universität Berlin, Germany

In recent years, an increasing interest was generated in ultraviolet (UV) light-emitting diodes (LEDs), owing to their several fields of application, such as sanification and disinfection, and to their superior efficiency and lower environmental impact compared to traditional UV light sources. Despite that, these devices still suffer from several problems that lead to a limited lifetime compared to their visible counterpart.
Nowadays, state-of-the-art commercial UV-C LEDs emitting in the 265 to 275 nm wavelength range show a limited lifetime that decreases, together with EQE, with decreasing emitting wavelengths. This could not be a problem if the useful lifetime of the source is determined based on the total number of deliverable doses for the disinfection of a specific virus species, for instance. If we consider the example of Sars-CoV-2, the disinfection energy required is relatively low, and it was demonstrated that by reducing the operating current of the device, the number of provided doses could be six times higher, in the L70 standard. At the same time, considering the disinfection efficiency as a function of the emitting wavelength, a 265 nm LED with an L70 20% lower could provide higher doses with respect to a 275 nm device.
To better understand the physical mechanisms behind this limited lifetime, specific experiments were carried out on research-grade single quantum well (SQW) LEDs. The analysis highlights the correlation between the physical phenomena observed from electro-optical characterizations and degradation processes detected and modeled by means of capacitance deep-levels transient spectroscopy (C-DLTS), deep-levels optical spectroscopy (DLOS), and numerical simulations based on TCAD models. These studies on SQW LEDs were conducted to identify the types of degradation mechanisms, which can be divided into optical and electrical ones.
Regarding the degradation of the optical characteristics, two different trends can typically be observed comparing high and low bias levels. By using conventional rate equations, it was demonstrated that a simple increase in non-radiative recombination is not sufficient to reproduce the experimentally-observed changes in the L-I curve but is required the consideration of a decreasing injection efficiency. While the first degradation mechanism is confirmed by several works, the latter is still under investigation, though most preliminary investigations relate it to the accumulation of charged centers in the active region, and to the subsequent formation of a higher injection barrier for holes.
Regarding the electrical degradation mechanisms, the worsening of p-contact conductivity and the increase in the concentration of deep-levels participating favoring trap-assisted tunneling (TAT) and sub-turn-on conduction are commonly identified during aging. The former process, associated with an increase in the device turn-on voltage can typically be ascribed to the current-induced deactivation of the magnesium (Mg) dopant located in the proximity of the region-S interface. The reduction in effective dopant concentration causes the increase in the width of the space-charge region (SCR) of the p-Schottky contact, thus lowering the hole tunneling probability from the metal to the semiconductor.
The stress-induced de-activation of Mg in the p-GaN contact layer was also confirmed by C-DLTS measurements and by TCAD simulations.
TAT-assisted conduction was simulated with TCAD models, placing traps in the interlayer region, with an increasing concentration toward the EBL. The energy of these traps was extracted from DLOS measurements, and using their concentration as a fitting parameter allowed to match the I-V curves during the ageing. Moreover, their increase can be associated with a diffusion process from the p-side toward the n-side ascribable to the hydrogen diffusion.

11:00 AM EL11.01.02
Defect Control Strategies for AlN-Based Alloys NaseemUd Din[1], Cheng-WeiLee[1], KeisukeYazawa[1,2], WilliamNemeth[2], RebeccaSmaha[2], NancyHaegel[2] and PrashunGorai[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

Tetrahedrally-bonded III-N and related alloys are useful for a wide range of applications, from optoelectronics to dielectric electromechanics. Heterostructural AlN-based alloys offer unique properties for piezoelectrics, ferroelectrics, and other emerging applications. Atomic-scale point defects and impurities can strongly affect the functional properties of materials, and therefore, it is crucial to understand the nature of these defects and mechanisms through which their concentrations may be controlled in AlN-based alloys. In this study, we employ density functional theory with alloy modeling and point defect calculations to investigate native point defects and unintentional impurities in $Al_{1-x}Gd_xN$ and $Al_{1-x}Sc_xN$ alloys in the wurtzite phase. We find that the native defect chemistry in both AlN-based alloys is generally similar while differences can be attributed to their electronic band gaps. Among the native defects that introduce deep mid-gap states, nitrogen vacancies (V_N) are predicted to be in the highest concentration, especially under N-poor growth conditions. We predict and experimentally demonstrate that V_N formation can be suppressed in thin films through growth in N-rich environments [1]. Like AlN, we also find that both $Al_{1-x}Gd_xN$ and $Al_{1-x}Sc_xN$ alloys are prone to high levels of unintentional O incorporation, which indirectly leads to even higher concentrations of deep defects. Growth under N-rich/reducing conditions is predicted to minimize and partially alleviate the effects of O incorporation. The results of this study provide valuable insights into the defect behavior in wurtzite nitride-based alloys, which can guide their design and optimization for various applications.

Time-Resolved Cathodoluminescence Spectroscopy of Oxygen Related Defects in AlN Layers BarbaraSzafranski, LukasPeters, AndreasWaag and TobiasVoss; Braunschweig University of Technology, Germany

For the fabrication of AlGaN UV LEDs, a high quality AlN buffer layer on sapphire substrate is a prerequisite for increasing the quantum efficiency. However, in MOVPE it is challenging to achieve a low threading dislocation density (TDD), high transparency of the AlN buffer layer and high light outcoupling efficiencies at the same time. Additional processing challenges arise due to excessive wafer bow caused by differences in thermal expansion coefficients between LED stack and substrate. AlN is one of the few compound semiconductors where annealing at high temperatures (HTA) leads to a substantial improvement of the crystal quality without dissociation of the compound. At the same time, the optical transparency is increased and bowing problems are reduced, since much thinner AlN HTA layers can be used in comparison to thick MOVPE-grown buffers. Typical HTA AlN thicknesses are below 500 nm. However, during the annealing process, a large number of point defects is introduced. Among those, oxygen is one of the most prominent ones due to the higher chemical affinity of aluminum for oxygen than for nitrogen.
We analyzed the influence of oxygen defects in AlN layers with cathodoluminescence (CL) spectroscopy. For all experiments, we used an AlN sample fabricated by PVD on *c*-oriented sapphire substrates. The 425 nm thick AlN layer was treated with HTA at 1680°C for 2 hours in N_2 atmosphere at normal pressure. SIMS measurements revealed a high oxygen concentration of 2×10^{20} cm^{-3} for the studied AlN sample.
At room temperature, CL spectroscopy shows a broad (FWHM ~ 400 meV) oxygen related luminescence band centered at about 3.54 eV (350 nm). To study the charge carrier dynamics of the oxygen-related defects in AlN, time-resolved CL measurements have been performed. The defect related emission is characterized by a complex multiexponential decay with a fast component of less than 100 ns and a slow component of longer than 10 µs. We attribute the short decay time to the radiative transition from the conduction band-edge states to $(V_{Al}\text{-}O_N)^-$ or $(V_{Al}\text{-}O_N)^{2-}$. The long recombination times might be related to carriers deeply trapped in spatially separated regions of the sample by the impurity-derived electric fields. Further we will discuss the influence of the oxygen concentration in AlN on the recombination times.

Microscale Electronic Properties of Epitaxial Gallium Nitride Surface Defects AndrewWinchester[1], MichaelMastro[2], TravisAnderson[2], JenniferHite[2] and SujitraPookpanratana[1]; [1]National Institute of Standards and Technology, United States; [2]U.S. Naval Research Laboratory, United States

The wide bandgap material GaN is desired for next-generation high power electronics beyond Si and SiC. However, the vertical structures needed for scalable devices suffer from issues related to dislocations and defects, which propagate from the substrate into the epitaxially grown device area. Substrate developments such as strain patterning to coalesce dislocation bundles and alternate scalable growth methods such as the ammonothermal process have produced higher structural quality substrates. However, in both cases, the remaining dislocations and defects are still a major concern for high power device performance and reliability. For example, threading dislocations with screw components are known to exhibit leakage current and are predicted to have mid-bandgap states, while newer ammonothermal GaN substrates may exhibit different defect densities and distributions compared to GaN grown on foreign substrates. Therefore, determining the electronic properties of dislocations and defects at the microscale will provide valuable information for identifying “killer” defects.

Here, we use a combination of laser-based photoemission electron microscopy (PEEM) and conductive atomic force microscopy (cAFM) to investigate the local surface electronic properties of defects and dislocations in GaN epitaxially grown via MOCVD on different substrates. In epitaxy on patterned substrates, we identify surface defects located near strain centers that have a star-shaped appearance with central pits and extending cracks. These star defects exhibit a larger work function and a shifted valence band maximum, and further, show increased reverse bias leakage current compared to the surrounding GaN. For epitaxy on ammonothermal GaN substrates, we instead observe elongated triangular patches that sporadically occur on a face of certain growth ridges. These regions also show altered electronic structure compared to the surrounding GaN, but are instead more resistive under both forward and reverse bias conditions. Our results provide evidence for defective sites likely related to extended dislocations that will lead to degraded device performance.

11:45 AM EL11.01.05
Defects in Gallium Oxide Imaged by Photoluminescence Microscopy MatthewD. McCluskey, CassandraRemple, BenjaminDutton and JohnS. McCloy; Washington State University, United States

Photoluminescence (PL) spectroscopy is an important method to characterize dopants and defects in gallium oxide. Common features in the PL spectrum include the intrinsic UV band, blue and green bands that involve donor-acceptor pairs, and red emission due to Cr^{3+} impurities. PL mapping with excitation wavelengths ranging from 266 to 532 nm reveals the spatial distribution of these features with submicron resolution. In Czochralski-grown β-Ga_2O_3:Fe, the Cr^{3+} emission intensity shows striations that are attributed due to inhomogeneities during growth. Ir^{4+} can also be imaged through resonant Raman scattering. By comparing the two signals, we can gain insight into Fermi level variations across the sample. In addition to defects in the bulk, PL microscopy has revealed several specific defects on the surface. Some of these localized centers are very bright UV emitters. Raman scans of these bright emitters revealed hydrocarbon peaks, which may point toward the origin of the light emission.

SESSION EL11.02: UWBG RF and Power Devices
Session Chairs: Alan Doolittle and Robert Kaplar
Monday Afternoon, November27, 2023
Hynes, Level 2, Room 210

UWBG Semiconductors–The Next Leap in RF and Power Electronics Thomas EKazior[1] and SharonWoodruff[2]; [1]DARPA, United States; [2]Booz Allen Hamilton, United States

Just as the wide bandgap (WBG) semiconductors, GaN and SiC, are revolutionizing RF and power electronics for defense and commercial applications, the unique properties of the ultra-wide bandgap (UWBG) semiconductors hold promise to create the next revolution. However, these materials are in their infancy, and many technical challenges must be overcome before their promise can become a reality. This invited talk will provide an overview of several UWBG research areas of interest to DARPA. These include: 1) methods to integrate dissimilar semiconductor materials, such as UWBG and narrow bandgap (NBG) semiconductors, to create new device structures that leverage the unique properties of the individual material layers, funded under the Heterogeneous Heterostructures (H2) program; 2) methods to integrate high thermal conductivity UWBG materials with WBG and NBG materials to overcome thermal and electric field bottlenecks in traditional RF power devices, funded under the Technologies for Heat Removal in Electronics at the Device Scale (THREADS) program; 3) new approaches to create large diameter, low defect density, single crystal diamond substrates, funded under the Large Area Device-Quality Diamond Substrates (LADDIS) program; 4) the synthesis of doped UWBG materials, the creation of novel UWBG heterostructures and the engineering of electrical and thermal interfaces funded under various smaller efforts; and 5) exploiting the high breakdown field of UWBG materials to achieve unprecedented levels of RF power handling.

2:00 PM *EL11.02.02
Bridging the Gap: Overcoming Materials and Device Challenges that Limit UWBG Semiconductor Progress DavidJ. Meyer, VirginiaWheeler, MatthewHardy, EricJin, AndrewLang,

NeerajNepal, JasonRoussos, VikrantGokhale, JamesChamplain, BrianDowney and JeffreyCalame; Naval Research Laboratory, United States

Ultrawide bandgap semiconductors (UWBGS) offer a myriad of electrical, optical, thermal, and mechanical properties that have the potential to unlock previously unattainable levels of performance in coupled-phenomena devices. Despite their known theoretical advantages, progress in UWBGS materials and devices has been inhibited by a number of challenges over the past few decades. Practical considerations such as cost, size and consistency of substrate material have made it difficult for the research community to systematically study technical questions that exist with the synthesis and processing of UWBGS. It is exciting to see recent progress in wafer size and affordability of UWBGS substrates such as single crystal diamond, AlN, and Ga_2O_3; however, proof-of-concept device demonstrations that clearly display the performance benefits of these materials are still needed to further attract interest in the technology.

While the breakdown strength advantages of UWBGS have been clearly verified in the lab by several groups, there are additional challenges that need to be overcome in order to establish this technology's long-term applicability. This talk will discuss a few of these challenges along with potential approaches being explored to provide solutions:

Challenge #1: Realizing highly mobile electronic charge at sufficient density within UWBGS channels and thin films – Conventional approaches such as impurity doping in UWBGS are difficult because many impurities form deep levels within the bandgap (typically 0.2 eV or deeper), resulting in low room-temperature ionization efficiency. Additionally, conventional thin film growth approaches may not provide an energetically favorable environment for the incorporation of dopant atoms on the desired lattice site. Lastly, UWBGS materials often have high levels of point or extended defects that can serve as compensation dopants, limiting the concentration of free carriers. A synthesis approach that has been studied by a few groups is the use of metal-modulated molecular beam epitaxy (MME) for the kinetically-controlled incorporation of impurities in AlN thin films. We will discuss our group's efforts involving Si-doping of AlN with MME.

Challenge #2: Managing high electric fields present in UWBGS devices – Common device passivation layers such as SiN_x and gate dielectrics such as HfO_2 have electric field breakdown strengths in the ~5-10 MV/cm range. As the breakdown strength of UWBGS materials exceeds this range and devices start to operate at 100's and 1000's of volts, passive dielectrics in the device will quickly become potential points for catastrophic failure. As much effort as the community is investing in UWBGS thin films, it should also be working to develop complementary dielectrics necessary for device passivation or gate insulation to support long-term reliability. In this talk, we will discuss the concept of relative permittivity engineering for dielectric superjunctions and their use to spread the peak electric fields in UWBGS devices.

Challenge #3: Improving the thermal management of high power UWBGS devices – A potential future application of UWBGS is in the area of RF power transistors. The current state-of-the-art, GaN, is typically operated in a backed-off power state to prevent acceleration of failure mechanisms due to excessive self-heating during operation, limiting its ultimate RF output power density. While the physics of failure mechanisms in UWBGS devices are largely unknown at present, it is likely that thermal management of these devices will need to be co-designed alongside electrical considerations in order for the technology to realize performance benefits. This talk will discuss strategies for device integration with diamond for improved thermal management.

2:30 PM *EL11.02.03
Comparative Operation of Ultra-Wide Bandgap Devices for Voltage/Power Conversion JackD. Flicker[1], RobertJ. Kaplar[1], JonahShoemaker[2] and StephenM. Goodnick[2]; [1]Sandia National Laboratories, United States; [2]Arizona State University, United States

Ultra-Wide-Bandgap (UWBG) semiconductors hold great promise for future power conversion applications, especially for incorporation at grid-level currents and voltages (10s-100s of kV,100s of A). Figures of Merit (FOMs) are often used as a first means to understand the impact of semiconductor material parameters on power semiconductor performance, and, in particular, the Unipolar (or Baliga) FOM is often cited for this purpose. However, the use of UWBG materials in a given application requires the fabrication of devices followed by system insertion. While the benefit of UWBG incorporation in power converters should roughly scale with the UFOM, there are several factors of importance for UWBG incorporation in switching power converters that are not explicitly included in UFOM-type calculations including switching behavior, incomplete ionization, mobility, and temperature dependence.

This talk will give an overview of work under the Ultra Materials for a Resilient, Smart Electricity Grid, a Department of Energy Basic Energy Sciences Energy Frontier Research Center, dedicated to evaluating the impact of UWBG materials in grid-level power electronic converters. Toolsets and modeling efforts will be introduced to evaluate how material characteristics of UWBG semiconductors percolate up to system-level improvements, especially regarding power dissipation for different material systems and device types in switching power converters. An optimization technique for two- and three-terminal devices will be introduced that calculates the minimum power dissipation in a switching power converter for a given system operational regime (reverse voltage, forward current density, frequency, duty cycle, and temperature), thereby allowing utilization of the optimal material/device combination for that application. A variety of UWBG device types and materials systems will be directly compared, e.g. diamond, gallium oxide, and aluminum nitride. This gives an overall roadmap for materials systems and device structures that can be utilized to target UWBGs to specific application areas.

3:00 PMBREAK

3:30 PM *EL11.02.04
Semiconducting AlN Electrical Devices AlanDoolittle[1,1] and SamuelGraham[2]; [1]Georgia Institute of Technology, United States; [2]University of Maryland, United States

Aluminum nitride (AlN) is a material of great interest for high performance power electronics, extreme environment semiconductor devices, radio frequency devices, and deep ultraviolet (DUV) optoelectronics due to its excellent electrical and thermal properties. Compared to other commonly used semiconductors (i.e., Si, SiC, GaN, and β-Ga2O3), AlN has the highest critical electric field and theoretical breakdown voltage, which lead to the highest Baliga's and Johnson's figures-of-merit (BFOM & JFOM)3. AlN also has the second highest saturation velocity, and thermal conductivity among semiconductors with a commercially available substrate3. However, AlN has traditionally only been an insulator without the ability to be converted to a semiconductor via doping. We recently demonstrated substantial bulk doping (carrier concentrations above 1018 cm-3) for both p- and n-type AlN using Be and Si dopants, respectively. From these results, we also demonstrated rectification and a 6 V turn-on in AlN PN diodes1,2,3.

Electrical characterization of homojunction aluminum nitride (AlN) PIN diodes is presented along with an update on the prospects for an AlN FET. Recently, using the metal modulated epitaxy (MME) variation of molecular beam epitaxy that controls the surface chemistry to enable low temperature, high quality epitaxy, substantial bulk n- and p-doping in AlN as well as AlN homojunction PN diodes are demonstrated, overcoming the longstanding barrier to doping of AlN1,2. P-type (p=4.4x1018 cm-3, 0.04 ohm-cm) and N-type (n=3x1018 cm-3, 0.02 ohm-cm) bulk conducting AlN is demonstrated with a narrow window for substrate temperatures for achieving semiconducting AlN. With proper surface cleaning procedures, MME grown AlN is indistinguishable from the HVPE AlN on sapphire template via TEM. Current-voltage-temperature (IVT) data from 25 °C to 300 °C is used to investigate these diodes. Diodes with poor substrate cleaning shows a kinked, temperature independent IV behavior in the low forward voltage range associated with defect assisted tunneling originating from stacking faults near the re-growth interface. No such kink, no stacking faults but still temperature independent IV is observed for properly cleaned substrates. These quasi-vertical devices consist of 1 μm highly n-type AlN:Si, a lightly Si-doped intrinsic AlN layer with varied thickness, and a 200 nm highly p-type AlN:Be.

IVT measurements from 25 °C to 300 °C in deep forward bias is presently limited by high series resistance originating from contacts to the plasma etched n-type AlN layer which has ~100x higher contact resistance than as-grown n-type AlN. However, the current increases by ~2 orders of magnitude as temperature increases with contact limited specific-resistance improving by >250x with an activation energy of ~0.3 eV. Forward current below the turn on voltage appear to be dominated by tunneling as suggested by temperature independence. Transistor structures will be discussed and at present are, again, contact limited to ~0.1 A/mm and only modest current modulation. Contact metallization, surface preparation of the AlN templates, and various device geometry parameters as important areas for future optimization in order to allow AlN devices to eventually push the limits in the field power electronics.

4:00 PM EL11.02.05
Impact of Buffer Layer on the Thermal Performance of Multi Channel AlGaN/GaN Transistors GeorgesPavlidis[1], MuhammadJamil[1], BivekBista[1], FrancisVasquez[1] and AndreaCentrone[2]; [1]University of Connecticut, United States; [2]National Institute of Standards and Technology, United States

The formation of the two dimensional electron gas (2DEG) in AlGaN/GaN high electron mobility transistors (HEMTs) has enabled devices that can operate at both high frequencies (> GHz) and high voltages (> 3 kV). These advantageous characteristics have translated to the commercialization of superior DC converters and high-power density radio frequency (RF) devices. The current record performances of single channel AlGaN/GaN RF transistors, however, have been thermally limited to power densities that are significantly lower than the expected theoretical

limits. One approach to improve the power density is the implementation of superlattice based multichannel transistors. The stacking of adjacent 2DEGs has been proven to increase the current density and transconductance of HEMTs.

To maintain a low ON-resistance, the heat generated in these nanostructured devices must be efficiently removed which requires in-depth knowledge of nanoscale thermal transport. Two challenges to overcome include the low cross plane thermal conductivity of superlattices and the high thermal resistance of a thick AlGaN buffer layer. This study investigates the impact of implementing a thinner GaN buffer layer with higher thermal conductivity. Furthermore, to assess the feasibility of simplifying the thin film structure, the thermal performance of non-castellated multichannel HEMTs is assessed via two techniques: scanning thermal microscopy (SThM) and Raman thermometry. For direct comparison, a multichannel device with a thin GaN buffer layer is demonstrated to achieve the similar thermal resistance to a device that is epitaxially grown on a AlGaN buffer layer that has fewer number of channels. A thermal finite element model (FEM) is developed to explain the discrepancy between the temperatures measured via SThM (surface temperature) and Raman thermometry (depth average). The peak temperature is found to be in the proximity of the topmost channel which highlights the importance of surface temperature techniques, such as SThM, for accurate extraction of thermal resistance. Finally, the challenges associated with SThM measurements on structures with small channel spacing and thick metal contacts is discussed and a numerical solution via FEM modelling is proposed.

4:15 PM EL11.02.06
X-Band AlGaN/GaN HEMT with Output Power over 20 W/mm and PAE over 50% using High Purity GaN Channel KenjiHomma, MaciejMatys, AtsushiYamada, ToshihiroOhki and NorikazuNakamura; Fujitsu Limited, Japan

An AlGaN/GaN high electron mobility transistor (HEMT) is still attractive devices for high frequency amplifier applications due to excellent properties of nitride materials like a wide band gap and large breakdown field. In the recent years, several reports concerning the high output power characteristics of AlGaN/GaN HEMT for X-band applications have been published [1,2]. Practical devices are required to satisfy not only high output but also power saving performance by high efficiency. In this work, we report on our success in simultaneously achieving a power density of more than 20 W/mm and an efficiency of more than 50% in the X-band.
A high-performance X-band AlGaN/GaN HEMT were grown by metal-organic chemical vapor deposition (MOCVD) on a SiC substrate. The devices exhibited a peak transconductance (Gm) of 335 mS/mm and high maximum drain current of 1.34 A/mm. The load-pull measurements performed at 8 GHz corresponding to the target device operating frequency in X-band for devices with gate lengths of 0.25 µm demonstrated a peak power added efficiency (PAE) of 52.6% and a maximum output power density of 21.2 W/mm at 60 V. To the best of our knowledge this is the highest power ever reported for X-band AlGaN/GaN HEMT at Vds = 60 V. We achieved these results by improvement of the current collapse (dc-RF dispersion) in terms of optimizing the growth conditions of the GaN channel on top of the Fe-doped GaN buffer in AlGaN/AlN/GaN heterostructures. In particular, we investigated the impact of growth parameters of the GaN channel layer, such as the growth rate, and V/III ratio on the AlGaN/AlN/GaN HEMT performance. We found that the GaN channel layers grown with the high V/III ratio (about 5000) lead to a suppression of the current collapse in AlGaN/AlN/GaN HEMTs. Based on the photoluminescence (PL) measurements, we attributed the current collapse suppression to the reduction of GaN channel acceptor-like traps related to the carbon impurities. More precisely, for the GaN channel layers grown with the V/III ratio of about 5000, we observed a significant decreases of yellow luminescence from the AlGaN/AlN/GaN heterostructure, which directly correlated with the current collapse improvement. We believe that the achieved progress represents an important step toward the development of high power AlGaN/GaN HEMTs.

Ultra-Wide Bandgap AlGaN-Based N-Polar High Electron Mobility Transistors: From Materials to Devices MalihaNoshin, XinyiWen, RohithSoman, XiaoqingXu and SrabantiChowdhury; Stanford University, United States

Ultrawide bandgap (UWBG) materials are being widely investigated for high-power and high-frequency electronics [1,2]. While emerging UWBG materials like Ga_2O_3 possess large bandgap and high critical electric field, AlGaN compositions can potentially have larger Figure of Merit owing to higher sheet carrier concentration and larger mobility. Recently, using N-polar all AlGaN-HEMT we showed simultaneously large drive current, low on-state leakage current as well as > 400 V breakdown voltage [3].

In this work, we discuss the growth and optimization as well as the characterization of N-polar AlGaN channel HEMT with varying Al concentrations. We also probe the composition-dependent surface morphology and transport in these materials, aided by simulation and Hall measurements.

For the growth of the N-polar all-AlGaN HEMT structures, we used the metal-organic chemical vapor deposition (MOCVD) method. We used c-plane sapphire substrates with a 4° miscut towards *a*-plane for achieving smooth and high-quality epitaxy. We demonstrated four different HEMT structures with Al mole fraction x=20%, 30%, 59% and 73% in the $Al_xGa_{1-x}N$ channel layer. The growth of such MOCVD-grown N-polar all-AlGaN HEMT was optimized at higher temperatures with higher TMAl flow to achieve a crack-free growth and lower dislocation density within the structures.

We measured the stoichiometries of the structures using both symmetric and asymmetric 2θ-ω scans in X-ray diffraction to incorporate strain effect. After KOH etching the N-polar HEMT showed hexagonal hillock-like structures, confirming the N-polarity of our grown samples. Atomic force microscopy imaging confirmed the good surface morphology with a root mean square surface roughness of <1 nm under 5 µm x 5 µm scan size. We also found that the surface roughness increased for HEMTs with the higher Al mole fraction AlGaN in the channel and barrier layers which can be from strain due to larger lattice mismatch between layers.

To develop a fundamental understanding of the material property and device performance, we explored the effect of Al mole fraction in the transport characteristics of the HEMT structures using Hall measurement. We found a decreasing trend in the mobility with increasing Al mole fraction in the AlGaN channel that can be correlated to alloy-scattering [4] and optical phonon-scattering dominated transport, further explored in our TCAD simulations. Our simulation showed that beyond 73% Al mole fraction, the mobility increases again. Comparing our simulation with the Hall mobility numbers, we can discern that mobility degradation due to surface undulation might be more pronounced for HEMT structures with higher Al percentages. We also fabricated N-polar all-AlGaN HEMT devices with 20% Al composition in the channel. A 10 µm channel length device offered a drive current of ~250 mA/mm. The high drive current can be attributed to the formation of better contacts on the lower-bandgap material and the natural formation of a back-barrier.

To summarize, in this work we reported experimental demonstration of device-quality epitaxial growth of N-polar all-AlGaN HEMT. The success of this study which will be discussed at the presentation led to the first demonstration of >400V breakdown voltage N-polar AlGaN HEMTs. We also explored the correlation between the material surface morphology and transport properties for varying Al compositions. This work will deepen our understanding of the optimization of N-polar AlGaN HEMT for high-power applications.

We acknowledge the funding from ONR (Award No N00014-19-1-2611- P00004) and Dr. Paul Maki for supporting this work.

Polarity Inversion of Scandium Aluminum Nitride (ScAlN) Piezoelectric Thin Films via Addition of Element in Group IVB (C, Si, Ge or Sn) Sri AyuAnggraini, MasatoUehara, KenjiHirata, HiroshiYamada and MoritoAkiyama; National Institute of Advanced Industrial Science and Technology, Japan

The discovery of scandium aluminum nitride (ScAlN) piezoelectric thin film has successfully brought promising improvement to the performance of modern wireless communication technology, particularly radio frequency (RF) filter [1,2]. The shift toward 6G communication system demands RF filter that can work at much higher frequency and wider bandwidth to allow efficient data transmission. Since integrating multilayers of piezoelectric thin films with different polarities enable an RF filter to function at much higher frequency [3], stacking Al-polar and N-polar ScAlN thin films is expected to be an effective strategy to achieve high-performance RF filter. As a result, controlling the polarity of ScAlN has become paramount for the development of next generation RF filter. Addition of element such as silicon (Si) or germanium (Ge) into AlN was reported to capable of inversing the polarity of aluminum nitride (AlN) [3,4] as well as ScAlN [5,6]. Therefore, in this study, we investigated the effect of addition of each element in group IVB (carbon (C), Si, Ge, tin (Sn)) on the polarization direction of ScAlN thin films.
All thin films were deposited on Si (100) wafer by using radio frequency magnetron sputtering system. Our study reveals that addition of C into ScAlN resulted in thin films with positive piezoelectric coefficient (d_{33}), which means addition of C into ScAlN maintained the polarity of ScAlN to be Al-polar. However, addition of either Si or Ge into ScAlN resulted in thin films

with negative d_{33} and the d_{33} values have similar magnitude with that of ScAlN. This suggested that addition of Si or Ge could inverse the polarity of ScAlN from Al-polar into N-polar, without significantly decreasing the value of d_{33}. In case of Sn, the negative d_{33} that was obtained upon the addition of Sn into ScAlN is an indication that addition of Sn could led to thin films with N-polarity. However, the d_{33} values of ScSnAlN are lower than that of ScAlN. Our study confirmed that the formation of N-polar ScAlN is largely controlled by both concentration of each additive element (in this case: Si, Ge, Sn) and the concentration of Sc. Effect of addition of each element on polarity distribution, crystal structure and surface states were also investigated in this study.

Prospects of Diamond Devices in High-Temperature and High-Power Applications SrabantiChowdhury; Stanford University, United States

Electrification is driving us closer to our goal of a sustainable society. Highly efficient and reliable ways of converting, delivering, and conditioning power call for innovations at every level, from systems to semiconductors. Beyond Si, GaN, and SiC, Diamond, with a bandgap of 5.47eV is being explored for its large critical electric field (3x more than SiC), and high thermal conductivity (6x more than SiC). Doping diamond p-type has been less challenging than n-type. However, in comparison with other wider bandgap materials such as Ga_2O_3 and AlN, n-type diamond has shown promises demonstrating high blocking voltage (>2kV) Schottky/p-i-n diodes quite routinely [1-2].
We have studied three notable features of diamond to help us understand its scope and applicability in power electronics - first, its voltage handling capability, second its high-temperature operability, and lastly its role as an optical switch and an isolator. While PIN diodes fabricated on (100) and (111)-samples, demonstrated a higher blocking voltage in (100) compared to (111) viz. 1kV, the maximum electric field of ~4MV/cm was registered in (111). We also noted that P incorporation, along with surface stability, was greater in (111) over (100), the latter leading to Schottky-PIN diodes in (100), while PIN behavior was intact in (111) [1-4]. We studied and reported up to 600ºC operation in Schottky-PIN diodes for operation under harsh and high-temperature environments [5]. With a proper packaging scheme, the devices were stable to handle high temperatures. This could lead to unprecedented advantages for high-voltage electronics where local junction temperatures in devices can rise to 300ºC or more under specific operating conditions.
Furthermore, to study the possibility of the diamond as a photoconductive switch, or optically triggered device, we fabricated and characterized planar interdigitated photoconductive switches using a single crystalline diamond with 30 µm, electrode gaps [6]. 532 and 1064 nm Nd: YAG laser pulses with energies up to 3.5 mJ/pulse were used to trigger the switches. Photoresponses with sub-bandgap excitation were measured at bias voltages ranging from 10 to 100 V, corresponding to electric fields of 3.3–33 kV/cm. The ratio of resistances measured under dark and under illumination was of the order of 10^{11}. While this value is comparable to those achieved by other wide bandgap materials, the minimum resistances of the devices could be improved.
Based on these three studies, along with reverse recovery analysis [2,7] that we conducted over the past seven years, we envision a diamond-based platform to be suitable for delivering high-temperature tolerant power electronics platforms that can transform the field. Although there remain significant challenges, such as designing edge termination and tackling surface reconstructions, the results so far are remarkably promising.

Diamond for Next Generation Power Electronic Devices EtienneGheeraert[1,2]; [1]University Grenoble Alpes, France; [2]University of Tsukuba, Japan

The key to the efficient transmission and conversion of low-carbon electrical energy is the improvement of power electronic devices. Diamond is considered to be the ultimate wide bandgap semiconductor material for applications in high power electronics due to its exceptional thermal and electronic properties. Two recent developments - the emergence of commercially available electronic grade single crystals and a scientific breakthrough in creating a MOS channel in diamond technology, have now opened new opportunities for the fabrication and commercialisation of diamond power transistors.
These will result in substantial improvements in the performance of power electronic systems by offering higher blocking voltages, improved efficiency and reliability, as well as reduced thermal requirements thus opening the door to more efficient green electronic systems.
In the literature, several diamond-based field-effect-transistors (FETs) have already revealed good on state performance and high blocking voltage capability (~3kV) in a wide range of operating temperatures. The possibility of generating an inversion regime in diamond metal-oxide-semiconductor FET (MOSFET), and the new Deep Depletion regime (D2MOSFET) specific to wide bandgap semiconductors pave the way for a new generation of power devices. The critical part of the transistor is the gate oxide, with electrical charge traps located within the oxide or at its interface with the semiconductor. These traps can screen the gate potential and shift the threshold voltage, making the devices unusable.
The current research carried out mainly in Japan and Europe will be presented, with the various device architectures explored, including MOSFET, MESFET, D2MOSFET and rectifiers.

High Breakdown Voltage Diamond Schottky Barrier Diode via Submicron Fin Channel ShumiaoZhang and Hong-XingWang; Xi'an Jiaotong University, China

Diamond electric devices have potential to be apply for high power applications owing to superior physics and electrical properties. For diamond-based Schottky barrier diode(SBD), the research focus on high breakdown voltage to achieve high power devices. In previous studies, field plate, floating diffused guard rings, fluorine termination, and trench MOS structure have been used to improve reverse blocking characteristic. Trench MOS with fin width is a novel method to improve the capacity of SBD to withstand high voltage. On account of extremely narrow mesa, the lateral depletion at sidewall wide enough to pinch-off leakage current through mesa. In addition, charge-coupling effect is strong for fin channel MOS SBD and can uniform distribution of electric field effectively. Thus, fin channel MOS structure is beneficial to alleviate electric field crowding at the edge of the electrode and avoid premature breakdown.
In this work, submicron fin channel diamond SBD is fabricated by anodic aluminum oxide(PAA) and inductively coupled plasma (ICP) technology. And SiO_2 dielectric layer is deposited on fin channel to realize MOS structure and adjust electric field distribution in diamond. Furthermore, the impact of width of the mesa on breakdown characteristics for diamond SBD has also been investigated.

Theoretical Models of High-Field Transport and Impact Ionization in Ultra-Wide Band Gap Semiconductors EnricoBellotti, MikeZhu and MasahikoMatsubara; Boston University, United States

Theoretical models that attempt to predict high-field carrier transport parameters and the values of the carriers' ionization coefficients are important since they provide an estimate of the expected values and a first order evaluation of the material performance. The direct measurement of ionization coefficients in wide and ultra-wide band gap semiconductor materials is challenging due to the need to operate at high field strengths and the requirement of specific test structures that enable single carrier injection. More often than not, ionization coefficients are inferred from current multiplication data measured in p-n junctions or transistors structures. Unfortunately, sub-par material quality, processing issues and inappropriate measuring techniques have led to ionization coefficients values that are contradictory and with large variation among different datasets.

Developing theoretical models presents its own set of challenges. The established approach is based on a full electronics structure description of the semiconductor material and a suitable model to quantify the interaction of carriers with phonons, impurities and material imperfections. While this methodology has been successful with conventional elemental and compound semiconductors, and it has been applied to some wide band gap materials such as GaN, 4H-SiC [1,2] and diamond, a number of open issues still exists. The main difficulty is the determination of the carrier-phonon scattering strength at high electric field strengths that cannot be inferred from low-field mobility measurements.

Among all wide band gap semiconductors, 4H-SiC [3] and GaN [4] are the material for which ionization coefficients have been measured by several groups. In the case of GaN, different measured ionization coefficients datasets are available and seems to provide a consistent indication of the expected values. Corresponding theoretical models based on full-band Monte Carlo simulations have been able to predict the correct trends, namely the fact that holes dominate the ionization process, but a quantitative agreement between predicted and measured values has only been achieved recently [5].

This talk will provide an overview of the currently available experimentally measured ionization coefficients for wide band gap semiconductors and compare them to the ones obtained with theoretical models of different complexity. Specifically the development of the theoretical models for high-field transport for 4H-SiC, GaN will be discussed. Three different approaches, one based on empirical carrier-phonon scattering rates, one using the rigid pseudo ion model, and the direct evaluation of the interaction parameters based on a ab-initio DFT approach will be compared, and the outcome for each one of them benchmarked against the measured values. Additionally, the models will be applied to determine the ionization coefficients in ultra-wide band-gap semiconductors including AlGaN alloys, cubic BN [6] and diamond.

Quantitative Disorder Metrics and Structure-Property Relationships in Ga-Based Ultra-Wide Bandgap Semiconductors RobertMakin[1], AndrewS. Messecar[1], NancyS. Muyanja[2], KateWislang[3], RodrigoMartinez-Gazoni[3], MartinAllen[3] and SteveDurbin[1]; [1]Western Michigan University, United States; [2]University of Michigan–Ann Arbor, United States; [3]University of Canterbury, New Zealand

In the context of epitaxial semiconductor layers prepared for electronic devices, disorder is frequently an important consideration. One well-known model for quantifying disorder was developed by Bragg and Williams in the early 1930s, who were concerned with accurately describing the varying degrees of atomic ordering in metal alloys. In their formulation, a numerical order parameter (S) is defined as having a value between 0 (fully randomized lattice) and unity (fully ordered lattice). Traditionally this order parameter is measured using x-ray diffraction techniques, but we have recently demonstrated that electron diffraction, Raman spectroscopy and electron microscopy are equally viable experimental methods[1]. Following the approach of Laks, Wei and Zunger as applied to semiconductor alloys, it is possible to employ spin-based modeling in conjunction with cluster expansion theory (out to pair-interaction terms) to express a material property P as $P(x,S) = [P(x=0.5, S=1) – P(x,S=0)]S^2 – P(x,S=0)$, provided that P is dominated by pair interactions. Here, S is the Bragg-Williams order parameter, and x represents the composition (e.g., x = [Ga]/([Ga]+[N])). Consequently, the expectation is that some properties may exhibit a linear dependence on S^2 provided that composition is properly accounted for; in fact, this is what has been observed in the case of a number of different semiconductor materials.

In the present study, forty-four Ga_2O_3 and twenty-eight distinct GaN samples were considered. Ga_2O_3 layers were grown either by plasma-assisted molecular beam epitaxy or a sol-gel method; GaN was grown by plasma-assisted molecular beam epitaxy. An additional set of samples identified in the literature was also included. The Bragg-Williams order parameter was measured using either in-situ reflection high-energy diffraction, Raman spectroscopy, or electron microscopy image analysis, with several samples characterized by multiple techniques (with S typically agreeing to three decimal places). For the GaN samples measured, S^2 ranged from approximately (0.02 to 0.52), with both nitrogen-rich and gallium-rich compositions in addition to stoichiometric material included. For Ga_2O_3, experimentally-determined values of S^2 ranged from (0.08) to (0.53). As would be expected, a range of band gap energies was measured for the GaN samples, including evidence of inverted bands for some gallium-rich samples as indicated by the observed temperature dependence. In the case of Ga_2O_3, only stoichiometric samples were included in the initial study, with a range of measured band gap energy between 3.2 eV at $S^2 = 0.53$ to 5.0 eV at $S^2 = 0.08$. For the GaN samples, Hall effect mobility values were also measured, with a linear relationship between mobility and S^2 and higher mobility values for Ga-rich samples at the same value of S^2. Extrapolation of the experimental points suggests that further tuning of S could lead to slightly higher mobility values than what have been reported for undoped epitaxial layers. There are several ways to tune S in a plasma-assisted molecular beam epitaxy process, with a weak dependence on temperature and a stronger dependence on plasma conditions. In contrast, for Ga_2O_3 grown by PLD, a strong dependence of S^2 on oxygen partial pressure is observed, with a weaker dependence on sapphire substrate plane. For Ga_2O_3 grown by dehydoxylation of GaOOH, a linear relationship between temperature and S^2 is observed. Consequently, process parameters can be tuned during epilayer growth to achieve a specific value of S and composition (x), and thereby engineer a desired value of band gap and potentially mobility.

2:15 PM EL11.05.03
Deciphering 3*d* Transition Metal Dopants in GaN (and Wide Band Gap Materials) using Ground State and Excited State Density Functional TheoryPeterA. Schultz[1], JesseJ. Lutz[1], ReneeVan Ginhoven[2] and ArthurH. Edwards[2]; [1]Sandia National Laboratories, United States; [2]Air Force Research Laboratory, United States

Doping of gallium nitride (GaN) and (ultra-)wide band gap, (U)WBG, materials is used to control the Fermi level and create functional defects for optoelectronic and spintronic applications. Harnessing the greater temperature tolerance, faster switching speeds, and larger breakdown voltages possible with III-nitrides would profoundly improve the performance of power electronics. To exploit the technological potential of 3d-doped (U)WBG requires greater understanding of 3*d* defects than currently exists. Firm identification and characterization of defects in (U)WBG remains fraught. The mismatch between what experiment can measure and definitively identify and what theory can reliably compute is a particularly acute challenge in 3*d*-doped GaN. Using a generalized gradient approximation (GGA) to density functional theory (DFT) along with a non-jellium local moment countercharge (LMCC) treatment of the charge boundary conditions, we demonstrate accurate predictions of defect levels of magnetic 3d dopants in GaN unhindered by a band gap problem and in agreement with available experimental data. We implement an occupation-constrained DFT (occ-DFT) to self-consistently obtain excited state total energies, and thereby predict vertical and adiabatic optical excitation energies corresponding to photoluminescence (PL) data. These GGA excited-state results agree quantitatively with PL measurements, whereas literature hybrid functional calculations fail qualitatively. In concert, ground state (defect levels) and excited state (PL) calculations mandate wide reinterpretation of GaN experimental literature. The Mn dopant is shown to take charge states as deep as (2+), with corroborating evidence anchored at one end by accurate prediction of the 1.4 eV PL for the Mn(0) and the other end by accurate prediction of PL for a d^2 Mn(2+) defect. The 1.19 eV PL in n-type GaN, attributed to Cr^{+4} and touted as a promising candidate for a quantum color center, cannot be the Cr(1+)–the Cr(1+) is stable only in midgap. A combined ground-state/excited-state modeling approach enables more confident chemical identification of defects in (U)WBG, aiding the search to identify, characterize, and design doping regimens to create functional defects with auspicious electronic properties.

Yellow Luminescence in GaN: Predictions for Candidate Defects at Zero and 12 GPa Hydrostatic Pressure ArthurH. Edwards[1] and PeterA. Schultz[2]; [1]Air Force Research Laboratory, United States; [2]Sandia National Laboratories, United States

Yellow luminescence (YL) has held great interest in GaN. The identity(ies) of the YL defect(s) has been controversial for many years. Recent experimental work by Zvanut *et al.* and by Narita *et al.* proved that carbon substituting on a nitrogen (C_N) site is at least one of the components. This identification is supported by recent theoretical results, buttressed by the photoluminescence studies of Reshchicov and coworkers, who resolved the zero phonon line (ZPL) and other phonon replicas. These theoretical studies have found other defect candidates predicted to have PL_{max} and ZPL close to experiment for YL. There is prior data for YL obtained at high hydrostatic pressure, showing that YL band strongly shifts and broadens, making assignment to a single defect untenable. We perform a detailed study of C_N, as well as other candidate defects (V_{Ga}, C_N:O_N, V_{Ga}:O_NH_2, $V_{Ga}H_3$) at 0 GPa and 12 GPa using the standard PBE exchange correlation functional with the local moment counter charge (LMCC) method, an alternative to the standard *jellium* approximation for electrostatic boundary conditions. Prior published LMCC results show that the method reproduces a reasonable proxy for the band gap (3.56 eV (LMCC), vs. 3.3 eV (exp.)) bounding by the span of all defect levels arising from localized charge states for an extensive set of intrinsic and extrinsic defects. We use this “defect band gap” both to estimate the change in the experimental gap as a function of pressure, and to assign new band edges for calculation of PL_{max} at 12 GPa. At 0 GPa our results agree well with Lyons *et al.*: V_{Ga}, V_{Ga}:O_NH_2, and C_N have PL_{max} within ~0.1 eV of experiment (2.18 eV), and also yield accurate prediction for the ZPL. We are in reasonable agreement with Lyons *et al.* that V_{Ga}:H_3 is within 0.2 eV of experiment ZPL. Our new results at 12 GPa provide crucial chemically differentiating information. First, we find that the prediction of the slope of E_G vs. pressure using the extremal defect levels as band edge bounds (36 meV/GPa) is in very good agreement with several experimental values (36-47), where the larger values were taken from the linear coefficient of a quadratic fit, and the lowest was taken from a purely linear fit. For V_{Ga}, V_{Ga}:O_NH_2, and C_N , we find that predicted PL_{max} are no longer close in energy: the values range from 2.51 eV to 2.83 eV. Almost all of the change in PL_{max} is in the ZPL. Even though the Frank-Condon shifts (FCS), the energy difference between PL_{max} and the ZPL, are quite different for each defect, ranging from 0.2 to 0.55 eV, the changes in FCS with pressure are minimal--~10-20 meV. These results point to using hydrostatic pressure, combined with computational predictions, to chemically discriminate PL.

2:45 PM EL11.05.05

Stability and Molecular Pathways to The Formation of Spin Defects in Wide Band Gap Semiconductors for Quantum Technologies ElizabethM. Lee; University of California, Irvine, United States

Spin defects in wide-bandgap semiconductors provide a promising platform to create qubits for quantum technologies. Their synthesis, however, presents considerable challenges, and the mechanisms responsible for their generation or annihilation are poorly understood. Here, we elucidate spin defect formation processes in a solid-state crystals for leading qubit candidates—the divacancy complex in silicon carbide [1] and the nitrogen vacancy (NV) center in diamond. Using *ab initio* molecular dynamics with enhanced sampling techniques, we characterize the formation mechanism of spin defects. We then predict the conditions favoring the formation of spin defects over the competing process of other undesirable defects. Moreover, we identify pathways to create new spin defects and determine their electronic properties using hybrid density functional calculations. The detailed view of the mechanisms that underpin the formation and dynamics of spin defects presented here may facilitate the realization of qubits for designing room temperature quantum devices.

Rutile GeO_2 and $GeSnO_2$ Alloys: A New Family of Ultra-Wide-Band Semiconductors for Power Electronics SieunChae[1], HanjongPaik[2], KelseyMenge[1], KyleBushick[1], JohnT. Heron[1] and EmmanouilKioupakis[1]; [1]University of Michigan, United States; [2]The University of Oklahoma, United States

Ultra-wide-band-gap (UWBG) semiconductors are promising for higher efficiency, reduced size, and lower cost in power-electronics applications. UWBG materials such as diamond, cubic boron nitride (cBN), β-Ga_2O_3, and AlGaN alloys promise orders-of-magnitude improvements in power density compared to current technologies (Si, SiC, and GaN). However, none of the above UWBG materials offers all the desired properties needed for high-performance electronics and, despite decades of research, very few alternative UWBG semiconductors have been developed to date. There is therefore a pressing need to develop synergistic methods that combine predictive theory with experimental synthesis and validation in order to discover and design new UWBG semiconductors that can overcome the limitations of current technologies.

In recent years, our team has advanced the development of rutile GeO_2 and its alloys with SnO_2 as a novel family of UWBG semiconductors that can surpass the state of the art in power electronics. Our predictive atomistic calculations demonstrate that these alloys exhibit superior fundamental properties that can overcome the limitations of current materials. Their band gaps fall in the ultra-wide range, spanning from 3.6 eV for SnO_2 to 4.68 eV for rutile GeO_2. They exhibit ambipolar dopability, with Sb_{Ge}, As_{Ge}, Ta_{Ge}, H_i, and F_O acting as shallow donors, while Al_{Ge} and Ga_{Ge} acting as acceptors. The predicted carrier mobilities are high (up to 377 cm^2/Vs for electrons and up to 29 cm^2/Vs for holes at room temperature), while the relatively light carrier effective masses prevent the formation of self-trapped polarons. The predicted thermal conductivity is high (up to 51 W/m K at room temperature) and surpasses β-Ga_2O_3, a prediction that we verified experimentally with thermal measurements in unoptimized polycrystalline bulk samples. Overall, we find that the Baliga figure of merit of rutile GeO_2, modified to account for donor ionization, surpasses all known semiconductors, demonstrating its unique potential for energy-efficient power electronics.

Experimentally, we demonstrate the synthesis of single-crystalline GeO_2-based thin films and substrates, which are prerequisites for the fabrication of epitaxial devices. Our results demonstrate the epitaxial stability of GeSnO2 alloys over their entire composition range, while the demonstration of epitaxy on high-quality rutile GeO_2 substrates opens up the possibility of epitaxial single-crystalline thin films. Overall, our work demonstrates the promise of rutile GeO_2-based materials for advancing the state of the art in power electronic devices.

Influence of Local Coordination on the Electronic Structure of Ga_2O_3AnnaRegoutz[1], LauraRatcliff[2], TakayoshiOshima[3], FelixNippert[4], BenjaminJanzen[4], EliasKluth[5], RuedigerGoldhahn[5], MartinFeneberg[5], PieroMazzolini[6], OliverBierwagen[6], CharlotteWouters[7], MosbahNofal[7], MartinAlbrecht[7], JackSwallow[8], LeanneJones[8], PardeepThakur[9], Tien-LinLee[9], CurranKalha[1], ChristophSchlueter[10], TimVeal[8], JoelB. Varley[11] and MarkusWagner[4,6]; [1]University College London, United Kingdom; [2]University of Bristol, United Kingdom; [3]Saga University, Japan; [4]Technische Universität Berlin, Germany; [5]Otto von Guericke Universität Magdeburg, Germany; [6]Paul-Drude-Instit für Festkörperelektronik, Germany; [7]Leibniz Institute for Crystal Growth, Germany; [8]University of Liverpool, United Kingdom; [9]Diamond Light Source, United Kingdom; [10]DESY, Germany; [11]Lawrence Livermore National Laboratory, United States

Ga_2O_3 is a key ultra-wide band gap oxide offering a rich structural space, with a number of accessible polymorphs. Its most stable form is monoclinic β-Ga_2O_3 , but other polymorphs, including hexagonal α-Ga_2O_3 , cubic γ-Ga_2O_3 , and orthorhombic ε(κ)-Ga_2O_3 , are of increasing interest. Although this wealth of possible structures opens opportunities to control and tune structure, electronic structure, and ultimately physical characteristics, the polymorphs beyond β-Ga_2O_3 remain comparatively unexplored. Experimental results are particularly scarce due to current limitations in producing high-quality materials and the lack of theoretical results for the more structurally complex polymorphs.

This study presents an in-depth exploration of the relationship between local coordination environments and the electronic structure of the α, β, γ, and ε(κ) polymorphs of Ga_2O_3 . The samples investigated are either bulk single crystals or epitaxial films grown using molecular beam epitaxy (MBE) or atomic layer deposition (ALD), selecting the highest quality samples available for each of the polymorphs. We report high-resolution valence band spectra from soft and hard X-ray photoelectron spectroscopy (SXPS and HAXPES) which are directly compared to theoretical partial and total electronic densities of states as calculated within the framework of density functional theory (DFT). Both deep and shallow core level spectra are also compared to DFT results to explore the influence of structure, rather than solely the oxidation state, on the core level behavior. X-ray absorption spectroscopy (XAS) is used to probe the unoccupied states and in combination with SXPS is used to gain an estimate of the changes in the band gaps of the polymorphs. For the highly disordered γ-Ga_2O_3 polymorph, we combine DFT with machine learning to screen one million potential structures of γ-Ga_2O_3 to develop a robust atomistic model. We can clearly show that only the lowest energy structural models are able to describe the experimental results from SXPS and HAXPES, providing a new avenue to understand disordered oxides.

Ultimately, this work presents a systematic and comprehensive study of the electronic structure of Ga_2O_3 polymorphs, providing an insight into electronic trends and their relationship to crystal structure. This comparative study helps to discern trends between the different structures and advances our understanding of this polymorphic material. It lays the foundation for further exploration of Ga_2O_3 in applications beyond its β phase.

First Principles Investigations of NV-Like Centers in Oxides VrindaaSomjit[1], JoelDavidsson[2], YuJin[3] and GiuliaGalli[3,1]; [1]Argonne National Laboratory, United States; [2]Linköping University, Sweden; [3]The University of Chicago, United States

The nitrogen vacancy (NV-) center in diamond is a prototypical spin defect with favorable properties, such as long coherence times, and optical addressability and readout. However, the drawbacks of this defect, including incompatibility with telecommunication fiber optics infrastructure and manufacturing challenges, continue to prompt investigations into other host material systems. Recent predictions [1] suggest that several oxides, including CeO_2, CaO, and MgO, may possess long coherence times and thus could serve as promising hosts for quantum applications. However, the defects in these oxide hosts that exhibit such long coherence times are yet to be identified. By leveraging a high-throughput first principles workflow [2], we have identified that MgO and CaO can host NV-like centers with promising electronic and optical properties. Using first principles methods including constrained occupation density functional theory and time-dependent density functional theory [3], we report that these defects have a stable spin triplet state and report their absorption, emission, and zero-phonon lines. Interestingly, we also find that strain can tune the excited state potential energy surface of these defect, changing their optical transition energies and ionic displacements by altering the interaction with higher energy excited states. This work provides crucial insight into point defects in a class of promising oxide host materials for quantum applications, as well as points to routes to further engineer them through strain.

Efficient and Accurate Calculations of Electronic Excited States of the Negatively Charged NV-Center in Diamond HannesJonsson; University of Iceland, Iceland

Electronic structure calculations of the properties of ultra-wide-bandgap materials and the effect of dopants in such materials can play an important role in the development of high-performance devices for e.g. quantum information science and ultraviolet optoelectronic emitters and detectors. Results of calculations based on the most commonly used method for electronic structure calculations of solids, density functional theory (DFT), reported in the literature on one of the most commonly used systems, the negatively charged NV-center in diamond, have been contradictory and controversial, leaving the impression that much more computationally intensive methods are needed to get accurate results [1]. This applies in particular to the excited states of the defect relevant for optical generation a pure spin state where DFT calculations from different groups have not even agreed on the ordering of the relevant energy levels, the two excited singlet states and the first excited triplet state. A new approach for calculating excited electronic states using density functionals based on direct optimisation and convergence on saddle points on the energy surface [2,3] has, however, been found to give remarkably close results to 'beyond RPA' embedding calculations and experimental data [4]. This is an important result as it opens the door for large scale, reliable calculations of other doped ultra-wide-bandgap materials without excessive computational effort. The approach presented makes calculations of excited states in materials similar in computational effort as ground state DFT calculations.

Theory of Optically Detected Magnetic Resonance of a Silicon Vacancy in Silicon Carbide DavidFehr and MichaelE. Flatte; University of Iowa, United States

Optically detected magnetic resonance (ODMR) is one tool that can be used to probe the spin character of optically-active color centers in a nondestructive manner, with applications including the identification of radiation-induced defects in semiconductors and quantum magnetometry [1,2]. In ODMR, a color center is optically pumped while a Zeeman magnetic field is swept and the resulting photoluminescence (PL) is measured on a detector. A microwave field is also applied to induce resonant Rabi oscillations, seen as extrema in the PL contrast, and creates a characteristic and reproducible curve. A detailed and fully quantitative simulation of the ODMR of a color center would provide confidence that the foundations of nonequilibrium optical and spin dynamics relevant for ODMR are sufficiently understood, while allowing for the extraction of reliable parameters for spin coherence times, optical transition rates, and microwave coupling strengths.

In this work we simulate room-temperature ODMR of the negatively charged silicon vacancy V_{Si}^- V(2) site in 6H-SiC, an emerging candidate for quantum magnetometry, using Lindblad master equations and density matrix populations and compare with experimental results [2]. V_{Si}^- in 6H-SiC ODMR can be described as a synthetic atom with S=3/2 ground and excited spin manifolds, separated by 1.397 eV, and a metastable state in the energy gap between these manifolds [2,3]. The Hamiltonian of each spin manifold can be divided into terms which cause coherent transitions between states and subsequent resonances, the magnetic and electric components of the microwave field, and terms that dictate the positions of the resonances, the Zeeman field and zero field splitting. In ODMR the ground and excited spin manifolds are coupled via absorption, spontaneous emission, and nonradiative pathways through the metastable state and we simulate these processes, as well as pure dephasing, with a Lindblad master equation [4]. Using the steady-state solution of the master equation and excited manifold density matrix populations, we calculate ODMR curves to compare with experimental results [2].

Through comparison of our calculations with experimental results [2], we show that a vast amount of information is contained in a single ODMR curve. By fitting our model to experimental results [2] we are able to extract spin Hamiltonian parameters such as zero field splitting, g-factors, microwave electric and magnetic field strengths, Stark coupling coefficients [5], and hyperfine couplings. We are also able to extract absorption, spontaneous emission, and intersystem crossing rates as well as coherence times T_2*. Finally, we stress the flexibility of these calculations and their natural extension to ODMR theories of other color centers and polytypes of SiC, and their natural extension to color centers in other wide or ultra-wide bandgap materials, which would be desirable for quantum sensing applications or radiation-induced defect identification.

Diamond P-i-N and Schottky P-i-N Diodes for High Power Limiters JosephineChang[1], HarshadSurdi[2], MasonBressler[1], FranzKoeck[2], BryceWinters[1], StephenM. Goodnick[2], TrevorThornton[2] and RobertJ. Nemanich[2]; [1]Northrop Grumman Corporation, United States; [2]Arizona State University, United States

Diamond P-i-N and Schottky P-i-N diodes are a promising new technology for high power limiters. Receivers, solid-state amplifiers, and detectors commonly use P-i-N and/or Schottky

diodes for protection from high power incident signals. Limiters reflect the majority of excess RF power, but inevitably absorb some portion of the incoming power as well. As dissipated power converts to heat, the thermal impedance and temperature resilience of the limiter diode becomes the primary factor determining device lifetime, reliability, and power handling. Si and GaAs-based P-i-N and Schottky diodes and even SiC-based Schottky diodes suffer non-recoverable thermal overload upon excess power dissipation. Diamond, by contrast, offers superior thermal conductivity and temperature resilience. Diamond also provides good charge carrier mobility and high electric breakdown field making it an ideal material for next generation high power RF limiters.

Power limiter circuits frequently rely on solid-state P-i-N and/or Schottky diodes to act as a protective buffer for microwave components that are susceptible to damage from high-power signals. Limiters must transmit low power signals with minimal attenuation or distortion, while attenuating high power signals so as not to exceed a prescribed maximum. While solid state power limiters offer the advantages of a long operating life, small size, and flexible use, including integration with other MMIC components, they often require a pre-limiter stage due to limitations in power handling and spike leakage. Diamond diodes with high power handling and low spike leakage promise to eliminate the need for a prelimiter stage by offering significantly enhanced power handling and reduced spike leakage.

In a shunt-connected diode power limiter circuit, the diode remains off for low input signals, with any diode off-capacitance (C_{off}) contributing to insertion loss (attenuation of low power signals) and limiting the frequency bandwidth. When the magnitude of the input signal exceeds a threshold, the shunt-connected diode turns on. In the on state, the diode acts as a short to ground, resulting in reflection of most incoming RF power. However, on-resistance (R_{on}) in the diode results in dissipation of some portion of incident power through the limiter circuit. As incident power increases, the power absorbed by the power limiter circuit increases as well. Device overheating from this dissipated power is the primary failure mechanism that sets the maximum power handling of a diode. Using a larger diode can increase power handling at the expense of greater C_{off} and thus greater insertion loss.

The cutoff frequency figure of merit captures the tradeoff between C_{off} and R_{on}, and can serve as a useful metric for evaluating the suitability of limiter device technologies for RF applications. Commercially available high power Si P-i-N diodes have an F_{CO} of around 700GHz. The F_{CO} figure of merit, however, does not account for the power dissipation capability of a device. Two devices with the same F_{CO} may dissipate the same power under the same incident conditions, but if one device can handle a greater heat load, it will have better power handling. Therefore, fabricating diodes in a material such as diamond offers a route to dramatically increasing power handling without insertion loss penalty. Compared to the conventional materials systems used for diodes—including Si, GaAs, and SiC—diamond offers over 20x higher thermal conductivity and 2-3x higher maximum operating temperature. While significant material growth and processing challenges remain before diamond matures as an electronics material, the advent of single-crystal substrates and breakthroughs in bipolar dopant incorporation have spurred rapid advances in recent years. If diamond diodes can be achieved with F_{CO} of several hundred GHz, they could be a viable high power-handling alternative for the Si or GaAs diodes in use today.

8:30 AM EL11.06/EL14.09.02
Improved Nitrogen-Doped Diamond Photoconductivity by Electrode Design KellyWoo, MohamadaliMalakoutian, BhawaniShankar and SrabantiChowdhury; Stanford University, United States

In photoconductive semiconductor switches (PCSS), the conductance between two terminals on a semiconductor is modulated by the absorption of optical radiation in the gap between the electrodes. This switching device can be applied to pulsed power technology for high speed and jitter free switching. These may include radar, particle acceleration, and pulsed high-power lasers. More recently, as we move towards electrification of the grid, trigger isolation enabled by PCSSs may enable safer mechanisms for making and breaking high power circuits as well. However, typical materials studied for photoconductive switching, such as Si and GaAs suffer from thermal runaway effects at high power [1]. Since diamond is an ideal material for high power electronics due to its large bandgap (5.47 eV), high breakdown electric field (10 MV/cm), high carrier mobility, high thermal conductivity (10-20 W/cm.K), and low coefficient of thermal expansion (~1.1um/mK) [2], we chose to study its photoconductive properties and potential as a high power optoelectronic switch.
Past studies have shown photoconductivity in intrinsic diamond by UV-band excimers in high electric fields up to 2 MV/cm [3]. In our devices, however, we utilize nitrogen doped substrates to excite carriers by sub-bandgap photon energies while maintaining the desirable properties of diamond that would facilitate higher breakdown field and better thermal management [4]. In this case, a lower energy, a below bandgap Vis-NIR excitation source is sufficient, which increases the feasibility of PCSS integration. In designing extrinsic PCSS, on/off current ratios should be maximized for high performance switching. In the off state, the material conductance primarily depends on the number of ionized dopants, which is very low in the case of nitrogen doped diamond due to the high activation energy. In the on state, the conduction is increased due to the photogeneration of free carriers through ionization of dopants and traps. In this work, we aim to increase the on-state conductivity by using different metal electrode stacks on both lateral and vertical PCSS configurations. In the vertical configuration, we also aim to demonstrate the higher power capabilities of an extrinsic diamond PCSS.
Testing of the extrinsic diamond PCSS was performed by optically exciting with a frequency doubled Nd:YAG pulsed laser (532 nm) with an output energy of <1 mJ and a full width half maximum (FWHM) of 10 ns. The nitrogen diamond HPHT substrates from Element Six had an average doping concentration on the order of 10^{19}. Our experiments have shown pulsed photoresponses with FWHMs like those of the laser pulse itself, thus nanosecond order rise and fall times were observed. Two different contact stacks were tested: Ti/Pt/Au and Ti/ITO. Because a thin Ti adhesion layer was used, the Ti/ITO contact was measured to be transparent to 532 nm light. In vertical PCSS devices, the on state current was observed to be as much as 70% higher when using Ti/ITO instead of Ti/Pt/Au. This is due to the reduced shadowing effect by opaque contacts and reduced contact resistance by the photogeneration of carriers beneath the contacts. Furthermore, the devices were tested up to biases of 500 V across a drift region of 300 um, resulting in >0.8 A peak photocurrent and showed no signs of breakdown. Through this study, Ti/ITO was established as an effective contact metal for high power PCSS applications, which can be further developed and optimized for higher performance.
This work was supported by ULTRA, an Energy Frontier Research Center funded by the U.S. DOE.

Formation of Ohmic Contacts to (001) Diamond with Nitrogen-Doped Nanocarbon Surface Layers EvangelineAmonoo, VishalJha, TrevorThornton, FranzKoeck, RobertJ. Nemanich and TerryL. Alford; Arizona State University, United States

The electrical properties of Ohmic contacts (*i.e.*, the specific contact resistance) was investigated using the transfer length method (TLM). In this study, the TLM method was employed to analyze the properties of Ohmic contacts using a tri-layer stack of Ti/Pt/Au contacts on a nitrogen-doped n-type conducting nanocarbon (nanoC, (Patent No.: US 11,380,763 B2) epitaxial film grown on a (001) diamond substrate. Samples were annealed to monitor any changes in electrical conductivity and specific contact resistance values between the electrode and the nanoC layer were 8×10^{-5} Ωcm^2. This is significantly lower than previously reported values by almost two orders of magnitude. The improved contact resistivity was attributed to two factors. Firstly, the increased amount of nitrogen incorporation into the nanocarbon film enhanced the electrical conductivity. Nitrogen doping also introduced additional charge carriers, improving conduction properties in the nanocarbon layer. Secondly, the presence of electrically active defects in the film further contributed to the increase in conduction. These findings demonstrate the potential for improved Ohmic contacts in nanocarbon-based electronic devices, offering opportunities for enhanced performance.

9:00 AM *EL11.06/EL14.09.04
Schottky Barrier Diodes Based on B-Doped Single Crystal Diamond Films – An Experimental and Theoretical Methodology KenHaenen[1,2]; [1]Hasselt University, Belgium; [2]IMEC vzw, Belgium

The growth of high quality heavily (p+) B-doped single crystal diamond (SCD) layers is prerequisite for the successful realisation of diamond-based high-power electronics. This presentation will zoom in on a combined experimental and theoretical approach of the impact of methane concentration on the deposition of heavily boron-doped (p^+) single crystal diamond (SCD), in turn influencing the performance of Schottky barrier diodes based on said layers.

Using (100)-oriented high-pressure high-temperature substrates, optimized CVD growth conditions led to ~ 1.6 µm lightly B-doped (p^-) SCD films with an acceptor concentration of (1.0 ± 0.5) $\times 10^{16}$ cm^{-3} on top of the p^+ layers [1]. To fabricate pseudo-vertical Schottky barrier diodes, Ohmic and Schottky contacts were sputtered on the p^+ and p^- layers, respectively.

It was already observed that the forward operation current of the diodes increased proportionally with increasing $[CH_4]/[H_2]$ ratio (from 0.5 % to 3 %) used for the CVD of p^+ layer. This increase in current is associated with an increase in the doping level of the p^+ layers, a direct result of the increase of CH_4 concentration in the CVD plasma [1]. The Schottky barrier height and ideality factor of the diodes were determined and compared with theoretical calculations, where an ideal diode (n = 1) with a barrier height variation over the Schottky diode area agreed reasonably well with our experimental results. The diodes fabricated on samples with the p^+ layers grown at higher $[CH_4]/[H_2]$ behaved similarly, except for their non-ideality (n > 1) [2]. To conclude, the voltage-dependent ideality factor of the Schottky diodes will be discussed.

Electrochemical Application of Boron-Doped Diamond Electordes—Electrochemical Sensors and CO_2 Reduction YasuakiEinaga; Keio University, Japan

Boron-doped diamond (BDD) electrodes are very attractive material, because of their wide potential window, low background current, chemical inertness, and mechanical durability.[1] In these years, we have reported several examples for electrochemical sensor applications including novel microsensing systems for in vivo real time detection of local drug kinetics.[2] Furthermore, applications for electrochemical organic synthesis[3] and electrochemiluminescence (ECL) systems[4] are also reported. Here, recent developments on electrochemical CO_2 reduction using BDD electrodes are presented.
In 2018, we investigated the electrochemical reduction of CO_2 in a flow cell using BDD electrodes. The faradaic efficiency (FE) for the production of HCOOH was as high as 94.7%. Furthermore, the selectivity for the production of HCOOH was more than 99%. The rate of the production was increased to 473 μmol $m^{-2}s^{-1}$ at a current density of 15 mA cm^{-2} with a FE of 61%. The FE and the production rate are almost the same as or larger than those achieved using Sn and Pb electrodes. In addition, the stability of the BDD electrodes was confirmed by 24 hours operation.[5]
Then, in 2019, we were able to control the selectivity and efficiency with which carbon monoxide (CO) is produced by optimizing certain parameters and conditions used in the electrochemical process with BDD electrodes, such as the electrolyte, the boron concentration of the BDD electrode, and the applied potential. With a BDD electrode with 1% boron used for the cathode and $KClO_4$ for the catholyte, the selectivity for producing carbon monoxide was high. On the other hand, with a BDD electrode with 0.1% boron used for the cathode and KCl for the catholyte, the production of formic acid was the most evident. *In-situ* ATR-IR measurements during electrolysis showed that CO_2 anion radical intermediates were adsorbed on the BDD surface in the $KClO_4$ aqueous solution. Here, switchable product selectivity was achieved when reducing CO_2 using BDD electrodes.[6]
Recently, in order to operate on a large scale for industrial applications, an intermittent flow cell system was presented. A stop-start motion of the flow conditions in the intermittent cell was created using a piston pump, and this considerably increases the rate of electrochemical conversion of CO_2 to HCOOH compared to a continuous flow system.[7] Furthermore, we found that an initial electrochemical CO_2 reduction reaction could significantly improved the reaction current and Faradaic efficiency of the CO_2 reduction on BDD electrodes.[8] The effect is referred to as the "self-activation" of BDD. Here, the mechanisms and the effect of self-activation is discussed.

High Production of Hydrogen Peroxide from Carbonated Water Through Electrochemical Synthesis by Boron-Doped Diamond YusukeTatsumi[1], AndreaFiorani[1], IrkhamIrkham[2] and YasuakiEinaga[1]; [1]Keio University, Japan, Japan; [2]Universitas Padjajaran, Indonesia

Introduction H_2O_2 is recognized as a powerful oxidizing, bleaching and water treatment agent. It attracts great interest as a green oxidant because it decomposes to water and oxygen. Most of H_2O_2 is nowadays produced by large-scale anthraquinone auto-oxidation (AO) process, but recently efforts have been made to establish alternative synthetic strategies, because AO process employs anthraquinone, known as a carcinogen, in addition to organic solvents. Electrochemical methods offer some advantage, such as direct synthesis in aqueous electrolytes, and oxygen or water as starting reagents. The boron-doped diamond (BDD) electrode is physically and chemically stable, and it is known for its specific electrochemical property to produce OH radical easily[1]. For the purpose of analytical applications, we previously demonstrated that BDD electrode can produce H_2O_2 from water oxidation. Here, we focused our attention on the optimization of H_2O_2 production on BDD.

Experimental Electrochemical experiments were conducted in a two-chamber cell separated by a Nafion membrane with a three-electrode setup (working electrode and counter electrode: BDD with 1% B/C ratio, reference electrode: Ag/AgCl). H_2O_2 was produced by electrochemical oxidation in chronoamperometry (CA) at 2.5 V. We investigated the effect of electrolyte solution on the H_2O_2 production by comparing the electrolyte salt (phosphate and carbonate), and by pH variation. H_2O_2 was detected by UV-visible spectrophotometry after the reaction with $KMnO_4$.

Results & Discussion CA was conducted for 2 hours in 1 M $KHCO_3$ and 1 M K_2CO_3 aqueous solution respectively as the anolyte, and time production was compared. The maximum production was 16.8 μmol cm^{-2}, whereas it was 118 μmol cm^{-2} with K_2CO_3. This suggests that CO_3^{2-} anion was superior to HCO_3^- anion for H_2O_2 formation. Due to their equilibrium between CO_3^{2-} and HCO_3^-, the ratio of their presence changes with pH. To verify the contribution of CO_3^{2-} to increased H_2O_2 production, 1 M $KHCO_3$ solution and 1 M K_2CO_3 solution were mixed to reach the desired pH. CA performed from pH 8 to 12 demonstrated that the amount of H_2O_2 production increased concurrent to the CO_3^{2-} fraction.
To confirm whether this was due to the effect of the basic solution or carbonate ions, hydrogen peroxide production was conducted either by using 1 M K_2CO_3 or 1 M K_3PO_4 solutions (pH 11.9 and 12.9, respectively), and it was found that only the K_2CO_3 solution produced hydrogen peroxide.
Concerning the mechanism, our laboratory suggested that OH radicals generated by electrochemical oxidation of OH^- on BDD oxidized CO_3^{2-} to $C_2O_6^{2-}$, that reacts with water finally producing hydrogen peroxide by hydrolysis.[2,3] Hydrogen peroxide formation in this work can be considered to have proceeded by a similar reaction pathway.
In addition to the BDD electrode, glassy carbon (GC), fluorinated tin oxide (FTO), and Ni electrodes were used in a 2-hour electrolysis to compare the time dependence of hydrogen peroxide production. The results showed that BDD >> GC > FTO > Ni. Characterization of GC and BDD by SEM after electrolysis demonstrated that the surface of GC electrode was clearly damaged and corroded, while BDD did not reveal any apparent change confirming the high stability of BDD surface. From these results, we demonstrated that BDD can be used profitably to synthetize hydrogen peroxide with a high production rate from aqueous solutions containing carbonate.

Ammonia Synthesis by Electrochemical Reduction of Nitrate Anion using Boron-Doped Diamond Electrode SatoruKuramochi, AndreaFiorani and YasuakiEinaga; Keio University, Japan

Introduction Ammonia is currently in great demand as fertilizer or as industrial raw material, however environmental pollution caused by reactive nitrogen species emitted from factories and agricultural wastewater might be an issue. (1) This is in fact true for nitrate, one of the reactive nitrogen species. Therefore, electrochemical nitrate reduction which produces ammonia is a twofold attracting method: 1) abatement of pollutant (nitrate), and 2) highly useful product (ammonia). In addition, it works under mild conditions. Currently, several metal electrodes and many highly complexed catalysts have been reported for electrochemical nitrate reduction. (2) On the other hand, we focused our attention on boron-doped diamond (BDD) electrodes, which have the advantages to be metal-free and a simple bulky material lend high durability to BDD. Therefore, the objective of this study is to generate ammonia by electrochemical nitrate

reduction by using BDD electrodes.
Experimental The working electrode was a BDD electrode which was fabricated by Microwave Plasma assisted Chemical Vapor Deposition method, the counter electrode was a platinum plate, the reference electrode was a Ag/AgCl KCl saturated, and the electrolyte was sodium nitrate in water. The optimum potential was determined by performing 1-hour potentiostatic reduction in a cell divided by a Nafion membrane. The mass transport effect on ammonia production was determined by changing the cell setup and stirring conditions. The effect of pH and the composition of the supporting electrolyte (e.g., sodium hydroxide concentration) on the Faraday efficiency of ammonia production was also investigated. In addition, the time dependence of ammonia production by electrochemical nitrate reduction was measured over several hours. Ammonia, nitrite and nitrate were quantified by spectrophotometric method.
Results & Discussion The results of constant potential reduction in a divided flow cell showed that ammonia production and Faradaic efficiency were highest at -1.8 V vs. Ag/AgCl. Comparing Faradaic efficiencies by cell and stirring conditions, the divided batch cell with stirring had the highest ammonia production and Faradaic efficiency. This is because the products are not oxidized at the counter electrode in a divided batch cell and the reduction of nitrate anions is diffusion-controlled reaction. When the pH was changed in a phosphate buffer electrolyte, the ammonia Faradaic efficiency was around 70-80% regardless of the pH, without a significant difference. On the other hand, raising the concentration of the supporting electrolyte, in this case sodium hydroxide, increased the Faradaic efficiency of ammonia production. In particular, the ammonia production Faradaic efficiency reached 96.4% when 0.1 M sodium nitrate solution was added of 1 M sodium hydroxide. We found a positive correlation between concentration of sodium hydroxide and charge transfer resistance. During the several hour reduction in 0.1 M sodium nitrate solution, ammonia production was slower than nitrite production at the beginning, but as time progressed, the amount of ammonia production increased while that of nitrite production leveled off. This result suggests that ammonia production by electrochemical nitrate reduction includes sequential reactions. During the 6 hours reduction in 0.1 M sodium nitrate solution added with 1 M sodium hydroxide solution, ammonia production was faster than nitrite production. This result suggests that high concentration of sodium hydroxide promote nitrite reduction to ammonia.

High-Temperature Annealed Al(Ga)N Templates Deposited by PLD for Optimized Epitaxial Growth of UV-C LEDs KevinGuy[1], AlyZaiter[2], MathieuBernard[1], JulienBrault[2], Jean-YvesDuboz[2], GuyFeuillet[1] and FlorianDupont[1]; [1]University Grenoble Alpes, CEA, LETI, France; [2]Centre de Recherche sur l'Hétéro-Epitaxie et ses Applications, CNRS, France

UV-C LEDs are intended to replace Hg-based UV lamps in sterilization and bacterial/viral decontamination systems. UV-C LEDs are currently not efficient enough to consider their use on a large scale, due to a poor external quantum efficiency up to 10%. One of the main issues concerns the high dislocation density in the epitaxial Al(Ga)N layers constituting the active layers of the diode. Using Al(Ga)N templates instead of regular AlN templates could be a solution to increase UV-C LEDs efficiency.

This work focuses on the realization of cost-effective Al(Ga)N templates on sapphire by low-temperature sputtering and PLD (Pulsed Laser Deposition). For the first time, AlGaN layers are deposited directly on sapphire substrates by PLD. A great effort has been made to optimize both the deposition conditions and the substrate preparation. Al(Ga)N templates were characterized by XRD (X-Ray Diffraction), AFM (Atomic Force Microscopy) and SEM (Scanning Electron Microscopy). The pros and cons of sputtering and PLD will be discussed by comparing the roughness and the crystallinity of Al(Ga)N templates. The high temperature face-to-face annealing technique is used to strongly increase the crystallinity of the materials. Modifying the annealing temperature and atmosphere can greatly affect the surface morphology and the roughness of Al(Ga)N, which is of great interest for the subsequent growth of UV-C LEDs.

This work is part of the LABEX GANEXT, and realized in close collaboration between CEA-Leti (Grenoble) and CNRS-CRHEA (Valbonne).

Self-Powered DUV Photodetectors and Their Emerging Applications TaehyunPark and HocheonYoo; Gachon University, Korea (the Republic of)

Among the various range of ultraviolet rays (400 nm – 10 nm), the deep ultraviolet (DUV) region (280 nm – 200 nm) has been recently spotlighted in risk factor monitoring, chemical, and biological sensing fields owing to its specific light-matter interaction in biomaterials, noise-free detection based on solar blindness, and limited environmental generation conditions including partial discharge, missile plume, and flame. However, there are still challenges to using DUV photodetectors (PDs) in practical applications mentioned above as follows. First, material selection with appropriate energy bandgap, and cost-effectiveness for large-scale fabrication is limited. Second, efficient DUV transparent electrodes to reduce the transmittance loss are absent. Third, high-power consumption issues during the operation limit the use of DUV PDs as a unit sensor of the comprehensive range monitoring system.
Here, we introduce our recent efforts implementing cost-effective solution-processed self-powered DUV PDs by systematic strategies including widened energy bandgap through size modulation to quantum dots, synthesizing ultra-wide bandgap oxide semiconductors with great stability, and controlling junction characteristics for effective self-powered operation. We also present our representative DUV PDs-based emerging applications: (i) partial discharge detection [1], (ii) flame sensing for fire monitoring [2], and (iii) blood component identification [3] through facile, and real-time optoelectronic approach. By introducing comprehensive strategies for solution-processed self-powered DUV PDs, this talk suggests the significance and future aspects of the DUV PDs for various emerging applications.

Reliability Investigation on 265 nm UV-C LEDs from a Commercial Point of View FrancescoPiva, MatteoBuffolo, CarloDe Santi, GaudenzioMeneghesso, EnricoZanoni, MatteoMeneghini and NicolaTrivellin; University of Padova, Italy

The reliability of ultraviolet light-emitting diodes (UV LEDs) has acquired relevant importance over the last few years, thanks to increasing requests for disinfection systems, particularly against the Sars-CoV-2 virus. For this reason, it is important to understand how these LEDs perform over time, to identify the criticalities that system designers had to consider.
UV-C LEDs are the perfect solution as a UV light source because they are smaller, lighter, with a faster start-up, and environmentally friendly with respect to the classical mercury-based UV lamp. However, these LEDs do not have the same performance as their visible counterparts, showing a still limited lifetime and a low emitted optical power.
In this work, we studied four interesting devices found on the market, with a nominal emitting wavelength of 265 nm and promising electrical-optical characteristics and lifetimes. We carried out accelerating lifetime tests on each sample, choosing as stress current their absolute maximum reported in the datasheet, and evaluating their electrical (J-V), optical (L-J) and spectral (PSD-J) characteristics.
From the electrical characteristics, we found: (i) an increase in subthreshold leakage current in all devices, corresponding to an increase in parasitic conduction paths in the active region associated with an increase in defect generation. (ii) The high operating voltages, from 6 to 8 V, implied elevated power dissipation over time, which led to a fast decrease in optical power. (iii) To provide useful data for the design phase, we extrapolated the junction temperatures, obtaining values from 44 to 84 °C.
Optical characteristics represented an interesting turning point: two devices reached an L90 higher than 140 h, and three of them presented an L70 of at least 650 h. Just one LED showed a limited L70 of 190 h, aligned with classical results reported in the literature. It is interesting to note that one LED does not show significant degradation after 330 h of stress test, caused by a conservative choice of the manufacturer, which indicated an absolute maximum current density much lower with respect to the other devices. For this reason, we decided to exclude this sample from the following analyzes. In terms of emitted optical power, a LED (called LED S) distinguished itself from the others by an OP an order of magnitude higher at the same current density, although it was not the best for lifetime duration.

To conclude our analyses, we decided to compare the most promising LED with emitting wavelength of 265 nm with the most promising LED at 275 nm, studied in previous tests. From the J-V comparison, we noted similar behaviors, with a lower turn-on voltage for the 265 nm device; OP-J followed similar trends, with a higher optical recovery for the 275 nm LED, which implies a slightly longer lifetime. Instead, PSD-J characterization highlighted the same parasitic spectral peaks in both samples, suggesting similar issues in structure optimization.
Other interesting results came when we compared the total number of doses to disinfect the Covid-19 virus that an LED can provide during its lifetime. Considering a dose of 3 mJ/cm2, the best 265 nm LED can provide double doses with respect to the 275 nm LED, but their cost is higher, due to the elevated cost of the device. In fact, normalizing these results for device expense, we found that 275 nm LED is the right choice for a disinfection system. But both results are outdated if we consider LED S: despite its lower lifetime, the higher total emitted optical power allowed it to provide 6.5 times the number of doses per LED with respect to the best 265 nm LED, and 3 times the number of doses per LED per Euro with respect to the best 275 nm LED.
These results are important design considerations because they show the importance of achieving the best trade-off between wavelength, optical power, and reliability to build an efficient disinfection system.

4:15 PM EL11.09.04
Device Design Considerations for a Monolithically Integrated III-Nitride Infrared-Visible Detector-Emitter AlirezaLanjani[1], BenjaminMcEwen[1], EmmaRocco[1], VincentMeyers[1], DavidHill[2], W.K. Chan[2] and Fatemeh (Shadi)Shahedipour-Sandvik[1]; [1]University of Albany, United States; [2]SRI International, United States

Quantum well infrared photodetectors (QWIPs) have been used for applications such as telecommunication and thermal imaging in astronomy and defense. Recently, III-nitride materials have attracted much attention in the design of QWIPs owing to their large conduction band offset (CBO) up to 2 eV [1], which makes it suitable for a variety of intersubband transition (ISBT) energies [2]. The system's polarization in the c-direction offers additional design flexibility, permitting further tuning of band offset and therefore of ISBT energies.

One of the challenges impeding the use of III-nitride QWIPs in many applications, such as thermal imaging, is the need for wavelength up-conversion to permit emission in the visible range. Without integrated up-conversion, the QWIP must have an additional readout circuit, which increases the device complexity, size, and weight which is undesirable in many applications such as handheld devices. This challenge was overcome in another material system where monolithic integration of a GaAs/AlGaAs QWIP and light emitting diode (LED) was proposed in 1997 [3] and successfully demonstrated [4]. The principle of integrated QWIP-LED for wavelength upconversion is the photoexcitation of carriers from IR spectral radiation in quantum wells by ISBT and then injection of excited carrier towards the LED for generation of visible light [5]. Such structures require precise control over the thickness of layers and interfaces. Growth of several nm thick layers with high quality interfaces (e.g., in QWIP) is quite challenging in metal organic chemical vapor deposition (MOCVD) of III-nitrides. Of key importance in interface quality is the RMS roughness of each layer, controlled by the time lapse between growth of barrier/well/barrier and growth rate in the layers. Thicknesses of less than 5 nm were required in our QWIP design.

In this work, we present for the first time a design for a monolithically integrated III-N detector-emitter with a target absorption wavelength of 1.5 µm and emission in the visible range. Parametric tuning of QWIP layers compositions and thicknesses is performed with parallel simulations using classical (Sentaurus TCAD) and quantum mechanical (nextnano) modelling. The impact of doping and polarization charges at heterointerfaces of the QWIP structure on the band alignment and absorption are discussed. It is found that p-type doping of the QWIP superlattice is required for absorption of TE polarized light. Doping and composition of the transition layers between QWIP and LED were optimized to promote higher carrier injection efficiency. Experimental limitations and experimental material characteristics are considered to achieve a realistic design. We will present characterization of initial proof-of-concept structures grown by MOCVD, comparing simulated design to experimental characteristics.

Broadband Photodetectors with Zinc Gallate Spinel Structure for Broadband IR-Vis-UV Wavelength Detection SeungmeKang, WangmyungChoi and HocheonYoo; Gachon University, Korea (the Republic of)

The detection range of light wavelengths is a crucial factor for photodetectors (PDs) since they need to be capable of detecting a wide spectrum of optical signals. The active layer, located between the electrodes, plays a significant role in the photodetection performance of broadband photodetectors (BPDs). Recent studies have focused on exploring photosensitive materials that can generate electron-hole pairs from photon energy using simple fabrication techniques and are stable in air. Among these materials, metal oxides show promise as active layers for BPDs. However, previously reported metal oxide BPDs have limitations, such as lower photodetection performance and the need for external bias at specific target wavelengths, when compared to narrow-band PDs. In this study, we propose a BPD with a spinel structure capable of detecting a wide range of wavelengths from ultraviolet (UV) to infrared (IR) by synthesizing zinc gallate (ZnGa2O4) using a solution process. The BPD device was fabricated through a straightforward spin-coating process and thermal evaporation. We formed an n-type ZnGa2O4 layer and a top titanium (Ti) electrode on p-type silicon. The resulting BPD demonstrated distinct photoresponse across various wavelengths, ranging from UV-C to the visible and IR regions. Notably, we achieved an IPhoto/IDark ratio of up to 105 AA-1 at 0 V, indicating that our BPD is suitable for self-powered operation without the need for any external voltage application. To assess the uniformity of the BPD, we fabricated a 10 x 10 array and confirmed the possibility of broadband detection in all 100 devices.

Achieving Highly Reliable, High Mobility Spinel SinglePphase IZTO Thin-Film Transistors at a Low Temperature of 300°C Gwang-BokKim; Hanyang University, Korea (the Republic of)

In this study, $In_{0.22}Zn_dSn_{0.78-d}O_{1.89-d}$ [d = 0.55] films featuring a spinel single phase are effectively produced at a low temperature of 300 °C by meticulously designing the cation composition and employing a catalytic chemical reaction. Thin-film transistors (TFTs) with an amorphous $In_{0.22}Zn_dSn_{0.78-d}O_{1.89-d}$ [d = 0.55] channel exhibit a respectable mobility of 41.0 cm^2/Vs, which is a result of the cooperative intercalation of In and Sn ions. On the other hand, TFTs with polycrystalline spinel $In_{0.22}Zn_dSn_{0.78-d}O_{1.89-d}$ [d = 0.55] channel layers, created through metal-induced crystallization at 300 °C, display an impressive field-effect mobility of approximately 83.2 cm^2/Vs and outstanding stability against external gate bias stress. This can be attributed to the consistent formation of the highly ordered spinel phase. We deduce that the cubic spinel phase of $Zn_{2-y}Sn_{1-y}In_{2y}O_4$ (y = 0.45) film holds great potential as a replacement for semiconducting polysilicon in the backplane channel components of mobile active-matrix organic light-emitting diode displays.

8:00 PM EL11.10.02
Effects of Sn Doping Concentration of α-Ga_2O_3 Films Grown by Mist-CVD Jang hyeokPark and You SeungRim; Sejong University, Korea (the Republic of)

Recently, gallium oxide (Ga_2O_3) has been considered the next-generation power semiconductor materials because it has a wide band-gap of 4.9-5.3eV. For the growth of epitaxial Ga_2O_3 films, hydride vapor phase epitaxy, metal organic chemical vapor deposition, molecular beam epitaxy, and mist chemical vapor deposition (Mist-CVD) have been proposed. Among them, Mist-CVD has several advantages. It can easily control the chemical compositions and phases as well as does low-cost deposition due to simple equipment and can grow high quality Ga_2O_3 epitaxial films without vacuum systems. Especially, hetero-epitaxial growth we did is essential because it enables high quality thin film growth while the integration of different materials.
In this work, Sn-doped α-Ga_2O_3 (006) thin films are grown on c-plane sapphire (006) substrates by mist-CVD. And then, we conducted analysis of Sn-doped α-Ga_2O_3 thin films with varying doping concentration. The crystal structure and orientation were investigated by XRD θ−2θ. When Sn doping concentration of α-Ga_2O_3 was increased from undoped to 10% and 20%, the calculated FWHM were 421.236arcsec, 600.372arcsec and 292.14arcsec. It showed crystallinity of high quality Ga_2O_3 films despite of doping concentration. When the Sn doping concentration of α-Ga_2O_3 was increased from undoped to 10% and 20%, the calculated optical band gaps were 4.90eV, 4.95eV and 5.65eV. Blue shift in band gap which is believed to be

caused by the Burstein-Moss shift was observed in Sn-doped α-Ga_2O_3 films. Carrier concentration and electrical characteristics were extracted from fabricated Sn-doped α-Ga_2O_3 Schottky barrier diodes (SBDs).
We analyzed Sn-doped α-Ga_2O_3 thin films and carrier concentration control of α-Ga_2O_3 by increasing the Sn doping concentration. This allowed us to demonstrate doping control of Mist-CVD-based α-Ga_2O_3 epitaxial films and revealed the great potential of α-Ga_2O_3 SBDs.

Site-Selective Laser-Induced Crystallization of Amorphous GaO_x for the Micropatterning of Ga_2O_3 Thin Films DaishiShiojiri[1], RyoyaKai[2], SatoruKaneko[1,2], AkifumiMatsuda[2] and MamoruYoshimoto[2]; [1]Kanagawa Institute of Industrial Science and Technology, Japan; [2]Tokyo Institute of Technology, Japan

Wide-gap semiconducting materials have been investigated for practical use in various devices because of advantages in these materials' excellent electronic and optical properties, such as a combination of visible light transparency with electrical conductivity, high voltage resistance, and ultraviolet (UV) light emission and absorption. In past decades, materials with band gaps (E_g) in the 3–4 eV range, such as GaN and SiC, have been the main focus of research efforts. To extend the range of applications using high-power deep-UV light, it is necessary to exploit semiconductors with an E_g above 4 eV.
Ga_2O_3 has been identified as a great potential wide-gap semiconductor with an E_g of > 4 eV. Ga_2O_3 thin films are promising for a variety of UV optoelectronic applications and technologies, such as deep-UV–transparent conductive oxides, UV photodetectors, and high-breakdown-voltage field-effect transistor devices. Among the Ga_2O_3 polymorphs, β-Ga_2O_3 (monoclinic, space group: C 2/m) is identified as thermodynamically stable phase. Its crystalline thin films have been mostly prepared at moderate to relatively high temperatures (> 400°C) by processes such as pulsed laser deposition, metal-organic vapor phase epitaxy, molecular beam epitaxy, and others. In addition, the surface-structure patterning of the single-crystalline β phase is important for device applications, but there are few reports of low-toxicity and low-temperature fabrication methods, especially for those at room temperature.
Excimer laser annealing (ELA) has been widely used for the solid-phase crystallization of amorphous thin films at low temperatures, such as in the manufacturing of poly-Si thin film transistors with large areas in industrial. The laser annealing process exhibits the advantages of high photon energy and a lack of thermal effects in unirradiated areas, and these features would be applicable to the crystallization of amorphous materials of oxide materials with large band gaps.
Previously, we reported the room-temperature fabrication of highly oriented β-Ga_2O_3 thin films on α-Al_2O_3 substrates [1]. We have also reported the fabrication of epitaxial β-Ga_2O_3 films on epitaxial NiO(111)-buffered α-Al_2O_3 substrates using the ELA process [2, 3]. In this study, we report the effects of laser intensity, annealing time, and film thickness on the crystallinity, surface morphology, and optical properties of Ga_2O_3 thin films to discuss the mechanisms of the excimer laser crystallization. In addition, we also report on a fully room-temperature surface-patterning method for wide-gap β-Ga_2O_3, characterized by the site-selective laser-induced crystallization of amorphous GaO_x thin films and by acid-solution etching processes.

Remote Epitaxy of 4H-SiC on Epitaxial Graphene/SiC DoyoonLee, Bo-InPark, KiseokKim and JeehwanKim; Massachusetts Institute of Technology, United States

Remote epitaxy technique has the possibility of impacting many research areas including SiC and GaN SMART power, integration of opto- and electronic devices, HEMT performance, flexible electronics and quantum sciences. SiC, a wide band gap semiconductor, has attracted attention because of its various band gap depending on its polytype, superior thermal conductivity and chemical stability which enable SiC to outperform GaN for applications in extremely harsh operating conditions such as high temperature, aerospace, radioactive environment, etc. In addition, SiC recently has been used as a template for state-of-art such as topological insulator and color center for quantum applications. In spite of its usefulness, the expensive wafer cost of SiC has hindered its scalability and commercialization. Even though the remote epitaxy has proven that it can dramatically reduce wafer cost by reusing substrate, the remote epitaxy of SiC has not been demonstrated.
In this work, we focus on the remote epitaxy of 4H-SiC, which is directly grown on epitaxial graphene (EG) on 4H-SiC (0001) substrate using a chemical vapor deposition (CVD) reactor. The epitaxial graphene was grown via Si sublimation of 4H-SiC substrate. Both on-axis (4H-SiC) and off-axis (4H-SiC cut 4° off-axis towards the [11-20]) substrates were investigated. Following the epitaxial graphene growth, SiC growth was performed. Growth parameters were modified to eliminate SiC polytype conversion and other extended defects and to preserve the graphene at elevated temperatures during the growth for successful remote epitaxy. The epitaxial SiC films were characterized using scanning electron microscopy (SEM), transmission electron microscopy (TEM) and electron backscattering diffraction (EBSD). To evaluate the ability to grow 4H-SiC remote-epitaxially, a Ni metal stressor technique was used to exfoliate the SiC epitaxial film and demonstrated exfoliation yields of up to 50 – 70 %.

Color Spectroscopy for Failure Analysis of Silicon Carbide Single Crystals using Energy Level Analysis HyoungseukChoi; Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Single crystal silicon carbide (SiC), which has a closed-packed crystal structure, is a wide-bandgap (WBG) material applicable to power electronic devices. During crystal growth, many types of SiC stacking order can be produced within the bulk of a single crystal because of temperature fluctuations in the crucible. The different stacking-order types are called "polytypes". These SiC polytypes have the same densities and share a single Gibbs free energy, but the electronic band structures vary, resulting in different ultraviolet photoluminescence (UVPL) wavelengths. The inclusion of the wrong polytype in SiC single crystals is an issue of interest because it is one of the causes of degradation in the reliability of power devices that use them. For example, 4H-SiC is widely used for the fabrication of power electronics, and the inclusion of 3C-SiC within 4H-SiC crystals has been the subject of considerable research with much effort directed toward the control of polytype formation. Therefore, a rapid testing procedure for polytype analysis is important for the mass production of SiC crystals.
Commercial SiC may be categorized as either conductive SiC or high-purity semi-insulating (HPSI) SiC. HPSI SiC includes very few dopant atoms, and hence it has an intrinsic bandgap in the ultraviolet range, corresponding to colorless photoemission. Conductive SiC may be doped with N, P, Al, or B to generate additional energy levels with different colors, depending on their polytype. In conductive SiC, N and P dopants result in shallow donor levels, and Al-doping results in a shallow acceptor level. However, doping with B creates a deeper acceptor level, allowing a donor-acceptor pair (DAP) with an energy difference in the visible range to be created. These B-doping-induced DAP recombination energies result in UVPL emission from conductive SiC.
Color spectroscopy can measure energy levels via transformation of ultraviolet photoluminescence (UVPL) color images into a color space in which emission energies have been indexed. It can be applied to the measurement of electronic energies in various materials that have energy-level differences in the visible range (1.65–3 eV). We demonstrate that color spectroscopy provides potential for cost-effective, simple, non-destructive, and full-field measurement of energy levels and can be applied widely, including in laboratories and on production lines. In this study, we developed a new spectroscopic technique named "color spectroscopy" and applied it to the analysis of the different polytypes of silicon carbide single crystals. Raman and photoluminescence spectroscopic data are compared with the results of our method to verify its accuracy. We show that color spectroscopy can provide very accurate energy-level measurements and has potential as a characterization tool in many fields.

Ozone Gas Sensing and Photo-Refreshing in Solution-Processed IGZO-TFTs HiroharuSasajima, TakaakiMorimoto and KeisukeIshii; National Defense Academy, Japan

In recent years, flexible devices, in which semiconductor circuits are fabricated on polymer film or paper, have been attracting much attention. One of the leading candidates of material for them is Indium Gallium Zinc Oxide (IGZO). Because of higher mobility and lower leakage current than conventional a-Si, it is used as a material for thin-film transistor (TFT) on flat panel displays. Since the connectional fabrication process, namely vacuum process is not cost-effective for fabricating large electronic devices, solution processes such as coating and printing one promising as the inexpensive preparation methods. We have reported that IGZO-TFTs can be fabricated by the solution process. On the other hand, flexible devices should consist of not only TFTs but also various devices such as sensors, which have never been reported as solution-processed IGZO devices.
Although ozone gas is widely used in various industrial fields, since high concentration ozone is harmful to the human body, the concentration should be exactly controlled. We are developing an ozone gas sensor based on solution-processed IGZO-TFTs. We have already detected high concentration ozone (100 ppm) by using these TFTs successfully. However, for practical use, they have to detect ozone at less than 10 ppm, at which ozone becomes harmful. In this study, the sensitivity of solution-processed IGZO-TFTs to 5 ppm ozone was evaluated. In order to improve the ozone detection sensitivity, we also optimized the fabrication conditions and elucidated the reaction mechanism of this sensor. In addition, we clarified that the refresh behavior essential for repeated use as a sensor is induced by the irradiation of visible photons (1.7-3.1 eV).
The precursor solutions for the fabrication of solution-processed IGZO-TFTs were prepared by dissolving nitrate hydrates of In, Ga, and Zn in 2-methoxyethanol and mixing each solution at a ratio of In: Ga: Zn = 6: 1: 3. This precursor solution was dropped onto a p-type Si substrate with a SiO_2 thermal oxide film, spin-coated, and fired in air for 1 hour. Then, the Al drain and source electrodes were formed by vapor evaporation on this IGZO film to fabricate a TFT. Here, p-Si is also used as a gate electrode.
To evaluate the ozone detection sensitivity, the drain current (I_D) was measured with and without ozone exposure, while the TFT was turned on by applying +40 V to the gate and drain electrodes. Here, the reduction rate of I_D by ozone exposure for 1 minute was defined as the ozone detection sensitivity *S*. At samples spin-coated at 2000 rpm and fired below 340 °C, *S* exceeds 10^3 even when the ozone concentration is as low as 5 ppm. In the O 1s XPS spectrum, the intensity of a peak due to OH groups becomes larger in the samples measured with high *S*. The FT-IR peak intensity due to the stretching vibrations of the OH shows a similar trend. This indicates that the OH groups in the IGZO film contribute to the reaction mechanism to ozone.
To recover the I_D reduced by ozone, IGZO-TFTs in the on-state were irradiated with photons at energies of 1.7 to 3.1 eV for 5 min. After photon irradiation above 2.6 eV, I_D recovered significantly, indicating that these TFTs can be reused as a sensor. This threshold is slightly smaller than the band gap energy of 3.05 eV estimated from the optical absorption spectrum. Considering the reported band diagram, the recovery of I_D can be caused by the excitation of electrons from a state near the valence band to the donor level of IGZO. Furthermore, the ozone-induced I_D reduction can be caused by the reverse reaction, i.e., the electron desorption in the donor level by ozone.

8:00 PM EL11.10.07
Theoretical Analysis of Threshold Voltage Shift with Operating Temperature of Self-Aligned Coplanar IZTO Thin Film Transistors MinjaeKim; Hanyang University, Korea (the Republic of)

With the rise of the Internet-of-Things and 5G networks, electronic devices with low power consumption are crucial. However, as FETs are downscaled to meet performance demands, self-heating-induced instability becomes a challenge due to limited heat dissipation paths. This leads to thermally accelerated degradation and increased power consumption. The self-heating effect in TFTs, especially those used in organic light-emitting diode (OLED) displays, has not been extensively studied. The study focuses on amorphous indium-zinc-tin oxide (a-IZTO) TFTs, which offer high field-effect mobility and low off-current. The study identifies intrinsic and extrinsic factors contributing to temperature-dependent VTH instability, including subgap density-of-state (DOS) and interface traps. The paper presents an analytical model for temperature-dependent VTH instability and validates it through experiments, DOS extraction, and simulations. The diffusion of hydrogen in a-IZTO TFTs is also examined, and optimal hydrogen incorporation is found to improve performance and thermal VTH stability. The study highlights the importance of material and device design parameters, such as subgap DOS, channel thickness, and gate capacitance, in optimizing oxide semiconductor TFTs for applications like OLED displays, augmented and virtual reality, memory, and logic devices.
In this study, we investigated the impact of temperature on the stability of the threshold voltage (VTH) in self-aligned coplanar amorphous indium-zinc-tin oxide (a-IZTO) thin-film transistors (TFTs). We developed an analytical model that revealed the importance of device geometry and reducing the subgap density-of-state (DOS) in achieving high stability in a-IZTO TFTs. The validity of the model was confirmed through experiments and computer simulations. The study also examined the role of hydrogen impurities in the performance and VTH stability of a-IZTO TFTs. It was found that incorporating hydrogen in the a-IZTO channels improved TFT performance and thermal stability due to hydrogen acting as a passivation center. However, excessive hydrogen incorporation increased the subgap DOS distribution, resulting in a slight deterioration in thermal stability. Consquently, two strategies were identified to improve the temperature stability of VTH in oxide TFTs. Firstly, minimizing the subgap DOS distribution can be achieved through a post-deposition annealing (PDA) temperature of 320 °C, resulting in reduced subgap DOS and improved thermal stability. This can be attributed to the passivation effect of hydrogen during PDA. Secondly, geometrical engineering of the channel thickness (Tch) and oxide capacitance (COX) can help mitigate the effect of temperature on the VTH shift. A thinner channel and/or higher COX were shown to be effective in achieving stable VTH at varying temperatures. The study discussed the use of careful thermal annealing, mass ensification of the channel layer, and interface matching between the channel and gate dielectrics to obtain super-steep IV characteristics in metal oxides, which can further reduce subgap DOS distribution and enhance thermal stability. The findings of the study have implications for future designs of stable oxide semiconductor TFTs, particularly in applications such as organic light-emitting diodes, augmented and virtual reality, memory, logic, and monolithic three-dimensional devices. Experimental results and computer simulations validated the analytical model, providing valuable insights for the design of oxide TFTs with improved temperature stability of VTH.

8:00 PM EL11.10.08
Selective Deposition of Fluid Skin Restorer Passivation Layers for IGZO TFTs using Electrohydrodynamic Jet Printing for Enhanced Electrical Characteristics and Stability YoungWookKim, Min SeongKim, Jong HyukAhn, Hyung TaeKim, SujinLee and Hyun JaeKim; Yonsei University, Korea (the Republic of)

Amorphous oxide semiconductors (AOSs) are commonly used as active layer materials in thin-film transistors (TFTs) due to their notable advantages. Especially, indium−gallium-zinc-oxide (IGZO) based TFTs among AOS-TFTs include attractive mobility (~ 10 cm^2/Vs), low off current (< 100 pA), and high transparency (> 80%) in the visible region, making them suitable for display backplanes. However, IGZO TFTs exhibit critical instability issues when exposed to light, temperature variations, bias stress, and ambient gases. One of the significant challenges is the threshold voltage (V_{th}) shifts caused by O_2 and H_2O exposure in the atmosphere. The adsorption/desorption of O_2 and H_2O molecules can shift the V_{th} of IGZO TFTs in a positive or negative direction, acting as donor-like or acceptor-like states, respectively. To mitigate this problem, optimal passivation layers (PVLs) are required to prevent the IGZO channel layer from coming into contact with the ambient environment, and numerous studies have focused on developing inorganic and organic material PVLs to address these challenges. Inorganic materials such as SiO_2 and Al_2O_3 have been commonly used, but they require high temperatures and expensive vacuum processes. These conditions are unsuitable for flexible display devices, which are typically manufactured on polymer substrates with low glass-transition temperature (< 200ºC). Moreover, the limited flexibility and brittle properties of inorganic PVLs pose further constraints. In order to overcome the limitations of inorganic PVL, PVL utilizing organic materials such as polydimethylsiloxane (PDMS) and Poly (methyl methacrylate)) (PMMA) have been studied. However, due to its unique material properties, organic PVL is inferior to inorganic PVL in the view of barrier performance against ambient gases.
In this study, organic material fluid skin restorer (FSR) with low gas permeability was introduced as PVL of IGZO TFT. To reduce the viscosity of FSR, the solution was prepared by dissolving FSR in ethanol to a concentration of 2 wt% at room temperature with physical stirring. The FSR PVL has an advantage in minimizing the thermal degradation on the device by annealing for 5 min at a low temperature of 100ºC compared to PMMA PVL which required 150ºC, and 20 min. The electrical characteristics and stability under positive bias stress (PBS) exhibited improvement compared to the devices without FSR PVL, specifically in terms of field-effect mobility 7.22 to 18.95 cm^2/Vs, on/off current ratio 2.23 10^8 to 7.54 10^8, and subthreshold swing 0.46 to 0.43 V/decade. The Vth shift under PBS of FSR PVL for 10,000s decreased from 6.16V to 4.67V compared to the devices without PVL. These improvements are expected to be due to the diffusion of atoms, such as nitrogen and oxygen from the FSR to the channel layer, and the blocking of the adsorption/desorption of ambient gases such as O_2 and H_2O. Moreover, the electrohydrodynamic (EHD) jet printing method enables selective deposition of FSR on IGZO TFTs. Given its selectivity, transparency, and impressive performance, this material holds a great promise as a valuable resource in the field of printing electronics and transparent devices (e.g., flexible displays, wearable sensors).

Thin Films of Zn(S, O) and (Zn, Mg)O as Wide-Band Gap Components in SnS Solar Cells LuisA. López Cruz, P. KarunakaranNair and M.T. SanthammaNair; Universidad Nacional Autonoma de Mexico, Mexico

Thin films of sulfides and oxides of zinc such as Zn(S, O) and (Zn,Mg) O as wide band gap buffers are known to provide better band alignments than CdS in heterojuction solar cells with SnS absorber. We used chemical bath deposition for obtaining thin films of Zn(O, S) and RF sputtering for (Zn, Mg)O films. Thin films of zinc sulfide deposited from aqueous chemical baths of soluble complexes of Zn(II) and thioacetamide or thiourea as sulfide-ion source, are Zn(O, S) with a sulfur to zinc ratio of 0.28 to 0.34. The optical bandgap of these films deposited on quartz substrates is around 4 eV. Variations in crystal structure, chemical composition, and band gaps occur in the films when the films are heated with S- and Se-vapor at 400 – 500 °C. For example, the films showed XRD peaks characteristic of cubic ZnS and a S/Zn of 0.89 after they are annealed in presence of S at 500 °C under nitrogen. The thin films of (Zn, Mg)O obtained by co-sputtering showed hexagonal crystal structure with band gap 3.2 to 3.8 eV. The electrical conductivity in both these films is of the order of 10^{-8} Ω^{-1} cm^{-1}. Photovoltaic structures incorporating these films with chemically deposited SnS of cubic and orthorhombic structures as absorber components showed V_{oc} of 480 mV in the case of Zn(O,S) and 508 mV in the case of (Zn, Mg)O buffers.

Characterization of Gold-Catalyzed Gallium Oxide Nanowires GeordanDorsey[1], AntonioMoore[1], WarrenCollins[1], AkiraUeda[1,2], VirginiaLorenz[3], ArendM. van der Zande[3] and

RichardMu[2]; [1]Fisk University, United States; [2]Tennessee State University, United States; [3]University of Illinois at Urbana-Champaign, United States

The growth of β-gallium oxide (Ga_2O_3) nanowires has been achieved by the vapor-solid-liquid method on silicon wafer substrates. In Argon atmosphere, pure gallium was heated to produce gallium vapor and oxidized by background impurities, inside a vertical tube furnace. Since β-Ga_2O_3 is the most thermodynamically stable phase of Ga_2O_3 at standard temperature and pressure, and has the monoclinic crystal structure, β- Ga_2O_3 nanowires were grown in a specific direction. For the growth of β- Ga_2O_3, the substrates were prepared by treating silicon wafers with hydrofluoric acid, then sputter-coated with a 2 nano meter gold layer. The correlation between the gold nanoparticle diameter and the morphology of the Ga_2O_3 nanowires was studied. The growth orientation was also investigated for nanowires on these two kinds of substrates via Transmission Electron Microscopy (TEM) characterization. The elemental composition was also verified using Energy-dispersive X-ray spectroscopy (EDS).

The authors acknowledge the support of the NSF through the Partnership for Research and Education in Materials (PREM) program DMR-2122169, the University of Illinois at Urbana-Champaign Materials Research Science and Engineering Center DMR-1720633, and NSF HBCU-RISE Program HRD-1924241

Epitaxial Growth and Semiconductor Properties of Novel UWBG Oxides for Power Electronic Devices KingsleyO. Egbo[1], EmilyGarrity[2], Cheng-WeiLee[2], BrooksTellekamp[1], VladanStevanovic[2] and AndriyZakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Electronic devices suitable for high power, high voltage operation and which can withstand high-temperature environments are required for applications in electric vehicles, gas turbines, gas and oil drilling, and other energy-dense systems. For these devices, the active layer determines the application space possible, and ultrawide bandgap semiconductors with suitable carrier mobility and power figure of merit ensure a high breakdown field and limited temperature-induced leakage which are required for high-voltage and high-temperature applications respectively. Among ultrawide bandgap materials, most oxides offer further advantages for operation in oxidizing and reducing conditions as they are chemically robust.
A recent high throughput search predicted thirty candidate oxide materials with properties suitable for power electronic applications and among these candidate materials, $InBO_3$, Mg_2GeO_4, and $In_2Ge_2O_7$ were identified as having the best potential in high-power device application[1]. Here, we explore the thin film growth and properties of these three novel ternary oxides. Thin films of these novel ternary oxides are grown by Pulsed laser deposition using a KrF Excimer laser of wavelength 248 nm in a vacuum chamber with a base pressure of 10^{-8} Torr. Ceramic targets of these ternary oxides were ablated at an average pulse repetition rate of 8Hz and laser energy of 300mJ on different single crystalline substrates. Structural, composition and optoelectronic properties of the thin films are explored by x-ray diffraction, x-ray fluorescence, spectroscopic ellipsometry, and x-ray photoelectron spectroscopy.
Structural characterization shows that epitaxial spinel-type Mg_2GeO_4(100) is obtained on ~1.8% lattice mismatch $MgAl_2O_4$(100) and MgO (100) substrates. $In_2Ge_2O_7$(220) is grown on Al_2O_3(00.6) and $InBO_3$ thin films on Al_2O_3(00.6) and YSZ (100) are polycrystalline. Spectroscopic ellipsometry analysis gives a bandgap value of 4.9 eV, 4.0 eV, and 5.1 eV for $InBO_3$, $In_2Ge_2O_7$, and Mg_2GeO_4 respectively which matches closely to theoretical predicted values[1]. Preliminary transport measurement for undoped thin films shows that both $InBO_3$ and Mg_2GeO_4 are semi-insulating while $In_2Ge_2O_7$ shows sheet resistance >1MΩ. However, detailed defect chemistry calculations further provide insight into the dopability of these materials. Results show that $InBO_3$ has defect chemistry that allows n-type doping under In-rich/O-poor synthesis. Zr also acts as a donor in both $InBO_3$ and $In_2Ge_2O_7$.
These results provide the basis for further material exploration and characterization of these new set of ultra-wide bandgap ternary oxide materials and will pave the way for their potential integration in high-power devices.

Study on Enhanced Electron Field Emission Properties of Graphene Quantum Dots Synthesized by Pulsed LASER Ablation Vincent R.Walsh Rivera, Muhammad ShehzadSultan, Amanda M.Gracia Mercado, BradWeiner and GerardoMorell; University of Puerto Rico - Río Piedras, United States

Graphene quantum dots (GQDs) and Nitrogen doped graphene quantum dots (N-GQDs) were synthesized by Pulsed LASER Ablation method. The nanostructure and chemical composition of the GQDs were analyzed by means of TEM, HRTEM, Raman, XPS, and FT-IR spectra. Field emission is a quantum mechanical phenomenon where electrons tunnel from the cathode to the anode through vacuum upon an applied electric field. So far field emission properties of two-dimensional (graphene) and one-dimensional (CNT) carbon nanostructures have been extensively studied. For the first time, to the best of our knowledge, the field emission behavior of GQDs and N-GQDs, deposited on n-Si (100) substrates, is studied. As a candidate of cold cathode, the GQDs display good field emission performance. The Field emission properties of GQDs and N-GQDs were studied by measuring turn-on field (*E*) and field enhancement factor β. The results show that nitrogen doping improved the field emission properties of GQDs by reducing turn-on field from 13.1V/μm (GQDs) to 7.9 V/μm (N-GQDs) and enhancing the field enhancement factor β from 1427(GQDs) to 2511(N-GQDs). The field emission behavior of pristine GQDs and N-GQDs is explained in terms of change in the effective microstructure as well as a reduction in the work function as probed by measured characterizations. The enhanced emission properties of N-GQDs are mainly attributed to the upshifting of fermi energy level and defects produced as a result of Nitrogen doping. The good emission performance of the GQDs field emitters suggests promising applications in next generation vacuum micro and nano electronic devices

Luminescence characteristics of low-voltage thick-film ELs with evaporated ZnS:Mn and spin-coated BaTiO3 dielectrics and microLEDs Shin-ichiYamamoto[1], KoichiWani[1], TaiseiKitawaki[1], OliverA. Durnan[2], VikrantKumar[2], ReemAlshanbari[2] and IoannisKymissis[2]; [1]Ryukoku University, Japan; [2]Columbia University, United States

Thin film electroluminescent (TFEL) devices have been mainly applied as all-solid-state flat panel displays and other light sources. A thin film EL display consists of an emission layer which is an inorganic phosphor, insulator layers, and top and bottom electrodes. The phosphor layer emits light when its luminescent center is excited by hot electrons accelerated by the applied voltage across the electrodes. Because of its rigid structure, high resistance to humidity, and self-emissive property, TFEL displays have a long life, good visibility, wide operating temperature range, and a thin profile.
The well-established structure of the TFEL is a double insulator type in which the phosphor layers are sandwiched by insulation layers. As TFELs are usually driven by an ac power supply, the double insulator structure assures a stable operation and long life. Variations of TFEL have been intensively investigated over decades. When a transparent conductor such as ITO is used for both electrodes, a transparent display is manufacturabe, which is commercially available aiming at head-up displays or automotive applications. Recently, new types of TFEL using quantum dots as the phosphor material are actively investigated.
Despite the above features, TFEL displays are not available as large size monitors or televisions because the operating voltage is high (>150V), brightness is not enough for television applications, and full-color devices are not ready. A variation of TFEL known as a thick dielectric EL or TDEL was developed to solve these problems. In this structure, a thick dielectric layer, which is a laminate of high-k material powders, replaces the thin film dielectric in TFEL. The dielectric powder in TDEL is well crystallized through its manufacturing process. It exhibits higher relative permittivity or dielectric constant *k* than a thin film dielectric, usually deposited by e-beam evaporation or sputtering. Such thick film dielectric layers have a high breakdown voltage and eventually bring about good reliability and high luminance for blue phosphors, which is inevitable for a full-color display. As thick dielectric layers are manufacturable by an atmospheric process, the manufacturing cost can be lower than TFELs. On the other hand, thick dielectric layers require a high temperature sintering process, and a planarization measure is needed on its surface to grow the phosphor layer on it. These constraints in the process prevent the TDEL from being commercialized as a display product.
In this paper, we investigated a structure and process of TDEL having high luminance with lower operating voltage than TFEL. Although the reported TDEL displays so far have a top emission structure, we employed a bottom emission structure instead. As for the thick film dielectric, paste material, which is a mixture of dielectric powders, a binder resin with solvent, and is curable at low temperatures, is employed. The phosphor layer is a conventional ZnS:Mn deposited by an electron beam evaporator and annealed in a sulfur environment. Aiming at a low operating voltage below 100V, the layer thicknesses are minimized. On the other hand, by using MOCVD GaN thin film, microELD was fabricated and compared with low voltage driving.

Manufacturing 2-Inch AlN and Beyond - The Road to 4-Inch AlN Substrates KaseyHogan, RobertBondokov, JustinMark, GriffinNorbury and JamesGrandusky; Crystal IS, United States

The bulk crystal growth process for aluminum nitride (AlN) has had significant development over the past decade and is now at manufacturing scale. Currently, Crystal IS produces multiple thousands of high quality 2-inch AlN substrates per year. These substrates have demonstrated symmetric (0002) X-ray rocking curve FWHM values as low as 6.7 arcseconds, low UV absorption coefficients of <10 cm^{-1} at 265 nm, and high room temperature thermal conductivities of 294 W m^{-1} K^{-1}. AlN has thrived in the UVC LED market as a better suited substrate over sapphire by providing closer lattice matching to $Al_{1-x}Ga_xN$-based epitaxial layers. There exists a desire for larger diameter (4-inch) substrates to realize the potential for AlN technology in power device applications. In 2022, Crystal IS demonstrated similar quality 3-inch AlN and has since continued to expand to the 4-inch diameter. We demonstrate the growth of 4-inch diameter AlN boules and subsequent wafer characterization, signaling the first commercially available 4-inch substrate to be realized in the near future.

High Performance Self-Powered UV Photodetector Based on Nitrogen-Doped Graphene Quantum Dot Schottky Diode Muhammad ShehzadSultan[1], WojciechJadwisienczak[2], BradWeiner[1] and GerardoMorell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]Ohio University, United States

We report a straightforward bottom-up approach for the synthesis of high-quality nitrogen-doped graphene quantum dots (NGQDs). This approach is cost-effective, environmentally friendly, and suitable for production of high quality NGQDs on large-scale. The as-synthesized NGQDs have high crystalline quality with an average size of 3.26 nm, are water soluble, and show strong fluorescence. The UV-vis spectra indicate that N-doping introduces new energy levels into the electronic structure of graphene, which tune the optical properties resulting in photoluminescence quantum yield (PLQY) of 73%. The NGQDs show excitation wavelength-dependent fluorescence with a maximum excitation and emission at 340 and 431 nm, respectively. Using the as-synthesized NGQDs, we fabricated a high-efficiency fast-response self-powered UV photodetector. Under the illumination of 365 nm UV light with power density of 25 mW/cm^2, the NGQD photodetector shows a high photoresponsivity of 37 A/W, detectivity of 1 * 10^{11} Jones, and external quantum efficiency (EQE) of 12.6 * 10^3 %. This UV photoresponse is fast, with rise time of 0.29 s and fall time of 0.33 s. This work paves the way for the development of graphene-based high-performance optoelectronic devices.

Novel Synthesis and Tuning Optical Properties of High Quantum Yield Nitrogen Doped Graphene Quantum Dots Muhammad ShehzadSultan[1], WojciechJadwisienczak[2], Alejandra P FloresRivera[1], BradWeiner[1] and GerardoMorell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]Ohio University, United States

The graphene quantum dots (GQDs) have attracted the attention of researchers due to their excellent properties and potential applications in biomedicines, energy storage devices and photovoltaics. The photoluminescence is one of the most important characteristics of GQDs. The doping of GQDs with Nitrogen atoms is one of the most effective ways to tune their photoluminescence emission and to increase quantum yield. In this work, high-quality Nitrogen-doped graphene quantum dots (N-GQDs) were synthesized by using pulsed laser synthesis method at various irradiation powers of pulsed laser and changing the concentration of nitrogen doping to effectively tune the photoluminescence emission and improve the quantum yield (QY) of as synthesized N-GQDs. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. To observe optical properties of as synthesized N-GQDs, the UV-vis and Photoluminescence measurements were carried out. The as-synthesized NGQDs exhibit high quality crystalline structure of graphene. A high quantum yield was exhibited by the obtained N-GQDs as compare to the pristine GQDs. The obtained N-GQDs with oxygen-rich functional groups exhibit a strong emission. This work may be helpful toexpand the scope of GQDs especially in biomedical applications.

Mechanisms Unveiled: A Comprehensive Study on Boosting Efficiency in GaN-Based Micro-LEDs MengyuanZhanghu, Byung-RyoolHyun and ZhaojunLiu; Southern University of Science and Technology, China

Micro Light Emitting Diodes (Micro-LEDs), with a size of 100µm or less, are predominantly utilized in display and lighting applications, thanks to their foundation in III-nitrides. Key materials used include GaN/InGaN for blue and green emissions, and AlGaInP for red. GaN-based LEDs are celebrated for their exceptional traits, such as self-illumination, high brightness, low power consumption, rapid response time, and enduring lifespan. When juxtaposed with traditional LEDs, which are over 100 µm in size, Micro-LEDs shine for their superior efficiency. This stems from enhanced thermal distribution, optimal current density distribution, and reduced junction temperature.

However, numerous studies have revealed a downside to Micro-LEDs. As the size of these devices becomes smaller, there's a notable decrease in external quantum efficiency (EQE) - a crucial measure of LED performance. This is attributed to sidewall damage incurred during plasma-assisted dry etching in device fabrication, causing non-radiative recombination centers at the surface of the active layers. Given the large perimeter-to-area ratio of smaller devices, they are particularly susceptible to such sidewall damage.

A prevalent technique to mitigate the impact of this damage involves the utilization of sidewall passivation via dielectric materials. Such treatment increases EQE, a combination of internal quantum efficiency (IQE) and light extraction efficiency (LEE), primarily by curtailing surface recombination according to the ABC model. Hence, devices equipped with passivation layers are anticipated to show higher IQE. Determined by the ratio of radiative recombination rate to total recombination rate, the IQE of an LED holds a significant correlation with the diode's ideality factor in the Shockley model. Micro-LEDs with improved IQE should, therefore, demonstrate an ideality factor approximating one - a physical expectation yet to be comprehensively explored!

To systematically probe this conjecture, we fabricated green GaN-based Micro-LEDs, varying in size from 20 to 100 µm and emitting at 520 nm, on a commercially available sapphire substrate. A 50 nm thermal ALD Al_2O_3 layer was then deposited at 300°C to passivate residual sidewall dangling bonds. Our findings unequivocally demonstrate that this passivation layer bolsters the EQE of Micro-LEDs. An increase in EQE/IQE of Micro-LEDs leads to a decline in ideality factors. As the size decreases, the EQE increases, while the ideality factor descends. It's been observed that the radiative ideality factor of Micro-LEDs can reach 1, aligning with the expectations of the Shockley model. Additionally, we found that the LEE of Micro-LEDs with a passivation layer increases as the device size diminishes. Optical simulations indicate that depositing a dielectric layer with a lower refractive index than III-nitride bolsters light extraction by enlarging the critical angle. In this discourse, we will share a comprehensive presentation of experimental outcomes, along with a detailed analysis of the correlation between the ideality factor and IQE, LEE, and their size dependence, as informed by the ABC and Shockley models.

SESSION EL11.11: Oxide Materials and Devices I

β-Gallium Oxide: Progress in Epitaxial Materials and Power Devices SriramKrishnamoorthy, SauravRoy and ArkkaBhattacharyya; University of California, Santa Barbara, United States

The availability of shallow donors and large area melt-grown bulk substrates are the key enablers for next-generation power devices based on β-Ga_2O_3. Three key results will be highlighted in this presentation. (1) We demonstrate a hybrid low temperature - high temperature (LT-HT) buffer/channel stack growth using metal organic vapor phase epitaxy with record carrier mobility values (range of 196–85 cm^2/Vs) over four orders of doping range ($2\times10^{16} – 1\times10^{20}$ cm^{-3}). Record electron mobility of 110 cm^2/Vs is also demonstrated in delta-doped (2D) channels (n_s = 9.2×10^{12} cm^{-2}). The improvement in transport properties was achieved mainly by realizing pristine doped channels, eliminating undesired parasitic conduction paths, and minimizing carrier compensation. Lateral transistors utilizing these uniformly Si-doped channels with LT buffers exhibit exceptional device performance. Planar and tri-gate transistors showed very low reverse leakage for breakdown voltages up to 3 kV. Due to enhanced electron mobility, these devices were able to exhibit low on-state resistances for a given device dimension. In conjunction with effective electric-field management (achieved max average breakdown field of over 4 MV/cm with tri-gate architectures), these devices were able to deliver a high power figure of merit of ∼1 GW/cm^2. (2) We report on the growth and characterization of in-situ Al_2O_3 dielectric on (010) β-Ga_2O_3 deposited using metalorganic chemical vapor deposition (MOCVD) to enhance the dielectric quality and lifetime. The dielectrics grown at 600 °C exhibited higher interface trap densities ($D_t = 3.2\times10^{12}$ cm^{-2}) and lower breakdown fields (E_{BR}=6 MV/cm) when compared to the dielectrics grown at 800 °C (E_{BR}= 10 MV/cm, D_t=5.4×10^{11} cm^{-2}) as is evident from the hysteresis and the trap density vs energy characterization which were determined using deep-UV assisted CV measurements and the current-voltage characteristics of the MOS capacitor test structures. The temperature-modulated dielectric sample (interfacial layer grown at 800 °C, and the bulk dielectric grown at 600 °C) has higher breakdown strength (E_{BR}=7.7 MV/cm) and lower trap density ($D_t = 1.1\times10^{12}$ cm^{-2}) compared to the dielectric grown at 600 °C. Time dependent dielectric breakdown (TDDB) (current vs stress time) was performed to characterize the long-term reliability of the grown dielectrics.This approach of in-situ dielectric deposition on β-Ga_2O_3 can pave the way for promising robust gate dielectrics for future β-Ga_2O_3 based high performance MOSFETs due to its promise of improved interface and bulk quality and long-term reliability compared to other conventional dielectric deposition techniques.(3) We report large area (1mm^2 and 4mm^2) β-Ga_2O_3 trench Schottky barrier diodes with high-k dielectric RESURF.The breakdown voltage of the BTO field-plated SBD increases to 2.1 kV from 816 V (planar SBD) whereas the breakdown voltage increases to 2.8-3kV for the trench SBD with high-k RESURF. The 1 mm^2 trench SBD exhibits a current of 3.7A(Pulsed)/2.9A(DC) and the 4mm^2 trench SBD exhibits a current of 15A(Pulsed)/9A(DC) at 5V. The breakdown (catastrophic) voltage of the 1mm^2 and 4mm^2 trench SBDs are measured to be 1.4 and 1.8kV, respectively. The rapid progress in the realization of high purity materials, high quality dielectrics , experimentally demonstrated high electric field handling capability along with a pathway to scaling to high absolute current ratings, indicates the promise and potential of Gallium Oxide for next-generation power electronics. This material is based upon work supported by the II-VI Block Gift Program and the Air Force Office of Scientific Research MURI award

9:00 AM EL11.11.02
Evaluating Both Gallium Oxide Wafer Growth Method Economics and Cost Comparision to other Wide Bandgap Materials SamanthaReese[1], KarenHeinselman[1], DrewHaven[2] and

AndriyZakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Saint-Gobain, United States

Gallium oxide (Ga_2O_3) is an emerging ultra-wide bandgap semiconductor which shows promise for use in high-power, high-temperature, optoelectronic, and sensing applications. Ga_2O_3's wider bandgap enables increased breakdown voltages and lower on-state resistances making it potentially superior to current commercially available materials such as silicon carbide and gallium nitride. Economically Ga_2O_3 is cost-competitive with the ability to be grown from melt. To best understand cost drivers and opportunities for research to enable cost reductions we present a techno-economic analysis that projects the cost of 6″ β-Ga_2O_3 wafers fabricated from crystals grown via edge-defined film-fed growth (EFG). We compare it to previously reported epi-wafers grown via the Czochralski (CZ) method. We further explore what are currently key drivers of cost, such as the historically high iridium prices and present cost-sensitivity analysis of other various drivers' impact on the final cost. The key result presented is that EFG has a 2× cost advantage compared to epi-wafers grown via the CZ method.

9:15 AM EL11.11.03
Thermodynamic Phase Control of Highly Crystalline and Oriented Ga_2O_3 Thin Films using Pulsed Laser Deposition AmitK. Khare and IgorShvets; Trinity College Dublin, The University of Dublin, Ireland

Among possible candidates to be the base materials for power electronics, Ga_2O_3 is particularly interesting owing to its excellent material properties (e.g. high-voltage blocking capability and high-temperature operation) that guarantee higher efficiency and lower loss with excellent compatibility with industrial production processes. Although, some of the fundamental materials issues, such as understanding the electronic structure and controllability of composition, require a focused effort to unravel its full potential. Here we present the phase control, stability and growth mechanisms of highly crystalline Ga_2O_3 thin films. β- and γ-Ga_2O_3 thin films are deposited on c- plane sapphire and MgO (100) substrates using pulsed laser deposition in ambient from the vacuum (1e-7 Torr) to oxygen partial pressure (OPP, 2 mTorr). Highly oriented γ- and β-Ga_2O_3 phases are stabilized at the same temperature, only changing the ambient during the film growth. Reflection high-energy electron diffraction and ex-situ high-resolution x-ray diffraction (HRXRD) confirmed the formation of single-phase films with excellent crystalline quality. It is found that the films crystallize in monoclinic β-phase with (-201)-orientation when deposited in oxygen ambient, while it crystallizes in the γ-phase with (111)-orientation when deposited in the vacuum. We observe that the difference between the lattice spacings of the (-201) β-phase and the (111) γ-phase is very subtle; therefore, HRXRD alone is not sufficient in identifying the distinct phases. All the films are electrical insulators at room temperature, suggesting minimal defect related to oxygen vacancies in β-Ga_2O_3, further supported by x-ray photoemission spectroscopy studies. Additionally, the Raman spectra revealed the phase control in Ga2O3 films because Raman active modes are present only in the β-phase, in contrast to the γ-phase.

9:30 AM EL11.11.04
Vertical α-Ga2O3 Device Applications Enabled by Same Crystal Structured Indium Tin Oxide Electrode via Mist Chemical Vapor Deposition KazukiShimazoe, HiroyukiNishinaka, TemmaOgawa and MasahiroYoshimoto; Kyoto Institute of Technology, Japan

Extensive research has been conducted on gallium oxide (Ga_2O_3), an ultra-wide bandgap material, in the field of power electronics and deep UV optoelectronic devices. The band gap of Ga2O3 ranges from 4.4 to 5.3 eV, surpassing the bandgap of Si, SiC, and GaN, thus indicating its potential for enhanced device performance. Among the polymorphs of Ga_2O_3, namely α, β, δ, γ, and κ, α-Ga_2O_3 is characterized by the highest bandgap of 5.3 eV. [1] This α phase exhibits promising potential in power-switching and deep-UV optoelectronics devices, such as Schottky barrier diodes and photodetectors, owing to its ultra-wide bandgap. [2-3] A vertical device structure can provide low on-resistivity and rapid response. One way to realize vertical structure is by inserting a conductive layer under the active layer. However, the growth of metastable α-Ga_2O_3 necessitates an epitaxial growth on other substrates, and an insulating α-Al_2O_3 substrate is usually used, making realizing vertical structure challenging. To address this issue, we featured high-conductive rhombohedral indium tin oxide (rh-ITO) as the bottom electrode. This rh-ITO exhibits the same crystal structure as α-Ga2O3; therefore, it is expected that α-Ga_2O_3 is grown epitaxially on the rh-ITO electrode. This study demonstrates heteroepitaxial growth of α-Ga_2O_3 on rh-ITO electrode and its device applications.
Mist CVD was utilized for the epitaxial growth of oxide thin films. Initially, we investigated the growth of α-Ga_2O_3 on rh-ITO, however, orthorhombic κ-Ga_2O_3 was grown on bare rh-ITO thin films because of the large lattice mismatch between α-Ga_2O_3 and rh-ITO (-9.2%). Therefore, to decrease the lattice mismatch, α-Fe_2O_3 buffer layers with a small lattice mismatch (-1.0 %) were utilized for the growth of α-Ga_2O_3 thin films. XRD 2θ-ω scans determined that the α-Fe_2O_3 buffer layer allowed the growth of α-Ga_2O_3 thin films on rh-ITO thin films. Furthermore, XRD phi scans revealed that α-Ga_2O_3 thin films were successfully grown in the same in-plane orientations as rh-ITO and c-plane sapphire substrates. These XRD measurements indicated that α-Ga_2O_3 thin films were epitaxially grown on the rh-ITO/c-plane sapphire substrates.
Next, we conducted device operations using α-Ga_2O_3 thin films with rh-ITO thin films as bottom electrodes, and fabricated two device architectures, deep-UV photodetectors, and Schottky barrier diodes. For photodetectors, PEDOT:PSS thin films, exhibiting high transparency in the deep UV region to the visible light region, high conductivity, and large work function were utilized for top electrodes. PEDOT:PSS thin films were deposited by mist deposition[4]. The n-type α-Ga_2O_3 and PEDOT:PSS showed Schottky behavior enabling the separation of the photo-exited hole-electron pairs. The spectral photoresponsivity of the photodetector was measured using a short-circuit current and demonstrated the ability to detect UV-C region light without any bias voltage. The photoresponsivity at 220 nm was 9.7×10^{-4} A/W, exceeding that of a self-powered lateral structured α-Ga2O3 photodetector, thereby suggesting its association with the vertical structure, which can reduce the recombination of photogenerated carriers[3]. Furthermore, we investigated the Schottky barrier diode based on α-Ga_2O_3 with Ni/Au electrode deposited by thermal evaporation. Current-voltage measurements confirmed the rectification characteristics of the diode, which can be attributed to the Schottky contact between Ni and α-Ga_2O_3. These results demonstrate the device applications of α-Ga_2O_3 grown on rh-ITO bottom electrodes using mist chemical vapor deposition, including deep-UV photodetectors and Schottky barrier diodes.

High-Temperature Characteristics of β-Ga_2O_3-Based p-i-n Heterojunction Rectifiers KingsleyO. Egbo[1], WilliamCallahan[1], BrooksTellekamp[1], RyanO'Hayre[2] and AndriyZakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Electronic device performance and reliability under extreme conditions such as at very high temperatures is essential for several applications in the industrial, energy, and automotive sectors. Wide band gap semiconductor devices using SiC and GaN have demonstrated operation in the 400-600°C temperature range for prolonged periods of time. However, >600°C operation in oxidizing and reducing conditions requires the next generation of chemically robust ultra-wide band gap semiconductor devices where GaN and SiC fail. Wide bandgap β-Ga_2O_3, an important material for high-power device applications, also shows promise for high-temperature electronics due to reduced temperature-activated parasitic leakage and chemical stability. Ga_2O_3 is not p-type dopable therefore currently studied devices use heterojunction architectures, often with p-type NiO. Unfortunately, NiO and Ga_2O_3 are not predicted to be thermodynamically stable at high temperatures. $NiGa_2O_4$, however, is stable in contact with Ga_2O_3 at high temperatures and is investigated for the first time in this work.
Here, we explore the high-temperature characteristics of vertical heterojunction NiO/*β*-Ga_2O_3 and $NiGa_2O_4$/*β*-Ga_2O_3 p-i-n diodes fabricated using commercial HVPE grown drift layers (Novel Crystal Technology). For both heterojunctions pulsed laser deposition (PLD) was used to grow ~ 200 nm thick p-layer on a 1µm thick HVPE *β*-Ga_2O_3 (001) (~$3.5x10^{16}cm^{-3}$) layer deposited on an Sn-doped *β*-Ga_2O_3 wafer (~$2x10^{18}$ cm^{-3}). The device was processed using photolithography and the device area mesa isolation was achieved by argon dry etching[1]. Anode top contacts on the p-type layers were formed by depositing 30 nm Ni / 100 nm Au via e-beam evaporation while stable Ohmic back contact to Ga_2O_3 was formed by 5 nm Ti / 100 nm Au annealed under N_2 at 550 °C for 90 seconds[2]. Temperature-dependent current-voltage (*I-V*) characteristics were measured in vacuum (≤ 10^{-4} Torr) for temperature setpoints in the range of RT–800°C using a custom-built high-temperature probe station.
The rectification ratio was found to be 10^8 (2V) at room temperature (RT) for both the NiO/Ga_2O_3 and $NiGa_2O_4$/Ga2O3 devices, however, a lower turn on-voltage is observed for $NiGa_2O_4$ (1.4V compared to 1.8V) and is attributed to a smaller barrier height in $NiGa_2O_4$/Ga_2O_3. The turn-on voltage for both device stacks decreased monotonously with increasing temperature. However, while the specific on-resistance decreased rapidly with temperature for the NiO/Ga_2O_3 device, the decrease in specific on-resistance in $NiGa_2O_4$/Ga_2O_3 device was negligible. Thus, while the rectification ratio of the NiO/Ga_2O_3 device was $>10^3$ at 600°C, the $NiGa_2O_4$/Ga_2O_3 device showed a lower ratio of 10^2 due to small forward current attributed to low carrier density in $NiGa_2O_4$ compared to NiO. The measured reverse leakage current increased with temperature due to increasing intrinsic carriers, nonetheless, both devices maintained a leakage current density of $<10^{-3}$ A/cm^2 at 600°C.
To explore long-term continuous operation at high temperatures, the device was soaked at 600°C (>100 hours) and subjected to repeated thermal cycling (30 times) between room temperature and 550°C in flowing N_2 and in laboratory ambient air. Both devices show good stability however the NiO-Ga_2O_3 device had better performance compared to the $NiGa_2O_4$-Ga_2O_3 device due to a higher built-in voltage. These results suggest that irrespective of thermally driven leakage current increase, Ga2O3-based p-i-n diodes hold great potential for high-temperature operation with < 10^{-3} A/cm^2 leakage current density at > 600°C operating temperature.

Innovative Solutions to Overcome Challenges in Gallium Oxide Technology SrabantiChowdhury; Stanford University, United States

In any electronics application today, higher power density is desired. Switches are an integral part of every power converter, impacting its efficiency directly. RF transistors are the backbone of high-frequency power amplifiers for base stations or radars, impacting not only the sustainability of 5G but also national security and resilience. Although Silicon has been the backbone of electronics, it is amply clear when high temperature, high frequency, and high-power density when required simultaneously for an application, wide bandgap semiconductors like Silicon Carbide (SiC) and Gallium Nitride (GaN) are the forerunners. Already commercialized in some RF and power applications, they have pushed the roadmap further beyond Si, owing to their superior material quality. While SiC and GaN are making impressive headway, even wider bandgap semiconductors are being evaluated in labs to understand their role in electronics and optoelectronics. One of the emerging ultra-wide bandgap (UWBG) materials is Ga_2O_3. Vertical MOSFET was a critical milestone in the gallium oxide (Ga_2O_3) roadmap that was recently achieved [1]. Due to the lack of an effective current blocking layer in Ga_2O3, which is essential for any DMOS-like (double-diffused MOSFET) the achievement of a vertical MOSFET has been difficult. Using two novel findings first, a selective diffusion doping technique utilizing magnesium (Mg) doping spin-on-glass (SOG) as a dopant source to form a current blocking layer (CBL), and second, the first demonstration of a vertical Ga_2O_3 MOSFET with the Mg diffused CBL- Vertical Diffused Barrier Field-Effect-Transistor (VDBFET). At its very first stage of development, the device exhibited an excellent field effect-transistor (FET) behavior with a high on-off ratio of 10^9 and a decent saturation. If successful, this technology can lead to at least a 3x increase in power density in vertical switches over and above SiC and GaN, and at a lower cost per die.
Besides the lack of p-type Ga_2O_3, thermal management has been a challenge. For achieving high power density at high frequencies, with aggressive device scaling heat generation is unavoidable. However, the room temperature thermal conductivity of β-Ga_2O_3 (anisotropic; 11-27 W/mK) is the lowest among the technologically relevant semiconductor materials [2]. Polycrystalline diamond epitaxial growth on β-Ga_2O_3 for device-level thermal management was performed and reported in our recent study. Our study focused on establishing diamond growth conditions on β-Ga_2O_3accompanying the study of various nucleation strategies [3]. A growth window was identified, yielding uniform-coalesced films while maintaining interface smoothness. In this first demonstration of diamond growth on β- Ga_2O_3, a diamond thermal conductivity of 110 ± 33 W m^{-1} K^{-1} and a diamond/β- Ga_2O_3 thermal boundary resistance of 30.2 ± 1.8 m^2K G^{-1} W^{-1} were measured. The film stress was managed by growth optimization techniques preventing delamination of the diamond film. It marked a significant step toward device-level thermal management of β-Ga_2O_3 electronic devices.
These two recent experimental studies set the stage to systematically study and understand the challenges of Ga_2O_3technology and create a road map beyond GaN

Electrical and Thermal Properties of BeO Gate Dielectrics for β-Ga_2O_3 Power Devices DohwanJung[1], YoonseoJang[1], PrakashR. Sultane[2], ChristopherW. Bielawski[2] and JungwooOh[1]; [1]Yonsei University, Korea (the Republic of); [2]UNIST, Korea (the Republic of)

Monoclinic gallium oxide (β-Ga_2O_3) is a promising wide-bandgap semiconductor for power device application. β-Ga_2O_3 demonstrates superior material performance, including an ultra-wide bandgap of 4.8-4.9 eV, a high breakdown field of approximately 8 MV/cm, and a remarkable bulk electron mobility of ~300 $cm^2V^{-1}s^{-1}$, showing a Baliga's Figure of Merit (BFOM) of up to 3444. Despites these properties, the primary drawback of β-Ga_2O_3 lies in its heat management capabilities. It exhibits a low thermal conductivity of 10-30 $Wm^{-1}K^{-1}$, which is significantly lower compared to other power semiconductors such as GaN (220 $Wm^{-1}K^{-1}$) and SiC (280-342 $Wm^{-1}K^{-1}$), which potentially makes β-Ga_2O_3 susceptible to malfunctions under high-temperature operation.
The use of conventional gate dielectrics for β-Ga_2O_3 power devices might worsen the thermal dissipation issue. Oxides typically possess low thermal conductivity. For instance, SiO_2 exhibits approximately 1.4 $Wm^{-1}K^{-1}$, and HfO_2 exhibits approximately 1.2 $Wm^{-1}K^{-1}$ of thermal conductivity. To address these challenges, we propose beryllium oxide (BeO) gate dielectrics for β-Ga_2O_3 power devices. BeO possesses unique properties, including a bandgap energy of 10.6 eV, a high dielectric constant of 6.8, and most importantly, an extraordinarily high thermal conductivity of approximately 330 $Wm^{-1}K^{-1}$ coupled with high thermal stability. Its thermal conductivity is the highest among oxides, surpassing that of most metals except for copper and silver. Consequently, BeO holds significant potential in improving the heat dissipation capabilities of β-Ga_2O_3 power devices. However, its application to nanoscale front-end devices has been constrained by the absence of well-established thin film deposition techniques.
In this work, we developed the atomic layer deposition (ALD) of BeO. This technique enables the precise and high-quality deposition of thin film on the substrates. ALD BeO gate dielectrics were successfully grown on β-Ga_2O_3 substrates. We comprehensively analyzed the physical and electrical properties of ALD BeO deposited on β-Ga_2O_3. A BeO on β-Ga_2O_3 was confirmed via a survey scan of X-ray Photoelectron Spectroscopy (XPS). The cross-section TEM image revealed a uniform thickness and a sharp interface between BeO and β-Ga_2O_3. The crystalline growth of BeO in the (102) diffraction on the β-Ga_2O_3 substrate was confirmed using Grazing Incidence X-ray Diffraction (GI-XRD). In addition, we analyzed the electrical properties of BeO gate dielectrics on β-Ga_2O_3 power devices. We determined the conduction band offset (3.4 eV) between the BeO film and β-Ga_2O_3 substrate using Kraut's method, which involved the determination of the valence band offset (0.5 eV) using the XPS core level and valence band maximum energies of the BeO film and β-Ga_2O_3 substrate. The bandgap energies of BeO (8.6 eV) and β-Ga_2O_3 (4.7 eV) were determined using reflection electron energy loss spectroscopy (REELS). The large conduction band offset of ALD BeO on the β-Ga_2O_3 substantially lowered the gate leakage current of β-Ga_2O_3 MOS capacitors. The forward leakage current was 2.21×10^{-9} A/cm^2 at 1 MV/cm for 100 nm Mo electrodes/24 nm BeO dielectrics/β-Ga_2O_3 substrates, demonstrating the potential of ALD BeO as gate dielectrics for high-performance β-Ga_2O_3 power devices.

11:15 AM EL11.11.08
Vertical Van Der Waals Heterojunction Diodes Comprising 2D Semiconductors on 3D β-Ga_2O_3ChloeLeblanc[1], DinushaHerath Mudiyanselage[2], SeungukSong[1], HuairuoZhang[3,4], AlbertV. Davydov[3], HouqiangFu[2] and DeepM. Jariwala[1]; [1]University of Pennsylvania, United States; [2]Arizona State University, United States; [3]National Institute of Standards and Technology, United States; [4]Theiss Research, Inc., United States

Monocyclic Gallium oxide β-Ga_2O_3 is a promising candidate for high-power and high-temperature electronics and UV-range optoelectronic devices. Its advantageous properties include an ultra-wide bandgap, high critical electric field, and affordable bulk single crystal melt-growth techniques at the large production scale. However, single crystalline β-Ga_2O_3 substrates are seldom explored, in part due to the uncertain effects of the semiconductor's proven anisotropy. In this study, we fabricated 2D/3D β-Ga_2O_3 vertical heterojunctions and comprehensively assessed the effect of the choice of 2D material, contact metal and substrate crystalline orientation on their performance. Three orientations of degenerately n-doped β-Ga_2O_3 were considered: (001), (010) and (-201). Tungsten diselenide (WSe_2), tungsten disulfide (WS_2) and black phosphorus (BP) were chosen as 2D semiconductor materials for their popularity in high-performing optoelectronic devices, field-effect transistors (FETs) and light-emitting diodes (LEDs) among others. We compared Electron beam (E-beam) evaporated titanium (Ti), molybdenum trioxide (MoO_3) and palladium (Pd) as candidates for electrical contacts, with thicknesses based on previous reports of low-resistance: Ti/Au (10/90nm), MoO_3/Au (3/30nm), Pd/Au (30/70nm). The structure and properties of our fabricated devices were then evaluated using current-voltage (I-V) measurements at varying temperatures, atomic-force microscopy (AFM) techniques and technology computer-aided design (TCAD) simulations. Scanning transmission electron microscopy (STEM) cross-sectional images verified the clean interfaces of the heterostructures. We were able to realize high-performing diodes, whose ideality factors ranged from 1 to 3. Our findings suggest that heterojunction performance is optimized by the β-Ga_2O_3 orientation (-201), combined with 2D WS_2 exfoliated layers and Ti metal contacts, and show record rectification ratios (> 10^6) concurrently with ON current density (> 10^3 A/cm^2) for application in power rectifiers. The lowest ideality factors along the (-201) orientation were 1.18 (BP & Ti/Au contacts), 1.22 (WS_2 & Ti/Au contacts) and 1.43 (WS_2 & Pd/Au contacts) in line with some of the best 2D/3D van der Waals heterojunction diodes reported in the past. The TCAD simulations were able to verify this, and accurately mimic the (-201) heterostructures' behavior. At large biases and before the junctions reach saturation, the exponential current density increase matches the strongly rectifying property of ideal diodes. In such a linear regime, the devices are driven by the diffusion current across the internal 2D/3D potential barrier. Moreover, the reverse and low forward bias regions present current densities that are both very low (<10^{-10} A/μm^2) and independent of the applied voltage. Our findings demonstrate a facile fabrication of strongly rectifying and high ON current density Ga_2O_3-based heterojunction diodes and enables this material's potential for new avenues in solid state devices.

11:30 AM EL11.11.09
Implantation and Activation of Ge and Si Shallow Donors in β-Ga_2O_3 for Improved Ohmic Contact Formation KorneliusTetzner[1], AndreasThies[1], PalvanSeyidov[2], NicoThiele[1], Ta-ShunChou[2], JanaRehm[2], InaOstermay[1], ZbigniewGalazka[2], AndreasFiedler[2], AndreasPopp[2], JoachimWürfl[1] and OliverHilt[1]; [1]Ferdinand-Braun-Institut, Germany; [2]Leibniz-Institut für Kristallzüchtung, Germany

The recent developments in the fabrication of electronic devices based on the semiconductor β-Ga_2O_3 have demonstrated the high potential of this material to be used in next-generation power electronics applications. Due to the ultra-wide bandgap of 4.8 eV, a high breakdown strength of 8 MV/cm is expected, which could pave the way for power devices with even higher

breakdown voltages and efficiencies than are possible with the SiC and GaN counterparts. One major key requirement for high performance electronic devices based on ultrawide bandgap semiconductors such as β-Ga_2O_3 is the formation of low ohmic contact resistances in order to reduce conduction losses inside the devices. This becomes even more important for RF devices, where the channel resistance is much lower as in high-voltage devices. An effective way to reduce ohmic contact resistances is the use of ion implantation of shallow donors for local n-type doping of the contact region prior to ohmic metal deposition.
In this presentation, we report on the optimum annealing conditions for the activation of Ge-implanted (100) β-Ga_2O_3 in order to reach low ohmic contact resistances. In this regard, the influence of rapid thermal annealing treatment at temperatures between 900 and 1200 °C on the structural and electrical properties were analyzed. Our studies reveal significant changes in the surface morphology after high-temperature annealing above 1000 °C involving an increase in the surface roughness which is accompanied with a steady increase of the activation efficiency up to almost 20% at annealing temperatures of 1200 °C. Optimum annealing conditions were identified at 1100 °C at which the specific contact resistance is reduced by one order of magnitude down to 4.8×10^{-7} Ωcm^2 in comparison to non-implanted samples. In contrast to these findings, the surface morphology of Si-implanted (010) β-Ga_2O_3 with a comparable doping profile remains almost unchanged even after annealing at 1100 °C. Furthermore, the highest activation efficiency of around 60 % is reached at annealing temperatures between 900 and 1000 °C whereas higher temperatures lead to significant reduction. Our investigations verify the severe impact of the anisotropic nature of β-Ga_2O_3 on implantation processes of shallow donors which is particularly emphasized by the implantation instability of (100) β-Ga_2O_3 at high beam currents. Comparative experiments on β-Ga_2O_3 samples with different crystal orientations revealed a massive destruction of the (100) β-Ga_2O_3 surface after Ge implantation using beam currents around 1 µA whereas no damage was observed for (010) β-Ga_2O_3 using the same implantation conditions.
In summary, our results will reveal and identify important challenges but also the huge potential of ion implantation of shallow donors into β-Ga_2O_3 in order to reach low ohmic contact resistances.

Optimizing Si Implantation and Annealing in β-Ga_2O_3 and β-$(Al_xGa_{1-x})_2O_3$KatieR. Gann[1], NaomiPieczulewski[1], CameronGorsak[1], KarenHeinselman[2], KathleenSmith[1], ThaddeusAsel[3], BrentonNoesges[3], HuiliG. Xing[1], DebdeepJena[1], DavidMuller[1], HariP. Nair[1] and MichaelO. Thompson[1]; [1]Cornell University, United States; [2]National Renewable Energy Laboratory, United States; [3]Air Force Research Laboratory, United States

Optimizing thermal activation anneals for silicon ion implantation in β-Ga_2O_3 is critical for achieving low resistance contacts and selective area doping for advanced device structures. While activation has been widely reported, annealing conditions vary significantly and systematic annealing studies are lacking. We report the impact of time, temperature, and especially the annealing ambient, on the activation of Si in β-Ga_2O_3 at concentrations from 5×10^{18} cm^{-3}, to 1×10^{20} cm^{-3}, and in β-$(Al_xGa_{1-x})_2O_3$ ($x\leq25\%$) at concentrations up to 5×10^{19} cm^{-3}. Under optimized conditions, nearly full activation (>80%) and high mobility (>70 cm^2/V-s) are achieved in β-Ga_2O_3 at implant concentrations to 1×10^{20} cm^{-3}, with contact resistances below 0.16 Ω-mm for 5×10^{19} cm^{-3}. Similar optimized anneal conditions for β-$(Al_xGa_{1-x})_2O_3$ show promising results with high activation (50%) and mobility recovery (>60 cm^2/V-s) at 9% Al.

Unintentionally doped (UID) β-Ga_2O_3 films (>400 nm) were grown by plasma assisted molecular beam epitaxy, and β-$(Al_xGa_{1-x})_2O_3$ layers by metal-organic chemical vapor deposition, on Fe-doped (010) β-Ga_2O_3 substrates. Samples were ion implanted with Si at multiple energies to yield 65 or 100 nm box profiles with concentrations of 5×10^{18} cm^{-3}, 5×10^{19} cm^{-3}, or 1×10^{20} cm^{-3}. Dopant activation was achieved by annealing as-implanted films in a load-locked ultrahigh vacuum compatible quartz tube furnace at 1 bar pressure with precisely controlled gas ambient.

The impact of O_2 (partial pressure $<10^{-6}$ to 1 bar) and H_2O (to 25 ppm) in the annealing ambient condition was determined by mixing trace gases in research plus grade nitrogen (<1 ppm total impurities). To maintain the stability of the β-Ga_2O_3, P_{O2} must be greater than 10^{-9} bar, with annealing in vacuum or forming gas resulting in poor activation or decomposition, respectively. The upper limit for P_{O2} is strongly dependent on Si concentration: P_{O2} below 10^{-4} bar ensures Si activation (>85%) at 5×10^{19} cm^{-3} while lower concentration implants (5×10^{18} cm^{-3}) maintain high carrier activation to oxygen partial pressures above 10^{-2} bar. Water vapor is even more critical at ppm concentrations; 25 ppm H_2O reduces active carriers by an order of magnitude 5×10^{19} cm^{-3} implants. The effect is reversible, and activation can be recovered by annealing in a “dry” ambient. Optimal results were consistently obtained with the gas ambient intentionally dried below 10 ppb of H_2O.

Recovery of the mobility requires annealing temperatures above 900 °C, with increasing carrier activation and mobility to temperatures as high as 1050 °C, though SIMS shows substantial Si diffusion at temperatures above 1000 °C. 950 °C is identified as an optimized temperature with minimal Si diffusion, with optimal times between 5 and 30 minutes; shorter times show lower mobilities with longer durations showing carrier deactivation. “Over-annealing” behavior is observed at all temperatures and becomes increasingly significant with higher Si concentrations.

Lattice damage and recovery were determined using Rutherford Backscattering Channeling (RBS/C), scanning transmission electron microscopy (STEM), and X-ray diffraction (XRD). XRD showed no evidence of second phase formation and RBS/C and STEM show only partial damage from even 1×10^{20} cm^{-3} implants. In STEM, damage regions remain crystal-like with no evidence of full amorphization. The remnant aligned β-Ga_2O_3 is hypothesized to volumetrically seed lattice recovery during thermal annealing. Varying implant doses and implant temperatures (from liquid nitrogen cooled to 600 °C) were used to assess the impact of implant damage on lattice recovery.

In conclusion, we demonstrate the importance of optimizing anneal conditions to activate implanted Si carriers in β-Ga_2O_3 and extend this understanding to higher concentration Si implants and to activating implants in β-$(Al_xGa_{1-x})_2O_3$.

SESSION EL11.12: Oxide Materials and Devices II

1:30 PM *EL11.12.01
The Applied Science of Gallium Oxide: Lessons, Challenges and Goals DanielM. Dryden; Air Force Research Laboratory, United States

Gallium oxide (β-Ga_2O_3) is an emerging ultra-wide band gap semiconductor which shows promise across a range of applications due to its high critical breakdown field, readily available n-type dopant species, and low native substrate cost. The Air Force Research Laboratory is particularly interested in β-Ga_2O_3 for applications including high-frequency converter operation, power switching, and on-chip power conversion, all of which serve to improve the size, weight, power, and cost of sensors systems. Realizing the potential of β-Ga_2O_3 in prototype devices has necessitated clever solutions to challenging problems in materials science and materials engineering. In this talk, we will discuss some of the materials science and engineering challenges β-Ga_2O_3 has faced, as well as the solutions that have been implemented. We will discuss the identification and mitigation of Si contamination sources in β-Ga_2O_3 epitaxy, optimizing regrowth and liftoff for ohmic contact formation, defect engineering of the oxide-semiconductor interface in β-Ga_2O_3MOSFETs, and challenges in device design for high-temperature applications. We will also discuss open challenges in β-Ga_2O_3 that may have solutions in future materials science research.

2:00 PM EL11.12.02
Computational Thermochemical Stability Analysis of Metal/β-Ga_2O_3 Interface Cheng-WeiLee[1], AndriyZakutayev[2,1] and VladanStevanovic[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

Thermochemical stability of metal terminal contacts with wide-band-gap (WBG) semiconductors poses challenges for device fabrication. During the operation at high power and high temperature, such metal/oxide contacts can react and form interfacial layers that are electronically insulating. Experimental database of standard formation enthalpy of semiconductors can be used to estimate the stability of these metal/semiconductor interfaces but is mostly limited to binary materials. Furthermore, such estimation fails when a competing multi-component oxides (number of metal elements > 2) has a lower formation enthalpy per oxygen. On the other hand, density functional theory (DFT) databases include not only the binary but also most of the multi-component compounds documented in ICSD. Several efforts in the past, including the approach of fitted elemental-phase reference energies[1], has enabled prediction of formation enthalpy of these compounds using DFT results within chemical accuracy (~50 meV/atom).
Using β-Ga_2O_3 as an example, and building on these theoretical models, we perform thermochemical analysis to predict the stability of metal/β-Ga_2O_3 interfaces. β-Ga_2O_3 has great *n*-type performance as power electronics and electron affinity (EA) around 4.0 eV. Based on the Schottky-Mott rule, metals with work functions (WF) around 4.0 eV will be ideal as Ohmic contact for β-Ga_2O_3. From the stability analysis, we found that Cd, In, Sn, Tl, Pb, and Bi are stable with β-Ga_2O_3 and the difference in WF from 4.0 eV is ≤0.3 eV. But we also notice that these metal candidates have low melting temperatures (<400 °C) and require very low oxygen partial pressure ($<10^{-10}$ atm) to avoid oxidation when in contact with β-Ga_2O_3. Our results are also consistent with experimental findings [3,4] that the commonly used Ti contact is not stable with β-Ga_2O_3 at elevated temperature (~400 °C).
Based on the results for β-Ga_2O_3, we also identified a trend: Metals with smaller work functions, i.e. Fermi levels closer to vacuum level, are generally more reactive with oxygen molecules.

Such observation suggests that if a metal oxide's EA is smaller than the WF of its constituent metal, other metals with WF close to its EA will likely oxidize in contact with the metal oxide. For β-Ga_2O_3, the WF of Ga is ~4.3 eV from the vacuum level, which is larger than its EA at ~4.0 eV. To form Ohmic contacts, metals with EA around 4.0 eV are needed but the observed trend suggests that these metals are also likely to oxidize when in contact with Ga_2O_3. On the other hand, metals with WF > 4.3 eV are needed to have stable interfaces but these form Schottky contacts. Such dilemma suggests that alternative approaches are needed for β-Ga_2O_3 and one alternative is to heavily dope the region near stable Schottky contacts to balance conductivity and stability at metal/semiconductor interfaces. This computational approach can be also used to identify suitable metal contacts for other UWBG semiconductors.

Computationally Predicted Electronic Structure of β-Ga_2O_3(001) Interfaces with NiO Cheng-WeiLee[1], AndriyZakutayev[2,1] and VladanStevanovic[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

β-Ga_2O_3 is a promising ultra-wide band-gap oxide (E_g ~4.9 eV) due to its excellent *n*-type performance. Furthermore, high-quality and low-cost bulk single crystal can be grown from melt, making it particularly attractive for device fabrication and commercialization. However, no *p*-type doping has been realized for β-Ga_2O_3, preventing applications that involve homoepitaxial *p-n* junction. Instead, heterojunction is needed to fabricate device like MOSFET and β-Ga_2O_3(001)/NiO heterojunction have been shown to has better rectifying performance than β-Ga_2O_3/Ni Schottky diodes. Experimental J-V curve indicates existence of interfacial states but their identities remain unclear[1]. Furthermore, recently reported band alignment of the β-Ga_2O_3(001)/NiO heterojunction strongly depends on the synthesis conditions[2]. Therefore, a computational study connecting atomic details at the interfaces and band alignment is critical for further engineering of the heterojunctions. However, an atomistic interface model, which is non-trivial to construct, is needed to computationally study the electronic structure of a heterojunction. We found that the experimentally observed orientations of (001) and (111) are among the top three NiO surfaces that best match the β-Ga_2O_3 (001) substrate, utilizing the recently developed atom-to-atom structure-matching algorithm[3]. Such consistency provides the credibility for the atomistic interface model for the subsequent electronic-structure calculation. Furthermore, we estimated the energetics of oxygen incorporation at the interface under different synthesis conditions to identify the most relevant atomistic interface models.
Another critical challenge of modeling such heterojunction lies in the selection of proper exchange-correlation functionals that can correctly describe the band gaps of β-Ga_2O_3 and antiferromagnetic rock-salt NiO simultaneously. Hybrid functionals like HSE06 are known to reproduce the band gap of β-Ga_2O_3 when an adjusted mixing parameter (α=0.32) is used. But HSE06 requires a significantly smaller mixing parameter (~α=0.19) to reproduce the band gap of NiO (~3.5 eV). The nature of homogeneous screening for HSE06 makes it challenging to find a mixing parameter that can describe the electronic structure of the whole heterojunction correctly at the same time[4]. Fortunately for NiO, its conduction band edge near minimum is mostly composed of localized Ni d orbital, which can be adjusted via on-site potential[5].
In this talk, we will show that HSE06+U method can simultaneously reproduce the respective band gaps of β-Ga_2O_3 and NiO within the interface. We predicted that the estimated built-in potentials for β-Ga_2O_3(001)/NiO(111) and β-Ga_2O_3(001)/NiO(001) are 1.9 and 2.9 eV, respectively, which are consistent with experimental measurements[1,2]. We also compared band alignments based on our atomistic models to results based on electron affinity rule and branch-point energy. The significant differences between different methods support the necessity to calculate band alignments based on atomistic interface models. Lastly, our findings suggests that a single-phase ββ-Ga_2O_3(001)/NiO(001) heterojunction can have larger built-in potential and thus better rectifying performance than β-Ga_2O_3(001)/NiO with mixed NiO orientations.

Growth of Ga_2O_3 Nanowires Directly on Top of Interdigitated Electrodes for Their use as Chemoresistive Gas Sensor AnnaEstany-Macià[1,1], MarinaRojano-Mateos[1,1], JanRomano-deGea[2], PaoloPellegrino[1,1], MauricioMoreno-Sereno[1,1] and AlbertRomano-Rodriguez[1,1]; [1]Universitat de Barcelona, Spain; [2]Ecole Polytechnique de Lausanne (EPFL), Switzerland

Monoclinic β-Ga_2O_3 is a wide bandgap (4.9eV) semiconducting material that is used for the fabrication of high power and high temperature electronic devices. Like other metal oxides, this material can also be used for the fabrication of gas sensing devices. For this, chemiresistive thin films of β-Ga_2O_3 have been demonstrated to respond to different gases, like oxygen, hydrogen, methane, and carbon monoxide, at temperatures above 600°C. With the aim of lowering the operation temperature of this material to make it compatible with Internet-of-Things (IoT) applications, β-Ga_2O_3 nanowires (NWs) have been reported to respond, i.e., to change their resistance, to relative humidity at room temperature.
Following this last idea, in this work we present a fabrication route that allows the direct growth and integration of β-Ga_2O_3 NWs on top of substrates containing interdigitated electrodes. Here, the β-Ga_2O_3 has been directly synthesized on top of fused silica substrates containing interdigitated electrodes made from Cr/Pt. The growth of the nanowires was performed at atmospheric pressure and temperatures above 800°C inside a quartz tube inserted in a tubular furnace via a Vapor-Liquid-Solid mechanism, using gold as catalyst and a flux of 500 ml/min of argon as carrier. Two different methods for the generation of the precursor vapor have been used: either metallic gallium or a mixture of gallium oxide and graphite, for which a carbothermal reduction takes place. Structural and chemical characterization has been carried out using scanning (SEM) and transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). Furthermore, the samples have been mounted in a home-made stainless-steel miniaturized gas chamber and connected to a gas injections system through mass-flow controllers. Alternating pulses of different gases (diluted relative humidity (RH), CO and NO_2) and dry synthetic air have been introduced into the chamber while resistance changes were measured.
SEM confirms that long (above 10 micrometer) and thin (below 50 nanometer) nanowires have been synthesized, which bridge the gap between the interdigitated electrodes. Furthermore, TEM confirms the monocrystalline and almost defect-free nature of the NWs. A subtle difference between the NWs grown from the two precursor generation methods: for the carbothermal reduction, a carbon-rich shell layer is formed around the β-Ga_2O_3 NWs. This is confirmed by XPS and by Electron Energy Loss Spectroscopy inside the TEM. From an electrical point of view, the major difference is the value of the resistance in dry synthetic air, which is orders of magnitude lower for the NWs with the carbon shell. At room temperature, both type of sensors is sensitive to relative humidity and selective to almost all other gases.
In the presentation, the complete gas sensing behavior of these sensors will be presented and the differences will be discussed taking into account the differences in structural and chemical properties of the NWs.

2:45 PM EL11.12.05

Sol-Gel Synthesized β-Ga_2O_3 Nanostructures for Selective Detection of Formaldehyde SoumenGiri, BideshMahata, PrasantaK. Guha and Prof. PallabBanerji; IIT Kharagpur, India

Selective and accurate detection of formaldehyde (HCHO), one of the volatile organic compounds (VOCs), is crucial for various applications such as indoor air quality monitoring. Gallium oxide (Ga_2O_3) is a promising material due to its wide bandgap and distinctive physical and chemical properties for sensing applications. This study proposes a novel approach utilizing sol-gel technique to synthesize Ga_2O_3 nanostructures for VOC sensing such as formaldehyde, ethanol, acetone, 2-propanol, and toluene; and to investigate the kinetic parameters of the sensing materials using the Eley-Rideal model.
β-Ga_2O_3 was prepared by dissolving gallium (III) nitrate hydrate in different polar solvents at four different temperatures, viz. at 65 °C, 95 °C, 115 °C, and 135°C for 5 h while the solution pH was kept at 10. It was found that cocoon-shaped nanostructures of β-Ga_2O_3 were formed at a temperature of 65 °C through the stacking of small nanoplates. As the temperature was increased to 95 °C, the nanoplates began to merge and grow thicker and wider due to Ostwald's ripening. At 115 °C, further Ostwald's ripening occurred, leading to the transformation of the multi-layered structures into rod-shaped structures of length 0.97 μm and diameter 0.15 μm. When the temperature reached to 135 °C, the growth process resulted in the formation of nanorods, with an average length of 10 μm and diameter of 1.0 μm.
Drop casting was used to deposit the sensing materials, β-Ga_2O_3 onto a ceramic substrate with interdigitated electrodes made of gold. Compared to other nanostructures, such as nanoparticles, cocoon-like structures, nanoplates, and high aspect ratios of nanorods, a sensor based on β-Ga_2O_3 nanorod with a diameter of 150 nm, showed outstanding selectivity and sensitivity towards HCHO, even in the presence of other volatile organic compounds. The maximum response, $R = [(R_g - R_a) / R_a] \times 100\%$, where R_g and R_a has their usual meaning, for formaldehyde at 300 °C at a concentration of 300 ppm was found to be 23.2%. The Eley-Rideal model considers the direct interaction of gas molecules adsorbed on the sensor surface with the pre-adsorbed species. By fitting experimental data to theoretical response transient curves, key kinetic parameters such as adsorption and reaction rates were determined. The activation energy determined by the model for HCHO sensing at concentrations ranging from 50 to 300 ppm is found to be 0.05972 eV. The low activation energy indicates that the sensing method is reasonably efficient, needing low energy for HCHO molecules to react with the β-Ga_2O_3 nanorods and generate observable signals or changes.
β-Ga_2O_3, an *n*-type semiconductor, surprisingly exhibits *p*-type conductivity in our experiments. XPS analysis reveals that the overall concentration of absorbed oxygen, including oxygen vacancies and chemisorbed oxygen, exceeds that of lattice oxygen. A significant number of electrons in the conduction band are captured when oxygen species are adsorbed. Consequently, the electron concentration is reduced relative to the hole concentration, leading to the formation of an inversion layer and enabling β-Ga_2O_3 to display *p*-type conductivity. The electrons from the conduction band are efficiently trapped by adsorbed oxygen species, leading to a bending of the energy band and the creation of an inversion layer. At elevated temperatures (300 °C), the sensor reacts with reducing gases like HCHO to create H_2O, CO_2 and e^{-1}. The subsequent annihilation of released electrons with holes reduces the thickness of the hole accumulation layer, causing a decrease in the conductivity of β-Ga_2O_3 nanorods. When HCHO is removed, the released holes return to the valence band, increasing the hole concentration and decreasing the

resistance.

Epitaxial Growth and Phase Stability of α-$(Al,Ga)_2O_3$RienaJinno; The University of Tokyo, Japan

In recent years, ultra-wide bandgap (UWBG) semiconductor materials (E_g >3.4 eV) have attracted much attention as materials for high-power electronics and ultraviolet photonics. α-$(Al_xGa_{1-x})_2O_3$ is an oxide family possessing a UWBG energy spanning 5.4 to 8.6 eV [1]. At the present stage, n-type conductivity control is possible in the Ga-rich region (E_g~5.5 eV). However, a recent first-principles study predicts that Si can be an efficient shallow donor up to a bandgap of 7.5 eV (Al compositions of 0.71) for α-$(Al_xGa_{1-x})_2O_3$ [2]. The UWBG larger than 6 eV is unachievable in the nitride semiconductor family, offering the possibility to take semiconductor electronics and photonics into regimes that currently remain out of reach. This talk will focus on the recent progress of phase stability and plasma-assisted molecular beam epitaxy (PAMBE) of α-$(Al_xGa_{1-x})_2O_3$.
The challenge of α-$(Al_xGa_{1-x})_2O_3$ is related to the metastable characteristic of α-Ga_2O_3. The ground-state crystal structure of Al_2O_3 is rhombohedral corundum (α phase), while Ga_2O_3 takes the monoclinic β-gallia (β-phase). A theoretical study using hybrid density functional theory calculations elucidated that the β-phase is the preferred structure up to an Al concentration of 71%, and α-$(Al_xGa_{1-x})_2O_3$ is stable at x>0.7 [3]. In experiments, α-$(Al_xGa_{1-x})_2O_3$ with Al contents lower than 70% converted to the β-phase, while the Al-rich α-$(Al_xGa_{1-x})_2O_3$ is stable, in good agreement with the theoretical stability [4].
The epitaxial growth of α-$(Al_xGa_{1-x})_2O_3$ is typically conducted on sapphire (α-Al_2O_3) substrates. The growth of α-$(Al_xGa_{1-x})_2O_3$ by MBE suffered due to the inclusion of the β-phase, especially for growth on c-plane substrates. The c-plane facet was found to enhance the growth of β-Ga_2O_3 in MBE. The sapphire crystal plane perpendicular to the c-plane, such as a- or m-planes, allowed the growth of phase-pure α-$(Al_xGa_{1-x})_2O_3$ by avoiding the facets. Interestingly, the homoepitaxial growth of α-Al_2O_3 also required preventing the c-plane facet. The crystal orientation dictated epitaxy was also useful for metal-organic chemical vapor deposition and pulsed laser deposition [5,6]. If Al-rich α-$(Al_xGa_{1-x})_2O_3$ can be controllably doped, it would pave the way for α-$(Al_xGa_{1-x})_2O_3$-based high-power heterostructure electronic and photonic devices at bandgaps far beyond all materials available today.
This work was partially supported by NEDO Feasibility Study Program Uncharted Territory Challenge 2050.

4:00 PM EL11.12.07
MOCVD Grown High-Al Content *β*-$(Al_xGa_{1-x})_2O_3$ for Enabling 2DEGsCameronGorsak, JonathanP. McCandless, KatieR. Gann, HuiliG. Xing, DebdeepJena, MichaelO. Thompson and HariP. Nair; Cornell University, United States

The unique properties of *β*-Ga_2O_3 including its ultra-wide bandgap of ~4.8 eV, critical breakdown field of ~8 MV/cm, availability of large-area native substrates, and controllable n-type doping have enabled rapid development in both growth and device processing. However, compared to other wide bandgap semiconductors, the intrinsic channel mobility is relatively low. A potential pathway to overcome this mobility limit is through two-dimensional electron gas (2DEG) formed at the interface of δ-doped *β*-$(Al_xGa_{1-x})_2O_3$ and undoped *β*-Ga_2O_3. In this work, abrupt and smooth heterojunctions were growth at high Al concentrations using metal organic chemical vapor deposition (MOCVD) with TEGa and TEAl precursors.
Prior to growth, (010) *β*-Ga_2O_3 substrates were etched in hydrofluoric acid (HF) for 30 minutes to minimize parasitic interfacial Si doping. In pure *β*-Ga_2O_3, we have demonstrated mobilities of 156 and 114 cm^2/Vs for $1x10^{17}$ and $1x10^{18}$ $/cm^3$ Si doping, respectively, with sub-nm RMS roughness. However, as the Al concentration increases, multiple material challenges must be addressed including potential segregation, dopant activation, and maintaining film smoothness. Using TMAl and TEGa precursors, we demonstrate sub-2 nm RMS roughness for 130 nm *β*-$(Al_{0.09}Ga_{0.91})_2O_3$ films. However, the growth temperature of 900 °C is too high for δ-doping; to reduce the growth temperature, TMAl was replaced with TEAl as the Al precursor due to the reduced cracking temperature. Additionally, TEAl shows potentially lower carbon incorporation because it pyrolyzes via β-hydrogen elimination whereas the pyrolysis of TMAl can leave behind highly reactive methyl radicals that may incorporate into the film.
Surface roughness, carrier activation, and mobility as a function of Al concentration and doping conditions are reported.
Combining effective substrate etching to remove a parasitic conducting channel with smooth highly doped *β*-$(Al_xGa_{1-x})_2O_3$ will enable high mobility 2DEGs which will open the opportunity for devices with high switching speeds to operate in extreme environments.

4:15 PM EL11.12.08
Monoclinic $(In_xGa_{1-x})_2O_3$ Alloys Investigated by Cyclical Molecular Beam Epitaxy Growth and *In-Situ* EtchStephenSchaefer, AndriyZakutayev and BrooksTellekamp; National Renewable Energy Laboratory, United States

Gallium oxide (β-Ga_2O) has attracted attention as a candidate material for high-power diodes and transistors due to its wide bandgap, high breakdown voltage, controllable n-type dopability, and scalable melt growth of substrates. Its bandgap energy and electronic properties can be tuned by alloying with isoelectronic cations Al and In, however growth of the In-containing monoclinic alloy $(In_xGa_{1-x})_2O_3$ is challenging due to suboxide kinetics and the tendency for bixbyite In_2O_3 to phase separate.

This work uses cyclical growth and *in-situ* etching to rapidly investigate the $(In_xGa_{1-x})_2O_3$ growth space. Plasma-assisted molecular beam epitaxy (MBE) is used to grow $(In_xGa_{1-x})_2O_3$ on (010) oriented Fe doped Ga_2O_3 substrates at temperatures ranging from 590 to 770 °C and Ga and In beam equivalent pressures (BEP) ranging from 5×10^{-8} to 1×10^{-6} torr. Reflection high energy electron diffraction (RHEED) monitors the surface reconstruction and associated changes in streak *d*-spacing and FWHM during $(In_xGa_{1-x})_2O_3$ growth. The epilayer is then etched back *in-situ* by exposure to Ga flux without supplying oxygen plasma. Formation of the volatile suboxide Ga_2O and desorption of metallic In decomposes the $(In_xGa_{1-x})_2O_3$ film and recovers the initial Ga_2O_3 surface as evidenced by the FWHM of the RHEED streaks. Over 40 growth/etch cycles are achieved on a single substrate without degradation of RHEED surface reconstruction, and we acheive approximately 5x throughput improvement over traditional growth and characterization.

The [001] surface reconstruction remains a streaky 2× pattern typical of monoclinic Ga_2O_3 growth for high growth temperatures, high Ga flux, and low In flux. Conversely, the surface reconstruction becomes spotty with a reduced *d*-spacing for low growth temperatures, low Ga flux, and high In flux, suggestive of formation of bixbyite In_2O_3. In this manner the growth conditions corresponding to the lowest growth temperature, lowest Ga BEP, and highest In BEP that stabilize a streaky 2×RHEED reconstruction are rapidly identified, and targeted thick $(In_xGa_{1-x})_2O_3$ growths are carried out under these conditions.

400 – 500 nm thick $(In_xGa_{1-x})_2O_3$ epilayers were grown using conditions identified by the rapid throughput experiment. X-ray diffraction measurements of these films show pseudomorphic alloys with a graded composition that is initially In-rich with ~10% mole fraction. Reciprocal space maps indicate partial relaxation, in agreement with calibrated RHEED diffraction spot spacings. The RHEED *d*-spacing increases rapidly before slowly relaxing back to the Ga_2O_3 lattice *c*-plane spacing, suggesting growth is initially In-rich with reduced In content as growth progresses. Interestingly, growth at very high In fluxes results in slight contraction of *d*-spacing suggesting In-catalyzed Ga_2O_3 growth and negligible In incorporation. Depth-sensitive characterization including SEM and SIMS will be presented to demonstrate the competing In incorporation and suboxide kinetics for MBE growth of Ga_2O_3 alloys. Rapid identification of suitable Ga_2O_3 alloy growth conditions will lead to improved material quality, electrical properties, and bandgap tunability for ultra-wide bandgap devices.

Schottky Barrier Diode and MESFET based on Ge-Doped α-Ga_2O_3 Thin Film Grown by Mist-CVD TakeruWakamatsu[1], YukiIsobe[1], HitoshiTakane[1], KentaroKaneko[1,2] and KatsuhisaTanaka[1]; [1]Kyoto University, Japan; [2]Ritsumeikan University, Japan

Gallium oxide (Ga_2O_3), which is one of the ultra-wide bandgap semiconductors, has attracted considerable attention because of its potential applications for power electronics. Among polymorphs of Ga_2O_3, β-Ga_2O_3 is the most stable phase. Although β-Ga_2O_3-based devices such as Schottky barrier diode (SBD), MESFET and MOSFET have been reported thus far, the fact that β-Ga_2O_3 substrate is expensive and has a low thermal conductivity is a problem from a point of view of practical applications. On the other hand, α-Ga_2O_3, which is one of the metastable phases, can be grown on a sapphire substrate by heteroepitaxial growth techniques such as mist-CVD, HVPE and MEB. The sapphire substrate is cost-effective and has a high thermal conductivity, which is preferable for device applications. Nonetheless, there are not so many reports on the α-Ga_2O_3-based devices including SBD, MESFET and MOSFET. This is partly because the control of carrier density and achievement of high mobility are not so easy compared with β-Ga_2O_3. Recently, we successfully obtained Ge-doped α-Ga_2O_3 thin films by using mist-CVD method with the wider carrier density ranging from 10^{16} to 10^{19} cm^{-3} and the higher mobility 65.9 $cm^2V^{-1}s^{-1}$ than previous reported Sn-doped α-Ga_2O_3.[1] In this work, we report on the fabrication of SBD and MESFET based on the Ge-doped α-Ga_2O_3 thin films and confirm that the resultant devices exhibit rather high performance.

Ge-doped α-Ga_2O_3 thin films were grown on *m*-plane sapphire substrates by mist-CVD method. An α-Ga_2O_3 n^+ layer (900-1000 nm thick, the donor density, $N_d = 1\times10^{19}$ cm^3) and an α-Ga_2O_3 n^- drift layer (500-600 nm thick, UID) were grown on the *m*-plane sapphire substrate for SBD. To make a mesa structure, the n^- layer was etched by ICP-RIE following photolithography. As an ohmic electrode, Ti/Au (20 nm/100 nm thick) or Ti/Al/Ti/Au (30 nm/100 nm/30 nm/ 30 nm thick) was deposited on the n^+ layer by electron beam (EB) deposition. After that, the samples were annealed at 400, 450, 470 and 500 °C for 1 min in an N_2 atmosphere. Then, Ti/Au (20/100 nm thick) Schottky electrode was formed by EB deposition. The *I-V* characteristic of the resultant SBDs was measured and analyzed in terms of the thermionic emission model. The *n* value and the barrier height are 1.06-1.19 and 0.95-1.13 eV, respectively. The on-resistance decreases as the annealing temperature is increased. The lowest on-resistance is 3.7 mΩcm^2 achieved for the device with Ti/Au/Ti/Au ohmic electrode annealed at 500 °C. Also, we prepared MESFET as follows. First, Fe-doped buffer layer (800 nm thick), Ge-doped channel layer (300 nm thick) and n^+ layer (30 nm thick) were grown on an *m*-plane sapphire substrate. For the mesa device isolation, 500 nm-thick α-Ga_2O_3 was etched by ICP-RIE. A Ti/Au (20/100 nm thick) was deposited as source and drain electrodes. The n^+ layer on the channel layer was etched by ICP-RIE. A Ni/Au (30/100 nm thick) was deposited as a gate electrode. From the Hall effect measurements, the carrier concentration, the sheet carrier density, and the electron mobility were evaluated to be 2.1×10^{17} cm^{-3}, 4.9×10^{12} cm^{-2} and 44 $cm^2V^{-1}s^{-1}$, respectively. The *I*−*V* measurements were conducted for the device with $L_{GS}/L_G/L_{GD}$ = 3/3/12 µm, where L_{GS}, L_G, and L_{GD} are gate-to-source, gate and gate-to-drain lengths, respectively. From the output curve (V_{DS}−I_D characteristic), the maximum I_D and the on-resistance were estimated to be 24 mA/mm and 587 Ωmm (at V_{GS} = 2 V), respectively. The break down voltage is 364 V (at V_{GS} = -10 V). From the transfer curve (I_D−V_{GD} characteristic), the threshold voltage, the subthreshold slope and the on-off ratio were evaluated to be -9 V, 164 mV/dec and 10^9, respectively. These values are superior compared to a-Ga_2O_3-based MESFET reported previously, for which the break down voltage, the on-off ratio and the maximum I_D are 48 V, 2×10^7 and 35 mA.[2]

Demonstration of 3 kV Schottky Barrier Diodes on AlN Epilayers Grown on Bulk AlN Substrates by MOCVD DinushaHerath Mudiyanselage, DaweiWang, ZiyiHe, BingchenDa and HouqiangFu; Arizona State University, United States

Aluminum Nitride (AlN) is a promising material for next-generation power electronics due to its remarkable attributes, including an ultra-wide bandgap (6.2 eV), robust breakdown field (~12-15 MV/cm), and superior thermal conductivity (340 W/mK). AlN power devices have already shown promising development with high temperature stability and potential to improve energy efficiency and reduce system size for various power conversion applications. Nevertheless, several challenges persist in the growth and fabrication processes, including the high cost and lack of conductive substrates for AlN substrates, growth of high-quality AlN epilayers, and the need for proper Ohmic and Schottky contacts.
In this study, we have grown AlN epilayers on AlN bulk substrates with high Si doping concentration (~1×10^{19} cm^{-3}) to demonstrate lateral Schottky barrier diodes (SBDs) with kV-class capabilities. The device configuration incorporates Ti/Al/Ni/Au as Ohmic contacts and Pt/Au for the Schottky contact. The AlN epilayers were grown via metal-organic chemical vapor deposition (MOCVD), utilizing trimethylaluminum (TMAl) and ammonia (NH_3) as the Al and N sources, with SiH_4 employed as the *n*-type dopant Si precursor. The device structure entails a 1-µm-thick resistive UID AlN underlayer, a 200 nm Si-doped *n*-AlN layer, and a 2 nm UID GaN capping layer, to prevent the oxidation of underlying AlN epilayers. High-resolution X-ray diffraction (HRXRD) confirmed the crystallographic quality of the epilayers. Device fabrication started with rigorous cleaning using acetone, isopropyl alcohol and D.I. water aided by sonication, and HCl:H_2O (1:2) solution treatment. Subsequently, the Ohmic contacts were patterned using standard photolithography, followed by e-beam evaporation of Ti/Al/Ni/Au (25/50/25/50 nm) and liftoff. After that, 1000 °C, 1-minute annealing process in N_2 ambient was performed using rapid thermal annealing. Schottky contacts were subsequently patterned, with Pt/Au (30/120 nm) metal deposition and liftoff. The distance between Schottky and Ohmic contacts were varied between 50-350 µm. The devices were tested with a 4200 semiconductor parameter analyzer equipped with a controllable thermal chuck. High voltage measurements were carried out using a Keysight B1505A Power Device Analyzer. The devices exhibit remarkable ON/OFF ratios ranging from 10^5 to 10^8 across a temperature range of 298 - 623 K, exhibiting their robust temperature stability. The current of the devices increases linearly with temperature as more carriers are excited and enabled the current transport. The devices maintain a Schottky barrier height of approximately 0.9 eV, with this value increasing from 0.9 - 2.2 eV as temperature rises, while the ideality factor decreases from 4.8 - 2.5. This deviation from the thermionic emission model indicates a unique current transport mechanism mainly governed by the resistive nature of the AlN epilayers. Furthermore, temperature-dependent C-V measurements verify an increase in carrier concentration with rising temperature.
The devices demonstrate decent forward characteristics and exhibit breakdown voltages exceeding 3 kV. At –3 kV, the devices display a low leakage current of 200 nA. The observed leakage current variation with the area of the Ohmic contact region suggests that surface leakage governs the reverse leakage current. This work serves as a valuable reference for the development of kV-class AlN high-voltage, high-power devices, showcasing significant progress in the field.

High-Temperature Molecular Beam Epitaxy of Hexagonal Boron Nitride and hBN-Based Lateral Heterostructures SergeiV. Novikov[1], TinS. Cheng[1], JonathanBradford[1], TylerJames[1], ChristopherMellor[1], KenjiWatanabe[2], TakashiTaniguchi[2], IgorAharonovich[3], LuizF. Zagonel[4], BernardGil[5], GuillaumeCassabois[5] and PeterBeton[1]; [1]The University of Nottingham, United Kingdom; [2]National Institute for Materials Science, Japan; [3]University of Technology Sydney, Australia; [4]Institute of Physics, University of Campinas, Brazil; [5]Laboratoire Charles Coulomb, CNRS-Université de Montpellier, France

There has been a surge of interest in hexagonal boron nitride (hBN) due to its technological potential for deep ultraviolet (DUV) photonics, single photon emitters (SPEs) and through its incorporation into van der Waals (vdW) two-dimensional (2D) heterostructures as either a substrate, tunnel barrier or capping layer.

We have developed high-temperature molecular beam epitaxy (HT-MBE) of hexagonal boron nitride with the thicknesses up to 70 nm at growth temperatures from 1100ºC to 1700ºC using high-temperature sublimation and e-beam MBE sources for boron and nitrogen RF-plasma sources. By growing hBN on highly oriented pyrolytic graphite (HOPG) substrates, we have produced monolayer and few-layer thick boron nitride with atomically flat hBN surfaces, which are essential for 2D and DUV applications. The hBN coverage can be reproducibly controlled by the growth time, substrate temperature and boron to nitrogen flux ratios. We will discuss our recent measurements of a direct optical energy gap of ~6.1 eV [1] and electronic band gap of ~6.8 eV [2] in single monolayer hBN.

We will present data demonstrating that the single-photon emitters in hBN are related to carbon (C) incorporation [3] and will discuss different C-doping techniques that we are currently using in HT-MBE.

In addition to the conventional hBN–based vertical vdW heterostructures, recent studies worldwide have focused on the development of novel 2D lateral heterostructures. These vdW lateral heterostructures consist of multiple connected monolayer-thick materials within the same atomic plane and can have novel and unique transport and optical properties. Integration of graphene and hBN in lateral heterostructures can provide a route to engineer the material properties by quantum confinement of electrons or introduction of novel electronic and magnetic states at the interface. Whereas vertical 2D heterostructures can be produced by epitaxy or by exfoliating and stacking of 2D layers, lateral 2D heterostructures can only feasibly be produced by an epitaxial growth process.

We have demonstrated that lateral heterojunctions of hBN and graphene can be grown *in-situ* using HT-MBE. We used different types of the MBE carbon sources, including a sublimation carbon source, atomic carbon source and e-beam carbon source, to grow graphene monolayers on hBN substrates and hBN epitaxial layers at temperatures between 1000ºC and 1700ºC.

We will discuss HT-MBE of graphene monolayers in crystallographically oriented hBN trenches, formed *ex-situ* by catalytic Ni-nanoparticle etching. High-resolution atomic force microscopy (AFM) reveals that graphene monolayers grow epitaxially from the hBN etched trench edges, and merge to form a graphene nanoribbon network.

We will also discuss *in-situ* HT-MBE of monolayer-thick lateral hBN-graphene heterostructures. Monolayer-thick hBN, grown at a higher temperature of ~1400ºC, exhibited armchair edges, minimal aggregate presence, and a reduced but significant width of the hBN monolayer sheet. We have shown that in HT-MBE graphene grows preferentially laterally from the edges of hBN in a mode of step-flow growth, which results in the formation of lateral hBN-graphene heterojunctions. The graphene and hBN regions show a clear epitaxial relationship through the alignment of atomic lattices. Sequential HT-MBE growth of hBN, graphene and a second cycle of hBN growth resulted in the formation of monolayer-thick lateral hBN–graphene–hBN heterostructures, in which a strip of graphene is laterally embedded between monolayers of hBN.

Direct MOVPE Growth of High-Quality h-BN on the Wafer-Scale Sapphire: The Role of Substrate Off-Cut MateuszTokarczyk, AleksandraDabrowska, GrzegorzKowalski, RafalBozek, JakubIwanski, JohannesBinder, RomanStepniewski and AndrzejWysmolek; Faculty of Physics, University of Warsaw, Poland

Hexagonal boron nitride (h-BN) is an attractive wide bandgap 2D material for possible applications in electronic and optoelectronic devices based on van der Waals heterostructures [1], but direct growth of high-quality h-BN on the wafer-scale is still the bottleneck for future successful implementation of h-BN in industry. Although the synthesis of h-BN by metal-organic vapor phase epitaxy (MOVPE) has already been reported [1-3], there is a fundamental lack in understanding of many basic aspects of this process affecting obtaining a good structural quality and a smooth surface. In particular the role of the substrate off-cut, although well known as being of major importance for the growth of other materials, has not yet been fully addressed so far.
In this communication, we present a study that addresses the influence of the sapphire substrate off-cut angle on the final quality of h-BN obtained in a two-step growth procedure [3]. The main process starts with a self-limiting continuous flow growth (CFG) of a BN buffer followed by flow-modulated epitaxy (FME) in the second step of one MOVPE process and is used to study substrates with five different off-cuts angles for three different CFG times.
Based on results obtained by x-ray diffraction and x-ray reflectometry, Raman and Fourier-transform spectroscopy, atomic force microscopy and scanning electron microscopy, we present a comprehensive study that shows that the quality of h-BN epilayers dramatically depends on the off-cut angle of the c-plane sapphire substrate [4]. We demonstrate that the highest quality of h-BN layers is obtained for a sapphire substrate off-cut angle of 1 degree. Samples with this off-cut have the lowest amount of debris, 3D grains consisting of mostly h-BN material [5], on the surface. They also have most intense x-ray diffraction signal, minimal Raman phonon linewidth and thinnest amorphous BN part. We are able to explain these results by following the evolution of the whole interface, which includes a thin AlN layer coming from initial nitridation step at the beginning of MOVPE process. This AlN layer is shown to smooth out the surface forming (with sapphire) a kind of “effective substrate” which leads to the observed increase in quality.
A detailed analysis of the crystallographic structure of the h-BN obtained layers and mechanisms responsible for the existence of an optimal off-cut angle will be discussed.

9:15 AM EL11.13.03
Towards Growth of High Quality Cubic Boron Nitride using Fluorine Chemistry AliEbadi Yekta, AvaniPatel and RobertJ. Nemanich; Arizona State University, United States

Boron Nitride (BN) is an ultra-wide bandgap material having a bandgap of 6.4 eV and 5.9 eV for the cubic (c-BN) and hexagonal (h-BN) phases, respectively. The ultra-wide bandgap of both BN phases indicates a high breakdown voltage, possibly even greater than diamond [1]. Moreover, epitaxial c-BN on diamond is expected to have high thermal conductivity. Diamond and c-BN have a small lattice mismatch of 1.4 percent [2]. Therefore, diamond is a candidate for use as a substrate for growth of c-BN. However, the choice of an appropriate substrate among different types of diamond as well as crystallographic orientation can affect the quality of the grown c-BN films. Also, depending on the growth technique, it might be essential to use either p-type or n-type diamond to achieve high-quality c-BN films. The last but not the least in growing high-quality c-BN films is the method utilized to clean the substrate which is of great significance, too.
Physical vapor deposition (PVD) is one of the techniques that has shown success in growing c-BN layers. Magnetron sputtering, ion-assisted pulsed laser deposition (IAPLD), ion beam-assisted deposition (IBAD) and mass selected ion beam deposition (MSIBD) are some methods under PVD category that have been exploited to grow pure c-BN [3]. However, utilizing high energy ion bombardment as well as high bias voltage is a must in such methods. Therefore, we should expect high compressive stress on the films which leads to defect formation and delamination of very thick films. Also, slow growth rate of PVD methods, few nm/hrs, prevent us from getting thick, pure c-BN films. To overcome the above obstacles Chemical vapor deposition (CVD) is also suggested for growing c-BN. These methods include DC jet plasma CVD, RF plasma CVD, inductively coupled PECVD and electron cyclotron resonance microwave plasma CVD (ECR MPCVD). The advantage of CVD over PVD is that ion bombardment and high bias voltage are not present to impose comressive stress and the resulting defects. Besides that, faster growth rate of CVD techniques opens up a lot of opportunities to get thick films of c-BN in short processing times [3]. Among the CVD methods, ECR MPCVD has been the most successful technique in getting thich and pure c-BN films due to the fact that processing is done in very low pressure environment down to even Torr. This reduces the contaminants that can interfere with the reaction and improves the precursors reaction on the substrate surface.

In this study we have explored achieving both thick and high quality c-BN films on polycrystalline boron-doped diamond at fast, 100 nm/hrs, and slower, 50 nm/hrs, growth rate. ECR MPCVD method in combination with Fluorine chemistry using H_2, BF_3, N_2, He and Ar gases was utilized. Substrate is negatively biased, i.e. -60 V, with respect to the grounded chamber to facilitate growth of c-BN layers. Fluorine atoms that manage to reach the substrate etch the sp^2 B-N bondings formed during the growth facilitating sp^3 B-N bond formation. That is achieved by use of limited H_2 flow rate. On the other hand, Cleaning the substrate is critical in getting a high quality interface. High flow rate of H_2 plasma cleaning in ECR MPCVD chamber resulted in damage to diamond surface and that prevented us from getting smooth interface. However, when H_2 flow rate was reduced we observed fewer damage to the substrate and that improved the quality of c-BN/diamond interface.
Then, we increased flow rates of the gas precursors while keeping gas ratios and applied voltage bias fixed. This resulted in growth of c-BN at a faster rate. The H_2:BF_3 ratios of 2:2 and 4:4 sccm resulted in 50 nm/hrs and 100 nm/hrs of BN, respectively. We then utilized in-situ X-ray photoemission spectroscopy (XPS) to confirm the presence of only sp^3 bonding states at the surface of the grown film (Fig.1). Also, data acquired from ellipsometry confirms the growth rates of the two scenarios mentioned above.

Computational Investigation of Optical Properties of Boron Nitride Quantum Dots ChandlerMartin and ArindamChakraborty; Syracuse University, United States

Boron nitride (BN) is a promising material for bright single photon source with applications in optical quantum technologies. The photoluminescence properties of BN can be modulated by optimizing the size and dopant characteristics of BN quantum dots. This work presents a systematic investigation of emission characteristics of BN quantum dots in the size range of 1-10nm. The electron-hole binding energies and radiative and non-radiative electron-hole recombination rates were calculated for dots in the size range of 1-10nm. First-principles quantum mechanical calculations were performed using the frequency-dependent geminal screened electron-hole interaction kernel (FD-GSIK) method, and the recombination probability was evaluated from the correlated electron-hole reduced density matrix. The FD-GSIK method is a real-space method that uses an explicitly-correlated operator to include many-body quasiparticle correlation effect in the electronically excited state calculation. The scaling of electron-hole binding energies and electron-hole recombination probability as a function of dot size will be presented, and the impact of surface defects on radiative electron-hole recombination will be discussed.

Pushing the Limits of Diffraction Imaging in the Scanning Electron Microscope for the Structural Characterisation of Semiconductor Thin Films and Microstructures CarolTrager-Cowan[1], JochenBruckbauer[1], RyanMcDermott[1], DaleWaters[1], KieranHiller[1], BenHourahine[1], GrzegorzCios[2] and AimoWinkelmann[2,1]; [1]University of Strathclyde, United Kingdom; [2]AGH University of Science and Technology, Poland

To achieve the best performance from the next generation of wide bandgap semiconductor-based devices, it is crucial that we understand and optimise the structural properties (i.e., crystal structure, extended defects, misorientation and strain) of the new materials used in their manufacture. Many new materials are produced using non-planar growth techniques such as selected area growth or epitaxial overgrowth, resulting in material where defect densities, misorientation and strain vary on the micron and/or nanoscale. To fully understand and optimise subsequent devices requires a characterisation tool capable of rapidly and non-destructively mapping structural properties on the micron and nanoscale.
Using advanced electron diffraction techniques in the scanning electron microscope (SEM), namely electron channelling contrast imaging (ECCI) and electron backscatter diffraction (EBSD) imaging, together with bespoke analysis software utilising pattern matching to accurate simulations of EBSD patterns and novel strain and defect analysis software, we are now able to map microstructure, defects, misorientation and strain in semiconductor thin films and 3-D microstructures with a spatial resolution of order 100 nm, a misorientation resolution of order 0.5 mrad (0.03°) and a strain resolution of order 5×10^{-4}. To date, we have characterised GaN thin films containing both wurtzite and zincblende material; mapped polarity in GaN microstructures; determined dislocation density and types in planar and non-planar GaN, AlGaN and AlN thin films; imaged misfit dislocations in AlGaN HEMT structures; imaged stacking faults in non-polar and semi-polar wurtzite GaN; and mapped strain in GaN thin films [1-5]. The benefits of imaging in the SEM include minimal sample preparation and the ability to produce images from areas ranging in size from square microns to square centimetres. Diffraction analysis can also be combined with energy dispersive X-ray spectroscopy; hyperspectral cathodoluminescence imaging; and electron beam induced current to provide complementary, non-destructive high resolution information on the structural, compositional, luminescence and electrical properties of materials [1-3]. In our presentation we will illustrate our present capabilities with recent results and explore the potential of diffraction imaging in the SEM to underpin fast optimisation of new materials and device structures.

Evaluation of Band Alignment of Rutile-$Sn_{1-x}Ge_xO_2$ by XPS YoNagashima[1], AkiraChikamatsu[2], DaichiOka[3] and YasushiHirose[3]; [1]The University of Tokyo, Japan; [2]Ochanomizu University, Japan; [3]Tokyo Metropolitan University, Japan

Introduction: An alloy of rutile-type SnO_2 and GeO_2 ($Sn_{1-x}Ge_xO_2$: SGO) is an ultrawide-gap oxide semiconductor. SGO is expected to be applicable for power electronic and ultraviolet optoelectronic devices because of its wide tunability of bandgap from ~3.7 eV to ~4.7 eV [1, 2]. A unique feature of SGO is a possibility of ambipolar doping, originating from shallow valence band maximum (VBM) of rutile GeO_2 (x=1), predicted by first-principles calculations [3, 4]. Although the band alignment (band edge position) of SGO is important for considering dopability in SGO as well as for designing SGO-based heterostructure devices, it has not been experimentally investigated yet. In this study, therefore, we evaluated the position of VBM of a series of SGO epitaxial thin films (x=0-0.6) using X-ray photoelectron spectroscopy (XPS) and determined its band alignment.
Methods: The (001)-oriented SGO thin films (x=0-0.6) were epitaxially grown on Nb:TiO_2 (001) substrates by the pulsed laser deposition [1]. Crystal structure and Ge/Sn ratio of the films were confirmed by X-ray diffraction and energy-dispersive X-ray spectroscopy, respectively. In the XPS measurements, valence band and O 2s spectra of the SGO films were measured at 300 K with an Al-Kα X-ray source. The variation of the VBM from the vacuum level as a function of the chemical composition was evaluated using the position of O 2s peak as a reference. Before the XPS measurement, the SGO thin films were annealed at 800 °C for 6 hours in air to remove Sn^{2+} component from the surface.
Results: VBM of the SGO films became shallower monotonically by 0.5 eV with increase of x from 0 to 0.6, which qualitatively agreed with the prediction by first-principles calculations [3]. On the other hand, the position of VBM was still deeper than the practical level of Fermi energy pinning level for p-type doping, requiring further increase of Ge to realize ambipolar doping. We also estimated the position of conduction band minimum (CBM) using the band gap of SGO determined from the optical absorption spectroscopy. As x increased from 0 to 0.6, CBM also became shallower by 0.8 eV. This rise of CBM position can explain the reduction of donor activation ratio with increasing x, observed in Ta-doped SGO thin films. These results also indicated that a heterostructure consisting of SGO thin films with different Sn/Ge ratio will become a type-II heterojunction.

Low-Temperature Electrical Properties of r-$Ge_xSn_{1-x}O_2$ Alloy Film HitoshiTakane[1], ItsuhiroKakeya[1], HirokazuIzumi[2], TakeruWakamatsu[1], YukiIsobe[1], KentaroKaneko[3] and KatsuhisaTanaka[1]; [1]Kyoto University, Japan; [2]Hyogo Prefectural Institute of Technology, Japan; [3]Ritsumeikan University, Japan

Rutile-type wide and ultrawide band-gap oxide semiconductors, such as r-GeO_2 and r-SnO_2, are emerging materials for high-power electronics and deep ultraviolet optoelectronics devices [1,2]. Recently, their alloy (r-$Ge_xSn_{1-x}O_2$) has also gained attentions due to the possibility to modulate its bandgap and electrical properties by tuning the Ge:Sn compositional ratio [2-4]. In addition, Sn-rich r-$Ge_xSn_{1-x}O_2$ exhibits excellent n-type conductivity, which is favorable for future device-oriented researches [2,3]. However, details of its electrical properties including carrier transport mechanisms have not been elucidated yet.
In this study, we investigated low-temperature electron transport properties of Sn-rich r-$Ge_xSn_{1-x}O_2$ thin films (x=0.28 and 0.41). Temperature-dependent Hall effect measurements suggest that the hopping conduction is dominant at low temperatures (< 100 K) in both r-$Ge_{0.41}Sn_{0.59}O_2$ and r-$Ge_{0.28}Sn_{0.72}O_2$. Temperature-dependent resistivity measurements indicate that the hopping mechanism at lower temperatures ($T \leq 15$ K) is explained by the Efros-Shklovskii variable-range hopping (ES VRH), that is, hopping over the states within the Coulomb gap. In the temperature region, both r-$Ge_{0.41}Sn_{0.59}O_2$ and r-$Ge_{0.28}Sn_{0.72}O_2$ exhibit both negative and positive magnetoresistances. Based on the theory of quantum interference that includes effects of both frozen- and free-electron spins [5], it is found that the negative and positive components are attributed to the quantum interference and field-induced spin-alignment, respectively, and the transport mechanism at $T \leq 15$ K for both r-$Ge_{0.41}Sn_{0.59}O_2$ and r-$Ge_{0.28}Sn_{0.72}O_2$ corresponds to the ES VRH with large number of scattering centers. The results are coincident with those obtained by the temperature dependence of resistivity. At $T \geq 30$ K, the negative magnetoresistance induced by the quantum-interference effect decreases as the temperature increases. Moreover, at $T \geq 150$ K, both r-$Ge_{0.41}Sn_{0.59}O_2$ and r-$Ge_{0.28}Sn_{0.72}O_2$ show temperature-independent positive magnetoresistance induced by the Lorentz force. It is considered that these results indicate a mixture of the Mott VRH and thermally activated band conduction (T < 100 K) and almost pure thermally activated band conduction ($T \geq 150$ K).
We believe that our experimental and analytical results provide a basis for the development of not only r-$Ge_xSn_{1-x}O_2$, but also all the other rutile-type wide and ultrawide band-gap oxide semiconductors.

Investigation on Electronic and Magnetic Properties of Ti Doped Diamond Nanowire using First-Principles JianingSu and Hong-XingWang; Xi'an Jiaotong University, China

The dilute magnetic semiconductor (DMS) has attracted significant attention as it unifies the characters of semiconductor and magnetism into single hybrid devices for spintronic applications. The key issue of current research is to search for DMS materials with ferromagnetic ordering at or above room temperature due to that the low Curie temperatures (T_C) prevents spintronic devices from being used at room temperature. Dietl's theoretical investigations showed that the Tc of a DMS varied with the host lattice constant as $1/a^3$, indicating that semiconductor with small lattice constant would be a potential candidate for ferromagnetic ordering at room temperature. Diamond possesses the smallest lattice constant among semiconductors (a=3.567 Å), which makes it an excellent candidate DMS material for spintronic applications at room temperature. In addition, one-dimensional (1D) magnetic nanowire can limit all spin rotations to a single axis, which makes it to be potential candidate for spin transistor.
In this work, the electronic and magnetic properties of Ti-doped diamond nanowire were investigated by first-principles calculation. The results revealed that Ti-doped diamond nanowire with vacancy possessed stable ferromagnetism with a magnetic moment of 2 μB, while Ti-doped diamond nanowire without vacancy was non-magnetic. Moreover, The Ti-doped diamond nanowire with vacancy exhibited the half metallic behavior and the spin polarization of 100% near the Fermi level with half-metal bandgap of 0.236 eV, while Ti-doped diamond nanowire without vacancy has metallic property. The density of states implied that magnetism originated from the p-d hybridization between the Ti-3d, Ti-2p and C-2p states. The *p-d* hybridization leads to that the spin-down DOS is pushed above the Fermi level while the spin-up DOS is moved lower than Fermi level, which increases the occupation probability of electrons in the spin-up DOS and results in the spin polarization. Therefore, the Ti-doped diamond nanowire with vacancy would be a promising novel type of dilute magnetic semiconductor and could possess a great potential application in spintronic devices.

SESSION EL11.15: UWBG Epitaxy

Electrical Conductivity in Ultra-Wide Bandgap MaterialsP.Reddy[1], R.Kirste[2], JTweedie[2], RamonCollazo[1] and Z.Sitar[1,2]; [1]North Carolina State University, United States; [2]Adroit Materials, Inc., United States

AlN is a UWBG material (E_g = 6.1 eV) for the realization of UV optoelectronics and high-power, high-frequency electronics. Although most challenges in crystal growth and epitaxy of AlN have been overcome, achieving controlled electrical conductivity of technological interest has proven to be challenging. While controlling the chemical and electrochemical potentials during doping has been crucial for achieving doping and compensation control, the obtained conductivity was still modest. The presumed DX formation has been considered an insurmountable killer defect as it pins the Fermi level and imposes a low limit on the achievable free carrier concentration. We have developed several novel equilibrium and non-equilibrium approaches for doping and point defect management in AlN and shown that donors in AlN do not undergo a DX transition but rather are distributed between a shallow and deep state. We have shown that the shallow state can be kinetically stabilized to obtain highly-conducting n-type AlN with mobilities approaching 400 cm^2/Vs. These results have enabled the first demonstration of AlN Schottky diodes capable of >3 $kAcm^{-2}$ with a critical breakdown field exceeding 10 $MVcm^{-1}$.

Zlatko Sitar is a Kobe Steel distinguished Professor of Materials Science and Engineering, Physics, and Electrical Engineering at NCSU. His research is concerned with bulk and thin film growth, characterization, property control, and device development in ultrawide bandgap semiconductors. He has developed and commercialized processes for growth of AlN crystals, epitaxy on AlN wafers, and doping control in this material. Based on his research, he founded HexaTech, Inc., focusing on AlN wafer technology, and Adroit Materials, Inc., focusing on high performance devices on native GaN and AlN substrates slated for DoD and NASA applications.

Surface, Structural and Optical Studies of GaN Grown on Si by MOCVD Manika TunNafisa, IkramTalukder, Zhe ChuanFeng, BenjaminKlein and IanT. Ferguson; Kennesaw State University, United States

In the last two decades, there has been considerable research focused on investigating GaN films grown on silicon as a wide bandgap semiconductor material. Optical techniques, such as ellipsometry, have been widely employed for characterizing thin films and bulk materials, enabling the determination of layer thicknesses and surface roughness. X-ray diffraction (XRD) has proven to be an essential tool for analyzing semiconductor crystal structures, while Raman spectroscopy provides insights into the composition and homogeneity of epitaxial semiconductor samples. This study examines four GaN thin films grown on silicon substrates using metalorganic chemical vapor deposition (MOCVD). Variable angle spectroscopic ellipsometry (VASE) measurements were conducted to determine film thickness and surface roughness as well as the dependence of n & k versus wavelength in 250-1000 nm for these GaN on Si samples. The obtained results indicate specific values for each sample: the first sample has a film thickness of 180 nm and a surface roughness of 47 nm, the second sample has a thickness of 106 nm and a surface roughness of 8 nm, the third sample has a thickness of 1004 nm and a surface roughness of 3 nm, and the fourth sample has a thickness of 1510 nm and a surface roughness of 2 nm, as derived from Spectroscopic ellipsometry (SE) fits. The highest recorded refractive index among the four samples is 2.76, XRD measurements were performed on the first two samples, while Raman scattering measurements were conducted on the remaining two samples. The XRD experiments involved wide scans and fine scans with step sizes of 0.1° and 0.005°, respectively. The XRD analysis revealed distinct peaks corresponding to silicon (002) and (004) orientations at approximately 28° and 90°, respectively, in the first sample. Additionally, a weak peak at around 35° indicated the presence of the GaN (0002) peak. In the second sample, the XRD analysis demonstrated clear peaks for the Si substrate (002) and (004) orientations at 28° and 90°, respectively, along with distinct peaks corresponding to GaN at (0002), (0004), and (0006) orientations. Notably, the first-order GaN peak was observed at approximately 34.6°, the second-order peak at around 73°, and the third-order peak at approximately 127°, providing valuable information about the crystallographic properties of the GaN films. Raman scattering measurements were conducted on two samples under a microscope at room temperature, employing different excitation laser powers (5%, 1%, and 0.5%). The first Raman experiment revealed characteristic peaks at 520 cm^{-1} for Si, confirming its crystalline nature, while peaks at 565 cm^{-1} corresponded to the GaN crystallinity characteristics of the E_2 (High) and A_1 (LO) vibrational modes. In the second Raman experiment, distinctive peaks at 520 cm^{-1}, 567 cm^{-1}, and 734 cm^{-1} were identified for Si, GaN E_2 (High), and GaN A_1 (LO), respectively, further supporting the exceptional crystalline purity of the GaN films grown on silicon substrates. Through these comprehensive surface, structural, and optical characterizations, our study provides compelling evidence of the exceptional crystalline purity of the investigated GaN films on silicon substrates. These findings, achieved through Ellipsometry, XRD, and Raman spectroscopy techniques, enhance our understanding of the surface, structural, and optical properties of GaN films and open up exciting possibilities for their utilization for high-power and spintronic applications.

Direct Growth of Wafer-Scale Self-Separated GaN on Reusable Two-Dimensional Material Substrate Chang HsunHuang[1], Chia-YiWu[2] and Yi-ChiaChou[1]; [1]National Taiwan University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

Gallium nitride (GaN) is extensively employed in light-emitting diodes, lasers, and high-power electronic devices due to its wide direct band gap and chemical stability.[1] Given the difficulty of obtaining high-quality GaN substrates, most current GaN-based devices are heteroepitaxially grown on foreign substrates, such as sapphire, Si, and silicon carbide.[2] However, the conventional growth of GaN films on these substrates generates a high defect density and considerable biaxial strain, attributed to the large lattice and thermal mismatch between the GaN films and their substrates. Thus, the lack of GaN native substrates is the main obstacle for the extending development of GaN-based devices. Although several conventional methods exist for obtaining free-standing GaN, such as laser lift-off, void-assisted separation, and chemical etching of the intermediate layer between GaN and the original substrate, the process of removing the substrate from a thick GaN film is complicated, expensive, and time-consuming. Furthermore, the original substrate can be damaged or contaminated during this process.[3]

Recently, the van der Waals epitaxial growth of III-V films on two-dimensional (2D) materials has been proposed to effectively mitigate the lattice mismatch effect caused by the weak bonds between III-V films and 2D materials.[4] Fluorphlogopite mica is a thermally stable material with a flexible atomic flat surface and low commercial cost, making it an ideal 2D material substrate. However, the dangling bond-free surface of 2D materials suppresses the nucleation of the III-V film, limiting the growth of large-area single crystals. Although some studies have proposed graphene as an intermediate layer in bridging techniques for growing and lifting off III-V films,[5] the integration of GaN growth with mica for self-separation is a relatively unexplored area.

In this research, we successfully grew a 2-inch thick GaN film with high uniformity on a fluorphlogopite mica substrate via hydride vapor phase epitaxy. The 2-inch thick GaN film easily self-separated from the mica substrate during rapid cooling. After the film growth process, the residual GaN on the mica substrate was effectively eliminated through deionized water, owing to the hydrophilic characteristic of mica and the weak bonding between GaN and mica. Moreover, we demonstrated the capability of reusing the mica substrates by repeatedly growing self-separated GaN films on the same substrate. Additionally, to verify that the thick GaN film was of device quality, we demonstrated a completely functional ultraviolet light-emitting diode with a wavelength of 378 nm. In summary, our proposed approach may facilitate the epitaxy of large-area single-crystalline GaN on 2D materials, offering a new substrate option in the self-separation technology of III-V materials.

New Insights into Q-Carbon: Novel Interlayer in Gan-Diamond Integration for Improved Heat Dissipation Saif Al ArafinTaqy, Pallab KumarSarkar and ArifulHaque; Texas State University, United States

The recent surge in high-power electronic device research has led to the development of various wide bandgap materials. GaN is such a material with immense potential due to its many impressive characteristics, such as high electron mobility and high breakdown voltage, leading to smaller device footprints with better power densities and high efficiency. However, heat dissipation has become a significant concern in high-power semiconductor devices made of GaN, which stems from the combination of low thermal conductivity and increasing power density. This study aims to resolve this issue by incorporating a Q-carbon (quenched form of carbon) interlayer to form continuous diamond films, which have the highest thermal conductivity of any material. Q-carbon is a novel form of carbon that has been rapidly cooled after melting, resulting in its unique properties and potential for use in electronic applications and device fabrication. The growth of large-area Q-carbon has been restricted to low thermally conductive substrates due to the non-equilibrium nature of the synthesis process and a narrow range of parameters. This study addresses the abovementioned limitations by conducting a comprehensive parameter optimization of diamond-like carbon (DLC), the fundamental structure necessary for synthesizing Q-carbon. Initially, the deposition of DLC films onto sapphire substrates is accomplished through the utilization of graphitic carbon targets via pulsed laser deposition (PLD), and subsequent pulsed laser annealing (PLA) is employed to generate Q-carbon, with a comprehensive regulation of laser, deposition, and annealing parameters. The DLC films deposited in their as-formed state exhibit an sp^3 content ranging from 15% to 82%, which is achieved by optimizing the laser energy density, frequency, and deposition temperature during the process of PLD. SLIM simulation is employed to determine the optimal energy level of pulsed laser annealing (PLA) necessary for the synthesis of extensive Q-carbon. The experimental outcomes are then replicated by subjecting diverse diamond-like carbon (DLC) films to PLA with varying energy densities, spanning from 0.3 J/cm^2 to 1.2 J/cm^2, to obtain Q-carbon. The present study demonstrates that the synthesis of large-area Q carbon can be achieved by adjusting the parameters of PLD and PLA. This research broadens the scope of feasible thermally conductive substrates and provides fundamental parameters for future investigations on Q-carbon. Subsequently, we focus on GaN as a relatively higher thermally conductive substrate (conductivity ~200 $Wm^{-1}K^{-1}$) compared to the other substrates in the existing literature to employ the knowledge of large-area Q-carbon growth on various DLC films. This study incorporates a thin Q-carbon interlayer by utilizing low sp^3 DLC film as the precursor and attempts to provide a solution to address the challenges associated with the integration of diamond and GaN for necessary thermal management capability. Incorporating a low thermally conductive DLC film and appropriate annealing parameters assist in achieving a Q-carbon interlayer on GaN. The utilization of Q-carbon on GaN serves as a nucleation substrate for producing high-quality HFCVD diamond with uniformity while protecting the GaN layer from deterioration and resolving the thermal mismatch between GaN and diamond. The distinctive combination of features possesses the capability to address the predicament of heat management in GaN devices, thereby advancing the attainment of GaN's theoretical potential in the domains of wireless/5-g communications, high-power devices, and other intricate microelectronic systems.

Molecular Beam Epitaxy of Superconducting ZrN Thin Films on GaN Substrates BrelonJ. May, KevinD. Vallejo, DavidHurley and KrzysztofGofryk; Idaho National Laboratory, United States

Group III-Nitride materials have found applications in optoelectronics and photonic devices due to the large variation in direct bandgap spanning from the infrared to the deep ultraviolet. Recent research has pursued the integration of this well-established material system with transition-metal nitrides to create complex heterostructures with additional magnetic or superconducting functionality. ZrN is a well-known refractory conductor with high oxidation resistance, high hardness, and has been shown to be a superconductor at low temperatures. The estimated lattice mismatch of ZrN with InN, GaN, and AlN is 8.5%, -1.5%, and -4.2%, respectively, suggesting strain free as well as strain-tunable growth on the ternary III-Ns. This work focuses on the epitaxial growth of ZrN on c-plane GaN substrates via molecular beam epitaxy. An electron beam evaporation source and an RF-plasma source were used to supply the Zr and active nitrogen, respectively. Neither reflection high energy electron diffraction (RHEED) and X-ray diffraction (XRD) revealed any crystallographic texture of ZrN deposited on fused silica at temperatures >700°C. However, growth of ZrN on c-plane GaN substrates at similar temperatures was epitaxial. RHEED revealed that the ZrN maintains the symmetry of the underlying GaN throughout the entire deposition, and post-growth examination via XRD showed (111) oriented ZrN thin films. RHEED patterns during the regrowth of GaN directly on thicker layers of higher symmetry ZrN suggest a preference for the formation of rotational domains and a slight degree of surface faceting. The electrical transport as a function of temperature and magnetic field of ZrN films has been measured. Initial results of uncapped ZrN thin films reveal a superconducting phase with a critical temperature of <10 K and a critical field of 2 T. The critical temperature of the films is lower than reports of bulk ZrN, which could be attributed to strain, the presence of off stoichiometry or structural disorder, and is under investigation. These results pave the way for integration of additional superconductors and quantum phenomena in existing III-N systems.

3:00 PM EL11.15.06

Reduction of Lattice Mismatch Induced Strain and Critical Thickness Identification for Long-Range Crystallinity Niobium Nitride on 6H-SiC for High Quality SNSPD Detectors AnnalieseDrechsler[1,2], PatrickShea[2] and AristosChristou[1]; [1]University of Maryland, United States; [2]Northrop Grumman Corporation, United States

Niobium nitride (NbN) films have garnered significant attention and research recently due to their high critical temperature (T_c) and their usage in infrared-sensitive superconducting nanowire single photon detectors (SNSPDs). Devices fabricated from NbN have demonstrated single photon detection to mid-wave infrared wavelengths, which unlocks possibilities for novel applications such as long-range laser detection and ranging (LiDAR), interferometry of signals in planetary emissions, quantum key decryption, and optical communications. Due to their polycrystalline nature, NbN films are sensitive to defects stemming from the deposition and fabrication processes referred to as constrictions. These film constrictions effectively reduce the cross-sectional area of the detector nanowire, which in turn limits the critical current and resultant detection efficiency and jitter. NbN films are still, however, among the most promising for practical use and array development due to their high T_c approaching 16K, thus necessitating the development of methods to reduce film defectivity.
NbN films utilized for SNSPD fabrication must be thin, typically <100 nanometers. As a result, the film quality and defectivity are highly correlated to the interface between the NbN film and underlying lattice, lattice-mismatch strain, and deposition parameters of the NbN processing. To optimize this interface, a material with similar lattice structures and parameters to NbN must be chosen to minimize intrinsic defect sources. Then the deposition process can be optimized to reduce extrinsic defects.
Silicon carbide (SiC) 6H polytype substrates were selected for use as the deposition substrate. 6H-SiC has an in-plane lattice parameter a=3.08Å, leading to a 3.57% lattice mismatch with hexagonal NbN with in-plane lattice parameter of 2.98Å and minimizing strain from lattice matching below the critical thickness. SiC can be later utilized to fabricate semiconductor components necessary for focal plan array (FPA) development. NbN films were sputtered onto the substrates in an AJA ATC Orion 8 sputtering tool utilizing a non-reactive RF magnetron process in an inert argon atmosphere to control resultant film stoichiometry. Deposition conditions such as temperature, gas flow, and pressure were modified, and the resultant films were characterized through x-ray diffraction to determine phase, orientation, crystallinity, and stress.
The temperature of the substrate during deposition runs was increased from ambient temperature to 600C. As temperature increased, XRD peak intensity increased, and crystallite size calculated from peak FWHM increased linearly from 26.07nm to 1618.1nm for P6m2 NbN. This substantial increase in crystallinity stemming from increased energy promoting nucleation and growth of higher order crystallites reduces the number of grain boundaries and resultant constrictions within a SNSPD to improve efficiency. High temperatures, however, are not always compatible with semiconductor fabrication necessary for FPA development so pressure modifications were also explored as an alternative. The deposition pressure was increased from 3mTorr linearly to 8mTorr. Similar improvements in crystallinity to temperature were observed. The critical thickness where the film stress cannot be accommodated through lattice matching was measured to extract the stress of these films. 3mTorr films demonstrated a critical thickness of 475A, while films with higher pressures increase that to >750A. This improvement points towards reduced film stress and reduced formation of threading dislocations to accommodate strain.
In conclusion, we studied the impact of substrate lattice matching and non-reactive sputtering of NbN films on 6H-SiC. Modifying the deposition temperature and pressure allowed for the development of films with long range crystallinity and low stress to enable defectivity reduction and facilitate the development of high-quality long wavelength SNSPDs.

Scalable Low Temperature Perovskite Epitaxy in Open Atomsphere ZhuotongSun, NivesStrkalj, ZiyiYuan and JudithL. Driscoll; University of Cambridge, United Kingdom

Epitaxial growth of single-crystalline oxides is one of the fundamental ways to integrate perovskite structures on semiconductors and other oxides, being very attractive for applications as well as fundamental studies, where the film uniformity is greatly enhanced in comparison to polycrystalline films with reduced grain boundaries, superior interfacial conductivity and integration with silicon. However, large-scale epitaxial implantation of complex oxides in consumer electronic devices remains a challenge. Epitaxial deposition techniques, such as molecular beam epitaxy (MBE) and pulsed laser deposition (PLD), require high-temperature and high vacuum systems, with a limited deposition area, which pose problems when during production. Other techniques, such chemical vapor deposition (CVD), can also be used to deposit complex oxides, but generally at growth or post-deposition annealing temperatures over 500°C to achieve epitaxy. Therefore, a thin-film growth technique with reduced complexity and less-energy-intensive conditions, giving epitaxial films in a short growth time is highly desired. Herein, we use an open atmospheric deposition technique, Spatial Atmospheric CVD, mimicking the film growth by PLD, to deposit highly crystalline, epitaxial binary oxide, on various single crystal substrates at 350°C, with similar electrical properties of PLD grown film. Thus, opening the possibility the low cost, large scale, high throughput of epitaxial devices commercially.

CuI Based p Type Thin Film Transistor WeiWei, MingGao, WangZhiyong and ChunxiangZhu; National University of Singapore, Singapore

CuI is a wide bandgap p type transparent semiconductor and owns a high potential to be used in the fields like thin film transistor, Optoelectronic, and memory devices etc. It has many advantages like high hole mobility, good electrical property with a structure disorder. However, a high hole concentration in the CuI leads to a low Current On-Off ratio (I_{ON-OFF}) for CuI TFT devices. To solve this issue, Br doping technique is proposed to lower down the hole concentration in the CuIBr film so that a better TFT device performance can be obtained. The density functional theory (DFT) results show that the copper vacancy formation energy increases with the CuBr content in the Br-doped CuI film, resulting in lower hole concentration. The CuIBr TFTs with different Br content were then fabricated. All the CuIBr films were synthesized by the solution method. When the Br concentration increases from 0% to 10%, the hole mobility decreases while the I_{ON-OFF} ratio increases from the order of 10^2 to 10^4. A Br doping concentration of 7.5% shows the best device performance with hole concentration about 5 $cm^2V^{-1}s^{-1}$ and I_{ON-OFF} ratio of 10^4. The good p type CuI TFT device performance is a good foundation for the later application of CuI in the fields, including Logic circuits, Optoelectronic etc.

Polarization-Dependent Optical Properties of Ce-Implanted Quartz YuichiroAbe[1,2], ShunKanai[1,3,4], ManatoKawahara[1,2], JunIshihara[5], MakotoKohda[2] and ShunsukeFukami[2,6]; [1]Tohoku University, Japan; [2]Graduate School of Engineering, Tohoku University, Japan; [3]PRESTO, Japan Science and Technology Agency, Japan; [4]National Institutes for Quantum Science and Technology, Japan; [5]Department of Applied Physics, Tokyo University of Science, Japan; [6]Inamori Research Institute for Science, Japan

Nitrogen-Vacancy centers in diamonds and divacancies in SiC are the representative material systems composing solid-state spin qubits with a long coherence time at room temperature [1-4]. While various functionalities, e.g., remote entanglement, quantum sensing, and quantum communications, have been achieved, new qubit material systems may offer a new range of opportunities. One of the most critical material parameters for many quantum applications is the relaxation time T_2. Here, we focus on quartz as a host material, the most common mineral on the earth, and has been predicted to have a long T_2 without nuclear purification [5]. We choose the Ce^{3+} center as a spin center, which often composes a stable spin center in the widegap oxides, e.g., in $Y_3Al_5O_{12}$, whose spin state can be controlled through the circularly polarized laser [6].
We implant Ce ion into a naturally abundant single-crystal quartz substrate at room temperature in the air. The implantation dose and energy are $1.0\times10^{14}cm^{-2}$ and 100 keV, respectively. Subsequently, the samples are annealed in Ar for 0-9 hours at 700-1000ºC. First, we investigate the unpolarized optical properties of Ce-implanted quartz. The unpolarized photoluminescence (PL) spectra are measured with unpolarized He-Cd laser excitation at 325 nm. The unpolarized PL shows similar spectra with the previous studies on the sputter-deposited SiO_2:Ce [7]: unpolarized PL spectra have a prominent peak at around 445 nm, which corresponds to the 4*f*-5*d* transitions with different spin-orbit interaction of the Ce^{3+} center. We investigate the unpolarized PL of the samples with various annealing conditions. Up to 800oC, as the annealing temperature increases, PL intensity increases, suggesting the formation of luminescent Ce^{3+}, while the further increase of the annealing temperature decreases the unpolarized PL intensity, suggesting the formation of the Ce clusters without bright luminescence.
Next, we investigate the polarized optical properties with the samples annealed at 800ºC. In a single Ce^{3+} center of YAG:Ce^{3+}, the polarization-dependent PL signal corresponding to the spin-dependent 4*f*-5*d* transition and the pulsed optically-detected magnetic resonance (ODMR) have been reported at 5 K [6]. We observe that a polarization-dependent optical signal of the Ce-implanted quartz is consistent with the 4*f*-5*d* transition of the isolated Ce^{3+} centers: σ^+ excitation offers a larger σ^+ PL emission than that with σ^+ at the peak wavelength, and the more prominent σ^- emission at the shoulder wavelength (~560 nm). The degree of circular polarization (DOCP) reaches 15% (5%) at peak (shoulder) wavelength at 5 K. The DOCP monotonically decreases with increasing the measurement temperature, which suggests that the spin-lattice relaxation time T_1 limits T_2 in this material system.

8:20 AM EL11/EL13.03
Optical Control of Spin in Amorphous SiO_2:Ce^{3+}ShunKanai[1,2,3], YuichiroAbe[1], ManatoKawahara[1], JunIshihara[1], MakotoKohda[1] and ShunsukeFukami[1,4]; [1]Tohoku University, Japan; [2]Japan Science and Technology Agency, Japan; [3]National Institute for Quantum Science and Technology, Japan; [4]Inamori Research Institute for Science, Japan

Defect centers in diamond and SiC are the most established spin centers as optically accessible solid-state qubits [1-4]. To develop other widegap host materials with new qubit functionalities [5], based on the Liouville-von Neumann equation and the cluster correlation expansion (CCE), we have predicted the spin coherence time T_2 of the oxide host materials and found that (1) single crystal *a*-quartz (SiO_2) has a long coherence time (T_2 ~ 3.4 ms) without nuclear purification and (2) T_2 does not significantly depend on the crystalline structure of the host material as long as the T_2 is limited by the interaction between electron spin – nuclear spin bath [6]. Here we focus on the amorphous SiO_2, namely glass, as a host material for its possible application to the qubit.
As an optically accessible spin center, we choose Ce^{3+} center because it often composes a stable spin state, and its spin state can be controlled through the circularly polarized laser in the widegap oxides [7]. We introduce Ce into pure SiO_2 glass substrate by ion implantation with a dose of $1.0\times10^{14}cm^{-2}$ and an energy of 100 keV. Subsequently, we anneal the samples in Ar for 2 hours at 500-1000ºC. The unpolarized photoluminescence (PL) spectra are measured with a He-Cd laser with an excitation wavelength of 325 nm. The PL shows similar spectra with the previous works on the sputter-deposited SiO_2:Ce [7]: PL spectra have a relatively broad peak over 400 – 550 nm and show a prominent peak at 430 nm and a shoulder at 460 nm, consistent with the 4*f*($^2F_{5/2}$)-5*d* and 4*f*($^2F_{7/2}$)-5*d* transitions in tetrahedral coordinate, respectively. We investigate the PL of the samples with various annealing conditions. The PL intensity gradually increases with annealing temperature up to 700~900ºC with the formation of luminescent isolated Ce^{3+} center and decreases with increasing the annealing temperature to 1000ºC due to the Ce cluster formation. Further increase of the annealing temperature increases the PL intensity again, corresponding to the formation of luminescent Ce silicate.
For the optical control of the spin, we investigate the polarization dependence of the optical properties of the samples annealed at 800ºC at 4 K. In a single Ce^{3+} center of YAG:Ce^{3+}, the polarization-dependent PL signal corresponding to the spin-dependent 4*f*-5*d* transition and the pulsed optically-detected magnetic resonance (ODMR) have been reported at 5 K [7]. Even in our sample with the Ce-implanted glass SiO_2, we observe a polarization-dependent optical signal is consistent with the 4*f*-5*d* transition of the isolated Ce^{3+} centers: the degree of circular polarization (DOCP) reaches 12% and -5% at peak and shoulder wavelengths, respectively. Our result shows that an isolated Ce^{3+} center can be formed in the glass substrate, and helicity-dependent optical property suggests that it takes a similar crystalline coordination to YAG:Ce^{3+} due to its short-range order.

Approximate Quasiparticle DFT+A-½ Method Applied to Ga_2O_3 and In_2O_3 Polymorphs ClaudioR. da Silva[1], FriedhelmBechstedt[2], LaraK. Teles[1] and MarceloMarques[1]; [1]Aeronautics

Institute of Technology, Brazil; [2]Friedrich-Schiller-Universität Jena, Germany

Gallium oxide (Ga_2O_3) and indium oxide (In_2O_3) are at the forefront of the recent progress in power semiconductor devices, which extend the range of power semiconductors from wide bandgap semiconductors (WBS) such as GaN and SiC to ultra-wide bandgap semiconductors (UWBS) such as Ga_2O_3 and Al_2O_3, sometimes alloyed with In_2O_3. These oxide semiconductors currently find themselves at a stage of development similar to that of the WBG semiconductors in the 1980s and therefore, several challenges related to the understanding of their properties have to be settled yet. Specifically for these oxides the well-known underestimation of DFT-based bandgap prediction is more complicated because it is also connected with the wrong position of the d-level in disagreement with the experimental results. Several techniques can be used to overcome these difficulties, but, in general, state-of-the-art methods (such as GW and hybrid functionals), are computationally extremely expensive, which makes them impractical for more complex systems as it is required for a deep investigation for these oxides with pronounced polymorphism and the need for large unit cells.
In this study we investigate the structural, optical and electronic properties of ten polymorphs of Ga_2O_3 and In_2O_3 using a fast and efficient approximate quasiparticle method called DFT+A-½ which at the same time could deal with the delocalized d-levels and the problem in underestimation of the energy bandgap. We provide approximate quasiparticle band structures and binding energies even for very complex systems such as defective spinel phase of Ga_2O_3 containing 160 atoms in a cell. Our results are in line with the state-of-the-art methods and experimental data providing energy bandgaps of about 4.6 eV to 5.1 eV for Ga_2O_3 polymorphs and, 2.4 eV to 3.3 eV for In_2O_3 polymorphs. Band edge optical properties including excitonic effects are explained in terms of effective masses and dielectric constants. Furthermore, we predict pressure-induced phase transitions between polymorphs of the same oxides derived from equations of state.

Fully Solution-Processed Ultraviolet Photodetector Based on Hydrothermally Grown ZnO Nanorod Array AjinkyaB. Palwe, TapeshKumar, SwetaRani, ShobhaShukla and SumitSaxena; IIT Bombay, India

Patterned nanostructures exhibit interesting optoelectronic characteristics due to light-matter interaction at the comparable dimension of incident light and material. At a comparable dimension, the optoelectronic response of the nanostructure-based devices is modulated by the size and the periodicity of the structure. Numerous techniques based on top-down and bottom-up approaches are used to obtain patterned nanostructure. However, the solution-based technique is considered to be best due to cost-effectiveness as well as large-area processing. Recently patterned structures of metal oxide semiconductors are getting attention for various optoelectronic devices like photodetectors, solar cells, etc. ZnO is an abundantly available metal oxide that has high absorption coefficient and is highly appropriate for low-cost ultraviolet photodetectors. The hydrothermally patterned ZNA was achieved in two steps of deposition starting with ZnO quantum dots (QDs) seed layer followed by hydrothermal reaction. The as-grown ZNA was treated with ZnO QDs to remove any pin-holes or trap sites. P-type polymer PEDOT:PSS was used for making heterojunction with n-type ZNAs. The carbon electrode at the top was deposited by screen printing of carbon paste.
The optical bandgap increases with decreasing the size/periodicity of the ZNA. ZNR based film and heterojunction devices are investigated for different sizes/periodicity using surface morphology and optoelectronic properties. The ZNA based heterojunction photodetectors have shown improved photoresponse under ultraviolet (UV) light. The maximum photoresponsivity of 9.2 A/W and external quantum efficiency of 3144% are achieved for the ZNA obtained by 20 mM precursor solution. The response time is also fast due to the reduction in surface pin-holes/traps.

KEYWORDS: *Hydrothermal deposition; Patterned ZnO; P-N junction, UV photodetector;*

WITHDRAWN 11/13/2023 EL11/EL13.06 2D Van Der Waals Multiferroics Designed by Layer Stacking EvgenyY. Tsymbal; University of Nebraska--Lincoln, United States

Van der Waals (vdW) assembly of two-dimensional (2D) materials allows polar layer stacking accompanied by the emergence of a switchable out-of-plane electric polarization. The vdW polar stacking can be employed to engineer 2D multiferroics from the recently discovered 2D magnets, whose magnetic properties can be controlled by the induced electric polarization. Here, we predict novel phenomena in the 2D magnets $MnBi_2Te_4$ and CrI_3 that are not present in their bulk form. We demonstrate that broken space-inversion (*P*) and time-reversal (*T*) symmetries produce a magnetoelectric effect. While the effect is small, in case of antiferromagnetic $MnBi_2Te_4$, symmetry couples electric and magnetic polarizations resulting in the reversal of an uncompensated magnetic moment with reversal of electric polarization. The broken *PT* symmetry in a polar-stacked $MnBi_2Te_4$ bilayer produces an intrinsic anomalous Hall effect (AHE) driven by the non-vanishing Berry curvature, which can be reversed by ferroelectric polarization. In a three-layer $MnBi_2Te_4$ film, switchable polarization at one of the interfaces drives a metal-insulator transition, as well as switching between the AHE and quantum AHE (QAHE). In case of ferromagnetic CrI_3, we predict that polar layer stacking of this 2D material supports antiskyrmions – topological quasiparticles with a swirling spin texture. Unlike the widely investigated skyrmions, antiskyrmions combine opposite spin helicity across the structure driven by the anisotropic Dzyaloshinskii-Moriya interaction (DMI). We show that the polar layer stacking of two monolayers of CrI_3 efficiently lowers the symmetry, resulting in the required anisotropic DMI. The DMI is reversible with ferroelectric polarization switching, offering the ability to control antiskyrmions by an electric field. Overall, this work emphasizes the topological properties in 2D vdW magnets induced by polar layer stacking which do not exist in bulk materials and can be controlled by an electric field. The work is supported by the grant DE-SC0023140 funded by the U.S. Department of Energy, Office of Science.

Magnetoelectric Heterostructure for Passive Internet of Things Vibration Sensor Node Application YifanHe, CunzhengDong, XiaxinLiu, MelaniaSt. Cyr, HaolingLi and NianSun; Northeastern University, United States

Vibration detection have been widely applied in multiple fields including mechanical machine malfunctioning diagnosis, structural health monitoring (SHM) as well as human activity monitoring. For many of the sensing applications, the vibration sensing data collected needs to be transmitted and further analyzed. This requires the vibration sensor being integrated with long-lasting or self-powered power source and compact, highly efficient data transmitting/receiving antenna as an Internet of Things (IOT) sensor node, especially in rather inaccessible and harsh environment such as sea water or deep soil. Some efforts [1,2] have been made to build a passive vibration sensor node, the researchers utilized ambient vibration as the potential power source, however, a separate antenna is still needed in those cases for data communication wireless module in an IOT sensor node. With demonstrated near field communication capability [3], the potential of magnetoelectric (ME) heterostructure as an IOT vibration sensor node has been investigated by conducting the vibration detection test and stray magnetic field energy harvesting test. The PZT-8 based ME heterostructure showed a vibration detection sensitivity of 188 mV/g and 163 mV/g with 0 and button magnet bias at corresponding frequencies, respectively. The vibration limit of detection with button magnet bias was 4 ug at 21.18 kHz. The magnetically tunable vibration performance is desirable for broadband operation. The energy harvesting test showed a maximum 94% of wireless power transfer (WPT) efficiency with a planer coil as magnetic field source. Compared to coil-to-coil WPT link, the ME heterostructure-coil link has ~7 times higher efficiency at rather long distance considering the magnetic flux concentration effect brought by the high permeability Metglas material in ME heterostructure.

Study on Doping Effect of Copper and Chromium Ions on the Magnetic and Magnetocaloric Properties of Single Crystal Mn_3O_4Md FarhanAzim[1], PramanandJoshi[2] and SanjayMishra[1]; [1]University of Memphis, United States; [2]The University of Texas at Arlington, United States

Magnetic refrigeration technology, which works on the magnetocaloric effect (MCE) of magnetic materials, has attracted the interest of numerous research groups over traditional gas refrigeration. It has several advantages, including being highly energy-efficient, environmentally friendly, and cost-effective. The major effort is directed in improving the magnetic entropy change along with the relative cooling power (RCP) of transition metal oxide magnetocaloric materials. This study reports the structural and magnetocaloric properties of $Cr_{1.5}Mn_{1.5}O_4$ and $Cu_{1.5}Mn_{1.5}O_4$ which were synthesized via the facile autocombustion technique. The second-order phase transition temperature may be supposed to appear at the temperature-dependent field-

cooled magnetization curve near room temperature. These compounds with individual ferromagnetic phase transition temperatures may vary between 40K and 80 K that consequently enhances the RCP value. Moreover, ferromagnetic ordering can be observed in these mixed-metal compounds due to the presence of uncompensated electronic state of Mn^{2+} and doped transition metal ions. The difference in the super exchange pathway between the metal ions via the oxygen can give rise to a large ferromagnetic interaction. The fundamental key of this work is to demonstrate the potentiality of enhancing the magnetic phase transition temperature and magnetocaloric effect in the framework via spin coupling mechanism of transition metal doped Mn_3O_4 nanocomposites.

Advances in Multiferroic Composites: Expanding the Horizons of Ferroelectric-Ferromagnetic Materials ProsunMondal, SrishtiPaliwal and Akhilesh KumarSingh; IIT (Bhu) Varanasi, India

Multiferroic composites have attracted significant attention due to their ability to exhibit both ferroelectric and ferromagnetic properties. These materials hold great promise for a wide range of technological applications, including memory devices, sensors, actuators, and energy harvesting. Multiferroic composites typically consist of a ferroelectric material and a ferromagnetic material, either as a composite structure or as a multi-layered system. The coupling between the ferroelectric and ferromagnetic properties can be achieved through strain-mediated, magnetoelectric, or exchange interactions. One common approach is to combine a ferroelectric material, such as $Pb(Zr,Ti)O_3$,$Bi(Na,K)TiO_3$,$(K,Na)NbO_3$ with a ferromagnetic material, such as cobalt ferrite ($CoFe_2O4$),$NiZnFe_2O_4$,$MnFe_2O_4$ etc. These composites exhibit magnetoelectric coupling, where an applied magnetic field induces an electric polarization and vice versa. Other combinations of ferroelectric and ferromagnetic materials have also been explored, including bismuth ferrite ($BiFeO_3$) with a variety of ferromagnetic materials. The challenges associated with achieving strong coupling between the ferroelectric and ferromagnetic phases are addressed here along with ongoing efforts to optimize material compositions and processing techniques. Another area of research focuses on exploring new multiferroic materials beyond the commonly studied systems. Identifying novel materials with improved properties and higher operating temperatures is essential for expanding the range of applications for multiferroic composites. Additionally, efforts are being made to understand the fundamental mechanisms behind the coupling between ferroelectric and ferromagnetic properties. This includes studying the role of defects, interfaces, and domain structures in the overall behavior of multiferroic composites. In summary, the abstract highlights the promising future of multiferroic composites as advanced functional materials. It underscores the importance of ongoing research and development efforts to address existing challenges and explore new avenues for their applications. By harnessing the full potential of multiferroic composites, it is anticipated that they will contribute to the development of innovative technologies with enhanced performance, functionality and efficiency.

Active Epsilon-Near-Zero Photonics AlekseiAnopchenko, QuynhDang, DavidDang, Christopher MGonzalez, Yu-HsunChen, Juan ManuelRaffo Calixto, SudipGurung and Ho Wai (Howard)Lee; University of California, Irvine, United States

Epsilon-near-zero materials have been shown to be as one of the most promising optical materials in the recent years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties. I will review our recent studies on the active linear, nonlinear, and emission properties of conducting oxide and metallic nitride epsilon-near-zero materials.

Discovery of novel active materials is fundamental for photonic applications. The epsilon-near-zero (ENZ) materials have been shown to be as one of the most promising optical materials in the recent years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties, including strong electromagnetic wave confinement, enhanced quantum emission near ENZ media, non-reciprocal magneto-optical effects, unique topological properties, and abnormally large optical nonlinearity. While ENZ optics have been investigated extensively in the last few years, the current commonly used ENZ materials suffer from limited optical enhancement because of the lack of precise control of ENZ frequency, loss, and thickness for efficient ENZ mode excitation. In addition, the active tunability and enhanced nonlinearity and emission properties in ENZ materials have yet been fully experimentally

explored.
This talk will review our recent studies on the active linear, nonlinear, and emission properties of conducting oxide and metallic nitride epsilon-near-zero materials in planar and optical fiber platforms [1-7]. I will present a method to engineer the field intensity enhancement of the Al-doped zinc oxide (AZO) ENZ thin films synthesized by atomic layer deposition (ALD) technique. I will then discuss the observation of abnormal nonlinear temporal dynamic of hot electrons and enhanced optical nonlinearity in AZO and ITO ENZ thin films under different pump fluences and excitation angles using a degenerate pump-probe spectroscopy technique. Finally, I will also discuss the first experimental demonstration of optically confined ENZ resonance excitation in an optical fiber waveguide uniformly coated with AZO nanolayer. These studies enrich the fundamental understanding of emission and nonlinear properties on ENZ thin films and the integration of ENZ materials and optical fiber will open the path to revolutionary ultracompact in-fiber optical devices for optical communication, imaging, sensing/laser applications.

Flat Optics for Dynamic Wavefront Manipulation MarkL. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of metasurfaces, i.e. nanostructured optical coatings, has further accelerated the development of flat optics through the realization that nanoscale antenna elements can be utilized to facilitate local and nonlocal control over the light scattering amplitude and phase. In this presentation, I will highlight recent efforts in our group to realize electrically-tunable metasurfaces employing nanomechanics, tunable transparent oxides, electrochemistry, microfluidics, phase change materials, and atomically-thin semiconductors. Such elements are capable of dynamic wavefront manipulation for optical beam steering, holography and future display technologies. The proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to a wide range of commercial applications.

Novel Machine-Learning Approaches Based on Metric Learning and Manifold Learning for the Design and Knowledge Discovery in Nanophotonics MohammadrezaZandehshahvar and AliAdibi; Georgia Institution of Technology, United States

This talk is focused on using the machine-learning (ML) approaches based on dimensionality reduction and manifold learning for considerably reducing the dimensionality of the forward and inverse problems in relating the input and output of a nanophotonic system. It is shown that by using manifold learning techniques and simplifying the resulting networks using pruning, the computation complexity of the underlying ML algorithms will be considerably reduced. Furthermore, the importance of using an optimally defined loss function (or metric) for ML algorithms in obtaining priceless information about the properties of photonic nanostructures will be emphasized. It is shown that by moving from conventional mean-squared error to more intelligent metrics, knowledge discovery in nanophotonics will be facilitated along with better visualization of the input-output relationship in these nanostructures. In addition to knowledge discovery, the resulting manifold-learning algorithms can be optimally trained to facilitate the inverse design of such nanostructures while minimizing the structural complexity. As such, this talk will provide the foundation for both knowledge discovery and design in photonic nanostructures using manifold learning and metric learning and their application to the highly desired metaphotonic structures as an example platform.

11:00 AM *EL12.01.02
Machine Learning Methods for Freeform Metamaterial Design JonathanA. Fan; Stanford University, United States

We will discuss computational algorithms based on deep neural networks that can accelerate the design and simulation of nanophotonic devices, using metasurfaces and metamaterials as a model system. We will discuss the use of generative networks to perform population-based optimization and elucidate how the neural network architecture can be tailored to effectively perform freeform optimization. We will also discuss how physics-augmented deep networks can be trained with a combination of data and physics constraints to serve as accurate surrogate electromagnetic solvers. A principal challenge involves configuring the algorithms in a manner that enables application to a wide range of problems, and we show how these concepts can generalize to the simulation and optimization of photonic devices involving a range of domain sizes, fitting parameters, and functions. Together, these algorithms can effectively search for the

global optimum three to four orders of magnitude faster than with conventional methods. We anticipate that with proper co-design of the neural network architecture with the scientific computing task, our surrogate solver and optimizer concepts can be adapted to large scale three-dimensional photonic systems.

11:30 AM *EL12.01.03
Three-Dimensional Metamaterial Absorber for Gas Molecular Sensing TakuoTanaka[1,2,3]; [1]RIKEN Center for Advanced Photonics, Japan; [2]RIKEN Cluster for Pioneering Research, Japan; [3]Tokushima University, Japan

Metamaterials have attracted considerable attention due to their capabilities to manipulate light. Recently we applied metamaterial light absorber for improving the sensitivity of IR spectroscopy. Owing to its plasmonically resonant interaction with incident light wave, and molecules, unwanted background and noises in IR spectroscopy were suppressed, and molecular signals are enhanced and clearly observed at the bottom of the suppressed background. This technique has already been applied for self-assembled monolayer of 16-mercaptohexadecanoic acid molecules on the surface of metamaterial absorber and atto-molar (10^{-18} mol) level molecular sensitivity was realized [1]. For liquid samples, to introduce target molecules into the hot spot region of the metamaterial absorber, we proposed a metamaterial absorptive device that incorporates with nanofluidics and demonstrated an ultra-high sensitivity of IR absorption detection [2, 3, 4]. In this paper, we introduced metamaterial absorber with three-dimensional vertical-oriented metal-insulator-metal (v-MIM) structure for ultra-sensitive infrared spectroscopic gas molecule sensing [5]. We designed the v-MIM structure with a nano-gap of 25 nm channel which enabled the delivery of small molecules into hot-spot region. We developed the fabrication technique to realize v-MIMs on the surface of Si substrate using electron-beam lithography and reactive ion etching techniques. Owing to small footprint of v-MIM comparing conventional lateral MIM structure, the density of hot spots was dramatically increased resulting in strong signal enhancement and efficient suppression of background light. This metamaterial was applied to carbon dioxide and butane detection designing to exhibit a resonance at 4033 cm^{-1} and 2945cm^{-1} which spectral overlap with the C=O and $–CH_2$ vibration mode, respectively. The mutual coupling of these two resonant modes creates a Fano resonance, and their distinct peaks are clearly observed in the corresponding transmission dips. In addition, owing to its small footprint, v-MIM structure allows the detection of a 20 ppm concentration with suppressed background and high selectivity in the mid-infrared region.

Large Scale Manufacturing Techniques for Metamaterials and Their Industrial Applications RagipPala; Meta Materials Inc., United States

Development of a scalable nanofabrication technique is essential for the practical realization of nanostructured materials in functional transparent films. META® has developed discrete platform-specific proprietary technologies for large-scale lithography, allowing the manufacture of nanostructures to be carried out with high uniformity and low cost. Using these manufacturing techniques at META®, we design and mass-produce nano-technology-based films with applications in a wide variety of products and markets.

In this talk, I will present large-scale manufacturing techniques at META® including nanoimprinting, roll-to-roll processing, and holographic lithography. I will also discuss various industrial applications in automotive, authentication, 5G communication and consumer electronics. Our customizable patented nano-optics include visual authentication technology, KolourOptik® Stripe, with a unique combination of multiple colors, 3D depth and omni-directional movement. I will describe NANOWEB®, META®'s Roll to roll lithographically fabricated conductor with superior electrical and optical properties. This functional film is configured as a nanostructured conformable metal wire mesh, that is transparent to the naked eye. I will explain how we utilize NANOWEB® to enable smart solutions for distinct functions including electro-optical dimming, transparent antennas, anti-fog heaters and EMI Shielding.

In addition, we are also using a first of its kind Plasma Fusion® deposition technology, which enables high speed coating of any alloy on any type of thin flexible plastic substrate. Large scale and efficient metallization coating of ultra-thin substrate with zero defect, is a critical step for example toward volume production of safe reliable lightweight battery materials, requiring hundreds of millions of square meters per year. We use this metallization step in our roll-to-roll production process for functional films, which for solid state NCORE™ battery current collectors will reduce battery weight, increase safety, significantly accelerate line speed, and hence reduce cost.

A Scalable Technology Platform for Creating Meta-Surface Based Optics and Waveguide Combiners for Augmented Reality RobertJ. Visser, LudovicGodet, RutgerThijssen, JinxinFu, RamiHourani, SageDoshay and GuannanChen; Applied Materials, United States

Optics is increasingly important in modern life, and advances in nanostructure-based flat optical devices hold great promise for revolutionary new opportunities in the display space. Augmented and Virtual Reality (ARVR) are expected to enable the next ubiquitous computing and communication platform.[1] Augmented Reality, Optical metasurfaces also leverage engineered nanostructures to offer the possibility of extreme wavefront control, enabling further miniaturization of imaging and display optical systems and exciting new applications not achievable with conventional optics. [2,3]
The Engineered Optics™ group at Applied Materials is enabling thinner, light-weight optical systems with precise wavefront engineering to make possible novel optical devices. We have leveraged Applied Materials' materials engineering expertise to develop a platform for the precision fabrication of nanostructured optical devices on 300mm glass wafers, as well as metrology, optical performance characterization, and back-end assembly of these devices. With this platform, we are producing waveguide combiners for AR/VR applications and optical metasurfaces for multi-functional wavefront control in the near infrared.An essential element in designing the process and making choices for equipment is scalability, laying the foundation for large scale industrial manufacturing in a later stage We have opted to focus on the use of optical lithography Nano Imprint Lithography and a 300 mm equipment for all the etch and deposition steps. This leverages all the experience and the availability of equipment from the Semiconductor Industry.
Waveguide combiners are a key component in lightweight augmented reality headset or glasses systems, but are difficult to fabricate to the high precision required for simultaneous high optical image quality of the AR content and clear vision of the real world. [1
The Engineered Optics platform includes a fully integrated front-end process flow to make surface relief grating-based waveguide combiner devices for our customers. All our tools are customized to enable handling of transparent substrates of a variety of refractive indices and thicknesses. We produce binary and slanted nanostructures using UV or nanoimprint lithography and etch in high-quality, low-loss optical materials. We can process single- or double-sided devices with high alignment fidelity, and can create desired features with global and local-area processing techniques.

The Engineered Optics platform offers full end-to-end capabilities: after front-end fabrication on 300mm substrates, we optically characterize device performance at the wafer level, then complete back-end singulation, edge blackening, stacking assembly, and final testing. Completed waveguide combiner devices can then be integrated with light engines and appropriate electronics, power sources, and housings to create final AR glasses or headset devices.
The Engineered Optics platform also enables direct fabrication of optical metasurfaces on transparent substrates, without transfer from silicon substrates. We can fabricate the extremely high aspect-ratio structures required for full 2π phase control in a variety of extremely low-loss, high-refractive index optical materials.
We are also looking at photonic integrated circuits, optical computing, optical data communication, and beyond.

Highly Efficient Color Separation and Focusing in Various Color Pattern Arrays of CMOS Image Sensor SookyoungRoh, SungmoAhn, ChoonlaeCho, HongkyuPark, SangeunMun, SangyunLee, JunhoLee and SeokhoYun; Samsung Advanced Institute of Technology, Korea (the Republic of)

We designed various types of nanoscale metaphotonic color-routing (MPCR) structures that can significantly improve the low-light performance of CMOS image sensors. Fabricated on a 1.12um Dual pixel sensor and a 0.64μm Quad-pixel sensor, the MPCR structure separates the incident light energy into the respective color pixels, resulting in a notable increase in quantum efficiency of up to 20%. Our experimental demonstration confirmed a luminance SNR improvement of +1.0 dB under low light condition of 20 lux. Furthermore, this improvement was consistently achieved across different types of color pattern arrangements, further validating the versatility and effectiveness of our MPCR structures.
Pixel miniaturization has been the main driver of product innovation in CMOS image sensors (CIS) for many years, and now pixel sizes are approaching the sub-wavelength diffraction limit. While downsizing pixels enables higher pixel densities and smaller form factors, there is a trade-off between pixel miniaturization and signal-to-noise ratio (SNR). Consequently, the overall performance of CIS is adversely affected due to the reduction in light-receiving areas [1]. To address these inherent physical limitations, alternative approaches involving efficient redistribution of incident light energy can be pursued through the integration of appropriately designed sub-wavelength scale photonic structures. Recent attempts to replace conventional color filters with metasurface structures are noteworthy in this regard [2-4], yet the performance and the process compatibility of the demonstrated devices have been far from commercialization, suffering from severe color crosstalk, poor angular response, complex or impractical fabrication processes, and additional color correction that resulted in lower-than-expected SNR gains.
In this work, we present a new approach to revolutionize current optical stack layers by incorporating sub-wavelength scale metaphotonic color-routing (MPCR) structures. Our research efforts have yielded a wide range of nanoscale MPCR structures with remarkable capabilities to significantly improve the low-light performance of CMOS image sensors. By integrating these structures, we aim to improve sensor performance by manipulating the incoming light more efficiently. We have directly integrated the MPCR structures onto both of Samsung's 1.12μm dual-pixel CIS and 0.64μm quad-pixel CIS. And we characterized the imaging properties along with quantum efficiency compared to the reference sensor. The fabrication process is 100% CMOS-compatible, promising commercialization of high-performance sub-wavelength-pixel CIS.

10:30 AM *EL12.03.04
Metasurfaces: From Lab to Mass Markets RobertDevlin; Metalenz, United States

Optical metasurfaces enable unprecedented control over all aspects of light (phase, wavelength, intensity, and polarization) with a single, planar semiconductor layer. Comprised of subwavelength nanostructures, a single metasurface can carry out optical functions typically requiring four or more conventional refractive and/or diffractive optics, bringing new forms of sensing to mobile form factor for the first time. In addition to the expanded functionality they provide, they also open a route to the manufacture of optical devices in the semiconductor foundry, because they are constructed from CMOS-compatible materials on a planar substrate. This presentation will discuss metasurfaces from fundamental concepts to commercialization and will explore how the performance and large-scale manufacturing advantages of this technology will ultimately allow Metalenz to proliferate forms of sensing that have previously only been accessible in scientific or industrial laboratories.

1:30 PM *EL12.05.01
Circularly Polarized Photoluminescence from Chiral Metamaterials and Large Area Fabrication VivianFerry; University of Minnesota, United States

Chirality controls light polarization, leading to emerging applications ranging from 3D displays to anti-counterfeiting to sensing. In the first example, I will show patterned, light-emitting metasurface structures, combining plasmonic structures and patterned, photoluminescent quantum dots. I will show how strategically placing these nanocrystals results in highly tailored circularly polarized photoluminescence, which realize simultaneously high polarization control and photoluminescence intensity. The light-emitting meta-atoms, which consist of cross-linked nanocrystals, are fabricated using direct-write electron beam lithography, realizing lateral feature sizes as small as 30 nm and heights in excess of 100 nm without degradation of the photoluminescence. I will then discuss an alternative strategy that uses additive manufacturing to create large-area metamaterials, and is roll-to-roll compatible. Finally, I will discuss the optical properties of chiral metamaterials formed by block co-polymer assembly and the effects of both the surface termination and bulk structure. I will show that it is possible to realize circular dichroism even in structures that are achiral in the bulk, due to the surface termination.

2:00 PM *EL12.05.02
Nanoscale 3D Printing of Structural Colors and Micro Optics JoelYang; Singapore University of Technology and Design, Singapore

Structural colors are generated from nanoscale structures of various materials due either to interference or optical resonance effects. The ability to achieve a wide range of colors by simply tuning geometric properties opens fascinating opportunities to the nanoengineer or nanoscientist to design colors using material properties, sizes and shapes as input parameters. This physical approach contrasts with the chemical approach for synthesizing pigments and dyes. Using semiconductor fabrication methods, 2D structures based on metals and high index dielectrics have been realized, e.g. nanodisks, ellipses, etc. defined with electron-beam lithography and vacuum deposition methods.

Recently, we have extended the generation of structural colors from 3D nanostructures created using two-photon polymerization lithography (TPL). The use of TPL, an additive manufacturing process with sub-micron print resolutions, to produce structures for optical effect is a relatively new endeavor [1]. We have previously shown the fabrication of nanopillars, gratings, mesh-like, and wood-pile photonic crystal structures that appear colorful under white-light illumination.

We now demonstrate the integration of these structural colors with other micro-optical elements, such as microlenses and spiral phase plates. Equipped with TPL as a nanoscale 3D printer, structural color geometries are conveniently integrated in a single print run with other user-defined optics. Doing so enables one to produce structured light from incoherent light sources, holographic color prints, and control of the light-field for 3D representation. We will discuss the use of structural colors combined with micro-optics for enhanced information content and optical security [2].

High-Numerical Aperture Metalenses with High Quality Factor ClaudioU. Hail, MorganFoley, RuzanSokhoyan, LiorMichaeli and HarryA. Atwater; California Institute of Technology, United States

In highly resonant optical elements, attaining a high quality factor typically comes at the cost of limited spatial control over the wavefront. Here, we report on dielectric, higher-order Mie-resonant metasurfaces that break this paradigm by realizing high-numerical aperture wavefront manipulation with high-quality factors. Our structure consists of high-index dielectric nanoparticles exhibiting a spectrally overlapped electric dipole and electric octupole mode, which allows for local wavefront manipulation. By appropriately tailoring the nanoparticle dimensions over a range of 545 – 555 nm with a period of 736 nm, we imposed a paraboloidal phase profile at an interface to realize radial metalenses for operation at near-infrared wavelengths with linear TE or TM polarization. The structures were fabricated from an amorphous silicon thin film on a glass substrate by a single step electron beam lithography and dry

etching process. We have experimentally demonstrated dielectric metalenses with numerical apertures of up to 0.8 and quality factors of up to 880, in some cases with diffraction-limited performance. Our findings represent a significant advancement compared to previous approaches that have been limited to low numerical apertures or one-dimensional wavefront manipulation.

3:15 PM *EL12.05.04
Wide Field-Of-View Metasurface Optics—From Fundamentals to Applications JuejunHu; Massachusetts Institute of Technology, United States

Wide field-of-view (FOV) is a much coveted features in many optical systems with wide applications ranging from automotive sensing to biomedical imaging. In this talk, we will start by introducing our work formulating the analytical design frameworks for wide FOV metasurfaces with two distinctive and yet related configurations: imaging and projection optics. We will then proceed to discuss several device implementations guided by the analytically derived designs with applications spanning 3-D sensing, extended depth-of-field imaging, and full-color projection display.

3:45 PM EL12.05.05
Hybrid Metalens Platform for Nanoparticle Levitation and Control in Vacuum MohamedS. Mohamed; ETH Zürich, Switzerland

Levitated nanoparticle systems have emerged as a promising approach for studying fundamental forces, investigating non-Gaussian quantum states, and probing material properties at the nanoscale. When operated under ultra-high vacuum (UHV), damping of nanoparticle mechanical motion is kept sufficiently low, reducing decoherence and sustaining a high-quality-factor mechanical oscillator which can be exploited for quantum-limited sensing.

One of the main challenges towards implementing nanoparticle levitation in vacuum is the required level of control over trapping potentials, feedback forces, and sources of noise. Control schemes should additionally satisfy vacuum-compatibility and stability requirements. A compact design implementation, especially in an integrated form factor, can further enable a wide range of experiments such as acceleration sensing in dynamic testing or quantum state manipulation in cryogenic systems.

Here, a hybrid chip-scale platform for trapping and control of dielectric nanoparticles in vacuum is presented. The platform features a primary optical trap generated through an optimized polarization-insensitive dielectric metalens which features focal length in the range of 50 – 200 µm and numerical aperture values of up to 0.98. Individual silicon meta-atoms are designed to provide complete 2π phase coverage in the near-infrared wavelength range, with average transmission values exceeding 90%. The near diffraction-limited performance of the metalens alleviates requirements on input power for stable optical trapping. The metalens is patterned in an epitaxial silicon-on-sapphire layer, which exhibits reduced optical losses in comparison to silicon layers prepared by alternative deposition methods. The sapphire substrate provides a broad transparency window for the incident trapping laser beam, while preventing heat build-up given its thermal properties.

The hybrid device design features metallic electrodes embedded within the metalens layer. A dual-ring electrode configuration serves to create a tunable-height Paul trap, where the trapping volume overlaps the focal spot of the optical metalens trap. This is to assist with the loading of nanoparticles into the device by virtue of the deep potential well of the Paul trap. Furthermore, the electrode layer comprises pads for nanoparticle feedback cooling by means of cold damping. The overall architecture can additionally accommodate customized static and dynamic electromagnetic potentials which can be readily applied to the trapped nanoparticle. The overall electrode design enables the above functionalities without significantly perturbing the generated optical potential of the metalens near the trapping zone.

The proposed design was fabricated using a refined approach relying on electron-beam patterning and etching, combined with metal lift-off. Initial testing confirmed UHV compatibility of the device down to a pressure of $\approx 10^{-7}$ mbar, at the limit of the experimental vacuum chamber. Optical trapping was demonstrated with the device using femtogram SiO_2 nanoparticles, down to a pressure of 1 mbar. The collected forward scattering signal allowed for nanoparticle motion tracking using split detection.

The demonstrated platform provides a robust approach for chip-scale nanoparticle levitation and control, which opens the door to highly promising applications in both fundamental and applied science.

8:00 PM EL12.07.01
Stretchable Dielectric Metasurfaces with Electrical Control HyunjungKang, JoohoonKim, DongminJeon and JunsukRho; Pohang University of Science and Technology, Korea (the Republic of)

Metasurfaces are a type of structured surface composed of subwavelength-sized elements that can manipulate light at the nanoscale. Structural colors of metasurfaces are engineered by manipulating light to produce color without relying on dyes. They utilize microscopic or nanoscale structures to interact with light and selectively reflect or transmit certain wavelengths. By designing the size and shape of the sub-wavelength structures, metasurfaces can exhibit a wide color gamut, high color saturation, and even iridescence through precise control over the interaction of light. To improve the tunability, some techniques using phase-transition materials and active materials have been developed. In addition, a stretchable structural color via mechanical stretching has been reported. However, mechanical stretching is difficult to achieve precise and localized stretching. Also, mechanical stress can cause emergency structural damage, material fatigue and deformation. Here, we demonstrate electrically tunable structural color pixels with full-spectrum in the range from 450 to 650 nm. Electrical stretching allows for enhanced control and uniform/reversible deformation of the metasurfaces. By embedding a SiN metasurface in a polydimethylsiloxane (PDMS) substrate and stretching it in radial direction, the distinct reflection colors are tuned. As the period of the meta-atom increases from 310 nm to 450 nm, red-shift of the reflection spectrum is realized, covering from blue color to red color. In addition, since the intensity of light can be adjusted using a polarizer, it shows high-resolution images by adjusting the contrast. The reversible structural colors are promising in anti-counterfeiting, and strain-sensing applications.

8:00 PM EL12.07.02
Single-Step Manufacturing of UV Metasurface using ZrO2 Nano-PER JoohoonKim and JunsukRho; Pohang University of Science and Technology, Korea (the Republic of)

UV light, essential in scientific and technological fields, has various applications ranging from spectroscopy and quantum optics to photolithography and biosensing. Traditional UV optics rely on large optical components, which offer limited functionality and versatility. In contrast, flat optics consisting of subwavelength optical scatter offer compact platforms for precise wavefront manipulation. They enable significant downsizing of optical components and provide diverse functionalities. Nonetheless, UV metasurfaces encounter persistent challenges such as the scarcity of UV materials with low-loss and high-index properties, exorbitant manufacturing costs, and low throughput associated with electron beam lithography [Adv. Mat. 30, 1802632, 2018]. Therefore, low-loss and high-index materials for UV metasurface have been actively studied in recent years: hafnium oxide [Light Sci. Appl. 9, 55, 2020], zinc oxide [Sci. Adv. 8, abn5644, 2022], silicon nitride [ACS Nano 16, 3546-3553, 2022], and niobium pentoxide [Laser Photonics Rev. 13, 1800289, 2019]. However, fabrication processes of the aforementioned materials include not only electron beam lithography but also multi-step etching with a high aspect ratio or atomic layer deposition of a thick layer. In this manuscript, we fully address this long-standing challenge by introducing a zirconium dioxide (ZrO2) nanoparticle-embedded resin (nano-PER) for a one-step printable platform for UV metasurface. The ZrO2 nano-PER is synthesized by dispersing ZrO2 nanoparticles in a UV-curable resin which makes nano-PER printable. Owing to the large bandgap and high refractive index of ZrO2 nanoparticles, the ZrO2 nano-PER has a high refractive index and low extinction coefficient over the broad UV regime. Thus, a designed meta-atom has a conversion efficiency of 88% (λ=325 nm) and 81% (λ=248 nm), respectively. In this method, high-efficiency UV metasurface can be replicated repeatedly using a single step of nanoimprint lithography without any secondary operations, resulting in high throughput and low cost. This method will provide real opportunities for practical applications of UV metasurfaces.

8:00 PM EL12.07.03
Metasurface Selective Nanoimprint by Continuous Lithography with Laser-Induced Graphene on Metal Thin Film Timothy Yee HimChan and Mitch GuijunLi; The Hong Kong University of Science and Technology, Hong Kong

Efficient and cost-effective fabrication of metasurfaces is crucial for their widespread application in thin film technologies such as optical modulation and chemical sensing. In this study, we propose a laser-based selective nanoimprint method that enables faster and more controlled fabrication of metasurfaces, facilitating the application of different molds onto the target surface with ease. Laser-induced graphene is deposited on a metal thin film, and it is placed on the flexible mold, then the metal thin film will be used to absorb the laser energy to provide pressure on the mold for nanoimprinting the mold pattern onto the target surface. The pressure from the laser source can be controlled precisely, and the target surface can be cured at the same time to stabilize the nanostructure imprinted. By pausing the laser irradiation during the curing process, the mold will return to its original position to create a pulling effect on the nanostructure, this can enhance the height of the nanostructure on the target surface to 2 times or more of the mold structure, from 2.54 µm of the original mold to 7.74 µm on the target surface. The presented approach offers a simple fabrication method with outstanding performance for the construction of selective metasurfaces. It utilizes laser-induced transfer techniques and laser-induced pressure to enable the efficient manufacturing of optical metasurfaces and other 2D-nanostructure-based applications. The demonstrated capabilities of this technique hold great promise for the advancement of metasurface technology and its integration into various thin film devices.

SESSION EL12.08: Tunable Metasurfaces

8:00 AM *EL12.08.01
Optical Metasurfaces for Dynamic Wavefront Control in the Visible Range RamonPaniagua Dominguez; Institute of Materials Research and Engineering (A*STAR), Singapore

The ability to dynamically manipulate propagating light is critically important in various applications, from optical communications, precision manufacturing or adaptive optics, to metrology and displays. While Spatial Light Modulator technologies offering dynamic control of wavefronts have been around for a long time, they have faced severe difficulties in increasing the spatial precision at which this can be done. As an alternative platform to common liquid crystals or micromirror-based devices, optical metasurfaces have opened a possible pathway to achieve dynamic wavefront control with sub-wavelength spatial resolution by endowing resonant nanoantennas with different tuning mechanisms. In this talk, we will present some of our recent efforts in this regard, particularly in two of the mechanisms that we find most promising for visible light manipulation, namely interfacing nanoantennas with liquid crystals and using low-loss phase-change materials with and without memory.

8:30 AM EL12.08.02
Dynamic Polarization Control across the Poincaré Sphere with Black Phosphorus Metasurfaces SamuelK. Seah, SouvikBiswas, MeirGrajower and HarryA. Atwater; California Institute of Technology, United States

Controlling polarization of light on-demand can unlock a multitude of applications in optical imaging, sensing, and computing. The electrically tunable crystalline anisotropy of black phosphorus (BP) holds promise for miniaturizing polarization modulators. Here, we report on plasmonic metasurfaces combined with van der Waals heterostructures incorporating twisted BP layers. This design builds on previous single BP layer Fabry-Pérot devices and increases the tuning range from linear trajectories to nearly half the area on the Poincaré sphere.

The proposed device leverages two independently electrically tunable BP layers that have their crystal axes orthogonally aligned, while careful design of the plasmonic nano-disks on top of the heterostructure allows critical coupling of light for enhanced dynamic range of polarization tuning. By incorporating boron-nitride spacer layers and capacitively gating the BP stacks against graphene gates within the heterostructure, we achieve the two degrees of freedom needed to tune polarization across the Poincaré sphere. We will discuss the effects of metasurface design and electronic doping on the Poincaré sphere, as well as highlight our efforts on the fabrication advances of the proposed device.

8:45 AM EL12.08.03
Free-Space Electro-Optic Modulators using High Quality Factor Metasurfaces SahilDagli, HallehBalch, SajjadAbdollahramezani, HamishM. Carr Delgado, VarunDolia, JeffersonDixon, ElissaKlopfer, Jung-HwanSong, JackHu, BabatundeOgunlade and JenniferA. Dionne; Stanford University, United States

Metasurfaces advance optical communications and imaging technologies through their highly miniaturized control of the amplitude, phase and polarization of light. Achieving active tunability within a compact footprint represents a step towards power-efficient, ultrafast data processing and computation. Here, we design, fabricate, and characterize high quality factor metasurfaces as an electro-optically tunable element for photonic devices. Our device uses a hybrid materials platform of silicon on lithium niobate, taking advantage of the high index and lossless properties of silicon and the electro-optic Pockels effect in lithium niobate. We design subwavelength (400 nm width) nanobars of 300 nm thick silicon atop a 300 nm lithium niobate thin film that are fabricated by well-established top-down lithography and wafer bonding techniques in 150x150 um metasurface devices. By introducing subtle geometric perturbations into each constituent nanobar, we enable leaky guided mode resonances coupled to normally-incident free-space light. These guided mode resonances enhance light matter interactions by exciting strongly localized optical fields in the lithium niobate, with mode quality factors exceeding 1000 in both theoretical and experimental demonstrations. Applying a voltage across individual nanoantennas shifts the spectral position of the high-Q resonance, modifying the amplitude of the scattered light from the antenna. We measure an electro-optic coefficient of 3 pm/V when switching the applied voltage between 0 and 20 V. To decrease the nanoantenna length required to generate high-Q resonances, we pattern the ends of the notched bar with photonic bandgap mirrors, enabling the lateral light recirculation of leaky guided waves without causing significant radiation leakage. This allows us to achieve compact (<15 um), high quality factor (>1000) resonator pixelated nanoelements. Our high-Q electro-optic devices provide a foundation for light-weight, reconfigurable, solid-state information processing.

GSSe and ITO: Novel Materials Combination for Metasurface and Optical Circuits NicolaPeserico and VolkerJ. Sorger; University of Florida, United States

With the increasing pressure driven by novel machine learning applications, new computing systems are required to match the need for low latency, low power consumption, and high capacity. The combination of novel materials, such as the Phase Change Material GSSe and the semiconductor ITO, can provide a strong boost for multiple applications. Here, we show how we leverage the integration of the two materials over several different applications, from building tunable metalens to architect an energy-efficient optical circuit accelerator for machine learning.

10:00 AM EL12.08.05
Toward High-Endurance Nonvolatile Reconfigurable Metasurfaces Hyun JungKim[1], KiumarsAryana[1], ScottBartram[1], StephenBorg[1], WilliamHumphreys[1], Cosmin-ConstantinPopescu[2], TianGu[2], JuejunHu[2], Hyung BinBae[3] and TaewooLee[3]; [1]NASA LaRC, United States; [2]Massachusetts Institute of Technology, United States; [3]KAIST Analysis Center for Research Advancement, Korea (the Republic of)

The applications of adaptive optics extend across multiple sectors, encompassing areas such as LiDAR, biological and chemical sensing, and free-space optical communications. The advent of metasurfaces optics with reconfigurability has offered a versatile platform for the design of compact optical components, offering a compelling alternative to their conventional bulky counterparts. In this study, we introduce the PROWESS (Phase change Reconfigurable Optical WavEfront Synthesis System project at NASA LaRC), electrically reconfigurable metasurfaces using low-loss, high-contrast phase change material (PCM), $Ge_2Sb_2Se_4Te$ integrated with IR-transparent silicon microheater for various practical applications.
The talk covers a reliable platform for switching large-scale PCM-based devices utilizing a microheater and an architecture for the metasurface switching within an integrated circuit configuration, which is compatible with standard foundry fabrication processes. The utilization of near- to midinfrared transparent silicon microheater in the proposed architecture opens possibilities for the development of reconfigurable transmissive optics such as filters, zoom lenses, and beam steering modules. We demonstrated switching of 140 µm × 140 µm PCM pixel, on a 200 µm × 200 µm silicon microheater for several thousand cycles. Further, we performed an in-depth investigation into the failure mechanism utilizing techniques such as transmission electron microscopy and thermal modeling. Guidelines for device performance improvement are proposed, and an improved design with larger endurance is shown in progress. With further progress, we aim to unlock the full potential of PCM-based devices and advance the field of adaptive optics with demonstrable examples including a reconfigurable beam steerer for ocean surface flash LiDAR and Navigation Doppler LiDAR for precise lunar landing missions.

Toward Accurate Thermal Modeling of Phase Change Material Based Photonic Devices KiumarsAryana[1], Hyun JungKim[1], Cosmin-ConstantinPopescu[2], StevenVitale[3], Hyung BinBae[4],

TaewooLee[4], TianGu[2] and JuejunHu[2]; [1]NASA Langley, United States; [2]Massachusetts Institute of Technology, United States; [3]Lincoln Laboratory, United States; [4]Korea Advanced Institute of Science and Technology, United States

Reconfigurable or programmable photonic devices are rapidly growing and have become an integral part of many optical systems. The ability to selectively modulate electromagnetic waves through electrical stimuli is crucial in the advancement of a variety of applications from data communication and computing devices to environmental science and space explorations. Chalcogenide-based phase change materials (PCMs) are one of the most promising material candidates for reconfigurable photonics due to their large optical contrast between their different solid-state structural phases. While significant efforts have been devoted to accurately simulating PCM-based devices, there are important aspects that have not been captured in prior models. In this study, we will highlight three key parameters that strongly influence the thermal and phase transition behavior in PCM-based devices: the enthalpy of fusion, the heat capacity change upon glass transition, as well as the thermal conductivity of liquid-phase PCMs. The PCMs studied here for examining the amorphization process are $Ge_2Sb_2Se_4Te$ and $Ge_2Sb_2Te_5$ with areal size on the order of 140 µm × 140 µm. We further investigated the important topic of switching energy scaling in PCM devices, which also helps explain why the three above-mentioned effects have long been overlooked in electronic PCM memories but only become important in photonics. Our findings offer insight to facilitate accurate modeling of PCM-based photonic devices and can inform the development of more efficient reconfigurable optics.

10:30 AM EL12.08.07
Embeddable and Steerable Metasurfaces for Active Control of Light Steering Seung YeolLee, YujieLuo and OgnjenIlic; University of Minnesota Twin Cities, United States

Photonic surfaces, such as metasurfaces and metagratings, offer precise control of optical properties such as wavelength, intensity, and polarization, with a crucial role in efficiently focusing and directing light for various applications, ranging from imaging and communication to LiDAR and display technologies. However, typical platforms for metasurface steering and focusing are static and macroscopic, which limits their ability for adaptive control and embedding. To overcome these challenges, we propose a novel design for a microscale magneto-photonic metasurface capable of actively delivering light with high efficiency to a specific location through remote manipulation of its translational or rotational motion using an external magnetic field. This composite particle consists of a tailored photonic surface integrated with a magnetic core. To enable effective beam steering during rotation, the photonic surface incorporates metagrating patterns designed to achieve high efficiencies (~90%) for both TM and TE polarizations. The magnetic core, incorporated through a lift-off method, consists of an anisotropic cobalt layer that facilitates programmable collective translational and rotational motion. We describe a control mechanism for positioning and orienting such metasurfaces to deliver light to the targeted spot. We present modeling and experimental data to demonstrate active light steering, and we discuss the tradeoffs associated with scaling the size of this magneto-photonic metasurface. The proposed approach offers a particle-based platform that enables high-fidelity light delivery within the biological transparency window, presenting promising potential for biophotonic applications.

10:45 AM EL12.08.08
Creation of Frequency Selective Absorbing (FSB) Metasurfaces using 2D Transition Metal Dichalcogenides (TMD) SuwarnaDatar, BishakhaRay and SiyadRahim; Defence Institute of Advanced Technology (DIAT)), India

Combining 2D materials and metastructures is a promising field of research with exotic outcomes like entangled quantum sources, enhanced non-linear effects and application in many interdisciplinary fields. 2-D transition metal-dichalcogenides (TMDs) which are semiconductor materials of the type MX_2, where M is a transition metal atom (like Ni, Fe, or Co) and X is a chalcogen atom (such as S or Se) are emerging class of materials which have excellent properties like atomic scale thickness, strong spin-orbit coupling, ability to form 2D nanosheets, direct band gap and many other mechanical and electronic properties. These properties make 2D materials lucrative as frequency selective absorbers (FSBs) because of strong electronic polarization and enhanced dielectric loss. By changing M in MX_2 one can achieve tunable microwave metadevices. In the present work we have developed inks made of 2-D TMDs. Research on hybrid materials like Fe doped MoS_2, doped MoS_2-rGO composite, MoS_2/$CoSe_2$ hybrids, among several others suggests that these materials have high reflection loss. Further, magnetic transition metal dichalcogenides such as $NiSe_2$, $CoSe_2$ and their heterostructures, expediate multiple reflections and scattering of the incident wave, thereby elongating the course of transmission of the incident microwave. This increases dissipation efficiency, along with large specific surface area, which caters to EM absorption. In the present work inks have been developed base on these materials to make them versatile for several applications. Metastructures using these paints have tunability of material properties like permeability and permittivity by changing meta structure thickness and dimension allowing to manipulate the electric and magnetic resonance at different frequencies independently, therefore, frequency selective structures can be made. Furthermore, in the present work, the structures have been made using 2D TMD whose conductivity has peaks depending on the percolation threshold at a given frequency for a particular concentration of the 2D structure in the paint. The analysis of the absorption by structures made of such composites is complex. Interestingly, it has been observed that unlike the meta structures created by metals where the absorption bandwidth and frequency, solely depend on the structures made, here they seem to also depend on the composition of 2D TMB which is encouraging. This provides an additional method to modulate the properties of FSA. The results are discussed to understand the role of 2D TMB in metadevice fabrication.

SESSION EL12.10: Nonlocal Metasurface in Frequency Space, BIC and Its Application for Tuning
Session Chairs: Yongmin Liu and Junsuk Rho
Wednesday Afternoon, November29, 2023
Hynes, Level 3, Room 305

1:30 PM EL12.10.01
High Quality Factor Meta-Reflect-Arrays for Electrical Programmable Wavefront Shaping LinLin[1,1], JackHu[2], SahilDagli[2], YuanMeng[1], ZhihaoXu[1], JenniferA. Dionne[2] and MarkLawrence[1]; [1]Washington University in St. Louis, United States; [2]Stanford University, United States

LiDAR technology allows high-resolution 3D mapping and object identification for distance measuring, revolutionizing remote sensing. It is crucial for autonomous vehicles, AR/VR devices, and AI robots. Among components of LiDAR systems, beam steering is the most crucial part for precise control of the laser beam's trajectory and scanning pattern. The existing techniques, including mechanically rotating mirrors or prisms, microelectromechanical systems (MEMS), liquid crystal (LC), digital micro-mirror devices (DMD), and optical phased arrays (OPAs) have slow response time, mechanical complexity, and bulkiness. For instance, the number of optical elements and the challenge of aligning additional optical elements limit OPA's achievable steering range and resolution. Recent flat optics or phase gradient metasurface spatial light modulators (SLMs) offer promising alternatives. Metasurfaces, which consist of densely arranged diffractive nanoantennas, can manipulate light with enhanced light-matter interaction on a subwavelength scale. However, achieving high diffraction efficiencies with strong modulation is still one of the greatest obstacles for metasurface SLMs. Narrowband resonances, characterized by a high quality factor (Q-factor), are well known to increase the efficiency of modulation. With Q-factor up to 10^7, micro-ring resonators used in integrated electro-optical modulators have achieved unity extinction modulation up to 40 GHz with a few volts. However, Q-factors for free-space light modulation with metasurfaces having subwavelength elements are typically on the order of 10.

To address the challenge of this weak modulation, a new class of silicon nanoantennas supporting high-Q dipolar guided mode resonances (DGMR) has been reported. By subtly breaking translational symmetry, DGMR nanoantennas are guided mode standing waves that can leak into free space and result in high-Q resonances with dipole radiation patterns perpendicular to the antenna. This makes them the ideal element for the efficient modulation of light scattering. While many interesting transfer functions have been explored using this scheme, universal wavefront shaping has yet to be experimentally demonstrated.

Here, we present a universal meta-reflect-array platform made from only high-Q DGMR nanoantennas acting as independent extremely sensitive pixels, enabling strong responses to weak structural tuning. When post-processed to incorporate a reflective ground plane, changes of<2.6% volume fraction across the array are found to facilitate efficient beam steering. To demonstrate that these devices are acting as phase gradient optics and not gratings, we realize beam steering to angles 32.3°, 25.3°, and 20.9°. To apply this concept to dynamic wave-shaping, we replace the structural perturbations with electro-thermal biasing. Although the thermo-optic coefficient of silicon is only $1.8x10^{-4}$ K^{-1}, The extreme sensitivity of DGMRs with high-Q of 2088 can be red-shifted efficiently with minimal temperature change. We exploit the temperature sensitivity by realizing a prototypical electrically programmable multi-element transmissive amplitude display consisting of a structurally uniform Si high-Q meta-reflect array with Ni resistive heating elements encapsulated above silica. With the second Au circuit patterned above, three distinct groups of Ni wires are separated and connected into three Au pads. Applying individual bias voltages to the conducting pads using an SMU, we can tune the intensity transmitted by each high-Q pixel. We have measured the electrically tunable transmission pattern resulting from different voltage distributions using an imaging spectrometer. This compact and efficient dynamic wave shaping prototype with programmable capability can be extended in the future to quicker mechanisms such as carrier injection and the Pockels effect with higher tuning speed, shedding light on high resolution modern flat display technologies and LiDAR beam-steering.

1:45 PM EL12.10.02
Eliminating Nearfield Coupling in Dense High-Quality-Factor Phase Gradient Metasurfaces SamuelAmeyaw, LinLin and MarkLawrence; Washington University in St. Louis, United

States

Recent developments in optical technologies call for precise wavefront manipulation and miniaturized and lightweight optical components. Phase gradient metasurfaces, have over the years proven to be a strong candidate for the realization of novel technologies especially in AR, VR, and LIDAR applications[1]**.** Resonance is a key property of the nanostructured building blocks of a phase gradient metasurface. Boosting the light matter interaction over subwavelength volumes allows many nanoscale objects to be combined to impose smooth spatially varying phase profiles on incident light waves[2].
A crucial metric by which to evaluate the performance of phase gradient metasurface is resolution, as it directly influences the accuracy achievable in wavefront shaping as well as the angular field of view. The resolution of phase gradient metasurfaces is predominantly limited by nearfield coupling between neighboring meta-atoms, preventing them from scattering light independently and generating crosstalk. The fact that the impact of coupling scales with Q typically forces a tradeoff between resolution and Q-factor. Coupling can be reduced by shrinking the evanescent decay lengths of the individual modes, thereby reducing the mode overlap. However, there will still be a Q for which the remaining coupling is a problem.
Here we show that extremely dense silicon metasurfaces supporting dipolar guided mode resonances can be engineered to entirely suppress near-field coupling for arbitrarily high Q. We reveal a zero-coupling regime occurs when nanoantennas are separated by anisotropic nanofins[3]. Rather than decreasing the field overlap, the fins enhance the longitudinal electric field, allowing it to interfere with the transverse electric field. For a specific nanoantenna width we demonstrate that the interference is perfect, effectively decoupling the high Q dipolar-guided mode resonators in proximity, enabling deep resolution and efficient diffraction.
To demonstrate the power of this new platform, we show how decoupled DGMR metasurfaces, backed by a mirror, can efficiently shape reflected diffraction when independent adjustments are applied to the refractive indices of each nanoantenna. Varying the refractive index of the outer pixels of a three pixel metasurface by only $1.7x10^{-5}$, we achieve steering to the $+1^{st}$ diffraction order with an efficiency of 85%. The tiny index modulation needed is a direct consequence of the giant Q of 192,474. Having a pixel pitch of $\lambda/1.6$, the steering also occurs at a large angle of 32^{o}.In beamsplitting we achieve diffraction efficiency of 99% with Q greater than 257,000 and δn of $1.5x10^{-5}$. Importantly, we believe the Q can be much higher, but such structures become increasingly difficult to model. By increasing the thickness of the silicon film to 383nm, the decoupled regime can even be found with sub-diffraction resolution, pixel pitch=$\lambda/2.2$.
In this case, beamsteering of incident light is achieved to the $+1^{st}$ diffraction order at an angle of 47^{o} with an efficiency of 85%. As the elements in this device have a Q of 68,797, the refractive index bias was only $1x10^{-4}$. Another symptom of nearfield coupling is angular dispersion. With the decoupled nanoantennas, we have been able to achieve angle independence such that the resonant shift of a DGMR with Q~45k stays below the FWHM for an angle of incidence from -45^{o} to 45^{o}. Our platform provides a route for dense high Q metasurfaces with independent addressability of the constituent meta-atoms paving the way for highly efficient nonlinear and dynamic wavefront shaping.

Magneto-Optic Control of Brewster Quasi Bound States in the Continuum AntonioGarcia-Martin; Instituto de Micro y Nanotecnologia, CSIC, Spain

Bound states in the continuum (BICs) emerge throughout Physics as leaky/resonant modes that remain, however, highly localized[1]. They have attracted much attention in Photonics, and especially in metasurfaces[2,3]. One of their most outstanding features is their divergent Q-factors, indeed arbitrarily large upon approaching the BIC condition (quasi-BICs) [4,5]. Here we investigate how to tune quasi-BICs in magneto-optic (MO) all-dielectric metasurfaces. The impact of the applied magnetic field in the BIC parameter space is revealed for a metasurface consisting of Si spheres with MO response. Through our coupled electric/magnetic dipole formulation, the MO activity is found to manifest itself through the interference of the (MO-induced) out-of-plane electric/magnetic dipole resonances with the in-plane magnetic/electric (directly induced) dipole, leading to a rich, magnetically-tuned quasi-BIC phenomenology, resembling the behavior of Brewster quasi-BICs for tilted vertical-dipole resonant metasurfaces. Such resemblance underlies our proposed design for a fast MO switch of a Brewster quasi-BIC by simply reversing the driving magnetic field. This MO-active BIC behavior is further confirmed in the optical regime for a realistic YIG nanodisk metasurface through numerical calculations. Our results present various mechanisms to magneto-optically manipulate BICs and quasi-BICs, which could be exploited throughout the electromagnetic spectrum with applications in lasing, filtering, and sensing [6].

2:15 PM EL12.10.04
Thermal and Electro-Optic Control of High-Q Metasurfaces for Dynamic Lensing HamishM. Carr Delgado[1], ElissaKlopfer[1], SahilDagli[1], JenniferA. Dionne[1,1] and MarkLawrence[2]; [1]Stanford University, United States; [2]Washington University in St. Louis, United States

Metasurfaces— arrays of subwavelength nanoantennas that control the phase, amplitude, and polarization of light—are a promising platform for novel and compact optical technologies and communication. However, dynamic control of metasurfaces remains challenging due to weak light-matter interactions and in compact, nanoscale devices. Here, we design and characterize a dynamically-tunable metasurface lens, with a high-quality-factor (high-Q) resonance working as both the basis of the lensing behavior and means for efficient modulation with thermal or electrical biasing. Our high-Q lens is constructed via a zone plate architecture consisting of alternating regions with and without resonant character. Both regions consist of 500 nm tall and 320 nm wide silicon nanobars atop a sapphire substrate. Nanobars in non-resonant regions are highly reflective, while nanobars in resonant regions are highly transmissive on resonance due to the inlcusion of periodic perturbations, which enable a guided mode resonance with measured Q-factors up to ~1350. By leveraging the thermo-optic effect of silicon, we dynamically control the spectral position of the high-Q resonance to achieve wavelength selectivity of the focusing behavior. Due to the sharp spectral linewidth and amplitude variation of the high-Q resonance, thermal tuning can further result in metasurface switching, where the lensing behavior is changed between on and off states in response to thermal stimuli. For a device utilizing only moderate Q-factors of ~350, the resonance's FWHM can be shifted with temperature changes of only 50 C, and the device can be fully switched off when operating at 100 C. These experiments provide a foundation for dynamic control of a local high-Q wavefront shaping metasurface. Next, to overcome the low switching speeds of thermal tunability, we simulate and fabricate silicon metasurfaces with a silicon nitride straining layer, which breaks the inversion symmetry of the silicon crystal, enabling a non-zero electro-optic coefficient. The stress imparted by the silicon nitride layer can be tuned by varying the deposition conditions to maximize the induced electro-optic effect in silicon. Simulations show a tunability in the resonant wavelength of ~44 pm per applied volt in a vertical bias configuration for an induced second order susceptibility of 40 pm/V, which can be achieved with moderate film strains. For resonances with quality factors ~7,000 in simulation, it is thus possible to switch the device from highly reflective to highly transmissive with low voltages ~15 V due to the narrow linewidth of the resonance. These devices provide a CMOS compatible platform for lightweight, compact, and reconfigurable solid state information processing.

SESSION EL12.11: Bottom-up Fabrication
Session Chairs: Junsuk Rho and Shuang Zhang
Thursday Morning, November30, 2023
Hynes, Level 3, Room 305

9:15 AM EL12.11.01
Self-Assembled Designer Monocrystalline Metasurfaces BeniaminoSciacca[1,2]; [1]CNRS, France; [2]Aix-Marseille Université, France

High-quality monocrystalline materials and nanostructures are key to high-efficiency optoelectronic devices, plasmonic materials and metasurfaces. A large variety of materials can be synthesized at low temperature in solution as colloidal single crystals, combining the advantages of high-quality material and low-cost fabrication, but the potential for large area integration into nanophotonic and plasmonic devices via nanoparticle assembly techniques still remain elusive. The two major bottleneck are:

1) Difficulty to achieve defect-free colloids self-assembly in truly arbitrary patterns
2) Poor optical and electronic properties resulting from the discreetness of individual building blocks.

In this talk I will present recent breakthroughs from our team tackling both challenges with a new approach that we have introduced based on nanocube epitaxy. In the first part I will focus on advances on directed-assembly with detailed insight into the mechanisms. I will show for the first time the fabrication of complex and truly arbitrary organisation of nanocubes on a large surface, with a single nanocube resolution. Examples includes 1D linear assembly (A. Capitaine et al., Small Methods 2023), 2D nanocube grid arrays for transparent electrodes (A. Capitaine et al, ACS Nano 2023), highly dense split-ring resonator absorbers and Pancharatnam–Berry metasurfaces (M. Fajri et al., in prep).

In the second part I will focus on advances on nanocube epitaxy, showing a general methodology to transform an arbitrary assembly of nanocubes (Ag, Au, Cu_2O, core-shell) into defect-free continuous nanostructures and *operando* mechanistic insights (B. Sciacca et al. Adv. Mat. 2017, A. Capitaine et al. Adv. Mat. 2022). This approach enables to obtain monocrystalline plasmonic and nanophotonic surfaces that can be readily printed on any substrate (flat, microstructured), but also to make nanocrystals with unconventional (à la carte) geometries, that can be used as colloids to go beyond Platonic solids.
Finally, I will show optical characterisation of the resulting large area metasurfaces, supported by numerical simulations.

I believe that this constitute a major breakthrough in the field, can inspire many scientists and lead the way for a new generation of bottom-up metasurfaces and their spread in industrially-relevant products.

9:30 AM EL12.11.02
Self-Assembled TiN-Based Metamaterials with Anisotropic Properties and Magneto-Optical Coupling Effects JiaweiSong[1], DiZhang[2], PingLu[3], HaohanWang[4], YizhiZhang[1], XiaoshanXu[4], JuliaDeitz[3], XinghangZhang[1] and HaiyanWang[1]; [1]Purdue University, United States; [2]Los Alamos National Laboratory, United States; [3]Sandia National Laboratories, United States; [4]University of Nebraska-Lincoln, United States

Transition metal nitrides (e.g., TiN) have shown tremendous promise for nanophotonic devices due to their low-loss plasmonic properties and superior high-temperature stability compared to noble metals. Coupling other functionalities with plasmonic nitrides as multifunctional nitride-based hybrid metamaterials presents an enormous opportunity for advanced integrated photonic devices. In this talk, we present a novel approach for creating TiN-based hybrid metamaterials in vertically aligned nanocomposites (VANs) form with anisotropic properties and magneto-optical coupling effects. First, we present a two-phase nanocomposite design that combines ferromagnetic $CoFe_2$ nanosheets within the plasmonic TiN matrix. The resulting hybrid metamaterials exhibit obvious anisotropic optical and magnetic responses, along with a pronounced magneto-optical coupling response, owing to the unique vertically aligned structure. Second, we demonstrate a complex three-phase nanocomposite design of Au-TiN-$CoFe_2$ nanocomposites. Compared to the co-growth method that yields three distinct morphologies of Au-$CoFe_2$ core-shell nanopillars, the templated growth resulted in the formation of highly ordered and uniform single-type core-shell nanopillars (i.e., the $CoFe_2$ shell with an Au core) in the TiN matrix. Both the co-growth and templated growth TiN-$CoFe_2$-Au films exhibit excellent epitaxial quality, hyperbolic dispersion, magnetic anisotropy, and magneto-optical coupling effects. These findings open up exciting opportunities for the development of advanced nanophotonic devices and applications that leverage the enhanced functionalities of plasmonic-magnetic hybrid metamaterials.

9:45 AM EL12.11.03
Fabrication of Spiky Gold Nanoparticles in Ordered Arrays with Tunable Nanofeatures JinJia, NadiaMetzkow, Sang-MinPark, YuhaoL. Wu, AlexanderD. Sample, BunditDiloknawarit, InsubJung and TeriW. Odom; Northwestern University, United States

Anisotropic gold nanoparticles (AuNPs) with branched spikes, known as spiky AuNPs, are attractive plasmonic materials due to their localized surface plasmon (LSP) resonances. Achieving precise control over the morphology and optical response of spiky AuNPs, as well as arranging AuNPs in ordered arrays on substrates are important for designing metamaterials, biosensors and optoelectronics. This talk will describe a substrate-bound seed-mediated synthesis approach to fabricate spiky AuNPs in ordered arrays with tunable nanofeatures. We will discuss advances in nanofabrication techniques that enable the patterning of AuNP seeds with designed shape and size. We will describe how different growth conditions can lead to the formation of different nanofeatures on the seeds, resulting in different LSP resonances. Finally, we will discuss the prospects of using spiky AuNP arrays for surface-enhanced Raman spectroscopy (SERS).

10:00 AMBREAK

10:30 AM EL12.11.04
Nanocube Assembly á La Carte Muhammad LuthfiFajri[1], IbtissemBouanane[2], FrédéricBedu[1], PeeranuchPoungsripong[1], OlivierMargeat[1], JudikaëlLeRouzo[2], PatriceGenevet[3] and BeniaminoSciacca[1]; [1]Aix Marseille University, CNRS, CINaM UMR 7325, France; [2]Aix Marseille University, CNRS, IMN2P UMR 7334, France; [3]Université Côte d'Azur, CNRS, CRHEA, France

Arrays of nanopatterns are of high interest in the multidisciplinary field of nanoscale photonics. Conventionally there are two approaches to fabricating such nanopatterns: top-down nanofabrication via electron beam lithography and bottom-up self-assembly. The former can create complex structures but lacks control over crystallinity, introduces surface roughness due to etching[1], is expensive and time-consuming, making it unfavorable for large-scale fabrication. Conversely, the latter is typically straightforward, affordable, and has better control over atomic composition and crystallinity. However, it struggles to fabricate complex nanopatterns due to thermodynamic constraints[2]. This has been partially circumvented with directed assembly strategies, which consist of colloidal nanoparticles in PDMS templates replicated from a nanofabricated master[3]. However, the nanopattern geometry that could be achieved effectively is still strongly limited to individual particles or low-density 1D arrays[4,5], whereas precise and deterministic arrangement of nanoparticles in truly complex and arbitrary nanopatterns (needed for nanophotonics and plasmonics applications) have so far remained elusive.

Here, we offer a new approach to obtain arbitrarily complex nanostructure arrays with a single nanoparticle resolution with no need for advanced equipment. Nanoparticles are first deposited at the air/water interface in a compact film and then transferred into a nanopatterned template. This highly versatile technique is independent from the specific nanopattern and can apply to a plethora of materials and shapes. We will show assembly of various materials (Ag, Au, Au-Cu_2O core-shell nanoparticles and nanocubes) into various complex nanopatterns, such as U-shapes, L-shapes, cross-shapes, S-shapes, T-shapes, Pancharatnam–Berry metasurfaces, and also split-ring resonators on PDMS, that cannot be obtained with conventional assembly techniques. Among other nanoparticle shapes, we focus on nanocubes because they are ideal building blocks for obtaining monocrystalline nanostructures[6,7]. We will show that such assemblies, in which each nanocube unit is precisely assembled as a Lego brick in complex extended arbitrary motifs, can subsequently be transformed into continuous nanostructures via nanocube epitaxy and then transfer-printed to various substrates, including flat and microstructured substrates. Finally, we will show optical characterizations and simulations of the metasurfaces obtained. This strategy potentially offers an alternative to a bottom-up fabrication for metal nanostructuring, which can then be applied to optoelectronic applications.

10:45 AM EL12.11.05
Meta-Structure IR Absorber Applied Microbolometer for Perfect Absorptance and Responsivity Improvement JeongeunMo[1,2], DasomWang[1], Ji-HunKang[3], Jeong MinBaik[2] and Won JunChoi[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Kongju National University, Korea (the Republic of)

In recent years, the demand for high-performance infrared image sensors has increased significantly in various fields, including military applications, medical imaging, and Advanced Driving Assistance Systems (ADAS). Microbolometers, which are cooler-free infrared image sensors, have gained popularity due to their affordability and convenience. However, to enhance the performance of microbolometers, it is crucial to achieve high responsivity and detectivity. Effective infrared (IR) absorption is essential for microbolometers to efficiently transfer heat to the thermistor layer and achieve high responsivity ($R_v = \alpha\eta I_b R_0/G(1 + \omega^2\tau^2)^{(1/2)}$). To address this requirement, we applied a meta-structured IR absorber to enhance the IR absorptance of microbolometers.
In this study, we employed an alternating metal-dielectric multilayer films with different refractive index as the IR absorbing medium. A periodic circular structure is introduced to multilayer

films for higher absorptance. This structure has been designed to decrease total volume of IR absorbing medium in order to get lower thermal mass so that heat can easily transfer to the thermistor layer. FDTD simulation is conducted to compare the dependence of different sizes of periodic circles and intervals on absorptance of meta-structured multilayered absorber. This result revealed significant improvement in the absorptance of incident light in LWIR region (8-14um), which is commonly used for object detection. For experimental demonstration, IR absorber is deposited by electron beam evaporator based on reported previous research. The experimental results confirmed that the meta-structured IR absorber exhibited higher absorptance compared to the non-meta-structured counterpart. Consequently, we expect that the application of meta-structured IR absorber to microbolometers will facilitate the temperature increase of the thermistor material, leading to a notable improvement in responsivity. In conclusion, the presented research will give an idea of increasing responsivity of microbolometer with drawing up absorptance of IR absorber with meta-structure.

11:00 AM EL12.11.06
Wafer-Scale Manufacturing of Centimeter-Sized Metasurfaces Down to the Deep-Ultraviolet Region JoohoonKim and JunsukRho; Pohang University of Science and Technology, Korea (the Republic of)

UV optics play a vital role in both science and technology, from spectroscopy and quantum optics to photolithography and biosensing. Conventional UV optics are primarily based on bulky optical components and have limited functionality and diversity. As an alternative, metasurfaces can provide fine wavefront-shaping platforms with a compact form-factor, resulting in drastic miniaturization of the device and capability of diverse functionality. However, metasurfaces operating in the UV regime face long-standing challenges, such as the scarcity of low-loss and high-index UV materials and patterning limitations (small patterning area, high cost, and low throughput). Recently, UV-transparent materials such as zinc oxide [Sci. Adv. 8, abn5644, 2022], silicon nitride [ACS Nano 16, 3546-3553, 2022], and hafnium oxide [Light Sci. Appl. 9, 55, 2020] have been actively studied; however, the fabrication process of these materials is not scalable or easy to manufacture because they include e-beam lithography and multi-step etching with thick layer deposition. Recently, our group developed a scalable manufacturing platform that can produce visible metasurfaces on the wafer scale [Nat. Mater. 22, 474-481 (2023)]. However, a UV-transparent material compatible with our scalable method and patterning resolution remains a challenge for scalable manufacturing of UV metasurfaces. In this work, we fully address this long-standing challenge and mass-produce centimeter-scale UV metalenses by introducing a zirconium dioxide (ZrO2)–polymer hybrid material and high-resolution ArF photolithography. We find that ZrO2 has both a high refractive index and low absorption in the UV regime, and is compatible with our scalable method using atomic layer deposition (ALD). Using scalable and easily manufacturable ZrO2–polymer hybrid material, we succeed in mass-producing centimeter-scale UV metalens for the first time. Owing to the high repeatability of nanoimprint lithography, our method can fabricate wafer-scale UV metalenses at extremely low cost and high throughput. Notably, thin-film coatings in hybrid materials enable strong light confinement, resulting in high efficiency of fabricated metalenses. The proposed method fully addresses the long-standing challenges in the field of UV metasurfaces and presents a practical possibility for the first time that UV metasurfaces can be applied in real life.

SESSION EL12.13: Advanced Nanophotonic Design Strategies
Session Chairs: Zhaowei Liu and Junsuk Rho
Thursday Afternoon, November30, 2023
Hynes, Level 3, Room 305

1:30 PM *EL12.13.01
Comprehensive Design of Metasurfaces: The Role of Symmetries in the Position of Complex Frequency Zero Singularities PatriceGenevet; Université Côte d'Azur, France

Metasurfaces are artificial optical interfaces designed to control the phase, the amplitude and the polarization of an optical wavefront. These optical surfaces rely on the coherent scattering of light by a sizable distribution of nano-scatterers of various shapes and material compositions. Metasurfaces hold great potential for on-chip integration of photonic components, significantly promoting the development of miniaturized optoelectronic systems.
Genevet group is working on the physics of Metasurfaces and their applications for directional light collection and emission (imaging systems and VCSEL arrays), and LiDARs. The group recently pioneered disruptive research on the developments in topological and tunable nanophotonics systems. This talk will concern fundamental properties of metasurfaces with emphasis on topological and vectorial metasurfaces. Our work starts from the observation from the fact that because of their radiative coupling to the environment, all optical components are intrinsically non-Hermitian systems, often described by reflection and transmission matrices with complex eigenfrequencies [1,2]. The control and the creation of zero singularities are shown to be the key ingredients to achieve full phase modulation of light. In particular, we rely on complex-frequency analysis to draw conclusions on the physics of metasurfaces and guide the designs towards the engineering of innovative nanophotonic devices. Symmetry breaking -- either explicit or spontaneous – thus plays significant role in the response of the system, moving the position of Zero singularities of the reflection or transmission matrices from the real axis to the upper part of the complex frequency plane. A universal 0 to 2π-phase gradient needed for wavefront modulation of an output channel as a function of the real frequency excitation is shown to be linked to the presence of discontinuity branch bridging a Zero and a Pole, i.e a pair of singularities, crossing the real axis[2]. This basic understanding helps us engineering electromagnetic fields at interfaces, including, but not limited to, metasurfaces[3-6]. Non-Hermitian topological features associated with exceptional degeneracies or branch cut crossing are shown to play a surprisingly pivotal role in the design of resonant photonic systems. With our works, we establish a general framework to predict and study the response of resonant systems in photonics and metaoptics.

Overcoming Optical Losses of Superlenses with Synthetic Waves of Complex Frequency ShuangZhang; University of Hong Kong, Hong Kong

In conventional optical imaging, Abbe diffraction limits the resolution of feature sizes to larger than half the wavelength. This limit is due to the loss of the subwavelength information carried by evanescent waves. To overcome this limitation, a negative refractive index lens has been proposed to enhance the evanescent waves to recover the deep-subwavelength resolution of imaging. Subsequently, superlenses, made of either natural materials with negative permittivities, or hyperbolic materials with mixed signs of dielectric constants along different directions, have been proposed to attain sub-diffractional limited imaging. Nevertheless, losses are non-negligible in materials with negative parameters, which reduces the deep-subwavelength information of the superlenses and seriously affects the resolution of imaging. To compensate the losses, it has been proposed that gain materials could be incorporated into metamaterial designs or plasmonics, but the setup is extremely complicated and the gain will inevitably introduce instability and noise into the system. Recently, complex-frequency waves with temporally growing or attenuating behaviors have been treated as virtual absorption or gain waves. Some theoretical proposals have been put forward to recover the deep-subwavelength information

carried by surface plasmons via excitation of complex-frequency waves (CFW) with temporal attenuation. However, synthesizing CFW is challenging in optical systems from a practical perspective.

To address this challenge, we synthesize CFW signals using a multi-frequency approach. We exploit the fact that a truncated CFW can be expressed as combination of multiple frequency components with coefficients following a Lorentzian spectral lineshape through the Fourier transformation. We perform measurements at multiple real frequencies and numerically synthesize the field distribution under CFW illumination by combining the measured field plots at different frequencies according to the Lorentzian lineshape. As a proof of the concept, both a SiC slab operating at optical frequencies and a bulk hyperbolic metamaterial operating at microwave frequencies are used as superlenses. We show that, while the spatial resolution of imaging at real frequencies is poor, caused by the inevitable material loss in these systems, an ultra-high resolution imaging can be obtained with the synthesized CFW consisting of multiple frequency components. Our approach successfully overcomes the challenges of experimentally implementing CFW in the time domain, which include the need for precise CFW synthesis and time-gated measurements after reaching the quasi-steady state, and holds great potential for high-resolution microscopy. Furthermore, the synthesized complex-frequency approach can be extended to other areas of optics, such as plasmonic sensing applications. By leveraging the enhanced quality factor of plasmonic structures, our approach has the potential to significantly improve sensitivity in sensing applications. In addition, the approach can be tailored to different systems and geometries, providing a flexible and versatile tool for improving optical performance.

Disordered Optical Metasurfaces to Create New Visual Effects PhilippeLalanne; CNRS, France

The visual appearance of flat surfaces and curved objects is paramount in life and technology for fine and applied arts.
The ERC project **UNSEEN** aims at creating metasurfaces that offer new visual appearances, unseen in nature so far. The metasurfaces are composed of disordered monolayers of high-index resonant nanoparticles, either deposited from a colloidal solution on solid support or fabricated with ebeam lithography.
We have developed two models to predict the scattering properties of disordered metasurfaces. They allow us to predict design the scattering properties for all wavelength and incident angles. We have validated the models by testing them with experimental data, we have also been able to design a metasurface that generate only two distinct colors (green and violet) under all incidence and viewing angles, a quite strange phenomenon if we consider that usual iridescence provides a continuous variation of color as the incident and viewing angles changes (think to a thin film). For more details on the topic, please refer to

Analysis of the Effect of Material Choice on the Performance of Metasurfaces JunkyeongPark, YounghwanYang, HyunjungKang and JunsukRho; Pohang University of Science and Technology, Korea (the Republic of)

A metasurface is a thin layer that operates at a scale smaller than the wavelength of light. It controls light by using meta-atoms, which are small structures arranged in a specific pattern. These meta-atoms are typically made of plasmonic or dielectric nanoantennas and have the ability to change the properties of light, such as its phase, amplitude, and polarization. As a result, metasurfaces find applications in various fields, including advanced displays, lenses, and sensors in the next generation. Particularly, due to their low optical losses, broadband operation, and compatibility with complementary technologies, dielectric metasurfaces are a promising platform for various photonic applications. Generally, dielectric materials with high refractive indices and low optical losses are favored for the development of highly efficient metasurfaces, which enable the creation of wide-angle beam steering and near-unity numerical aperture metalenses. Despite the intuitive choice of such materials, the relationship between material properties and metasurface performance remains unclear. In this presentation, we aim to determine the correlation between the refractive index and the performance of metasurfaces. Specifically, we investigate metalenses operating within the visible spectrum and evaluate their efficiency and full width at half maximum (FWHM). By examining these parameters, we aim to gain quantitative insights into how the refractive index influences the effectiveness of metasurfaces in manipulating light in the visible regime.

Breaking the Limitation of Polarization Multiplexing in Optical Metasurfaces with Engineered Noise RuwenPeng[1], YongminLiu[2] and MuWang[1,3]; [1]Nanjing University, China; [2]Northeastern University, United States; [3]American Physical Society, United States

Noise is usually undesired yet inevitable in science and engineering. However, by introducing the engineered noise to the precise solution of Jones matrix elements, we break the fundamental limit of polarization multiplexing capacity of metasurfaces that roots from the dimension constraints of the Jones matrix. We experimentally demonstrate up to 11 independent holographic images using a single metasurface illuminated by visible light with different polarizations. To the best of our knowledge, it is the highest capacity reported for polarization multiplexing. Combining the position multiplexing scheme, the metasurface can generate 36 distinct images, forming a holographic keyboard pattern. This discovery implies a new paradigm for high-capacity optical display, information encryption, and data storage.

Algorithmic Optimization of Disordered Plasmonic Metasurfaces using Far-Field Wavefront Shaping GauthierRoubaud[1], SylvainGigan[2], SamuelGrésillon[1] and SebastienBidault[1]; [1]ESPCI Paris, France; [2]Sorbonne Université, France

Plasmonic metasurfaces have broad applications in wavefront control, surface-enhanced spectroscopy or sensing. However, deterministic nanostructures do not allow an active tuning of these optical properties. By comparison, wavefront shaping techniques in disordered media have shown tremendous flexibility in actively modulating the propagation and focusing of light in space and time. We demonstrate here that delocalized modes in disordered plasmonic metasurfaces can be controlled using far-field wavefront shaping and algorithmic optimization schemes in order to locally modulate their optical responses.
By controlling the phase of an incoming femtosecond pulsed laser on a disordered gold metasurface, we optimize the two-photon induced luminescence (TPL) at a chosen position with a typical two-order of magnitude enhancement, indicating a far-field optimization of the optical near-field. The optimization process is performed using a random genetic algorithm and provides the highest enhancement when the metasurface features the highest degree of morphological complexity, close to the percolation threshold (Nano Lett. 20, 3291 (2020)).
Far-field wavefront shaping also provides new degrees of freedom to provide statistical imaging schemes that offset the structural complexity of disordered nanophotonic systems. For instance, using nonlinear luminescence images measured with randomly wavefront-shaped femtosecond excitations, we can independently map the localized and delocalized plasmonic modes on a disordered gold metasurface (ACS Photonics 8, 1973 (2021)).

Metasurfaces for Edge Detection and Quantitative Phase Imaging ZhaoweiLiu; University of California, San Diego, United States

Microscopy has been playing a crucial role in many science and engineering fields. Metasurface as a new emerging tool has shown its unique capability to manipulate light at scales previously thought impossible, opening doors for optical microscopy systems with ultracompact footprint. In my talk, I will present some of our recent development by using metasurfaces to build various compact microscopy systems. Specifically, I will discuss metasurface enabled edge detection, Fourier optical spin splitting microscopy, and various schemes to achieve quantitative phase imaging. Some biological imaging results will be presented by using such metasurface based microscopes.

Polarization Independent Broadband Metasurface Edge Detector in Visible Wavelengths IbrahimTanriover, SinaA. Dereshgi and KorayAydin; Northwestern University, United States

Image processing is of fundamental importance for many emerging technologies such as AR/VR glasses, autonomous driving, and biometric identification. Conventionally, image processing tasks are performed by digital computers. However, the processing time and power consumption of digital computers become a limiting factor with the increasing demand for real time, continuous data processing. With the advent of metamaterials and metasurfaces, optical computing platforms emerged as promising candidates to perform such image processing tasks. In recent years, numerous examples based on spin Hall effect, Pancharatnam–Berry phase, photonic crystals, and surface plasmons were realized. These studies have shown that metasurfaces offer real time image processing with low to none power consumption. However, the previous demonstrations suffer from one or few of the several limitations that are requiring angled incidence, polarization dependence, requiring additional polarizers, narrow operation band, being limited with 1D processing, requiring coherent light, and requiring digital post-processing.

Here, addressing these problems, we propose and demonstrate metasurfaces for 2D isotropic and polarization independent edge detection based on Fourier optics principles. We designed sub-wavelength metallic metasurfaces to perform edge detection. The metasurface consist of co-centric metallic rings that create a spatial transmission profile matching the Fourier transformation of the second order differentiation. We experimentally confirm polarization independent, broadband edge detection with high transmission efficiency under both coherent and non-coherent illumination along the visible range. By further simulations and measurements, we show that the operation range of the metasurface also covers the 800 nm to 1600 nm wavelength range in the near IR. Our results constitute an important step towards the application of metasurfaces for real-life image processing tasks.

10:30 AM EL12.15.03
Generation of Arbitrarily Directed Out-Of-Plane Split Beams with Reflective Metasurfaces BrianM. Wells, JosephF. Tripp and RichardJ. Williams; University of Hartford, United States

Metasurfaces, the planar equivalent of metamaterials, have recently gained significant attention due to their physically compact nature, versatility, and ultrathin thickness in the wave propagation direction, significantly suppressing undesirable losses and exotic electromagnetic properties in manipulating propagating waves. In recent years, metasurfaces have been applied to anomalous reflection and refraction, perfect absorption, flat lensing, wave plates, and cloaking. In this work, we present an out-of-plane beam-splitter reflector metasurface design that is not confined to the gradient metasurface paradigm and, as such, is not restricted to beam-splitting into diffraction orders. Instead, we can generate metasurface beam-splitters with arbitrary split beam directionality, including combined in-plane and out-of-plane splitting, such that one of the split beams remains in the plane of incidence while the other split beam is generated outside the plane of incidence.

A reflective metasurface exhibiting simultaneous in-plane and out-of-plane beam-splitting was designed using an approach based on the Fourier transform method of array synthesis. This method involves supplying the desired far-field scattering pattern of the metasurface, in this case, a far-field pattern with two main beams scattering in different planes, and then performing the inverse discrete Fourier transform on this far-field pattern to determine the spatially dependent reflection properties of the metasurface. To validate the approach, an impedance sheet-based simulation is performed to verify the desired beam-splitting phenomena as an initial step in the design process. This technique involves casting the spatially dependent complex reflection coefficients calculated from the Fourier transform method into a spatially dependent surface impedance. The metasurface is then simulated as a 2D plane, defined by the surface impedance. This allows for a fast-initial simulation of the metasurface beamsplitter before unit cell simulations. Both approaches are compared to full-wave, unit cell 3D FEM numerical simulations using realistic material parameters. An excellent agreement can be shown between all three approaches, thus illustrating the usefulness of the impedance sheet-based simulations method to obtain the metasurface far-field profile.

10:45 AM *EL12.15.04
Manipulating the State of Polarizations at the Nanoscale using a Nonlocal Metasurface Soo JinKim; Korea University, Korea (the Republic of)

Recent development of chiral metasurfaces attracts significant attention from researchers due to their unique abilities to manipulate the spin state of light at the nano-scale. Such functionalities can have potential applications in diverse fields, including quantum communications, biosensing, CD spectroscopy, and nano-scaled imaging. However, despite the progress in developing efficient and compact configurations, there still remain challenges in realizing an effective metasurface with strong circular dichroism (CD) and a spectrally narrow bandwidth of response for the potential applications of spectropolarimetrics.
In this presentation, I will show the nonlocal metasurfaces with a high-Q resonance and how such metasurfaces can be tailored to have the capability to effectively control the polarization state of incident light at a relatively narrow spectral range. We first demonstrate the conversion of polarizations in tranmitted light using a GMR-based nonlocal metasurface to achieve near-perfect flat-top tranmission spectra in simulation and efficiency over 0.8 in experiments using a method of electro-optic-based wavelength-scanning laser at a narrow spectral bandwidth. Following this, we also focus on the detection of the state of polarization using an ultrathin chiral metasurface by inducing collective chiral resonances in the constituent nanostructures. We design and show the selective transmission of the spin state of light using a nonlocal chiral metasurface, which experimentally features a CD value over 0.8 at a bandwidth less than 10 nm by judiciously arranging the nano-units to induce chirality without the need for precise fabrication of nano-chiral geometry. We further demonstrate that the minimally perturbed geometries of nano-units can efficiently detect the full Stokes parameters by directly tracking the azimuthal and ellipticity paths of the Poincare sphere at a spectrally narrow bandwidth. We believe that the proposed approaches could pave an alternative pathway to realize efficient nonlocal metasurfaces for diveser, nano-scaled polarimetric applications.

Scalable Classical and Quantum Photonics GiovanniScuri; Stanford University, United States

Novel computational techniques such as photonics inverse design, along with new nanofabrication approaches, play a crucial role in building scalable integrated classical and quantum photonics. Inverse design, a departure from the traditional photonics design approach, can lead to photonics much better than state of the art in many metrics (smaller, more efficient, more robust, a much higher density of integration). This is enabled by development of a computer software which efficiently searches through the space of all possible and fabricable photonic geometries, in any material of interest. On the other hand, future photonic systems also require integration and fabrication of traditional and non-traditional photonic materials, including silicon, silicon-carbide, diamond, sapphire, and strong electro-optic materials such as lithium niobate, strontium and barium titanate.

2:45 PM EL12.17.03
Surface Enhanced Raman Spectroscopy of 19th Century Japanese Artworks via Silver Nano-Island Films OmariKirkland[1], MarcoLeona[2] and JohnR. Lombardi[3]; [1]CUNY Graduate Center, United States; [2]Metropolitan Museum of Art, United States; [3]The City College of New York, United States

Surface Enhanced Raman Spectroscopy (SERS) is an extremely sensitive analytical technique. It is powerful enough to detect the presence of single molecules. As powerful as the technique is, there are limitations when applying SERS to the study of heritage objects. Many SERS experiments use citrate-stabilized silver nanoparticle (AgNP) colloids. The citrate groups present at the surface of the silver nanoparticles can interfere with a target analyte's absorption onto the substrate surface. This interference can lead to very low Raman signals of the target analyte leading to spectra that are dominated by citrate. Here we show that thermally evaporated silver nano-island films (AgNIFs) deposited on glass slides outperform the traditionally used AgNP colloids for the identification of the colorants present in textile samples from 19th century Japanese artworks. The presence of cochineal, lac dye, acid fuchsin, and shikonin were detectable via SERS using the AgNIFs substrate where the AgNP colloid spectra were dominated by citrate. A development chamber was also designed to transport dye molecules from the textile fiber sample onto the AgNIFs surface via a thin film liquid mobile phase created by a liquid-vapor equilibrium maintained within. The use of AgNIFs could prove successful with other textile heritage objects that were not possible to measure with SERS via AgNP colloids. The sensitivity of SERS may elucidate complex mixtures of colorants that are otherwise too trace in concentration to detect with other analytical methods, such as HPLC and GC-MS.

Water-Soluble Smart-Labeling Platform using Nanoimprint Lithography HyunjungKang, JoohoonKim, HongyoonKim and JunsukRho; Pohang University of Science and Technology, Korea (the Republic of)

The food packaging industry is increasingly focusing on sustainability and origin security. Biodegradable plastics and traceability systems like QR codes have been developed to address these concerns. However, there are challenges in ensuring sustainability and traceability. Biodegradable plastics have drawbacks such as specific conditions for degradation, greenhouse gas emissions, higher costs, and recycling difficulties. To overcome these challenges, a new sustainable and anti-counterfeit labeling platform is necessary. Also, traditional coloration methods using dyes and pigments have limitations, but structural coloration inspired by nature offers high resolution, color saturation, wide gamut, and resistance to fading. Recent advancements have demonstrated water-soluble structural colors using materials like polyvinyl alcohol (PVA) and hydroxypropyl cellulose (HPC). However, it has previously been limited by the need for silver deposition due to its low refractive index. We report a new water-soluble nanocomposite ink composed of HPC and TiO_2 nanoparticles to increase the refractive index. This ink allows for vivid colors, a wide gamut palette, high saturation, and brightness. The ink is used to print QR codes via nanoimprint lithography. The methods are cost-effective techniques and have minimal environmental impact. This labeling platform has the potential to address waste issues, enhance consumer trust, and provide accurate information about products.

3:45 PM EL12.18.02
Fabrication of Crystalline-Silicon Metasurfaces for Atom Trapping MinjeongKim[1], ChengyuFang[1], DavidA. Czaplewski[2], HongyanMei[1], ZhaoningYu[3], SanketDeshpande[1], YuzheXiao[1,4], XutingYang[3], AlanM. Dibos[2], MarkSaffman[3], JenniferT. Choy[1,3,3] and MikhailKats[1,3,3]; [1]University of Wisconsin - Madison, United States; [2]Argonne National Laboratory, United States; [3]University of Wisconsin–Madison, United States; [4]University of North Texas, United States

Optical bottle beams, distinguished by their localized light intensity minima surrounded by areas of higher intensity, can be used to trap neutral atoms and lower-index particles [1]. In particular, bottle beams are required for blue-detuned trapping of cold atoms, where the atoms are localized within low-intensity regions, resulting in smaller perturbation of the atoms by the trapping laser compared to the more-conventional, red-detuned traps where the atom is in a high-intensity region [2]. Complex beam profiles such as optical bottle beams can be synthesized using optical metasurfaces constructed from arrays of subwavelength structures that locally control the amplitude, phase, and/or polarization response at an interface [3]. Crystalline silicon, characterized by its indirect bandgap, exhibits moderate loss at wavelengths longer than about 500 nm [4], while polycrystalline and amorphous silicon have much higher absorption coefficients these wavelengths [5]. Here, we designed, fabricated, and characterized optical metasurfaces comprised of crystalline silicon for atom trapping, using silicon-on-sapphire (SOS) technology.
We employed a figure of merit to assess the effectiveness of our optical bottle-beam traps [1]. Through the simulation of a single unit cell, characterized by a pillar height of 500 nm and a periodicity of 360 nm, we designed metasurfaces for a wavelength of 770 nm, which is suitable for blue-detuned trapping of rubidium atoms. We fabricated bottle-beam-generating metasurfaces that are 2 mm on a side using a combination of electron beam lithography and silicon etching. In our process, the silicon thickness is 500 nm and the smallest lateral feature is 130 nm, resulting in an aspect ratio of 4:1. Our process is as follows: (1) A SiO2 hard mask is deposited using plasma-enhanced chemical vapor deposition (PECVD); (2) ZEP520A resist is spun onto the wafer; (3) E-beam exposure and development; (4) Etching of the SiO2 layer using CHF3 and O2 to defined the features in the hard mask; (5) Removal of the resist residue with O2 plasma; (6) Etching of the Si layer using HBr to produce pillars on sapphire; (7) Removal of the SiO2 hard mask with buffered oxide etchant (BOE).
The optical performance of the fabricated bottle-beam-generating metasurfaces was evaluated using a 795 nm distributed-Bragg-reflector (DBR) laser normally incident on the metasurface. Using a camera with an objective lens with a numerical aperture of 0.65, we observed the formation of an optical bottle beam with a diameter of 6 μm, in agreement with our electromagnetic modeling. Future work will include the design of more-complex atom-trapping field distributions, and the incorporation of these metasurfaces into atom trapping setups.

Laser-Based Selective Nanoimprint Method for Fabrication of Optical Metasurfaces as Modulating Layers for Fluorescent Materials Timothy Yee HimChan and Mitch GuijunLi; The Hong Kong University of Science and Technology, Hong Kong

The enhancement of fluorescent materials' performance is a significant research area aimed at expanding their utility and versatility. Optical metasurfaces have emerged as a viable solution to manipulate the optical properties of fluorescent material media. In this study, we propose a laser-based selective nanoimprint method that enables fast and controlled fabrication of metasurfaces specifically tailored as optical modulating layers for fluorescent crystals. The fabrication process involves depositing laser-induced graphene on a metal thin film, then it is placed on the flexible PDMS mold. The mold will undergo laser irradiation for pressurizing the photoresist, the metal thin film will be used as a protective layer to absorb the laser energy, and the laser energy will be converted to kinetic energy to provide pressure on the mold for nanoimprinting the mold pattern onto the photoresist. Precise control of laser-induced pressure allows for accurate replication of the mold pattern, while concurrently curing the photoresist to stabilize the imprinted nanostructures. The photoresist can be cured at the same time to stabilize the nanostructure imprinted, afterwards, we can apply the fluorescent solution to the photoresist by spin-coating. The fabricated metasurface can improve the absorption of the fluorescence materials and it can act as a better gain medium for the fluorescence crystal layer. We are also working on forming the metasurface directly on the crystal by replacing the photoresist with the solution, and then thermal treating the solution to promote fast crystallization.
This innovative approach presents a simple yet highly effective fabrication method for constructing selective metasurfaces as optical modulating layers for fluorescent materials. It utilizes laser-induced transfer techniques and laser-induced pressure to enable the efficient manufacturing of optical metasurfaces so that different metasurface structures and designs can be used for testing. The demonstrated capabilities of this technique hold great promise for the advancement of the integration between metasurface technology and fluorescent materials. The development of optimized metasurfaces as modulating layers can significantly enhance the optical properties and performance of fluorescent materials, paving the way for new applications in fields such as sensing, imaging, and optoelectronic devices.

Extreme Micro/Nanomanufacturing for Metasurface Applications HuigaoDuan; Hunan University, China

Micro/Nanomanufacturing has been playing a key role in the integrated-circuits industry and developing micro/nanosystems. Pushing the micro/nanomanufacturing towards ultrasmall dimension and ultrahigh precision is of great interest and importance for various applications. In this presentation, I will share our efforts in developing new processes such as sketch and peel

lithography, greyscale lithography and conformal filling with ion beam polishing portfolio to achieve the multiscale, multidimensional and high-precision fabrication capabilities for functional micro/nanostructures. Novel applications on metasurfaces, transparent electrodes, and optical metadevices will be demonstrated.

8:30 AM *EL12.19.02
Plasmonic Structural Color Paint DebashisChanda; University of Central Florida, United States

In nature, vibrant colors as those of many butterflies, birds, octopuses, or fishes, arise from microscopically textured surfaces. These vivid colors result from the coherent interaction between light and the structural arrangement of colorless materials found in their skin. In contrast, all manmade colors are pigment based and rely on the molecular absorption of their constituents, with each color requiring a different molecule. While traditional pigment-based colorants offer a viable commercial platform for large-volume and angle-insensitiveness, they are limited by their resolution, instability in atmosphere, color fading, and severe environmental toxicity. However, till date all attempts to industrial production of polarization and angle independent full-range structural colors have failed due to the angle-dependent colors and fabrication challenges. In this talk, we present a subwavelength plasmonic cavity that generates color by the hybridization of a metallic self-assembly with an ultrathin optical cavity. This configuration offers both polarization and angle insensitiveness, while simultaneously providing a full-color gamut of vibrant structural color paints. In this work, we presented this unique structural color generation mechanism and demonstrated color generation of these structures across the entire visible spectrum by tuning just the structural parameters. The self-assembly facilitates growing the stack on a sacrificial layer we produce a self-standing nanostructured color platform that, when mixed with a binder, can be transferred to any surface to impart full coloration with a single sub-micron layer of pigment. This structural color platform offers a highly integrable ultra-lightweight solution that bridges the gap from proof-of-concept to real-world industrial applications of non-toxic, fade resistant, and environmentally friendly colorants.

Multimode Coupling and Bound States in the Continuum in High-Index Metasurface VahidKarimi[1], NealRaney[2], AaronHolzer[1], Md SakibulIslam[1] and ViktoriiaBabicheva[1]; [1]University of New Mexico, United States; [2]Central New Mexico Community College, United States

Metasurfaces based on high-refractive-index materials have emerged as a promising platform for manipulating light at the nanoscale, enabling a wide range of applications in optics, photonics, and beyond. Through careful control of nanoantenna dimensions and arrangement, one can achieve tunable optical functionalities in high-index metasurfaces. By harnessing the unique properties of these materials, such as their strong light-matter interactions and efficient light confinement, metasurfaces offer unprecedented control over the propagation, polarization, and phase of light. This control opens up new possibilities for developing compact and versatile optical devices with enhanced functionalities, paving the way for advancements in areas such as imaging, sensing, communication, and integrated photonics.

Our investigation focused on a high-refractive-index metasurface, which offers exciting possibilities for manipulating light at the nanoscale. Through careful analysis, we discovered that this metasurface enables multimode coupling and bound states in the continuum, resulting in the emergence of narrow Fano resonances. By examining the reflection and transmission spectra obtained from our experiments, we observed the presence of multiple mode excitations and witnessed the occurrence of the generalized Kerker effect within the nanoantenna array. This highlights the metasurface's remarkable capability to control and manipulate light propagation at the nanoscale.

In addition to studying the metasurface, we also explored the influence of silicon quality on its optical properties. Our findings indicate that the rate of material deposition and subsequent rapid thermal annealing play pivotal roles in enhancing the optical properties of silicon. By mitigating oxidation and minimizing material defects, we observed a significant improvement in silicon quality. This improvement was characterized by an increase in the real part of the refractive index and a decrease in the imaginary part. These insights provide a deeper understanding of the interplay between metasurface design, light manipulation, and silicon quality. They open up avenues for further advancements in the field of metasurfaces, unlocking new possibilities for developing innovative photonic devices and systems with enhanced functionalities and improved performance.

The rapid thermal annealing process at high temperatures plays a vital role in reducing defects and impurities within the silicon material. This results in a more uniform and crystalline structure, leading to decreased light absorption, reduced optical losses, and enhanced light-matter interactions. These improvements in silicon quality enable precise tuning of collective modes within the metasurface, leading to the emergence of new photonic functionalities and improved sensing capabilities across various optical applications. Our investigation demonstrates the potential of high-index metasurfaces for achieving enhanced photonic functionalities. By controlling nanoantenna dimensions and optimizing silicon quality through rapid thermal annealing, we successfully manipulate light at the nanoscale, enabling the emergence of narrow Fano resonances and the realization of tunable optical functionalities. These findings open up exciting opportunities for advanced optical devices and applications, ranging from sensing to data communication and beyond.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science by Los Alamos National Laboratory (Contract 89233218CNA000001) and Sandia National Laboratories (Contract DE-NA-0003525).

Single-Metaatom-Driven Tri-Channel Metaholgraphic Displays Muhammad QasimMehmood and Muhammad AsharNaveed; Information Technology University of the Punjab, Lahore, Pakistan, Pakistan

Multi-functional metadevices promise enormous potential in realizing ultra-compact optical and photonics systems. One of the effective techniques to achieve multi-functionalities is the merger of holographic information and nano-printing. Such multiplexing can significantly enhance the information encoding capacity. Most current methodologies focus on interleaving or multilayer stacking to achieve this goal. These techniques combine the functionalities of multiple metaatoms at the cost of reduced efficiency, design complexity, and challenging fabrication. This work introduces a unique way of introducing tri-channel capacity in a single-layered metadevice. The proposed resonators combine a geometric phase-based spin-decoupling and Malus's law intensity modulation to achieve such a tri-functional. The proposed strategy effectively improves information capacity owing to the orientation degeneracy of spin-decoupling rather than layer stacking or super-cell designs. To validate the proposed method, a metadevice demonstrating two helicity-dependent holographic outputs is presented in the far field, whereas a continuous nano-printing image is in the near field.

8:30 AM *EL12.20.02
Some Novel Topological Surface Waves BaileZhang; Nanyang Technological University, Singapore

Topological surface waves are the topological modes on the surface of a 3D topological insulator or semimetal. Typically in a 3D topological insulator, the topological surface states exhibit Dirac cones, while a Weyl topological semimetal can support Fermi arc surface states. Here we discuss some novel types of topological surface states.

The first type is the topological surface states on a 3D Chern insulator. It is known that a 3D bandgap can be characterized by three Chern numbers, defined for three perpendicular planes in momentum space, forming a Chern vector. The vectorial nature of the Chern vector gives rise to novel structures of topological surface states, including torus knots and links. We have implemented a 3D photonic Chern insulator and demonstrated a (2,2) torus Hopf link for such topological surface states.

The second type is the topological surface states on a 3D valley crystal. Valley degree of freedom (DOF) is widely used as a binary DOF in valleytronic materials, and has recently been introduced into acoustic crystals and photonic crystals. Here we generalize the valley DOF into a 3D crystal and demonstrate 3D valley contrasting physics.

9:00 AM *EL12.20.03
Chiral Metaphotonics and Manipulations Cheng-WeiQiu; National University of Singapore, Singapore

In this talk, we will report the recent progress on how chirality could assist and transcend the designs of advanced metasurfaces, sensing, strong coupling, BIC photonics and optical micromanipulations. In particular, we will report our very recent results on realizing intrinsic chiral metasurfaces where the engineered slant geometry breaks both in-plane and out-of-plane

symmetries. Our result achieves intrinsic chiral bound states in the continuum with near-unity CD of 0.93 and quality factor exceeding 2300 for visible frequencies. We will also cast new perspectives on using photonic orbit angular momentum to effectively discriminate single-size and multi-scale chiral nanostructures.

9:30 AM *EL12.20.04
Optical Metasurfaces for Generating and Manipulating Grafted Vortex Beams XianzhongChen and HammadAhmed; Heriot-Watt University, United Kingdom

Inspired by plant grafting, the technique of generating a grafted vortex beam involves combining two or more spiral phase profiles of optical vortex beams. Recently, there has been significant interest in grafted perfect vortex beams (GPVBs) and perfect vector vortex beams (PVVBs) due to their distinctive optical properties and potential applications. GPVBs exhibit a constant intensity profile and a radius irrespective of topological charges. PVVBs are structured light beams with inhomogeneous polarization and spiral phase profiles. However, the existing method used for generating and manipulating these beams suffers from the complex optical system, large volume, and high cost. These optical systems are impractical for numerous applications, thus creating an urgent need for a compact, simple, and efficient approach to generating and manipulating these beams.

We propose and experimentally demonstrate a metasurface approach to generating and manipulating these beams. A single metasurface is used to generate various GPVBs in multiple channels and PVVBs without relying on the complicated optical setup. The uniqueness of this method is that the superimposed GPVBs have nonuniform orbital angular momentum and asymmetric singularity distributions in different channels, which can be further modulated by introducing initial phase difference in the metasurface design. Our work has demonstrated a compact metasurface platform that performs a sophisticated optical task that is extremely challenging or impossible with conventional optics, opening opportunities for the investigation and applications of these structured beams in a wide range of emerging application areas such as singular optics and quantum science.

Trompe L'oeil Ferromagnetism Sang WookCheong and Fei-TingHuang; Rutgers University, United States

Ferromagnetism can be characterized by non-zero magnetization (inducing magnetic attraction/repulsion), diagonal piezomagnetism, nonreciprocal circular dichroism (such as Faraday effect), odd-order (including linear) anomalous Hall effect, and magneto-optical Kerr effect. We identify all broken symmetries requiring each of the above phenomena, and also the relevant magnetic point groups (MPGs) with those broken symmetries. All of ferromagnetic point groups, relevant for ferromagnets, ferri-magnets and weak ferromagnets, can certainly exhibit all of those phenomena, including non-zero magnetization. Some of true antiferromagnets, which are defined as magnets whose MPGs do not belong to ferromagnetic point groups, can show those phenomena through magnetization induced by external perturbations such as applied current, electric fields, light illumination, and strain. Such MPGs are identified for each external perturbation. A number of exemplary materials for specific ferromagnetic-like phenomena will be discussed. Since high-density and ultrafast spintronic technologies can be enabled by antiferromagnets, our findings will be an essential guidance for the future magnetism-related science as well as technology.

Controlling the Topologically-Protected Magnetoelectric Switching in Multiferroic $GdMn_2O_5$AndreiPimenov[1], LouisPonet[2], JanekWettstein[1], AnnaPimenov[1], MaksimRyzhkov[1], KefengWang[3], Sang WookCheong[3], MaximMostovoy[4] and SergeyArtyukhin[5]; [1]TU Vienna, Austria; [2]Ecole Polytechnique Federale, Switzerland; [3]Rutgers, The State University of New Jersey, United States; [4]University of Groningen, Netherlands; [5]Istituto Italiano di Tecnologia, Italy

Manipulating magnetic moments by electric fields has been an everlasting goal for fundamental research. Recently, we could demonstrate a peculiar magnetoelectric behavior in multiferroic $GdMn_2O_5$ showing a switching through a cycle of four states when the magnetic field is ramped up and down [1]. In this sequence, half of the spins undergo a rotation of about 90° each time the magnetic field is ramped leading to a full-circle 360° rotation when applying and removing a magnetic field two times in a series. $GdMn_2O_5$ thus acts as a magnetic crankshaft that converts the back-and-forth variations of the magnetic field into a circular spin motion. This peculiar four-state magnetoelectric switching emerges as a topologically protected boundary between two different series, 1→2→3→4→1 and 1→4→3→2→1, respectively.
Further on, in a certain range of experimental parameters the 4-state sequence becomes topologically trivial. In this regime, the external electric field adds a key parameter of the switching. We show that in such case the electric voltage allows a full control over the four magnetoelectric states in $GdMn_2O_5$.

Thermodynamics of Multiferroics Long-QingChen; The Pennsylvania State University, United States

Multiferroics, by definition, are material systems, either as single phases or composites of multiple phases, that exhibit more than one ferroic orders such as ferroelectric, ferromagnetic, or ferroelastic order. One of the objectives of this presentation is to conceptually connect among the classical first and second laws of thermodynamics, the Maxwell relations relating various and multiferroic properties, the Landau theory description of multiferroic phase transitions, as well as thermodynamics and phase-field method of multiferroic domain structures and responses to external fields. It will start from the classical first and second laws of thermodynamics to establish the fundamental equation of thermodynamics for a multiferroic system as a function of its

basic thermodynamic variables. According to Gibbs, the fundamental equation of thermodynamics contains all the information about the equilibrium thermodynamic properties of a system, i.e., one can derive all the equilibrium ferroic and multiferroic properties of a system and their mutual relations from its fundamental equation of thermodynamics. On the other hand, irreversible thermodynamics considers all the ferroic phase transitions as internal irreversible thermodynamic processes within a material which generate entropy and dissipate chemical energy, allowing one to establish an energy function of both basic thermodynamic variables and the ferroic order parameters, e.g., through a Landau-type description, for a given multiferroic system. The thermodynamic description of a homogeneous system can be extended to inhomogeneous systems by introducing the contributions of ferroic domain wall energies through gradient or exchange energies as well as long-range elastic, electrostatic, and magnetic energies and by assuming that a local point of a domain structure can be described by the fundamental equation of thermodynamics in terms of both basic thermodynamic variables and ferroic order parameters. One can then apply the thermodynamic energy functions or functionals to construct multidomain and multiphase diagrams in the space of thermal, mechanical, electric, and magnetic variables using thermodynamic analysis, in analogy to the well-known temperature-composition phase diagrams or model the static and dynamic responses of a multiferroic domain structure to external stimuli using computational methods, such as the relaxational or dynamic phase-field method.

SESSION EL13.02: Magnetoelectric Heterostructures and Nanostructures I

Two-Step Phase Transition Enabled Superelasticity in Quasi-Two-Dimensional Freestanding Perovskite Ferroelectric Films MingjieXu and XiaoqingPan; University of California, United States

Perovskite ferroelectric materials have garnered significant attention due to their unique properties, including ferroelectricity, piezoelectricity, and high stability, making them promising for diverse applications in memory devices and sensors. However, the inherent weak elasticity and brittleness of most perovskite ferroelectrics pose challenges for their integration into flexible electronic devices.
In this study, we present the observation of superelasticity induced by a two-step phase transition in an 8-nm thick freestanding BiFeO3 (BFO) film. Through atomically resolved in situ transmission electron microscopy (TEM) combined with in situ scanning transmission electron microscopy (STEM), we investigate the lattice deformation and atomic rearrangement in the film under mechanical stress, revealing reversible phase transitions and continuous evolution of the c/a ratio. Notably, we observe a remarkably large c/a ratio of approximately 1.53 in a super-tetragonal (S) phase under a lattice strain of approximately 34.4%, surpassing the highest strain reported for freestanding BFO films. This exceptional superelasticity arises from reversible 2-step phase transitions: R-T-S phase transitions, rather than conventional R-T transitions. Density functional theory (DFT) calculations support the crucial role of these 2-step phase transitions in facilitating such unusually large strain.
The experimental results obtained through in situ TEM and STEM techniques provide a comprehensive understanding of lattice deformations and phase transitions occurring in the BFO film under mechanical stress. This work unveils unprecedented superelasticity in freestanding BiFeO3 films and elucidates its fundamental mechanisms, offering novel insights for the design of advanced flexible electronic devices. The exceptional superelastic behavior demonstrated by quasi-two-dimensional freestanding perovskite ferroelectric films highlights their immense potential for a wide range of applications, including flexible electronics, solid-state actuators, and other innovative technologies.

Achieving High Performance Magnetoelectrics using Nanostructured Thin Films JudithL. Driscoll[1], MuireannA. de hora[1], MarkusHellenbrand[1] and AdnanMehonic[2]; [1]University of Cambridge, United Kingdom; [2]University College London, United Kingdom

As the basic elements of computation are approaching their fundamental limitations, data intensive computation is shifting from being logic-centric to being memory centric. Current memory technologies are either volatile or if they are non-volatile have limitations. A very large body of work has been conducted on multiferroic/ magnetoelectric materials for high performance non-volatile memory, particularly in oxides but the systems are complex and typically don't give high performance at room temperature. Here we show how to nanoengineer thin film composite systems to have strong magnetoelectric effects at room temperature, either via strain coupling or ionic coupling. We compare the performance with novel resistive switching composites grown at CMOS compatible temperatures.

2:30 PM *EL13.02.04
Nanoscale Ferroelastic Writing of Ferroelectric Domains KathrinDorr; Martin-Luther-Universität-Halle-Wittenberg, Germany

There is a growing effort towards nanomechanics approaches using a scanning probe microscopy (SPM) tip in order to define patterns of ferroic properties. Next to micromachining, pressure-induced phase transitions or the flexoelectric effect, there is the emerging field of ferroelastic nanoscale manipulation. Ferroelasticity can provide access to mechanical manipulation of a local ferroic order parameter (such as magnetization or ferroelectric polarization), if the order parameter is coupled to a distinct lattice distortion. After giving an introduction to recent advances in the field, the talk addresses our work on mechanical tip-induced definition of ferroelectric domains in a prototype ferroelectric copolymer, P(VDF-TrFE). While there is an increasing track record of nanomechanical manipulation by SPM tip in fully crystalline ferroic films, semi-crystalline polymers offer a unique advantage because of their elasticity supporting damage-free strains of several percent.

The ferroelectric copolymer P(VDF-TrFE) (here with 22% TrFE) is one of the most often applied ferroelectric organic materials. The pseudo-hexagonal lattice of P(VDF-TrFE) supports six stable ferroelectric polarization orientations, and, strikingly, the lattice shrinks substantially along the polarization direction. As-prepared films show multiple few-nanometer-wide ferroelectric domains. The electric dipolar disorder is highly critical, leading to strong suppression of the functional electric responses such as dielectric permittivity, direct or inverse piezoelectric effects. In addition, electric poling and switching of P(VDF-TrFE) films require relatively large electric fields, preventing precise electric nanoscale domain writing because of the tip stray fields.

Our spin-coated P(VDF-TrFE) films consist of very densely packed fine crystalline lamellae of the ferroelectric beta-phase. There is a well-defined (110) out-of-plane texture, but no in-plane texture. After vertical electric poling, complex deliberate in-plane domain patterns with tip-related resolution of 50 nm have been defined [1] by scanning with moderate mechanical tip forces (100-300 nN). The mechanical treatment leaves the semicrystalline lamellar structure essentially unchanged, and the surface roughness remains below 3 nm (rms). Importantly for various functional devices, the in-plane piezoelectric response in written domains is massively enhanced, indicating the achievement of efficient ordering of electric dipoles. I will discuss opportunities to exploit mechanically defined nanoscale polarization patterns in functional devices. This work was partially funded by Deutsche Forschungsgemeinschaft (DFG), CRC 762 and TRR 102.

4:00 PM *EL13.03.01
Spin Hall Magnetoresistance and Quadratic Magneto-Optic Studies of Antiferromagnets KangL. Wang; University of California, Los Angeles, United States

Antiferromagnets with two sets of spins against each other pushes the operation of spintronics memory frequencies up to terahertz with a higher areal density, compared with the traditional

ferromagnets due to the absence of the stray field and the strong coupling among spins. However, the net zero magnetic moment makes it difficult in probing and controlling the spin state in antiferromagnet. In this presentation, we discuss electrical and optical approaches to detect and manipulate spins, which pave the way for utilizing antiferromagnet in novel spintronic devices. First, we will discuss the use of magneto-transport or unidirectional spin Hall magnetoresistance (USMR) in Fe_2O_3 bilayer AFM bilayer. USMR has been widely reported in the heavy metal / ferromagnet (HM/FM) bilayer systems. We observed USMR in Pt/α-Fe_2O_3 bilayers where the α-Fe_2O_3 is an antiferromagnetic (AFM) insulator. Systematic field and temperature-dependent measurements confirm the magnonic origin of the USMR. The appearance of AFM-USMR is driven by the imbalance of creation and annihilation of AFM magnons by spin-orbit torque due to the thermal fluctuation field. Theoretical modeling reveals that the USMR in Pt/α-Fe_2O_3 is determined by the antiferromagnetic magnon number with a non-monotonic field dependence as compared with that of ferromagnetic materials. The magnonic origin of USMR is further confirmed by temperature-dependent measurements. This first evidence of USMR in other HM/AFM bilayers may be expanded to include the large family of AF insulators and paves the way for the highly sensitive detection of AF spin states in emerging the AF spintronics.
Second, we will discuss the use of the quadratic magnetic-optical Kerr effect (QMOKE) to study dynamics of several AFMs. We will describe the experiments of e.g., α-MnTe; This antiferromagnet has a hexagonal close-packed structure with antiferromagnetic ordering along the c-axis. It is a collinear antiferromagnet with three in-plane easy axes, and its Néel temperature is approximately 310K [1,2], which is also known recently as an altermagnet, hosting anti-ferromagnetism in macroscopic scale and ferromagnetism in k space [3,4]. The hexagonal NiAs phase of MnTe (α-MnTe) is obtained by MBE on GaAs. We employ the time resolved pump-probe laser quadratic magnetic-optical Kerr effect (QMOKE) to study MnTe. The QMOKE of α-MnTe is more visible due to the spin splitting of electronic states in the k space. The pump process puts the Néel vector deviate from its equilibrium state. The pump results in the loss of the Néel order, referred to as the fast demagnetization, which endures for about 20 ps; the energy is redistributed between the electron, phonon and the magnon. This dynamics of the change of the Néel order is investigated through quadratic MOKE, reflecting the magnon dynamics. The dynamic study will also be used for other materials to compare the differences of the AFM dynamics.

4:30 PM *EL13.03.02
Ferroelectric Control of Spin-Charge Interconversion and Magnetism in Oxide Two-Dimensional Electron Gases ManuelBibes; CNRS/Thales, France

Two-dimensional electron gases (2DEG) based on $SrTiO_3$ (STO) display fascinating properties such as low-temperature superconductivity and Rashba spin-orbit coupling allowing to interconvert spin and charge currents through the Edelstein effect. We have introduced ferroelectricity in these 2DEGs in order to achieve a non-volatile electrical control of their properties. Practically, we replaced STO by Ca-substituted STO (Ca-STO) which is ferroelectric up to about 30 K and generated 2DEGs either by sputtering a thin Al film or growing perovskite overlayers by pulsed laser deposition. We will present spin-charge and charge-spin conversion measurements and their control by the ferroelectric state. We will also show how magnetism can be introduced in the system and use x-ray absorption spectroscopy and magnetotransport to demonstrate the coexistence of ferroelectricity and magnetism with metallicity. Our data evidence the non-volatile control of polar displacements, magnetization and anomalous Hall effect upon switching the polarization direction, indicating a magnetoelectric coupling. Our results provide new opportunities in quantum matter arising from the interplay between ferroelectricity, ferromagnetism, metallicity, and Rashba spin-orbit coupling in low dimensions.

Leveraging Colloidal Assembly to Texture Hexaferrites to Enable Better Performance in RF Devices JoseA. Martinez and RandallM. Erb; Northeastern University, United States

With the implementation of 5G, the telecommunications industry desires enhanced performance of incumbent radio-frequency(RF) devices. Non-reciprocal devices, circulators, and isolators are integral to RF communication systems by isolating the incoming signals from the outgoing signals, exhibiting different electromagnetic wave propagation characteristics in the forward and reverse directions. Such devices rely on soft and hard ferrite materials currently limited in performance by the current achievable saturation magnetization and coercive field levels. Significant work has been applied toward improving the materials synthesis of these ferrite materials to achieve better performance. Specifically, M-type hexagonal ferrites, such as SrFe12O19 (SrM) and BaFe12O19 (BaM), have been studied for their large coercivity, high Curie temperature, good chemical stability, and high corrosion resistance. Here, we investigate the role that both the composition and microstructure of these materials have on the material performance. We tailor the saturation magnetization and the particle geometry of SrM and BaM through hydrothermal synthesis and thermal treatment. Further, we investigate the role of microstructure texturing by aligning ferrite particles in the pre-sintered state by leveraging a colloidal assembly technique that takes advantage of anisotropic morphology, magnetic fields, and vibrational stimulus. We additionally provide perspective on the current materials limitations and opportunities in these magnetic RF devices.

8:00 PM EL13.04.02
Enhancement of Magnetic Properties of NdFeB Sintered Magnet by Grain Boundary Diffusion Process with TbAlCu Dong HyunLee[1,2], Seong ChanKim[1,3], JuyoungBaek[1], DonghwanKim[4], Sang HyubLee[4], HyesunYoo[2], DalhyunDo[3], Dong HwanKim[1], JongWookRoh[2] and JeongminKim[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of); [3]Keimyung University, Korea (the Republic of); [4]Star Group Ind. Co., Ltd., Korea (the Republic of)

A strong coercivity enhancement of the commercial NdFeB magnets with the magnetic properties of ${}_iH_c$ = 22.76–22.48 kOe and $(BH)_{max}$ = 48.61–48.58 MGOe is demonstrated by the grain boundary diffusion (GBD) process with low-melting point $Tb_{80}Al_{(x-20)}Cu_x$ (x = 0–20) alloys. The maximum coercivity enhancement was obtained from the diffused magnet with $Tb_{80}Al_{15}Cu_5$, in which the value increased from 12.25 to 22.76 kOe by GBD process. Microstructural investigation with the electron probe micro analysis reveals that the enhancement of coercivity in the GBD magnets is mainly due to magnetic isolation by continuous Nd-rich grain boundary phases and Tb-rich shells. Tb diffusion through grain boundaries at a lower temperature than 900 °C, and consequently developed continuous and thin Tb-rich shell structures. Especially, the partial replacement of Tb by Al and Cu in diffusion sources resulted in higher coercivity with consuming fewer Tb elements (0.8 wt%) in the samples with $Tb_{80}Al_{(x-20)}Cu_x$ which are much lower than that in the samples with Tb metal (1.0 wt%). The results show that Cu and Al addition in diffusion source can effectively improve Tb diffusion efficiency by modifying intergranular Nd-rich phase. This work may shed light on the reduction of heavy rare earth in NdFeB sintered magnets.

8:00 PM EL13.04.03
Evolution of Antiferromagnetic Spin Texture in MBE-Grown Epitaxial Multiferroic $BiFeO_3$MayaRamesh[1], PeterMeisenheimer[2], IsaacHarris[2], SajidHusain[2], ShiyuZhou[3], Zhi(. Yao[4], PaulStevenson[5], LucasCaretta[3], RamamoorthyRamesh[6] and DarrellSchlom[1]; [1]Cornell University, United States; [2]University of California, Berkeley, United States; [3]Brown University, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]Northeastern University, United States; [6]Rice University, United States

Bismuth ferrite (BiFeO3) is a lead-free magnetoelectric multiferroic showing antiferromagnetic order and a large spontaneous polarization at room temperature. This antiferromagnetic order in BiFeO3 is complex, where, as a consequence of the Dzyaloshinskii-Moriya interaction (DMI), a small canting of the antiferromagnetic order forms a chiral spin cycloid in bulk samples. Understanding the interplay between the ferroelectric polarization and the spin cycloid, as well as its electric field manipulation, is of significant interest for antiferromagnetic spintronics and next generation computation. There is still much to learn about BiFeO3's intrinsic antiferromagnetic structure in thin films, where epitaxial strain imposed by an underlying substrate can influence the spin texture. As a model system, we have synthesized epitaxial thin films (2-100 nm) of BiFeO3 on (110) TbScO3 substrates via oxide molecular-beam epitaxy (MBE). This allows us to synthesize BiFeO3 thin films with an unparalleled structural quality where even small amounts of strain (0.1% in the case of TbScO3) can have a large impact on the spin texture. In this work, we explore how epitaxial strain from the substrate affects the formation and orientation of the spin texture in BiFeO3 using nitrogen-vacancy magnetometry (NV magnetometry) and spin transport measurements. NV magnetometry uses a nitrogen vacancy implanted at the tip of a diamond cantilever which acts as a single-spin magnetometer to sensitively map nanoscale surface stray fields. By correlating the spin texture to ferroelectric information measured using piezoresponse force microscopy, we are able to explore coupling between the two order parameters. Electric-field-dependent transport shows that the spin cycloid can be manipulated by switching the ferroelectric polarization, which is of great interest in low dissipation magnonics and spintronics.

8:00 PM EL13.04.04

Sputter Deposited Ni-Based Intrinsic Magnetic Topological Insulator Thin Films RuiHuang[1], BinLuo[1], AlexandriaWill-Cole[1], SerhiyLeontsev[2], ValeriaLauter[3], MichaelMcConney[2], MichaelPage[2] and NianSun[1]; [1]Northeastern University, United States; [2]Air Force Research Laboratory, United States; [3]Oak Ridge National Laboratory, United States

Three-dimensional topological insulators (TIs) exhibit unique properties such as topologically protected Dirac surface states (TSS) that enable metallic surface states while the bulk remains insulating. These TIs, including $Bi_{1-x}Sb_x$ alloys and hexagonal X_2Q_3 compounds (X = Bi, Sb, $Bi_{1-x}Sb_x$; Q = Se, Te), also demonstrate the quantum anomalous Hall effect (QAHE). The QAHE occurs when a gap is created in the TSS by introducing perpendicular magnetic order and breaking time reversal symmetry, resulting in spin polarized, chiral edge currents while maintaining an insulating bulk state. Magnetic order can be introduced through compositional doping, stoichiometric intrinsic magnetic TI (MTI), or proximity-induced magnetization (PIM) methods. Although the QAHE has been observed in experiments for each of these methods, the temperatures involved are currently impractical for technology, being in the milliKelvin range. A phenomenological trend is that the magnetic ordering temperature (Curie temperature, T_C, or Néel temperature, T_N) is typically at least ten times higher than the observed QAHE temperature. In our previous work, we studied the interfacial magnetic phases of sputtered $Bi_2Te_3/Ni_{80}Fe_{20}$ and confirmed with selected area diffraction the existence of the $NiBi_2Te_4$ phase. We found a relatively high T_N of 63 K; thus, this phase is very promising to exhibit a high QAH state. Here we expand our work on Ni-based MTI materials through sputtering single-phase Ni-doped Bi_2Te_3 films, an intrinsic MTI. We present crystallographic structure characterization and temperature dependent magnetometry. To further understand the depth-dependent nuclear and magnetic structure we performed polarized neutron reflectometry.

Heterogeneous Strain Control by Interlayer Addition in Multiferroic $Bi_3Fe_2Mn_2O_x$ Resulting in Thick Film Growth JamesP. Barnard[1], JiananShen[1], YizhiZhang[1], JuanjuanLu[1], JiaweiSong[1], AleemSiddiqui[2], RaktimSarma[2,3] and HaiyanWang[1,1]; [1]Purdue University, United States; [2]Sandia National Laboratories, United States; [3]Center for Integrated Nanotechnologies, United States

In recent work on electronic devices based on multiferroic and ferroelectric materials, thicker films have become a necessity for certain applications, including MEMS magnetic actuators, magnetoelectric antennas designed for energy harvesting, and optical metasurface fabrication. A common roadblock for the synthesis of thicker films is the loss of film-substrate strain effects as the strain relaxes over the larger thickness. For example, the $Bi_3Fe_2Mn_2O_x$ (BFMO) Aurivillius supercell (SC) phase is a multiferroic system that depends on substrate strain to initiate the growth of the phase. In our work, a new re-seeding technique has been developed that utilizes a heterogeneous film topology to reestablish the required strain to maintain SC phase growth. This is done by the insertion of CeO_2 interlayers, which reintroduce the heteroepitaxial strain in the BFMO. The thick BFMO SC phase also maintains the desired ferroelectric and ferromagnetic properties as well as anisotropic optical properties. This technique allows for thicker growths of the BFMO SC phase (over 100 nm) and can also be applied to other supercell Aurivillius or strain-dependent films for device applications, effectively eliminating the current thickness limitations.

Studies of Structural, Magnetic and Dielectric Properties of Zinc Doped Nickel Ferrites for Spintronics Applications SunnyChoudhary, MohanBhattarai, SatyamKumar and RamKatiyar; University of Puerto Rico, Puerto Rico

This study investigates the impact of zinc doping at the nickel site in the parent nickel ferrite of stoichiometric formula $Ni_{(1-x)}Zn_xFe_2O_4$ ($0 \leq x \leq 1$) ; NZFO. The high-quality samples were prepared using a solid-state reaction route, employing the highly energy ball-milling. It has garnered considerable interest due to its versatile applications in the fields of electronics, telecommunications, and spintronic devices.
Experimental results of structural characterization show that there is no signature of impurity phase and confirmed the single phase with a characteristic cubic spinel structure by XRD analysis. We studied the vibrational modes of NZFO by Raman Spectroscopy which corroborated XRD analysis. Elemental analysis was carried out by EDS and XRF technique in which primary atomic stoichiometric ratios and percentages are approximately similar in both the analysis. SEM imaging revealed the morphology and microstructure of the prepared samples, exhibiting uniform particle distribution and well-defined grain boundaries. Dielectric measurements were performed across a wide frequency (100 Hz to 1MHz) and temperature range (200 to 600K) exhibited high dielectric constant and low loss tangent. The Temperature dependent magnetic behaviour of prepared samples were studied by Physical Property measurement system (PPMS).

Thin Film Surface Acoustic Wave Magnetic Field Sensors: Impact of the Thickness of the Magnetostrictive Layer JanaM. Meyer[1], LarsThormählen[2], StefanMoench[3], ThorstenGiese[1], SimonFichtner[1,2], VadimLebedev[3], AgneZukauskaite[4], EckhardQuandt[2] and FabianLofink[1,2]; [1]Fraunhofer ISIT, Germany; [2]Kiel University, Germany; [3]Fraunhofer IAF, Germany; [4]Fraunhofer FEP, Germany

For the fabrication of surface acoustic wave (SAW) sensors the use of piezoelectric single-crystal substrates (e.g., quartz) is established. Utilizing thin-film technology benefits from larger material flexibility, reduction in chip size, better integrability in standard MEMS and CMOS fabrication technology and thus better scalability. Additionally, it is possible to design multilayer stacks to customise the wave properties to the application purpose. [1] In this context, a piezoelectric AlScN thin film is a promising material, as it combines the advantages from AlN (e.g., high wave velocity, good mechanical and dielectric properties, high thermal conductivity, and high breakdown voltage) with improved electromechanical coupling due to alloying with Sc [2]. AlScN can be fabricated with standard semiconductor technology at reasonable cost on 200 mm silicon wafers.
By combining a SAW sensor with a magnetostrictive film, a magnetic field sensor can be realized that is based on the change of the Young's modulus (E effect) of magnetostrictive films in the presence of an external magnetic field that can be detected as a phase change of the SAW. [1] The SAW is generated by interdigital transducers on top of the piezoelectric AlScN thin film. By the application of a CMP polished SiO_2 layer on top of the AlScN, the magnetostrictive film quality is improved by reducing the roughness of the surface. The SiO_2 layer also acts as a guiding layer and is used to excite new surface confined SAW modes. High sensitivities of the SAW magnetic field sensor can be obtained by using magnetically soft magnetostrictive films with high magnetostriction like FeCoSiB or FeCoB. [3]
Different layer properties of the sensor stack can be varied (e.g., thickness) and different SAW modes aside from the fundamental Rayleigh mode (e.g., Sezawa mode or shear modes) can be excited in layered thin film structures. Crucial is the thickness of the magnetostrictive FeCoSiB film as it was shown that the sensitivity of the sensor is increasing with the magnetostrictive film thickness [4]. In contrast to the use of bulk piezoelectric substrates like quartz, a post annealing step to induce a uniaxial magnetic anisotropy is possible and the deposition temperature can be elevated to improve the magnetic anisotropy alignment. The influence on the phase shift induced by the applied magnetic field, on the corresponding sensitivity and especially on the frequency dependent noise behaviour of the sensor is investigated and the influence on the different SAW modes compared.
The SAW sensors can be used to measure weak fields at low frequencies as required for biomagnetic applications [5] but is also well suited for current sensing and control applications, such as power electronics [6], benefitting from the large dynamic range (up to 8 orders of magnitude), high bandwidth (> 1 MHz) and the possibility of an isolated measurement. The Structural, Dielectric and Ferromagnetic Analysis of $(BF)_{(1-x)}(BST)_x O_3$ for Magnetic Applications SatyamKumar, MohanK. Bhattarai, SunnyChoudhary, ShwetaShweta and RamKatiyar; University of Puerto Rico- Rio Piedras, United States

In this work, we studied the effect of doping BST $(Ba_{0.75}Sr_{0.25}TiO_3)_{(1-x)}$ in BFO ($BiFeO_3$). The $[(BF)_{(1-x)}(BST)_x O_3]$ ($0 < x < 0.2$) were synthesized by the solid state reaction route. The XRD spectra exhibited the pure perovskite phase and Raman spectroscopy analysis supported it. The SEM image reveals the uniform size of grains ~ 3 µm and EDS analysis shows the stoichiometry of various compositions, which is further supported by the XRF results.
The temperature-dependent dielectric measurement was carried out over a wide frequency band (100Hz- 1MHz) obtained high dielectric constant and low loss. The electrical measurement analysis shows the reduced leakage current due to Ba, Sr, and Ti doping on BFO. The electric field polarization (P-E hysteresis) shows a ferroelectric behavior, and the magnetic properties of the material were studied with the Physical Property Measurement System (PPMS) in VSM mode.

8:00 PM EL13.04.09
Experimental Investigation of Multiferroic Cobalt-Doped Bismuth Ferrite Nano-Composites for Sensitive Electric Field Detection IshaSharma and ParthaRoy Chaudhuri; Indian

Institute of Technology Kharagpur, India

In this study, we present an experimental investigation on the utilization of cobalt-doped bismuth ferrite, viz. $BiFe_{0.9}Co_{0.1}O_3$, nano-composites as a novel class of multiferroic materials for sensitive electric field detection. The choice is due to the fact that it has been established that bismuth ferrite (BFO: $BiFeO_3$) is the only known multiferroic material that exhibits substantial coupling between magnetic and ferroelectric order at room temperature. Hence, the same platform facilities the efficient detection of low magnetic fields also.

The experimental approach involves the thorough fabrication of the bismuth ferrite nano-composite sample, followed by a comprehensive characterization of its structural properties. To enhance the sensitivity of our device, we prioritized the gain multiplication factor to amplify the response of our sensing system. Hence, we employed an approach that involved the multiple routing of the light signal through the implementation of a variable cavity all-fiber Fabry-Perot configuration. In this configuration, we have coated an optimized composition of $BiFe_{0.9}Co_{0.1}O_3$ on the tip of an optical fiber, serving as a transducer. The fiber tip is placed like a cantilever, with its coated end remains freely suspended.

The detection of electric fields in our experimental scheme relies on the phenomenon that when the coated fiber is placed in an electric field, the induced polarization of the probe material leads to a bending effect, thereby resulting in the modulation of the cavity length. This modulation is utilized as a sensitive measure of the applied electric field.

Furthermore, we have presented a theoretical model that accurately predicts the experimentally obtained results, taking into account the multiple reflection-transmission processes occurring within the Fabry-Perot circuit integrated with the beam-deflection based cavity. Significantly, from the output transmitted profile of our developed electric field sensing scheme, we can estimate the polarisation properties of sample materials under varying electric field conditions. The detailed methodology of calculation of the polarisation values is reported in our previous research work. While performing the experiment, we kept 3.0 cm long cantilever length with coated thickness of 0.31 mm.

The electric field sensing device based on beam deflection that we propose in this study exhibits excellent performance characteristics and represents a highly promising approach for the design and implementation of all-dielectric electric field sensors. Also, being an all fiber product, it offers a range of advantageous features when compared to conventional techniques. These advantages include enhanced safety, flexibility, small size and immunity to electromagnetic interference (EMI) etc.

8:00 PM EL13.04.10
Thermoelectric Study of CsMnBi ShubhamR. Singh[1], NirpendraSingh[2] and UdoSchwingenschlogl[1]; [1]King Abdullah University of Science and Technology (KAUST), Saudi Arabia; [2]Khalifa University of Science and Technology, United Arab Emirates

We have studied antiferromagnetic and ferromagnetic CsMnBi at room temperature using the linearized Boltzmann transport equation. First-principles calculations show for the antiferromagnetic phase a direct band gap of 0.23 eV when the spin-orbit coupling is considered, while metallicity is found for the ferromagnetic phase. A Seebeck coefficient of 0.58 mV/K is achieved by p-doping. The phonon band structure shows overlap in energy between the acoustic and low-frequency optical branches, resulting in strong scattering and low lattice thermal conductivity (0.09 and 0.34 W/mK for the antiferromagnetic and ferromagnetic phase, respectively). This points to a high figure of merit.

8:00 PM EL13.04.11
A Miniaturized Magnetoelectric Wireless Power Transfer System with an Integrated DC Magnetic Bias HaoRen; ShanghaiTech University, China

In this abstract, we present a miniaturized magnetoelectric wireless power transfer (MEWPT) system with a MEWPT receiving antenna and a spiral-coil-based transmitter. Four DC magnets are integrated onto the MEWPT receiving antenna to significantly reduce its overall dimension while providing a DC magnetic bias of 190 Oe for optimal performance. Electrochemical polarization characterizations are adopted to analyze the performance of the WPT receiving antenna, which reveal that maximum output power of 4.096 and 1.155 mW are obtained when the distance between the transmitter and receiving antenna are 0 and 0.5 cm, respectively, which corresponds to record energy conversion efficiency(ECE) of 2.64% and 0.654%, the highest among all MEWPT systems to date. The output power is improved by at least 49.3 times compared with the MEWPT system without integrated DC magnets. We demonstrate that the MEWPT system can power low power electronics, showing its potential applications in internet of things (IoT) and implantable medical devices (IMD).

Wireless power transfer (WPT) system, which transfers energy without a physical link, has received significant research interest. Due to the advantages of small dimension, low operation frequency and low transmission loss, MEWPT systems have been presented in the past few years as a promising technology. However, MEWPT systems require a DC magnetic bias for optimal performance and prior arts have implemented large electromagnets, Helmholtz coils or externally positioned magnet bias systems, which increases the system dimension. Furthermore, prior MEWPT studies report low energy conversion efficiency (ECE). In this paper, we report a miniaturized MEWPT system with an integrated DC magnetic bias, which significantly reduces the MEWPT system dimension. A 10-turn spiral coil is implemented as the WPT transmitter and a ferrite plate backplate is integrated on the spiral coil to enhance its transmitting performance. Electrochemical polarization characterizations, including the output voltage versus current characterization and output power versus current characterizations are adopted to systematically analyze the performance of the MEWPT receiving antenna. The equivalent internal resistance of the MEWPT receiving antenna is obtained by linearly fitting the output voltage versus current curve. The MEWPT receiving antenna shows an output power of 4.096 mW and 1.155 mW when the distance between the transmitter and receiving antenna is 0 cm and 0.5 cm, which corresponds to record ECE of 2.64% and 0.654% among all MEWPT systems to date. The equivalent internal resistance of the MEWPT receiving antenna is measured to be 5.04 kΩ when the output power is at 4.096 mW. We demonstrate that the MEWPT system can wirelessly power low power light emitting diodes and microchips at a distance of 0.5 cm, which demonstrates the potential applications in IoT and IMD. As the input voltage to the inductive coil transmitter decreases, the output voltage of the receiving antenna linearly decreases. The directivity and off-axis characteristics of the MEWPT receiving antenna are also measured, which shows that the directivity and off-axis distance have a significant impact on the MEWPT receiving antenna performance.

8:00 PM EL13.04.12
Electrical Control of Magnetic Texture in a Multiferroic Oxide PeterMeisenheimer[1], ShiyuZhou[2], HongruiZhang[1], SajidHusain[1], IsaacHarris[1], LucasCaretta[2], PaulStevenson[3] and RamamoorthyRamesh[1,4]; [1]University of California, Berkeley, United States; [2]Brown University, United States; [3]Northeastern University, United States; [4]Rice University, United States

Materials for antiferromagnetic spintronics are becoming a popular topic due to their potential applications in next generation technologies. A primary advantage lies in their stability with external magnetic fields and potentially ultrafast spin dynamics, making them promising candidates for high-speed data storage and processing. A key challenge in this field, however, is the control of the antiferromagnetic order parameter on the nanometer scales applicable to solid state technologies. Bismuth ferrite is a multiferroic material that exhibits both ferroelectric and antiferromagnetic properties at room temperature, making it a unique candidate in the development of electrically controllable magnetic devices. In this material, the magnetic moments are arranged into a long-range spin cycloid, resulting in a unique set of magnetic properties that are intimately tied to the ferroelectric order parameter. Here we show that the propagation axis of this spin cycloid can be deterministically controlled with careful tuning of the ferroelectric order. Through precise application of electric fields, we show reversable control of the spin texture in $BiFeO_3$ thin films and deterministic spin transport that can be traced back to changes in the nanoscale magnetic structure.

8:00 PM EL13.04.13
Influence of K Substitution on Electronic, Structural and Magnetic Properties of La_2FeMnO_6: Experimental and Theoretical Study SumanMondal[1], VishalKotha[2] and AmritaBhattacharya[1]; [1]Indian Institute of Technology Bombay, India; [2]Weizmann Institute of Science, Israel

The study investigates the influence of monovalent substitution on the electronic, structural, and magnetic properties of La_2FeMnO_6 (LFMO) through a combination of experimental techniques and first principles Density Functional Theory (DFT) calculations. A low temperature (270 °C) one step hydrothermal process was employed to control the synthesis of K substitution within the LFMO lattice. Simultaneously, primitive LFMO samples were synthesized using the molten salt synthesis (MSS) process. The hydrothermal process yielded well-defined microcubes, while the MSS LFMO exhibited faceted nanocubes with an average size below 100 nm. Raman spectroscopy analysis revealed a noticeable shift in phonon modes with K doping, indicating a strong spin-lattice coupling. DFT calculations of the cubic phase of LFMO in a checkered configuration confirmed the ground state to be ferromagnetic, which was further validated through experimental investigations and theoretical calculations. Furthermore, the study highlights the significant impact of particle size on the magnetic properties and Curie temperature of LFMO, providing detailed insights into this phenomenon.

8:00 PM EL13.04.14
Creating a Three-Dimensional Intrinsic Electric Dipole on Rotated CrI_3 Bilayers Shiva PrasadPoudel; University of Arkansas, Fayetteville, United States

New multiferroic platforms by sliding or rotation are being explored in two-dimensional (2D) materials [1,2,3]. Antiferromagnetically-coupled CrI_3 bilayers are one of the most studied magneto-electric multiferroic 2D materials [4]. Without considering magnetism, those bilayers possess a crystalline point of inversion, which can only be removed by antiparallel spin configuration between their two monolayers [4]. However, relative rotations between layers break the crystalline point of inversion, resulting in an inherent electric dipole moment **P**. Magnetoelectric couplings can be enhanced this way on a two-dimensional bilayer that is experimentally accessible [5].

This work was funded by MonArk NSF Quantum Foundry, supported by the National Science Foundation Q-AMASE-i program under NSF Award DMR-1906383. Calculations were performed on Cori at the National Energy Research Scientific Computing Center (NERSC), a U.S. Department of Energy Office of Science user facility operated under contract No. DE-AC02-05CH1231, the Arkansas High-Performance Computing Center's Pinnacle supercomputer, and the Tempest Research Cluster at Montana State University.

Interfacial Néel Temperature Tuning for Voltage-Controlled Antiferromagnetic Spintronics ChristianBinek[1,2], AtherMahmood[1,2], JamieL. Weaver[3], Syed Qamar AbbasShah[1,2], JeffreyW. Lynn[3] and PeterDowben[1,2]; [1]University of Nebraska-Lincoln, United States; [2]Nebraska Center for Materials and Nanoscience, United States; [3]National Institute of Standards and Technology, United States

Nonvolatile, voltage-controlled Néel vector rotation in the absence of an applied magnetic field is a much-desired material property in the context of antiferromagnetic spintronics. It enables ultra-low power, ultra-fast, nonvolatile memory, and logic device applications. We achieve this voltage-control by Boron (B) alloying the magnetoelectric antiferromagnet Cr_2O_3. It transforms Cr_2O_3 into a multifunctional single-phase material enabling electric field driven $\pi/2$ rotation of the Néel vector.
Voltage-controlled Néel vector rotation is detected with the help of heavy metal (Pt) Hall-bars in proximity of pulsed laser deposited B:Cr_2O_3 films. Together with results from scanning probe microscopy measurements which are sensitive to topography and surface boundary magnetization, the mechanism of voltage-controlled Néel vector reorientation is explained in terms of voltage-induced orientation of polar nanoregions. Their macroscopic orientation polarization is accompanied by piezoelectric straining which causes reorientation of the magnetic easy axis due to magnetoelastic coupling.
To facilitate operation of B:Cr_2O_3-based devices in CMOS environments, the Néel temperature, T_N, of the functional film must be tunable to values significantly above room temperature. Cold neutron depth profiling and x-ray photoemission spectroscopy depth profiling reveal thermally activated B-accumulation at the B:Cr_2O_3/ vacuum interface in thin films deposited on Al_2O_3 substrates. We attribute the B-enrichment to surface segregation. Magnetotransport data confirm thermally controlled B-accumulation at the interface where the device properties reside. The increased B-concentration increases T_N from 334 K pre annealing to T_N=477 K post annealing within an interface layer of about 50 nm thickness. Scaling analysis determines T_N as a function of the annealing temperature. Stability of post-annealing device properties is evident from reproducible Néel vector rotation at 370 K performed over the course of weeks.

A Lattice Perspective on Bismuth Ferrite DoruC. Lupascu; University of Duisburg-Essen, Germany

Bismuth ferrite is our Drosophila system for multiferroicity at room temperature. One of the facts that has been giving the society large headaches is its low magnetoelectric coupling. In this presentation it is shown that this decoupling of the magnetic and electric orders happens fundamentally at the unit cell level. Antiferromagnetism and the cycloidal ordering of the Dzyaloshinskii–Moriya interaction generated magnetic moments are not even necessary to be considered for explaining the low coupling.
Our data from a nuclear solid state technique show that the magneto-electric coupling in the magnetic sub-lattice is actually enormous. The oxygen octahedral around the iron site experience a large tilt due to the onset of magnetic ordering. The Bi-containing complementary sub-lattice on the other hand is practically unaffected by this large structural change in its direct vicinity. Relation to classical magnetoelectric coupling schemes are drawn.
The second part of the presentation will then deal with applications of this knowledge to the tuning of magnetic, electric and photon interaction properties in custom designed nanoparticles. Photocatalytic applications, hyperthermia treatment and net magnetization studies will be shown for nanoparticles differently doped on the two sub-lattices tuning strain and magnetic coupling. Surface effects will be considered.

9:00 AM *EL13.05.03
Dynamical Multiferroicity and Magnetic Topological Structures Induced by Orbital Angular Momentum of Light in a Non-Magnetic Material LingyuanGao, SergeiProkhorenko, YousraNahas and LaurentBellaiche; University of Arkansas, Fayetteville, United States

Many efforts have been made in studying effective magnetization resulting from the temporally varying electric polarization [1, 2]. Such dynamical polarization can be produced by driving collective motions of ions, usually termed as “phonons” in solid-state language. Moreover, numerous recent studies show that light can control the magnetization in crystals by driving optical phonon modes and tuning structural distortions [3-6]. At the zone center of reciprocal space, infrared (IR)- and Raman-active modes, related to electric polarization and polarizability, respectively, can be excited with an ultrafast Terahertz (THz) laser pulse.

In this Talk, we will present an alternative approach to induce effective magnetic field established on the mechanism of dynamical multiferroicity. Instead of focusing on coherently excited chiral phonons, we drive real-space circular motions of ions with a particular type of light–optical vortex (OV) beam. Such light carries an orbital angular momentum (OAM) [7-9], and can manipulate the motion of microparticles as an optical tweezer [10-12]. As a prototype example, we use first-principles-based simulations and demonstrate that in ultrathin ferroelectric Pb(Zr, Ti)O_3 films, microscopic electric dipoles indeed rotate with the time-varying OAM field. As a result, orbital magnetic moments of ions are effectively generated resulting in a non-negligible magnetic field even in non-magnetic materials. More intriguingly, we will show that the microscopic magnetic moments on a single layer of this quasi 2D system are arranged in a vortex-type configuration, proving that topological magnetic structures—magnetic merons—can also be produced out of orbital magnetic moments of ions and dynamical multiferroicity.

Three's Company: On Order Parameters in Magnetic Ferroelectrics ManfredFiebig; ETH Zurich, Switzerland

In magnetic ferroelectrics ("multiferroics"), magnetic and electric orders emerge independently ("type I"), or the former induces the latter ("type 2"). For type I, magnetic and electric order parameters are independent, and for type II, they are rigidly coupled. I argue that multiferroics with a coexistence of three order parameters combine the best of the type-I and type-II worlds. We have rigidly coupled order parameters, yet with a certain freedom to link magnetization and polarization to each other. Inversion, magnetoelectric transfer of domain patterns, or antiferromagnetic domain vortex formation are among its consequences. While these examples are of a predominantly conceptual nature, there are also connections to device applications that I will discuss.

The Spin Spiral in Multiferroic BiFeO3—Effects of Strain and Electric Field RamamoorthyRamesh[1] and PeterMeisenheimer[2]; [1]Rice University, United States; [2]University of California, Berkeley, United States

The multiferroic BiFeO3 (BFO) system seems to have an unending fountain of scientific and technological questions that the community is able to focus on. With the advent of NV-diamond based ultrahigh resolution magnetic probes, it is now possible to image with very high spatial resolution the spatial mapping of the spin spiral. Using epitaxial thin films (prepared by MBE, PLD and Sputtering), we are attempting to answer two questions: 1. What happens to the spin spiral as we impose epitaxial strain on the BFO layer through heteroepitaxy ? This is being studied by using substrates of different lattice mismatch with BFO as well as the thickness of the BFO layer. 2. The second question pertains to what happens to the spin spiral when the ferroelectric polarization is switched by applying an electric field. This we are exploring using a combination of NV diamond based imaging as well as nonlocal spin transport studies. These studies are providing us with a wealth of information on the intrinsic magnetoelectric coupling in this system. These experimental studies are being complemented with theoretical studies to throw light on the origins of the spin transport behavior.

Switchable, Anisotropic Magnon Propagation Through the Spin Cycloid in Multiferroic $BiFeO_3$IsaacHarris[1,2], SajidHusain[2,1], MayaRamesh[3], PeterMeisenheimer[1], DarrellSchlom[3], Zhi(. Yao[2] and RamamoorthyRamesh[4,1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Cornell University, United States; [4]Rice University, United States

Magneto-electric spin orbit (MESO) devices have been proposed as an alternative to CMOS devices for computational logic and memory, providing a possible solution to greatly reduce the energy consumption of conventional computers. This is expected to be done by electric field control of the magnetic order parameter of a ferromagnet through the magnetoelectric coupling of a $BiFeO_3$ (BFO) multiferroic attached to a ferromagnet. Here, we demonstrate a simplified version of a MESO device where we remove the ferromagnet entirely, and directly manipulate and measure the antiferromagnetic order of the BFO with electric fields and magnon detection, respectively. Using only the antiferromagnetic BFO in the MESO device is an attractive proposal for such a spintronic memory element due to its robustness against external fields, its lack of stray fields, and its fast switching dynamics. Furthermore, the insulating nature of BFO greatly reduces Ohmic losses in the transfer of spin information via magnons, creating a pathway for realizing ultra-low power spintronics. First, we present a bi-stable state switching of the AFM order, controlled by electric fields and measured using the inverse spin Hall effect in a platinum detector wire. Second, we demonstrate anisotropic magnon propagation in BFO, where the direction of magnon transport relative to the propagation of the spin cycloid in BFO – made visible by novel nitrogen vacancy center imaging techniques – is paramount to the retention of magnon spin information. With a better understanding of the controllable magnons in $BiFeO_3$, we aim to demonstrate novel AFM memory devices for energy efficient spintronic applications.

11:15 AM EL13.05.07
Observation of Optical Magnetoelectric Effect in an Antiferromagnetic Metal TbB_4TakeshiHayashida[1], KeitoArakawa[1], KentaKimura[1,2], RyusukeMisawa[1], TatsuyaMiyamoto[1], HiroshiOkamoto[1], FumitoshiIga[3] and TsuyoshiKimura[1,1]; [1]The University of Tokyo, Japan; [2]Osaka Metropolitan University, Japan; [3]Ibaraki University, Japan

In media breaking space-inversion and time-reversal symmetries simultaneously, intriguing cross-couplings between electric and magnetic properties emerge. A representative example is the linear magnetoelectric (ME) effect, that is, the induction of electric polarization P (magnetization M) by an applied magnetic field H (electric field E). The linear ME effect can be extended to optical frequency ω, known as the optical magnetoelectric effect (OME), in which $P(\omega)$ [$M(\omega)$] is induced by oscillating $H(\omega)$ [$E(\omega)$] of an electromagnetic wave [1]. The OME effect induces nonreciprocal optical phenomena, which will be effective for probing the ME coupling in metallic systems, where the linear ME effect responding to a static field is ill-defined. In this study, we investigate the OME effect in an antiferromagnetic (AFM) metal TbB_4.
TbB_4 exhibits two successive AFM phase transition at T_{N1} = 44 K and T_{N2} = 24 K [2]. The magnetic structure in the AFM1 phase at $T_{N2} \leq T \leq T_{N1}$ breaks both space-inversion and time-reversal symmetries (magnetic point group: 4/m'm'm') and allows for the diagonal ME coupling ($\alpha_{11} = \alpha_{22}$, and α_{33}, where α_{ij} is the ME tensor defined as $P_i = \alpha_{ij} H_j$). The diagonal terms of the ME tensor induce nonreciprocal rotation of reflected light (NRR), which refers to the rotation of the polarization of reflected light [3,4]. In the AFM1 phase of TbB_4, there are two distinct AFM domain states, and the rotation directions of NRR are opposite between the two. Therefore, for the detection of NRR in TbB_4, spatial distribution measurements are suitable. Here, we obtain two-dimensional maps of NRR, with magnitudes ranging from 10^{-5} to 10^{-4} rad in the visible light region, by adopting a difference image sensing technique using polarization modulation of incident light [5,6]. As a result, we have successfully detected NRR and visualized AFM domains in TbB_4. We expect that our achievement will further promote understanding of ME effects in metallic compounds.

Lattice Distortions, Electronic and Magnetic Orders in Multiferroic $BiFeO_3$ValeriPetkov; Central Michigan University, United States

The presence of a spin cycloid and zero net magnetization negate any linear magnetoelectric coupling (MEC) between the polarization and magnetization in $BiFeO_3$ (BFO), hampering its usage in practical applications. It has been found that the problem can be alleviated by reducing BFO to nanoscale dimensions or chemical substitution but the underlying physics behind the improved MEC remains unknown. In the talk, we will show results from recent total x-ray scattering studies on nanosized [1] and La substituted [2] BFO indicating that both approaches have a common structural origin. That is, both approaches induce lattice distortions, which reduce the lattice symmetry leading to nonzero magnetization while largely preserving the ferroelectricity. We argue that lattice degrees of freedom in multiferroics often appear as lattice distortions which entangle their electronic and magnetic orders, providing a convenient mechanism to manipulate them as desired.

Normal University, China; [6]University of Minnesota Twin Cities, United States; [7]The University of Hong Kong, China

Magnetic insulators (MI), possessing long-range magnetic order while being electrically insulating, allow spin propagation without electrons' motion and thus promise a unique paradigm of next-generation dissipationless magnetoelectric and magneto-optical devices. While two-dimensional (2D) MIs usher the prospects into the atomic-thin region, efficient electrical control as an essential prerequisite for practical devices remains elusive; fundamental obstacles arise from the difficulty of electrostatically doping insulators and the inability of external electric fields to effectively modify materials' crystal fields. Here, by constructing a heterostructure consisting of a functional thin film and a 2D magnetic insulator, we achieved a strong and reversible electrical control of magnetism. The wavefunction overlaps at the heterostructure interface differs greatly under opposite voltages applied, leading to effective control of the coercivities in magnetic hysteresis loops of the 2D magnets. The layered dependence study confirmed that this effective control occurs exclusively for 2D magnets instead of the bulk counterpart, owing to the electrically controllable interfacial wavefunction overlap that could effectively alter the interfacial crystal field. Our work opens up new avenues to usher 2D MIs towards future nanoscale spintronic, magnonic, and magneto-optical applications.

Removing Magnetic Noise from Composite Magnetoelectric Sensors JeffreyMcCord; Kiel University, Germany

Magnetic field sensors are devices that detect and measure magnetic fields around permanent magnets, electrical conductors, and electrical devices. As such, they are particularly relevant for magnetic applications in IoT, 5G, smartphones, energy, and biomedical engineering. In this context, dedicated research is currently being carried out on novel thin film magnetoelectric (ME) sensor concepts for the detection of magnetic fields down to the picotesla range.

Advanced wide-field magneto-optical Kerr effect microscopy [1] with high temporal resolution is used to study local effects in operating ME composite sensor structures. The realized magnetospatial analysis of working devices sheds light on magnetization changes due to domain nucleation, domain wall resonances, domain wall bending modes, precessional magnetization effects and spin-wave-like phenomena. Each of these is specific to different types of composite ME sensors, ranging from resonance to modulated to DE to SAW sensor systems. Complementary ME response, noise and detection limit analyses reveal the different magnetic noise mechanisms with different magnetic domain activities for the different sensor types (e.g. [2-5]). By understanding the complex magnetic interactions, strategies and implementations are identified to optimize sensor structures. Single magnetic domain layers are the basis for low noise magnetic thin film sensors due to the absence of magnetic domain walls.

The design and application of magnetic layered structures with minimal noise performance sensitivity is discussed. Beyond magnetic domain engineering [6], other schemes of magnetic noise suppression, based on a combination of sensing and pinning magnetic multilayer stacks are discussed. By introducing magnetic sensing layers with subtractive response to carrier excitations while maintaining sensitivity, the influence of the electrical carrier signal to noise is virtually eliminated [7]. The magnetically enforced reduction of the electrical background signal paves the way for ultra-low noise ME sensor applications capable of detecting picotesla magnetic fields. Fundamental limitations of composite ME sensors beyond magnetic domain activity will be further discussed [5].

Funding by the DFG for the CRC 1261 "Magnetoelectric Sensors: From Composite Materials to Biomagnetic Diagnostics" and collaborations within the CRC are acknowledged.

Dynamically Tunable, Narrowband Terahertz Emitters Designed by Tailoring Magnon-Phonon Interaction in Multilayer Heterostructures JiamianHu; University of Wisconsin-Madison, United States

A dynamically tunable, narrowband terahertz (THz) source is much needed for an accurate identification and imaging of chemical and biological species, with wide-ranging applications from security screening to medical imaging and to semiconductor inspection. However, existing pulsed THz sources are mostly single-cycle, broadband, and difficult to tune dynamically. In this presentation, the speaker will first introduce an approach that permits converting a femtosecond laser pulse into a multi-cycle, narrowband THz pulse via resonant magnon-phonon interaction. The peak frequency of the emitted THz pulse can be tuned by up to 50% through a varying bias magnetic field. The speaker will then present computational demonstration of this approach in several carefully designed ferromagnet and antiferromagnet based multilayer heterostructures, which allows us to cover without gaps different frequency ranges (deep millimeter-wave, sub-THz, and >1 THz) of the THz spectrum, tune the polarization, duration, and power of the emitted THz pulse. The demonstration was performed based on an in-house dynamical phase-field model that incorporates the coupled dynamics of magnons, phonons, photons, and plasmons in multiphase systems.

2:30 PM *EL13.06.03
Imaging of Magnetic Particles by Magnetic Susceptibility Particle Mapping (MSPM) ChristineSelhuber-Unkel; Heidelberg University, Germany

The imaging of magnetic particles is highly relevant in many biomedical investigations, including disease detection, diagnosis, and treatment. Magnetic Susceptibility Particle Mapping (MSPM) has the potential to emerge as an important tool in this context, as it can be used to detect magnetic nanoparticles in a lab scale device. The system is based on magnetoelectric (ME) sensors that make use of the Delta-E effect, in combination with a permanent magnet, which generates a bias field for the sensor and at the same time magnetizes the SPIONs. The SPIONs in the sample are magnetized by the permanent magnet and generate an additional magnetic field, which is recorded by the ME sensor. To demonstrate the capability of the MSPM as an imaging technique, magnetic particle distributions are assessed in 3D printing scaffolds. In addition, 3D microtumors based on MCF-7 and MDA-MB-231 breast cancer cells were labelled with magnetic nanoparticles assessed by MSPM. The data show the potential of the device as well as new avenues towards a lab scale investigation of biomedically relevant samples at the standard lab scale.

Nonreciprocity and Nonlinearity in Hybrid Magnetoacoustic Devices DerekBas[1], RomanVerba[2], PiyushShah[1], SerhiyLeontsev[1], AbbassHamadeh[3], MichaelWolf[1], AndrewFranson[1], AlexeiMatyushov[4], MichaelNewburger[1], PhilippPirro[3], MathiasWeiler[3], NianSun[4], VasylTyberkevych[5], AndreiSlavin[5] and MichaelPage[1]; [1]Air Force Research Laboratory, United States; [2]Institute of Magnetism, Ukraine; [3]Technische Universität Kaiserslautern, Germany; [4]Northeastern University, United States; [5]Oakland University, United States

Nonreciprocity, the property of merit for a variety of RF components such as isolators and circulators, is typically difficult to achieve with the magnitude required for applications. To this end, I will discuss discoveries of non-reciprocity and non-linearity in surface acoustic waves interacting with magnetic materials. Giant Nonreciprocity of 48.4 dB (ratio of 1:100,000) is achieved in the transmission of surface acoustic waves on a lithium niobate substrate coated with ferromagnet/insulator/ferromagnet (FeGaB/Al2O3/FeGaB) multilayer structure. This same structure has now also demonstrated very large phase shifts due to a similar interaction, and the nature of the magnetic ordering and coupling to the acoustic system will be discussed. Nonlinearity will also be discussed and is demonstrated using focused interdigitated transistors employing curved fingers, in contrast to the straight fingers typically used. These transducers are engineered to concentrate acoustic energy towards a small region in the center of the device allowing driven magnetic precession much higher than was previously possible. Enhanced acoustic absorption

and modeling of the response will be shown. These devices promise functionality which outperforms current state of the art high frequency devices in a novel acoustic wave system that facilitates unprecedented size, weight, and power reduction.

4:00 PM EL13.06.05

Miniaturized Delta-E Effect Magnetic Field Sensors FatihIlgaz[1], PatrickWiegand[1], BenjaminSpetzler[2], RobertRieger[1] and FranzFaupel[1]; [1]Kiel University, Germany; [2]Ilmenau University of Technology, Germany

Magnetoelectric delta-E effect sensors utilize the change in the elastic modulus of the magnetostrictive material upon applying a magnetic field, resulting in a shift in the resonance frequency. Such sensors have demonstrated the potential to detect small-amplitude and low-frequency magnetic fields. It was also shown that the limit of detection can be improved by using sensor arrays including a large number of sensor elements [1]. However, building compact arrays and achieving high spatial resolutions using mm-sized sensors is challenging. Moreover, the reproducibility of the sensors is significantly impacted by the anisotropic stress developing in the magnetic layer upon releasing the resonator during the fabrication process [2]. Additionally, sensors with a cantilever design suffer from inhomogeneous magnetic properties caused by different stress relaxation at the clamping region affecting their performance [3]. Here, we present an experimental and theoretical investigation of µm-sized delta-E effect sensors employing a free-free beam design that overcomes the limitations and challenges encountered in previous approaches. To control and minimize the residual stress in the magnetic layer, we use a shadow-mask deposition technique where the magnetic layer is deposited on the released resonators. The spatial stress distribution can be accurately determined by combining displacement measurements with a magneto-mechanical model. Different resonance modes are identified, and the dependency of the resonance frequency shift and the sensitivities on these modes are established. The influence of the anchors and the stiffness tensor components on the resonance frequency shift are analyzed by combining a magnetoelastic macrospin model and an electromechanical finite element model. Noise performance and the limit of detection of different sensor geometries are investigated to gain general insight into the relationship between geometry, resonance mode, and sensor performance. We demonstrate extreme stress control with a minimal change of smaller than 8 MPa in the normal stress components (σ_{11} and σ_{22}) and smaller than 2 MPa in the shear stress component (σ_{12}) following the deposition of the magnetic layer. We find that the delta-E effect and sensitivities exhibit strong dependence on resonance modes, attributed to distinct variations in local magnetic and mechanical properties specific to each mode. We identify the optimum mode shape and achieve detection limits below 300 pT/$Hz^{1/2}$ at 10 Hz, comparable to macroscopic sensors [4,5]. Overall, we demonstrate the successful production and miniaturization of delta-E effect sensors with high reproducibility and similar performance to the macroscopic sensors using the proposed manufacturing process and sensor design. The achieved miniaturization and reproducibility represent a significant step toward developing fully integrated sensor arrays and emphasize the potential for high spatial resolution and improved detection limits with large sensor arrays or using flux concentrators.

4:15 PM EL13.06.06

Love Wave Magnetic Field Sensor Operating Without External Bias Field FelixWeisheit[1], ViktorSchell[1], ElizavetaSpetzler[1], JeffreyMcCord[1], DirkMeyners[1], EckhardQuandt[1] and SusanaCardoso de Freitas[2]; [1]University of Kiel, Germany; [2]INESC Microsystems and Nanotechnologies, Portugal

Surface acoustic wave (SAW) technology is widely utilized in electronics as e.g. filters and sensors. One notable application is their implementation for magnetic field detection [1]. Currently, magnetic field sensors have achieved a limit of detection (LOD) below 40 pT*$Hz^{-1/2}$ within the frequency range of 1 Hz to 1 kHz. However, these sensors require an external bias field of approximately 0.4 mT to achieve the desired sensitivity [2]. Alternatively, newly developed SAW sensors incorporate a sensing layer of FeCoSiB deposited through ion beam deposition. These sensors can achieve a LOD of 71 pT*$Hz^{-1/2}$ at 10 Hz without the need for an external bias field. This eliminates the requirement for an additional magnetic field source during operation. The SAW sensor is constructed on a substrate of piezoelectric ST-cut quartz with gold interdigital transducers (IDTs) for generating the acoustic wave. A waveguiding layer made of amorphous SiO_2 is placed on top to confine the wave to the surface, resulting in Love waves. They exhibit an in-plane displacement perpendicular to the direction of propagation. The IDTs are arranged sequentially to create a delay line, and a magnetostrictive sensing element is positioned between them. This sensing layer consists of a single-layer amorphous $(Fe_{80}Co_{20})_{78}Si_{12}B_{10}$ thin film deposited using ion beam deposition. If a magnetic field is present, it induces changes in the elastic properties of the FeCoSiB due to the ΔE effect. This alteration in properties leads to a phase shift in the Love wave. The sensitivity of the sensor to the magnetic field is determined by measuring this phase shift. This measurement is carried out using a Zurich Instruments UHFLI lock-in amplifier, which employs dynamic phase detection. The phase noise analysis is performed using a Rhode & Schwarz FSWP phase noise analyzer.
The FeCoSiB coating on the new sensor does not exhibit ideal soft magnetic behavior, but instead displays a more hysteretic behavior with a coercivity field of 0.5 mT. Consequently, this leads to a shift in the sensitivity curve, wherein the maximum sensitivity of 1410 °/mT is achieved at a bias field of 0.75 mT. But, even in the remanence state, the sensor retains a sensitivity of 640 °/mT, whereas other sensors with a more ideal soft magnetic film have a sensitivity below 100 °/mT. To determine the LOD, the phase noise is divided by the sensitivity. The best sensor, in this case, achieves a LOD of 71 pT*$Hz^{-1/2}$ at 10 Hz and 24 pT*$Hz^{-1/2}$ at 100 Hz. The magnetic properties, as well as the findings when considering the sensitivities, will be presented. Furthermore, advances in utilizing $LiNbO_3$ single crystal substrate, which possesses a significantly higher electromechanical coupling factor than quartz, will be discussed. $LiNbO_3$ also allows higher excitation frequencies to be used, which is expected to result in a further increase in sensitivity.

4:30 PM EL13.06.07

Temperature Stability of Magnetic Materials for Highly Sensitive Magnetoelectric Sensors LarsThormählen[1], BinLuo[2], NianSun[2], EckhardQuandt[1] and DirkMeyners[1]; [1]University of Kiel, Germany; [2]Northeastern University, United States

The detection of magnetic signals is a significant research area where numerous magnetoelectric sensor systems, such as antennas, filters, and magnetometers, are being developed and tested [1]. The use of magnetic signals has the advantage over electrical signals that they are not affected by water, for example, which simplifies communication with underwater vessels and the measurement of biomagnetic signals [1, 2].
The development and fabrication of magnetoelectric cantilever sensors, based on microsystem techniques, are among the primary research focuses of the Collaborative Research Center 1261 at Kiel University [2, 3]. To construct such highly sensitive magnetic field sensors, a wide range of material parameters must be considered. For instance, piezoelectric layers require high piezoelectric coefficients, while magnetic layers should possess soft magnetic properties combined with high magnetostriction. Commonly used magnetostrictive materials are FeCoSiB and FeGaB. Amorphous magnetic materials have the advantage of avoiding undesired crystal anisotropies. To further enhance the magnetic behavior, exchange-bias multilayer systems are employed to minimize magnetic noise resulting from domain wall activity. Imprinting anisotropy in the multilayers is crucial for optimal performance, which can be achieved through sputter deposition in a magnetic field, as well as subsequent heat treatment at approximately 250 °C for FeCoSiB. However, higher annealing temperatures may be necessary depending on the blocking temperature of the selected antiferromagnet for biasing. which could lead to crystallization of the amorphous magnetic layers.
Another potential source of unintentional crystallization is the packaging of the devices at the end of production to protect them from environmental influences and facilitate handling. This common method typically requires temperatures of about 400 °C to create a vacuum-sealed capsule.
This study focuses on investigating different magnetostrictive materials such as FeCoSiB, FeGaB, FeGaC, and CoFeB, which are fabricated through sputter deposition with multicomponent targets and co-deposited layers [1]. The materials are evaluated using XRD, VSM, and magnetostriction measurements at different temperatures. The study aims to determine the temperature ranges at which a negative magnetic change occurs. For example, significant changes in the magnetic behavior of FeCoSiB are observed at temperatures above 300 °C, resulting in a degradation of sensor properties and rendering them unsuitable for vacuum encapsulation by standard wafer bonding.

Exploiting Structural and Electronic Coupling in Transition Metal Oxide Heterostructures Jean-MarcTriscone[1], HugoMeley[1], DuncanT. Alexander[2], ClémentineThibault[1], LuciaVarbaro[1], LukasKorosec[1], ClaribelDomìnguez[1], BernatMundet[3], JenniferFowlie[4], MartaGibert[5], MarcusSchmitt[6], PhilippeGhosez[6] and StefanoGariglio[1]; [1]University of Geneva, Switzerland; [2]EPFL, Switzerland; [3]Institut Català de Nanociència i Nanotecnologia (ICN2), Spain; [4]SLAC National Accelerator Laboratory, United States; [5]TU Wien, Austria; [6]Université de Liège, Belgium

In this talk, I will illustrate through some examples how electronic and structural coupling can lead to exciting novel properties in oxide films and heterostructures.
I will first recall how tri-linear coupling of structural instabilities can lead to improper ferroelectricity in $PbTiO_3/SrTiO_3$ superlattices [1]. I will then discuss how such a coupling of instabilities can be used to design artificial ferroelectric and possibly multiferroic materials with a focus on vanadate-based structures [2,3]. In these structures, it was found that the competition between the strain state and the coupling of oxygen octahedra rotations leads to an interesting “transition layer” and a reorientation of the orthorhombic long-axis. This competition can be used for designing an artificial interface with possibly designed electronic properties. The reorientation of the orthorhombic long-axis is also observed in $SmNiO_3/NdNiO_3$ nickelate superlattices [4,5] - when an additional insulating spacer layer of $LaAlO_3$ is introduced [6].

Interface-Dependent Magnetotransport Properties of Perovskite Lanthanum Manganite Thin Films PinkuRoy[1,2], AipingChen[2] and QuanxiJia[1]; [1]University at Buffalo, United States; [2]Los Alamos National Laboratory, United States

Enhanced functionalities and/or emergent behavior, often not accessible from the individual constituents, could be produced by interfacing certain materials at different length scales. Over the years, major advances have been made to synthesize high crystallinity epitaxial perovskite lanthanum manganite films with controlled microstructures and to gain a fundamental understanding of their physical properties. In this talk, we will discuss our strategies in the synthesis and characterization of epitaxial lanthanum manganite films. Using perovskite lanthanum manganite as the model system, we examine interface-dependent magnetotransport properties by creating both vertically aligned nanocomposite films and layered heterostructures. Specifically, we will discuss the effect of interfaces (both vertical and lateral interfaces) on the magentotranport properties of lanthanum manganite films.

9:00 AM *EL13.07.03
Novel Tetragonal Phase and Multiferroism in (1-x)$BiFeO_3$-(x)$BaTiO_3$ Films LaneW. Martin[1,2,3]; [1]Rice University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States

While bulk $BiFeO_3$ has a rhombohedral perovskite structure with the polarization lying along the {111}, the room temperature structure and polarization can be manipulated using strain and chemistry due the presence of numerous structural polymorphs. Under sufficiently large compressive (tensile) strains researchers have found super-tetragonal-like (orthorhombic) structures. Changing the structure can also change the resulting polarization and magnetism and thus the study of the polymorphism in this system has been a matter of great attention. Considerable work has been done on the super-tetragonal-like structure (with large $c/a \approx 1.25$ and predicted polarization as large as ~150 $\mu C/cm^2$), but it has been found that growing a phase-pure version of this material is challenging and limited to very thin films before it relaxes back to the parent structure. On the other hand, chemical substitution has also been widely used to modify $BiFeO_3$ since the polarization (structure) is strongly influenced by the $6s^2$ lone pair electrons of bismuth meaning that *A*-site substitution can greatly impact the structure and properties.

Here, we explore such concepts by examining the evolution of the structure and polar and magnetic properties of (1-x)$BiFeO_3$–(x)$BaTiO_3$ (x = 0-0.3) solid solution thin films. Films of varying compositions have been deposited using pulsed-laser deposition on a range of perovskite substrates. While for all values of x films grown on scandate substrates exhibit the expected rhombohedral (monoclinic) structure seen in most films (albeit with slightly larger lattice parameter), growth of films with x = 0.1, 0.2, and 0.3 on $SrTiO_3$ (001) substrates produces a new phase. Detailed X-ray diffraction, piezoresponse force microscopy, and scanning transmission electron microscopy reveal this new phase to be tetragonal and different from the previously observed super-tetragonal-like phase. Insights on this new structure are gleaned from first-principles calculations. Subsequent dielectric and polarization-electric field hysteresis loop studies show that the novel tetragonal phase exhibits a lower dielectric constant and increased polarization (as large as 120 mC/cm^2) and coercive field (~500 kV/cm) as compared to parent-phase $BiFeO_3$. In turn, the magnetic nature of the material is studied via inelastic light scattering, exchange bias, SQUID magnetometry, angle-dependent X-ray absorption spectroscopy and magnetic linear and circular dichroism, and scanning NV magnetometry measurements. A comparatively large in-plane magnetization is observed. Finally, the potential for magnetoelectric coupling in this system is probed. Overall, these findings suggest the discovery of a new phase of $BiFeO_3$ that, to the best of our knowledge, has not been observed before and works to provide understanding for why it forms and how it evolves from the parent phase.

Superconductivity in Layered Square Planar Nickelates JuliaMundy; Harvard University, United States

Since the discovery of high-temperature superconductivity in copper oxide materials, there have been sustained efforts to both understand the origins of this phase and discover new cuprate-like superconducting materials. One prime materials platform has been the rare-earth nickelates; indeed, superconductivity was recently discovered in the doped compound $Nd_{0.8}Sr_{0.2}NiO_2$ [1]. Undoped $NdNiO_2$ belongs to a series of layered square-planar nickelates with chemical formula $Nd_{n+1}Ni_nO_{2n+2}$ and is known as the ‘infinite-layer’ (n = ∞) nickelate. Here, we report the synthesis of the quintuple-layer (n = 5) member of this series, $Nd_6Ni_5O_{12}$, in which optimal cuprate-like electron filling ($d^{8.8}$) is achieved without chemical doping [2]. We observe a superconducting transition beginning at ~13 K. Electronic structure calculations, in tandem with magnetoresistive and spectroscopic measurements, suggest that $Nd_6Ni_5O_{12}$ interpolates between cuprate-like and infinite-layer nickelate-like behaviour. By engineering a distinct superconducting nickelate, we identify the square-planar nickelates as a new family of superconductors that can be tuned via both doping and dimensionality. [3]

Structural and Electronic Properties of Nickelate Based Superlattices LuciaVarbaro[1], ClaribelDomìnguez[1], JenniferFowlie[2], LukasKorosec[1], BernatMundet[3], DuncanT. Alexander[4] and Jean-MarcTriscone[1]; [1]University of Geneva, Switzerland; [2]SLAC National Accelerator Laboratory, United States; [3]Institut Català de Nanociència i Nanotecnologia (ICN2), Spain; [4]École Polytechnique Fédérale de Lausanne, Switzerland

Rare-earth nickelates belong to the wider family of perovskite oxides. These materials display a characteristic temperature-dependent metal-to-insulator transition (MIT) together with a lowering of the crystal symmetry related to the onset of a breathing distortion of the NiO_6 octahedra units [1,2]. Furthermore, below the Néel temperature ($T_N < T_{MI}$ for R = Lu - Sm and $T_N = T_{MI}$ for R = Nd, Pr), these compounds were found to exhibit antiferromagnetic order with the (1/4,1/4, 1/4) pseudocubic propagation vector [3-4]. In theory, it has been predicted that the coalescence of breathing distortion and non-centrosymmetric magnetic order could result in a breaking of inversion symmetry within the crystal lattice. Consequently, this would lead to the emergence of an electric dipole, classifying nickelates as type-II multiferroics. [5]. Raman spectroscopic data of $RNiO_3$ single crystals by Ardizzone and al. [6], show that, entering the magnetically ordered phase, additional vibrational modes appear as a possible signature of breaking of inversion symmetry.
In this work, we investigate nickelate thin films and superlattices. Raman experiments were performed on $NdNiO_3$ and $SmNiO_3$ thin films, revealing temperature evolution of the Raman spectra rather similar to the one reported in [6].

Moreover, the structural and electronic properties of nickelate superlattices were studied to investigate the characteristic length scale over which a metallic or an insulating phase can be established and the physics that sets it [7]. By growing $SmNiO_3/NdNiO_3$ superlattices and using experimental and theoretical methods we showed that this length scale depends on the interplay between the energy cost of the boundary between metallic and insulating phases and the energy gain of the bulk phases [7].
To further understand this unusual coupling and the evolution of the structural and electronic order parameters across these phase boundaries, $SmNiO_3/NdNiO_3$ superlattices were grown with additional insulating $LaAlO_3$ spacer layers, that should lead to a progressive decoupling of the nickelate layers.
Furthermore, the phase boundary cost of maintaining an interface between a metal and an insulator will be exploited as an additional parameter to tune the electronic properties of this class of materials, specifically alternating metallic layers and layers displaying a metal-to-insulator transition within a superlattice, with the aim of forcing a metal into an insulating phase by increasing the density of interfaces.
All the samples were grown using RF off axis magnetron sputtering, and are morphologically and structurally characterized using atomic force microscopy (AFM), X-ray diffraction (XRD) and STEM-EELS. Temperature dependent transport measurements will be presented for each different system, giving an overview on electronic and structural couplings, and more generally on the properties of these complex heterostructures.

Ferromagnetism and Ferroelectricity in a Superlattice of Antiferromagnetic Perovskite Oxides Without Ferroelectric Polarization AvijeetRay, Paresh C.Rout and UdoSchwingenschlögl; King Abdullah University of Science and Technology, Saudi Arabia

Using density functional theory with onsite Coulomb interaction, we study the structural, electronic, and magnetic properties of the $SrCrO_3/YCrO_3$ superlattice and their dependence on epitaxial strain. We discover that the superlattice adopts A-type antiferromagnetic (A-AFM) ordering in contrast to its constituents ($SrCrO_3$: C-AFM; $YCrO_3$: G-AFM) and retains it under compressive strain while becoming ferromagnetic (5 μ_B per formula unit) at +1% strain. The obtained ferroelectric polarization is significantly higher than that of the R_2NiMnO_6/La_2NiMnO_6 (R = Ce to Er) series of superlattices [Nat. Commun. 5, 4021 (2014)] due to a large difference between the antipolar displacements of the Sr and Y cations. The superlattice is a hybrid-improper multiferroic material with a spontaneous ferroelectric polarization (13.5 $\mu C/cm^2$) approaching that of bulk $BaTiO_3$ (19 $\mu C/cm^2$). The combination of ferromagnetism with ferroelectricity enables multistate memory applications. In addition, the charge-order-driven p-type semiconducting state of the ferromagnetic phase (despite the metallic nature of $SrCrO_3$) is a rare property and interesting for spintronics. Monte Carlo simulations demonstrate a magnetic critical temperature of 90 K for the A-AFM phase without strain and of 115 K for the ferromagnetic phase at +5% strain, for example.

Giant Magnetoelectric Effect and Interactive Control of Magnetic Anisotropy Driven by a Ferroelectric Phase Transition in Ferromagnetic-Piezoelectric Heterostructure ThomasR. Mion[1,2], MargoStaruch[2], PeterFinkel[2] and KonradBussmann[2]; [1]NOVA Research, United States; [2]U.S. Naval Research Laboratory, United States

Magnetoelectric materials and, to a larger extent, multiferroic heterostructures offer a novel route for electric field control of magnetism. We explored the induced magnetic anisotropy of an FeCo/Ag multilayer thin film deposited on the surface of 001 poled $(Pb(In_{1/2}Nb_{1/2})O_3$-$Pb(Mg_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ PIN-PMN-PT single crystal as it is electrically driven through a ferroelectric-ferroelectric phase transition. In PIN-PMN-PT an effective giant piezoelectric coefficient >10,000 pm/V occurs during the phase transition providing strain >0.25% along a principle strain direction. This effect translates into anisotropic strain to the magnetoelastic thin film inducing a giant magnetoelastic effect driven by the induced magnetic anisotropy along the principle strain direction. We measured an effective converse magnetoelectric coefficient ~1.4 x 10^-5 s/m when driven through the phase transition which was more than double the values obtained in the linear piezoelectric rhombohedral phase. The controllable and repeatable nature of the phase transition allows an interactive driving of the induced magnetization making the phenomenon attractive for application in spintronic devices.

Recent Advances and Future Opportunities with Magnetic X-Ray Spectromicroscopies PeterFischer[1,2]; [1]Lawrence Berkeley National Lab, United States; [2]University of California, Santa Cruz, United States

Spin textures in magnetic materials, and polarization textures in multiferroic materials hold the key to understand and control properties and behavior, that offer tremendous potential for novel applications in future information processing technologies with significant improvements in energy efficiency, processing speed, functionalities, and miniaturization of future microelectronic devices.
An emerging research field in nanomagnetism is the scientific and technological exploration of 3-dimensional magnetic nanostructures that opens the path to exciting novel physical phenomena, originating from the increased complexity in spin textures, topology, frustration, and tailored geometries in three dimensions. This has attracted significant scientific interest and led to intense research addressing a broad spectrum, including stability, dynamics, nucleation, and transport in novel spin textures, such as vortices, skyrmions, chiral bobbers, hopfions, torons, skyrmion tubes, etc. [1]. Analogous structures are also found in multiferroic (polar) materials, such as polar vortices [2], skyrmions [3] and hopfions [4].
Advanced characterization tools that provide magnetic sensitivity to spin textures, disentangling the role of individual components in heterogeneous material at high spatial resolution, ultimately at buried interfaces and in all three dimensions [5], and at high temporal resolution to capture the spin dynamics across scales, are required to address those questions, and are therefore of large scientific interest.
Various magnetic soft X-ray spectro-microscopies [6] using polarized soft x-rays provide unique characterization opportunities to study the statics and dynamics of spin textures in magnetic materials combining X-ray magnetic circular dichroism (X-MCD) as element specific, quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length, time, and energy scales.
Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new techniques, x-ray photo-correlation spectroscopy (XPCS) [7] that allow unprecedented studies of nanoscale heterogeneity, complexity, and fluctuations.
I will review recent achievements and future opportunities with magnetic x-ray spectro-microscopies. Examples will address static properties and dynamic behavior of magnetic hopfions [8] and a 3D metrology of skyrmions using soft x-ray laminography [9].

Imaging Magnetic Skyrmions and Perpendicular Domains under Voltage Control in Metallic Multilayers and 2D Materials. MassimoGhidini[1,2,3]; [1]University of Parma, Italy; [2]Diamond Light Source, United Kingdom; [3]University of Cambridge, United Kingdom

X-ray Photoemission electron microscopy and Magnetic Force Microscopy permit to image strain-coupled ferroelectric and ferromagnetic domains with submicron spatial resolution, thus revealing novel magnetoelectric effects in multiferroic heterostructures.
Here, we employ these complementary techniques to demonstrate voltage manipulation of skyrmions and perpendicular domains in magnetic multilayers and 2D materials overlying PMN-PT ferroelectric substrates. The resulting local magnetoelectric effects include transition from worm-like to skyrmion states, stripe domain displacement, nucleation/annihilation of isolated skyrmions and local magnetisation reversals.

Electrical Tuning of Spin-Wave Transport in Magnetic Insulators HosseinTaghinejad[1,2] and JamesG. Analytis[1,3]; [1]University of California, Berkeley, United States; [2]Kavli Energy NanoScience Institute, United States; [3]Lawrence Berkeley National Laboratory, United States

Spin-waves have recently gained popularity to replace electrons as carriers of information in emerging computing and signal processing technologies. Collective excitations of magnetic materials promise low-power operation and potentially faster data processing in a wide range of materials including insulators, which have traditionally been employed as only passive elements in the mainstream microelectronic technology. However, controlling the transport of spin-waves often requires the use of an external magnetic field, a major drawback that has hindered its widespread use in practice. Here, we introduce an all-electrical approach for full control over the transport of spin-waves in the archetype magnetic insulator Yttrium Iron Garnet (YIG), eliminating the use of external magnetic field. In our study we employ the spin-Hall physics at the interface of a heavy metal with YIG for the excitation and detection of spin waves at room temperature. We will discuss the potential applications of our developed technique for the design of practical devices based on spin-waves.

Enhancement of Spin-Orbit Torque in Pt/Co/HfO_x Heterostructures with Voltage-Controlled Oxygen Ion Migration ShuoWu, TianliJin, FunanTan, Ching IanAng, Gerard JosephLim and WensiangLew; Nanyang Technological University, Singapore

Spin-orbit torque (SOT) induced magnetization switching and SOT modulation have been intensely pursued and developed in recent years for efficient spintronic devices. Research has shown that the magnetic anisotropy of ferromagnet (FM) layers can be modified via inducing surface charges or orbital occupancy by interfacing with an oxide layer. Moreover, voltage-controlled oxygen migration can reduce the energy barrier for magnetization switching. The electric-field-driven interfacial oxygen mobility can affect both the SOT strength and sign. However, more research on the oxidation effects at the interfaces of the voltage-controlled magnetism in FM/oxide systems needs to be investigated. In this work, we report the enhancement of damping-like field and SOT efficiency of up to 60% and 23%, respectively, in perpendicularly magnetized Pt/Co/HfO_x heterostructures over Pt/Co system at an optimal thickness of 2 nm HfO_x. We further verify this enhanced SOT by applying voltages across the Pt/Co/HfO_x structure, which allows the O^{2-} migration from HfO_x to the Co layer. By using voltage-controlled oxygen ion modulation of interfacial oxidation, we show that the gate voltage affects not only coercivity and anisotropy fields but also the SOT efficiency at room temperature. Our work promotes the SOT enhancement and modulation by oxidation effects for energy-efficient spintronic devices.

Simulation of Magnetoelectric Sensors in Inhomogeneous Magnetic Fields MohsenSamadi, JuliusSchmalz, Mesut-ÖmürÖzden, GiuseppeBarbieri and MartinaGerken; Kiel University, Germany

Thin-film magnetoelectric (ME) sensors have the potential for room-temperature, magnetic-shielding-free measurement of a variety of biomagnetic fields from magnetocardiography over deep-brain stimulation signals (DBS) to magnetomyography [1, 2]. Approaches for modelling and simulation of the behavior of different types of magnetoelectric sensors are discussed. Besides the standard excitation with homogeneous magnetic fields, inhomogeneous magnetic-field excitation is considered as found in biomedical applications.

As a first sensor type, cantilever sensors based on strain-coupled thin-film magnetostrictive and piezoelectric layers and their response to inhomogeneous magnetic fields are reviewed [3]. A linear material model is used to calculate the small-signal behavior of sensors at the working point. The elastic, magnetic and electric properties are included in a coupled finite-element-method (FEM) simulation. Second, the magnetic-field response of electrically-modulated magnetoelectric cantilever sensors is investigated [4]. These sensors are electrically excited and operate in a mechanical mode with bending in the short cantilever direction (U-mode). They exhibit a high-quality factor and a promising limit of detection in the pico-Tesla range. It is demonstrated that for specific sensor dimensions and clamping structures a homogeneous response is obtained across the sensor. As a third sensor type, surface-acoustic-wave (SAW) magnetic-field sensors are considered. Our previous results [5] are extended to include microstructuring of the delay line to realize phononic crystals. It has been shown that resonances appear due to the acoustic-crystal structure [6, 7] and here their suitability to magnetic-field sensing is investigated. For all three types of sensors FEM simulation models and results are discussed.

In the next part of the talk, a multiscale simulation approach is introduced for a full system simulation including magnetoelectric sensors, a human head model and electric-dipole excitation to model deep-brain stimulation (DBS). Due to the thin layers in the sensor structure as well as the intricate structure of the brain with different types of tissues this is a highly challenging task. The head model is implemented based on MRI data [8]. Since mesh management is crucial for successfully running simulations, the three-dimensional model is extrapolated and morphological operations are used for filtering and smoothing. The trade-off between surface idealness and performance needs to be considered. The complexity is increased stepwise by starting with a simple three-shell model and proceeding to an increasing number of compartments and more detail. With the multiscale model we calculate electromagnetic field propagation through the head and the magnetoelectric sensor response. The combined calculations allow for the investigation of field concentration effects and inhomogeneous sensor excitation in a realistic geometry, secondary-source effects due to conductivity, as well as field effects in the human head caused by the sensor system.

Technologieentwicklung, Germany; [6]Northeastern University, United States; [7]Massachusetts Institute of Technology, United States

Yttrium iron garnet ($Y_3Fe_5O_{12}$, YIG) has a unique combination of low magnetic damping, high spin wave conductivity, and insulating properties that make it a highly attractive material for a variety of applications in the fields of magnetics and spintronics. While the room temperature magnetization dynamics of YIG have been extensively studied, there are limited reports correlating the low temperature magnetization dynamics to the material structure or growth method. Here we investigate liquid phase epitaxy grown YIG films and their magnetization dynamics at temperatures down to 10 K. We show there is negligible increase in the ferromagnetic resonance linewidth down to 10 K which is unique when compared with YIG films grown by other deposition methods. From the broadband ferromagnetic resonance measurements, polarized neutron reflectivity, and scanning transmission electron microscopy, we conclude that these liquid phase epitaxy grown films contain negligible rare-earth impurities present, specifically the suppression of Gd-diffusion from the $Gd_3Ga_5O_{12}$ substrate into the $Y_3Fe_5O_{12}$ film, and therefore consequently insignificant magnetic losses attributed to the slow relaxation mechanism. Overall, liquid phase epitaxy YIG films have a YIG/GGG interface that is 5 times sharper and has 10 times lower ferromagnetic resonance linewidths below 50 K than comparable YIG films produced by other deposition methods. Thus, YIG films grown by liquid phase epitaxy are ideal for low temperature experiments/applications that require low magnetic losses, such as quantum transduction and manipulation via magnon coupling. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

SESSION EL13.10: Magnetoelectric Sensors and Actuators III

Ferroics, Multiferroics and Magnetoelectrics: Reconsidering New Paths to Large Transduction, Ultra-Low Power Sensors and Giant Energy Conversion PeterFinkel, MargoStaruch, ThomasR. Mion and KonradBussmann; Naval Research Laboratory, United States

The ability to tune both magnetic and electric properties concomitantly in magnetoelectric (ME) composite heterostructures, consisting of magnetostrictive and piezoelectric phases coupled through strain with orders-of-magnitude larger ME coupling coefficient than single-phase multiferroics due to additional functionalities and makes them very promising in many applications and devices [1,2]. This has generated a revived interest in multiferroics, and is projected to play a critical role in next-generation applications ranging from transducers, tunable inductors, gyrators, magnetic sensors to high-frequency filters and communication devices. In this talk we highlight different approaches to achieve maximum ME coupling in heterostructures of magnetostrictive films deposited on domain-engineered relaxor ferroelectric single crystals. Much work has been done over the past decade to maximize the magnetoelectric (ME) coupling coefficient, α_{ME}, the figure of merit for these composites that can be enhanced through deliberate choice of materials as well as carefully controlling the interface. For the piezoelectric phase, relaxor ferroelectrics have attracted much attention recently due to a piezoelectric coefficient an order of magnitude larger than conventional lead zirconate-titanate [3] especially in proximity to morphotropic phase boundary. In the ME heterstructures we demonstrated that by exploiting the large ferroelectric phase transitional strain in piezoelectric substrate, the converse magnetoelectric coupling coefficient is expected to be greatly up to 4x enhanced as compared to linear piezoelectricity [4,5]. In this presentation, the impact of this enhancement will be examined and a path for utilization of this phenomenon in ME composites will be discussed. Magnetoelectric (ME) resonators are of significant interest for next generation near-dc magnetic field sensors, as the direct coupling of highly magnetostrictive (FeCo- or FeGa-based alloys) and piezoelectric phases (AlN) enables high magnetic field sub-nT sensitivity with exceptionally low operational power requirements. This talk highlights several programs within the Materials Science & Technology Division at US Naval Research Laboratory focused on the investigation and understanding physics of these ferroic and multiferroic materials, and how current research presents another opportunity to advance acoustic transduction devices, magnetic sensors and electrically small antennas.

Voltage Control of Exchange Coupling: A Novel Way to Switch MRAM Devices BhagwatiPrasad[1], AkashSurampalli[1], RajeshV. Chopdekar[2], AlanKalitsov[2], LeiWan[2], JordanKatine[2], DerekStewart[2] and TiffanySantos[2]; [1]Indian Institute of Science, India; [2]Western Digital Corporation, United States

Traditional memory devices based on spintronics leverage electric current to ingeniously regulate the direction and movement of electrons' spin, albeit at the expense of high energy consumption and limited device durability [1, 2]. As a result, with the increasing demand for faster, smaller, and extremely energy-efficient electronic devices, the pursuit of magnetism controlled by voltage has notably intensified. This field offers the potential to create ultra-low-power, non-volatile memory solutions for future computing systems [3, 4].
In this context, we present our latest research on magnetism controlled by voltage via voltage-controlled exchange coupling (VCEC) [5, 6]. To explore the control of exchange coupling through an electric field, we have fabricated magnetic heterostructures with varying thicknesses of Ru and Ir spacer layers. In these layered structures, two ferromagnets (free and reference layers) possessing perpendicular magnetic anisotropy are separated by a non-magnetic Ru and Ir spacer layer. This separation creates an oscillatory interlayer exchange coupling (IEC) as the Ru or Ir layer's thickness varies, as predicted by the RKKY theory.
To quantify the VCEC effect, a bias field is applied across the MgO layer, and resistance-magnetic field loops are measured while a DC bias voltage is in effect. This results in a visible gating effect in the minor loops of resistance-magnetic field plots, thus demonstrating the manipulation of exchange interactions between the free and reference layer via an applied electric field. In this way, we demonstrate modulation of the interlayer exchange coupling with the Ru and Ir spacer layers using non-ionic liquid gating such as MgO [6]. These findings provide a route for modifying the resistance states of spintronic devices, thereby paving the way for the creation of a new generation of energy-efficient computing devices.

9:15 AM EL13.10.03
Proving the Suitability of Polymer-Based Magnetoelectrics for Spintronic Applications PedroMartins[1], SenentxuLanceros-Mendez[2] and RuiCarvalho[1]; [1]Universidade do Minho, Portugal; [2]BCMaterials, Basque Center for Materials, Applications and Nanostructures, Spain

The rapid advancement of technology has generated significant requirements for electrical energy to power electronic devices. A pivotal aspect of this technological progress, for sensors, actuators, and memory devices, involves harnessing the spin of electrons in electronics, known as spintronics. However, a considerable portion of the electric power utilized in spintronics is dissipated as heat through the Joule effect (3–5% of the energy: thousands of millions of dollars annually). Consequently, there is a pressing need to explore novel approaches to develop energy-efficient devices, making it a prominent research topic within the realm of spintronics.
To address concerns regarding energy efficiency and the control of spin states, alternatives to the energy-consuming external magnetic field have been explored: the spin-polarized current injection. However, this approach still generates heat, negatively impacting the overall power efficiency of the device. In this scope, the utilization of applied voltages represents a promising strategy to reduce energy requirements. Materials with magnetoelectric (ME) properties have emerged as leading contenders for future spintronic advancements, as their magnetization and ferromagnetism can be controlled by an electric field.
By incorporating an additional magnetoelectric (ME) layer into the conventional three-layer spin-valve spintronic structure, it becomes possible to create electrically tunable spintronic

devices. This is achieved by exploiting the interface between the ME layer and the ferromagnetic-free layer. The introduction of this ME layer brings about a significant reduction in power consumption, estimated to be two orders of magnitude lower when compared to traditional devices.
In the broader context of the global technological landscape, which is witnessing the rapid and widespread implementation of revolutionary advancements such as Industry 4.0, the Internet of Things, and digitalization, the production of ME materials is facilitated by additive manufacturing tools. These tools not only enable the efficient manufacturing of ME materials but also ensure safety during the production process, productivity, reduced time requirements, miniaturization, and sustainability.
Among the different & available ME materials, polymer-based ME materials have been specifically selected to demonstrate their suitability for spintronic applications, due to their flexibility, high ME coupling, and printability, making them ideal for integration into spintronic devices. In particular, P(VDF-TrFE) (poly(vinylidene fluoride-trifluoroethylene)) has been selected as the piezoelectric matrix material due to its exceptional piezoelectric response, which is the highest among all polymers ($|d_{33}|\approx 30$ pC/N). Three different types of magnetostrictive fillers were incorporated into the polymer matrix: $CoFe_2O_4$ nanoparticles, Fe_3O_4 nanoparticles, and NdFeB microparticles.
Results show that an AC electric field of 10 V/f ≈ 13 MHz applied on samples with 20 wt.% of magnetic filler produced magnetic fields of ≈ 8 Oe in all three composites, that correspond to converse ME coefficients of 4.1, 4.4, and 6.5 mG.cm.V^{-1}, respectively for P(VDF-TrFE) composites with NdFeB, Fe_3O_4 and $CoFe_2O_4$ fillers. $CoFe_2O_4$ fillers induced the highest converse ME coefficient due to their highest magnetostriction (≈250 ppm)
Such performance holds promise for spintronic (low field sensing and memory applications) once the generated magnetic fields are greater than the ones needed for recently reported spin-valve structures (0.4 Oe).

2.87 GHz SAW Delay Lines for Efficient Spin Control of NV$^-$ Centers BinLuo[1], AndreasWinkler[2], HagenSchmidt[2], BenyaminDavaji[1], DerekBas[3], MichaelMcConney[3], MichaelPage[3], BeaverNathaniel[1], PaulStevenson[1] and NianSun[1]; [1]Northeastern University, United States; [2]Leibniz Institute for Solid State and Materials Research, Germany; [3]Air Force Research Laboratory, United States

Motivation
Owing to long coherence time, high fidelity and easy optical initiation and readout of quantum states tuned by magnetic excitations over a broad temperature range, NV$^-$ centers are intriguing solid-state platforms for quantum computing, communication, information processing and sensitive non-invasive nanoscale magnetic sensors. The SAW delay line driven spin wave enabled by magnon-phonon interactions exhibits superior properties of high-power efficiency, low noise and small footprint, leading to efficient voltage control of NV$^-$ center and quantum transduction between hybrid quantum systems. In this work, we present a 2D finite element (FEM) model for a fabricated SAW delay line with S11 minima at 2.87 GHz and ~ −10 dB insertion loss for NV center excitation. The consistency of S parameters between simulation and probing experiments makes the model prospective for SAW delay line design for chemical, biomedical, RF and quantum applications.

Methods
The transmission and receiving IDT Al electrodes with a fundamental mode of ~2.87 GHz were patterned on bulk $LiNbO_3$ substrate via laser lithography, e-beam lithography, e-beam metal evaporation and lift-off technique. The S parameters were measured by RF probes connected to a vector network analyzer. A 1:1 2D finite element model was built in COMSOL Multiphysics. The electrostatic module was combined with solid mechanics module to simulate piezoelectrically induced Rayleigh wave excited by SAW delay line under different attenuation conditions.

Results
The fabricated SAW delay line shows a low insertion loss of ~ −10 dB at 2.87 GHz, which is excellent to control the ground states of NV$^-$ centers. The simulated S parameters agree well with probe measurement. The displacement and electric field profile demonstrate a high transmission between IDT electrodes. The increased mechanical damping results in decreased Sxy magnitude and diminished modulation of the SAW resonance peak ("triple transit echo") caused by reflections between the IDTs near fundamental mode.

9:45 AM EL13.10.05
Highly Cyclable Voltage Control of Magnetism in Cobalt Ferrite Nanopillars for Memory and Neuromorphic Applications MuireannA. de hora[1], AlionaNicolenco[2], MonalishaPeda[3], TuhinMaity[4], BonanZhu[5], ShinbuhmLee[6], ZhuotongSun[1], JordiSort[3] and JudithL. Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]Cidetec, Spain; [3]Universitat Autònoma de Barcelona, Spain; [4]Indian Institute of Science Education and Research Thiruvananthapuram, India; [5]University College London, United Kingdom; [6]DGIST, Korea (the Republic of)

Research in digital memory is growing with the increase in popularity of artificial intelligence, machine learning, Internet of Things, and Big Data. This in turn has caused an energy demand that has triggered innovation towards non-volatile memory technologies that do not require continuous power supply. Magnetic memory is a promising non-volatile technology for storing data, but conventional magnetic memory concepts use electrical current to control magnetic properties (i.e. through electromagnets or spin-torque effects) and this can lead to significant energy loss by heat dissipation. On the other hand, tuning the properties of magnetic materials by voltage-driven ion migration (magneto-ionics) gives potential for energy-efficient, non-volatile magnetic memory and neuromorphic computing.

Our study shows large changes in both the magnetic moment at saturation (m_S) and coercivity (H_C), of 34% and 78%, respectively, in an array $CoFe_2O_4$ (CFO) epitaxial nanopillar electrodes (~50 nm diameter, ~ 70 nm pitch, and 90nm in height) with applied voltage of –10 V in a liquid electrolyte cell. Furthermore, a magneto-ionic response faster than 3 s and endurance >2,000 cycles are demonstrated. The response time is faster than for other magneto-ionic films of similar thickness, and cyclability is around two orders of magnitude higher than for other oxygen magneto-ionic systems. Using a range of characterisation techniques, the magnetic switching is shown to arise from modulation of oxygen content in the CFO. Also, the highly cyclable, self-assembled nanopillar structures were demonstrated to emulate various synaptic behaviours, exhibiting non-volatile, multilevel magnetic states for analog computing and high-density storage. Overall, CFO nanopillar arrays offer potential to be used as interconnected synapses for advanced neuromorphic computing applications.

10:00 AM EL13.10.06
Imaging of Voltage-Controlled Switching of Magnetization in Highly Magnetostrictive Epitaxial Fe-Ga Microstructures on PMN-PT MaiteGoiriena[1,2], ZhuyunXiao[3,4], RachelSteinhardt[5], VictorEstrada[3], NobumichiTamura[4], RajeshV. Chopdekar[4], AlfredoGarcía-Arribas[2], AbdonSepúlveda[3], DarrellSchlom[5,5], RobN. Candler[3,6] and JeffreyBokor[1,4]; [1]University of California, Berkeley, United States; [2]University of the Basque Country, Spain; [3]University of California, Los Angeles, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]Cornell University, United States; [6]California NanoSystems Institute, United States

The magnetoelectric behavior of epitaxial Fe-Ga microstructures on top of (001)-oriented PMN-PT piezoelectric substrate is investigated under magnetic electron microscopy (XMCD-PEEM). Additionally, micron-scale strain distribution in PMN-PT is characterized by X-ray microdiffraction and examined with respect to the results of the Fe-Ga magnetoelectric switching. The magnetic reorientation is found to be strongly correlated with the size, shape and crystallographic orientation of the microstructures. In the case of square-shaped structures, size dictates the degree of influence of the strain distribution on both the initialization of the ground state and on the dynamics of the magnetic reorientation during application of voltage. On the other hand, the case of the elliptical microstructures demonstrates the importance of the orientation of the long axis with respect to the crystallographic directions of the PMN-PT, which leads to completely different magnetic responses. This study demonstrates that engineering highly magnetostrictive epitaxial microdevices is possible. It further elucidates that voltage-induced actuation can be largely tuned to achieve the desired type of magnetic switching ranging from vortex circulation reversal, domain wall motion, to a large rotation of magnetization. Because of the outstanding properties of the investigated material system, the reported findings are expected to be of great interest for the realization of next-generation energy-efficient magnetic memory, sensing and actuation devices.

Hidden Order in Cr_2O_3 and α-Fe_2O_3 as a Predictor for (anti-)Magnetoelectricity XantheH. Verbeek, AndreaUrru and NicolaSpaldin; ETH Zürich, Switzerland

With first-principles calculations of Cr_2O_3 and its iron-based analog, α-Fe_2O_3, we show that the different magnetoelectric effects in these materials result from the ordering of hidden magnetic multipoles [1]. Starting from the established connection between ferroically-ordered magnetic quadrupoles and the linear magnetoelectric effect in Cr_2O_3, we explore the presence of additional multipoles. We reveal for the first time anti-ferroically ordered magnetic multipoles in both Cr_2O_3, and isostructural α-Fe_2O_3, in which the global inversion symmetry is preserved by the different magnetic dipolar ordering. Using symmetry considerations, we can relate each of these multipoles and their ordering to linear, quadratic, and cubic (anti-) magnetoelectric effects, where in an anti-magnetoelectric effect the induced moments are ordered antiferromagnetically in the unit cell. We confirm the predicted induced moments using first-principles calculations, showing the lowest response in α-Fe_2O_3, a centrosymmetric magnetic material, to be a linear anti-magnetoelectric effect, revealing the presence of the magnetoelectric coupling despite the preserved global inversion symmetry. Our results demonstrate the existence of hidden magnetic multipoles leading to local linear magnetoelectric responses, even in centrosymmetric magnetic materials, and broaden the definition of magnetoelectric materials by including those showing such local magnetoelectric responses.

New Developments in Transfer-Doped and Accumulation Channel Diamond Electronic Devices DavidA. Moran; University of Glasgow, United Kingdom

Transfer-doping of diamond has proven to be an attractive alternative to substitutional doping of diamond for the production of high-performance diamond electronic devices, such as Field Effect Transistors. The process, which relies in a low/negative electron affinity chemical termination of the diamond surface e.g. with hydrogen, combined with the application of a surface electron acceptor material of sufficiently high electron affinity, generates a high carrier density, shallow, sub-surface 2D hole gas that may be exploited as a conductive channel in several device applications.
Significant progress has been made recently in the further development of transfer doping processes in diamond, virtually eliminating previous issues such as inherent temperature and atmospheric sensitivity and associated instability. Through engineering of surface acceptor materials, charge mobility in the diamond has also seen significant improvement, leading to significant reduction in material resistivity. Alternative chemical surface terminations of diamond have also more recently demonstrated additional routes for the production of high performance electronic devices.
This presentation will attempt to provide an overview of these recent and exciting developments in the diamond electronic devices, and speculate on future directions and the potential impact of this accelerating area of research.

10:45 AM EL11.04/EL14.06.02
MOSFETs on (111) Highly Oriented Polycrystalline 1-Inch Diamond Substrate YukihiroChou[1], FugaAsai[1], KosukeOta[1], AtsushiHiraiwa[1], YoshikiNishibayashi[2] and HiroshiKawarada[1,1]; [1]Waseda University, Japan; [2]Sumitomo Electric Industries, Ltd., Japan

We fabricated 2DHG diamond MOSFETs on a (111) highly oriented polycrystalline 1-inch diamond substrate and confirmed that the devices correctly functioned as a FET. The area of the 1-inch substrate is about 55 times larger than that of conventional 3mm square substrate. In this work, we fabricated 220 devices on the 1-inch diamond substrate, and the yield rate was about 95 percent. We found that the yield rate on the 1inch substrate tends to be much higher than that on the 3mm square substrate.
Diamond has outstanding characteristics as a semiconductor, such as wide band gap (5.5 eV), high thermal conductivity (22 W/cmK), and high breakdown field (10 MV/cm). Therefore,

diamond is expected to be applied to the next generation's RF amplifier and power device. However, a problem in fabricating diamond devices is the low yield rate due to the small substrate size. In this work, we fabricated 2DHG diamond MOSFETs on the polycrystalline 1-inch diamond substrate, and we found that the yield rate was greatly improved.
The highly oriented (111) polycrystalline substrate was fabricated by Sumitomo Electric Industries, Ltd. All the devices on the 1-inch substrate are double-finger structure. Firstly, source and drain electrodes were deposited Ti/Pt/Au (20 nm/ 30 nm/ 90 nm). After H-termination and isolation, 200 nm of Al_2O_3 was deposited as the gate insulator. After that, 300 nm of Al was deposited as the gate electrode. 80 percent of all the devices have the gate length L_G = 5 µm and the others have L_G = 2 µm. There are 3 kinds of source-drain length L_{SD}, 10 µm, 15 µm, and 20 µm. Also, there are 3 kinds of total gate width W_{GT}, 1 mm, 2 mm, and 3 mm.
The highest maximum drain current density was obtained from the device of L_G = 2 µm, L_{SD} = 10 µm, and W_{GT} = 1 mm at V_{GS} = -40 V and V_{DS} = -40 V, and the result was 151 mA/mm. For all the devices that correctly functioned as a FET, the drain current density was in the range of 100 mA/mm to 150 mA/ mm. The decrease in current density was observed as the gate width expanded, but it is assumed that the effect of the grain boundary on the devices is not serious. About 95 percent of yield rate was achieved in this work, and the distribution of the devices that did not function were impartial on the 1-inch substrate. This is because, thanks to the substrate size, photoresists uniformly coated the whole substrate in the fabricating process.
In this work, we fabricated 2DHG diamond MOSFETs on a (111) highly oriented polycrystalline 1-inch diamond substrate and confirmed that the devices correctly functioned as a FET. The highest maximum drain current density was 151 mA/mm, and the yield rate of devices on the 1-inch substrate was greatly improved. Fabricating 2DHG diamond MOSFETs on polycrystalline 1-inch diamond substrate is possible and it contributes to the yield rate improvement.

11:00 AM EL11.04/EL14.06.03
Normally-Off H-Diamond Field Effect Transistors with ZrO_2/Zr Stack Gate FeiWang; Xi'an Jiaotong University, China

A normally-off hydrogen-terminated diamond (H-diamond) field effect transistor (FET) with ZrO_2/Zr stack gate was realized via electron beam evaporation. The threshold voltages range from -0.4 V to -2.5 V with different gate lengths, indicating ZrO_2/Zr could depleted the hole carrier densities at channel area, due to the difference of work function between Zr and hydrogen-terminated diamond and the fixed positive charges in ZrO_2 layer. The on/off ratio and subthreshold swing of device 2 are found to be 10^9 and 128 mV/decade, respectively. The device exhibits a relatively low drain-source leakage current of 10^{-8} mA/mm and an effective mobility as high as 652 cm^2/Vs is obtained at V_{GS} = -2 V. The 2 µm-gate length device shows a maximum drain current density of -74 mA/mm. This work reveals a simple fabrication process for ZrO_2/Zr/H-diamond FET, which will provide an alternative approach for low power device applications.

11:15 AM EL11.04/EL14.06.04
Gate Leakage Suppression of Normally-OFF Diamond FET by Hybrid Gate GenqiangChen and Hong-XingWang; Xi'an Jiaotong University, China

Diamond is a promising material to develop high-power and high-frequency device owing to its wide-band gap, high carrier mobility and extremely high thermal conductivity. Nevertheless, diamond can release its potential on the basis of its n-type doping. Luckily, diamond filed-effect transistor was survived from its hydrogen termination, which can induce a two-dimension hole gas (2DHG). However, the present hydrogen-terminated diamond filed-effect transistor based on 2DHG, naturally demonstrates normally-on operation, which goes against energy saving and safety. Normally-OFF FET is critical for logical circuit and switch systems. Metal-semiconductor (MES) FET with Schottky gate is a good approach to achieve normally-OFF hydrogen-terminated (C-H) diamond FETs, but the drawback is large gate leakage. In this work, a MOS-MES hybrid gate diamond FET (HGFET) with normally-OFF operation and low gate leakage current were attained. The hybrid gate was realized by adding nanoparticles Al_2O_3(nano-Al_2O_3) between Al/C-H diamond interface. The MES formed by Al/C-H plays a role of realizing normally-OFF operation. Of 57 devices, 100% shows normally-OFF operation and the threshold voltage varied from -0.2 V to -1.2 V. The MOS gate Al/nano-Al_2O_3/C-H diamond is used to lower the gate leakage current, which is 10^5-fold lower than that of FET without nano-Al_2O_3.The HGFET was expected to be a member in FET community.

11:30 AM EL11.04/EL14.06.05
High Quality Al_2O_3/(111) (OH)-Terminated Diamond Interface for MOSFETs Fabrication PietroArgenton[1], MartinKah[1], MarineCouret[2], NicolasRouger[2], DavidEon[1] and JulienPernot[1]; [1]University Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, France; [2]Université de Toulouse, LAPLACE, CNRS, INPT, France

The efficiency of power devices is critical nowadays for the rise of renewable energy. Wide-bandgap semiconductors, such as silicon carbide (SiC) and gallium nitride (GaN), have advantages over silicon due to their high breakdown electric field and high-temperature operation. However, p-channel wide-bandgap FETs have poor performance compared with their n-channel counterparts due to low hole mobility, which leads to a high ON resistance and high conduction loss. This has constrained the production of complementary circuits with integrated n-channel and p-channel transistors. Diamond is a wide-bandgap material that has a bulk intrinsic hole mobility very high respectively to SiC and GaN, which makes it promising for use in high-mobility p-channel transistors. Due to the high optical phonon frequency and high acoustic phonon velocity of diamond, the number of phonons that participate in carrier scattering is small. Having all the others wide band gap semiconductors characteristics like high electric field, high breakdown voltage and high thermal conductivity also makes diamond attractive for power applications.
Most diamond power metal–oxide–semiconductor field-effect transistors (MOSFETs) have been fabricated using H-terminated diamond surfaces (and afterwards the surface transfer doping) with their unique properties of two-dimensional hole gas (2DHG). The downside of this concept comes from the close proximity of the negatively charged surface acceptors with the 2DHG, the carrier mobility is limited by surface impurities, and increasing the carrier concentration dramatically decreases the hole mobility. Moreover, the negative charges cause a positive shift in the threshold voltage, leading to normally ON characteristics.
In this work we try to find an alternative by realizing p-type OH-terminated diamond surface, taking advantage of the fact that applying a negative potential to a MOS stack leads to an accumulation regime of holes on the diamond surface. However, this happens only if the Fermi level is not pinned due to interface states. Therefore, a good interface quality between diamond and oxide is needed. We realized a p-type diamond with a boron concentration approximately 10^{17} atom/cm^3 and a thickness of 0.5 µm on (111) EDP substrate followed by a OH-termination using a wet vapour annealing [1]. We have then realized some metal–oxide–semiconductor capacitors (MOSCAP) on top of it and studied their behaviour.
The frequency-dependent capacitance-voltage (C–V) characteristics were examined from depletion to accumulation regimes. The latter one was clearly observed with a very small leakage current. Moreover, we reached accumulation regime around 0V which can lead to a realization of a MOSFET with normally OFF characteristics with very high current in ON state, thanks to the 2DHG. With these promising results, we finally fabricate MOSFETs using the same procedure as MOSCAPs.
In the first part of this presentation, the method will be described in details. Then, the C-V characteristics will be reported and deeply analysed. Lastly, we will show and discuss the first results obtained regarding the MOSFETs and comparing them with finite element simulation as well.

11:45 AM EL11.04/EL14.06.06
Normally-Off Hydrogen-Terminated Diamond FET with High Temperature ALD Grown HfO_2DevanshSaraswat, MohamadaliMalakoutian, KellyWoo and SrabantiChowdhury; Stanford University, United States

Diamond is one of the best candidates for high-power, high-frequency applications due to desirable properties like high breakdown electric field (10 MV/cm), high carrier mobility (3800 cm^2 $V^{-1}s^{-1}$ for holes and 4500 cm^2 $V^{-1}s^{-1}$ for electrons) and high saturation velocity (>10^7 cm/s) [1].
Due to the difficulty in doping by conventional methods, the two-dimensional hole gas (2DHG) layer below the hydrogen-terminated diamond surface has been widely explored for fabricating field effect transistors. Prior studies have reported sheet density in the range of 10^{12}-10^{14} cm^{-3} [2] and mobility of 50-200 cm^2 $V^{-1}s^{-1}$ [3] for the 2DHG, including integrated CMOS operation at high temperatures[4]. For FET fabrication, it is essential to choose a dielectric that can minimize the gate leakage current as well as preserve the 2DHG in the channel. Various dielectrics such as Al_2O_3, ZrO_2, AlN and MoO_3 have been used as a gate dielectric for diamond HFETs. HfO_2 is a widely used high-k dielectric material due its superior dielectric properties, high breakdown field and large band offsets (ΔE_c=2.29 eV and ΔE_v=1.98 eV) with respect to H-terminated diamond [5]. In this work, Al_2O_3 and HfO_2 were compared as gate dielectric for HFETs. Normally off operation with two orders of higher current was achieved with high-temperature atomic layer deposition (ALD) grown HfO_2 in comparison with Al_2O_3 counterpart, as the gate dielectric.

For device fabrication, a (100) CVD-grown diamond substrate was used. The sample was first oxygen terminated by boiling in a 3:1 mixture of H_2SO_4 and HNO_3 at 200ºC for 30 minutes. Then, hydrogen termination was performed in a microwave plasma CVD reactor at 850ºC. This was followed by photolithography and oxygen plasma treatment for device isolation. Then, Ti/Pt/Au adhesion pads were deposited using e-beam evaporation. This was followed by gold deposition on hydrogen terminated regions to form the source and drain ohmic contacts. Subsequently, a 10 nm thick HfO_2 layer was deposited at 300ºC using ALD. Then, Al/Au gate metal contact with a gate length (L_G) of 1.5 µm was formed. The gate to drain distance (L_{GD}) varied from 1.75 µm to 3.25 µm. Finally, source and drain contacts were opened using a 6:1 buffered oxide etchant (BOE) wet etch.

After device fabrication, DC output characteristics were measured using a probe station. A maximum drain output current of 2.05 mA/mm was achieved for a V_{GS}=-4V. Gate leakage current ≤ 10^{-6} mA/mm and a current on/off ratio of 10^7 were measured. A maximum transconductance (g_m) of 2.06 mS/mm was obtained at V_{GS}=-2V. The threshold voltage was determined to be -1.2V, indicating a normally-off performance. In contrast, our Al_2O_3-based FETs showed poor performance which requires further investigation.

The normally-off behavior in this device is likely due to the decrease in the upward bend bending at the H-diamond surface. This is possibly a result of the desorption of acceptor species during the high-temperature ALD growth. Dielectrics grown at high temperatures are thermally more stable, making the device suitable for high-temperature applications. Further

improvement in the device performance can be possible by exposing the substrate to a NO_2 gas environment and by using multiple dielectric layer stacks to improve the channel mobility. The current results show the potential of using high-temperature ALD grown HfO_2 for achieving normally-off behavior in diamond HFETs[6].

Two-Inch High Quality Diamond Heteroepitaxial Growth on Sapphire Seong-WooKim; Orbray Co, Ltd, Japan

Diamond semiconductors, owing to their superior properties compared to SiC and GaN, can be used to develop high-end applications, such as power devices, high frequency devices, quantum devices, and sensors. However, the inch-scaled diamond wafer is essential. In this study, Two-inch-diameter high-quality diamond (001) layers were grown on sapphire (11-20) A-plane misoriented substrate. Step-flow growth in diamond is realized thanks to misoriented substrate, and releases tensile strain in diamond layer. Consequently, even if microneedle technique [1] is not used, without breakage, diamond layer naturally was delaminated from the sapphire substrate. The FWHM of (004) and (311) X-ray rocking curves of the diamond layer grown on sapphire substrate misoriented by 7° towards [1-100] direction were 75 and 140 arcsec, respectively, the lowest ever.

In this study, results on 3 types of high-end applications will be discussed. One of them is the world largest diamond detector with the dimensions of 20 mm ' 20 mm ' 0.5 mm was fabricated from a 30 mm ' 30 mm heteroepitaxial diamond wafer. The device demonstrated a nuclide discrimination capability for 133Ba, 137Cs and 60Co based on the pulse-height difference. The electrode was used as a cathode to apply -500 V bias voltage. The anode on another side was connected to a charge sensitive preamplifier. The anode was maintained at ground potential. The output signal from the preamplifier was acquired with a digitizer. A digital trapezoidal filter was applied to the waveforms to obtain pulse height spectra.

10:30 AM *EL11.07/EL14.10.02
Wide Bandgap Material Transfer as a Flagship Technology for Future High Power Devices JulieWidiez, GuillaumeGelineau, JérémieChrétien, CédricMasante, AlexandreMoulin, VladimirPrudkovskiy, NicolasTroutot, EmmanuelRolland, PatriceGergaud, DenisMariolle, SophieBarbet, LucieCorbin, VincentAmalbert, PierrickGilles, FrédéricMilesi, FrédéricMazen and LucieLe Van-Jodin; CEA-LETI, France

Today’s environmental requirements for energy efficiency call for better management of electrical energy with minimum leakage at all levels: from DC phone chargers to power transmission via electrical vehicles. Wide bandgap (WBG) semiconductors are better suited for high-voltage and low-loss power devices than traditional Si-based power devices. The most commonly used are SiC, GaN and diamond with bandgap values of 3.2 eV, 3.4 eV and 5.5 eV respectively. However, the challenge of producing these competitive materials economically and efficiently remains. For example, the fabrication of SiC substrates is very energy-intensive, since it is carried out at 2400°C, i.e. 1000°C higher than for Si. To cite another example, the size of diamond substrates today is no more than a few square millimeters, while 300 mm Si wafers are on the market, limiting the appeal of such a material.
The ability to transfer only a thin layer of high-quality WBG material on a substrate that offers either the advantage of being less expensive or the advantage of its own function (thermal, electrical or insulating…) is therefore very interesting. The Smart Cut™ process combines an ion implantation with a bonding step and allows to create a structure that otherwise could not be made using deposition techniques. Relatively new direct covalent bonding techniques now make it possible to relax the draconian characteristics imposed on surfaces and substrates to enable such bonding with materials renowned for their outstanding properties. This opens up new possibilities in terms of assembly.
Significant improvements in electrical performance have been achieved by combining the advantages of a polycrystalline substrate with very low resistivity and a high-quality 4H-SiC transferred layer [1, 2]. However, the H^+ ion implantation used for the Smart Cut™ process leads to electrical deactivation and partially disorders the material. We report studies of healing and reactivation mechanisms of a transferred 4H-SiC thin film over a wide range of temperatures. After 950°C (splitting temperature), the thin SiC layer is still insulating. A 1300°C anneal allows the material to fully relax and reorganize with no further evolution beyond this temperature. The dopant reactivation takes place at higher thermal budgets. The transferred layer then recovers the donor doping level and electrical conductivity after 1700°C [3].
We also develop the transfer of IIa diamond onto larger and less expensive substrates [4]. The two key technological steps of the Smart Cut™ process (ion implantation and bonding) are studied:
A simplified process using a single ion implantation step at high temperature has been developed [5]. The diamond material after such implantation is studied in terms of sp2/sp3 ratio (XPS), hydrogen concentration (SIMS) and exfoliation capability.
A wide range of bonding conditions are studied: direct bonding (manual, Surface Activated Bonding - SAB -), metal bonding (Ti, Au...) with a special care on bonding parameters (the flatness, the coefficient of thermal expansion and the roughness values). This part is particularly difficult because of the remarkable properties of diamond: its low coefficient of thermal expansion and its hardness make surface preparation and adhesion very challenging.

Low-Temperature Direct Bonding of Diamond—Approach for Fabricating Low-Thermal-Resistance Widegap Devices NaoteruShigekawa[1], RyoKagawa[1], JianboLiang[1], YasuoShimizu[2], YutakaOhno[2] and YasuyoshiNagai[2]; [1]Osaka Metropolitan University, Japan; [2]Tohoku University, Japan

Characteristics of semiconductor electron devices such as output powers are limited by their temperature rise due to Joule heating in operation (self-heating effects). Device structures with the lowest thermal resistance are, consequently, one of the most important topics in R&D for advanced devices, especially for devices with widegap semiconductors that handle high output powers with high frequencies. Diamond is assumed to be the ideal material as heat spreader because of its high thermal conductivity and excellent electrical properties. In this presentation, we describe results that we obtained by directly bonding of diamond to Si and GaN and discuss the future prospective of direct bonding of diamond. We used surface activated bonding (SAB) technologies, in which two wafers are bonded after removing native oxides on their surfaces by irradiating them with fast atom beams of Ar (surface activation process). In SAB, bonding process is completed without heating bonded wafers in most cases, i.e., junctions of semiconductors with different coefficients of thermal expansion (CTE) can be fabricated.
We bonded a high-pressure high-temperature (HPHT) diamond (001) wafer and a Si (100) wafer using SAB. We found that the diamond//Si junction withstood a 1000-°C annealing in spite of a large difference in CTEs between diamond and Si. A high-resolution TEM observation revealed that a poly crystalline SiC intermediate layer was formed at the bonding interface after the annealing, which was assumed to play a role of reducing impacts of the difference in CTEs.
We prepared a GaN//diamond junction by bonding a GaN (0001) surface grown on Si (111) wafer to a diamond (001) wafer and removing the Si (111) wafer for the growth of nitride. We annealed the GaN//diamond junctions at temperatures up to 1000 °C and found that the junctions were also tolerant against such a high-temperature annealing.

Recently we transferred an AlGaN/GaN epi layer to diamond using SAB and subsequently fabricated HEMTs. Ohmic contacts on nitride were formed by an annealing at 800-°C after bonding to diamond. The temperature rise of the GaN-on-diamond HEMTs was found to be lower than that of on-Si HEMTs with the same nitride structure. The results imply that direct bonding of diamond is promising for fabricating low-thermal-resistance semiconductor devices, especially after transferring active device layers to diamond wafers.

Diamond has unique material properties well suited for a broad range of quantum and electronic technologies. However, heterogeneous integration of diamond with other materials remains a challenge, mainly due to limited heteroepitaxial growth of single-crystal diamond. Here, we discuss a directly bonded single-crystal diamond membrane technique that enables a wide variety of materials integration, including bonding diamond to silicon, fused silica, sapphire, thermal oxides, and lithium niobate. Our direct bonding process combines diamond overgrowth, membrane transfer, and dry surface functionalization, resulting in minimal contamination for high yield and scalable integration. We have demonstrated direct-bonded diamond membranes with thicknesses as thin as 10 nm, and observe a sub-nanometer interfacial region. We demonstrate the use case for integrating these direct-bonded membranes for high-quality nano-photonics, and total internal reflection fluorescence (TIRF) microscopy applications. The demonstrated process provides a key advance in the necessary toolkit needed to realize heterogeneous diamond-based hybrid systems for quantum and electronic technologies.

Diamond Integration on GaN HEMTs: Overcoming the Challenges for Device-Level Thermal Management MohamadaliMalakoutian, RohithSoman, KellyWoo, AnnaKasperovich, JeongkyuKim and SrabantiChowdhury; Stanford University, United States

In the realm of higher frequency devices, where the gain is of utmost importance, the effective management of heat becomes crucial to maintain Power Added Efficiency (PAE) [1]. Ensuring efficient heat removal necessitates minimizing the thermal boundary resistance (*TBR*) between the heat source and the heat spreader, as well as establishing a low thermal resistance path to the heat sink [2]. The integration of diamond near the hot spot holds excellent potential due to its exceptional thermal properties. By incorporating diamond, heat can be effectively spread, thereby enhancing the heat transfer coefficient [3, 4]. The integration of diamond onto GaN HEMTs poses significant challenges, regardless of whether a diamond-first or device-first approach is employed.
In the diamond-first approach, the primary challenge lies in diamond surface roughness, which imposes a limitation on gate length <2 µm through lithography, non-uniformity in the diamond etching, and contacts/pads damage after diamond etching. To address this issue, we have implemented a polishing technique through ion-milling, achieving a surface smoothness of less than 10 nm RMS roughness before carrying out E-beam lithography, and developed a more selective etching process using O_2/SF_6 mixture in RIE. Additionally, a slanted etching technique was developed for rough diamond surfaces that starts with a 2 µm opening at the top and achieves a gate footprint of less than 100 nm, suitable for X- to W-band applications.
In the device-first approach, two key challenges arise: gate dielectric leakage (2-10 mA/mm) and ohmic loss (R_c=1.4 Ω.mm, R_{sh}=250 Ω/■). To overcome gate leakage, we have modified the gate metal stack from Au/Ni to Mo and employed a low-temperature (LT) diamond growth technique at 350-400°C [5], effectively reducing the leakage to <1 µA/mm. As for ohmic loss, we have successfully tackled it by incorporating a thicker N+ regrown region and using a 400°C diamond growth temperature (R_c=0.24 Ω.mm, R_{sh}=225 Ω/■). These combined measures have proven to be effective solutions in mitigating gate dielectric leakage and reducing the ohmic loss for higher current capabilities ~ 1 A/mm.
We have successfully integrated LT diamond on GaN HEMTs using the above-mentioned approaches. By implementing the all-around diamond scheme and connecting the top diamond to the heat sink through diamond vias, the channel thermal resistance (R_{th}) was reduced by 34% from 6.9 to 4.6 K.mm/W, realizing a higher heat transfer coefficient from the channel. This integration resulted in no dispersion (pulsed I-V at 400 ns gate pulse) and lower channel temperature (T_{ch}) compared to the case without diamond. With low *TBR* (3-5 m^2K/GW) and high thermal conductivity (*TC*:300-1000 W/m/K depending on the grain size and thickness), the average and peak T_{ch} dropped by 35% (200 to 130°C at 25 W/mm, measured by I-V thermometry) and over 50% (120°C at 20 W/mm, measured by thermoreflectance imaging), respectively [6]. Our technique not only addresses thermal management challenges for GaN-based power amplifiers but is also compatible with other technologies such as InP, Ga_2O_3, SiC, and Si. Proper thermal management can enhance the device's reliability and lifetime while providing a higher power at higher frequencies.

Diamond/Graphene (carbon sp^3-sp^2) Heterojunctions for Neuromorphic Electronic Devices KenjiUeda; Waseda University, Japan

Diamond/graphene (carbon sp^3-sp^2) interfaces have attracted much attention because they are sources of various interesting electronic phenomena. Many theorists suggest hybrid structures of diamond and graphene exhibit interesting electronic characters, however there are only limited experimental reports on electronic characters of carbon sp^3-sp^2 interfaces.
Recently, we newly found that diamond/graphene heterojunctions became photo-controllable memristors (photomemristors), which are optically controllable memory-resistors with both photo-switching and memory functions [1, 2]. The junctions also showed characteristic response to optical pulses, and brain mimic memory functions, that is, change of photomemory time from shorter to longer memory time depending on irradiated numbers of optical pulses [3]. These behaviors are analogous to transitions from short to long-term memory states of biological synapses. In addition, arrays using the diamond/graphene junctions can function as special types of image sensors which have selective memory function of optical information depending on the relative importance of the data as human brains perform.
These results suggest the diamond/graphene (C sp^3-sp^2) junctions are promising for fabricating novel neuromorphic visual information processing systems that are modulated by specific interests.

Diamond Material Pave the way for the Next Generation of Neuronal Implants LionelRousseau[1], EmmanuelS. Scorsone[2], GaëlleLissorgues[1], PatrickPoulichet[1], OlivierFrançais[1], BlaiseYvert[3], ClementHebert[3], SergePicaud[4] and JulieZhang[4]; [1]Université Gustave Eiffel - ESIEE Paris,ESYCOM UMR 9007, France; [2]Université Paris-Saclay, CEA, France; [3]GIN, France; [4]Sorbonne Université/ INSERM UMR_S968/ CNRS UMR 7210, France

Brain Computer Interface (BCI) offers a way to restore neuronal dysfunction due to degenerative diseases or accidents. Thus, it becomes possible to restore vision with retinal implant or to offer a way for tetraplegic to control a robot by thinking with electrodes implanted in the cortex and recently to do a digital bridge for paraplegic patient to stand-up and walk. But today these systems are limited by their insufficient stability. Neuronal implants require to operation during 10 years of lifetime, and collect data 24/7 and for 10 hours or more every day. But after several months of implantation, some modification can appear such as swelling of the passivation polymers thus inducing current leakage, or degradation of the electrode material.

With the last development of diamond growth process, it is now possible to integrate this material in micro and nano fabrication process as a standard material to produce sensors or neuronal implants Diamond properties are very attractive for medical application. Diamond is a biocompatible material and it has no native oxide, so there is no degradation when the structure is placed in water or harsh environment. Diamond is also a high density material, so there are no species that can migrate inside diamond In addition, conductive diamond, boron doped diamond (BBD) has a wide electrochemistry window that allow to give possibility to inject more current compare to classical metallic electrode.

We have developed a specific process to achieve a very thin full diamond implant combine conductive diamond for the electrode and intrinsic diamond as protective layer. With this structure we take advantages and strength of conductive and intrinsic diamond to achieve an hermetic implant. To validate our full diamond implant, we have done electrical characterizations impedance Spectroscopy and Cyclic Voltammetry. In-vivo experiments have been conducted on several set-ups to record Visual Evoked Potential and Auditory Evoked Potential, assessing the proper functionality of our implants.

To demonstrate their stability, we developed an accelerate long life set -up. The devices placed on PBS solution at a temperature of 77°c. Follow Arrhenius law, at this temperature acceleration factor is around 16, that means for one month in solution, is equivalent to one year and 4 months. This set up is composed of hotplate, and aluminum piece where we placed a hermetic containers with Phosphate Bovine Solution (PBS) and samples. To control integrity of samples an impedance meter is used to record periodically impedance. This type of set-up is also answer at ethical issue and reduce number of animal experimentation.

With this ageing setup, we compared InterDigited Electrodes (IDE) composed of metallic IDE covered with either intrinsic diamond or polymer like SU8. After 29 weeks (around 9 years), diamond is more stable with a variation of 3 % at 1 kHz (frequency of interest for neurons recording), compared to SU8 with 50 % of variation.

Therefore, intrinsic and doped diamond are very attractive for the next generation of neuronal implants.

Superconducting Diamond Microwave Resonators GeorginaM. Klemencic, JeromeCuenca, ThomasBrien, SoumenMandal, ScottManifold, SimonDoyle, AdrianPorch and OliverA. Williams; Cardiff University, United Kingdom

Superconducting microwave resonators form the foundation of an increasing number of superconducting technologies for quantum information processing[1] and radiation detection.[2] A specific example is the Kinetic Inductance Detector (KID), which uses a high-Q resonator as a photon detector for purposes ranging from astronomy to security.[3]

In a KID, radiation is detected when an incoming photon breaks a Cooper pair which decreases the frequency of the microwave resonator. The relative size of this shift increases with the penetration depth of the material. Noise in the form of random fluctuations in the resonant frequency can occur due to two-level systems (TLSs), generally ascribed to dangling bonds in amorphous oxides that form at the surface of metallic superconductors. For practical applications, optimising for both sensitivity and signal-to-noise ratio, the superconducting material used for a microwave resonator should ideally have a high penetration depth and a low population of TLSs.

Here, I will present our results on a detailed characterisation of a λ/2 microwave resonator with a fundamental frequency of 409 MHz at 300 mK patterned from boron-doped nanocrystalline diamond (BNCD).[4] We compare the observed resonant frequency to simulations based on the device geometry alone and show that the frequency is reduced by more than half, indicating a very large penetration depth enabled by the granularity of the material. I will also present early measurements of the effect of noise on this resonator and make a comparison to a single crystal equivalent device.

Our data show that BNCD is a good candidate for fabricating microwave resonators requiring a high kinetic inductance fraction. Knowledge of the penetration depth of a material is also vital for the design of low-frequency superconducting devices, including SQUIDs. Our results, therefore, pave the way for more complex superconducting circuits based on BNCD.

Reduction of Etching Damage and SQUID Operation of Single-Crystalline Diamond Josephson Junctions by Ridge Conduction Structure YutaroHashimoto[1], ChiyukiWakabayashi[1], YasuhiroTakahashi[1], YoshihikoTakano[2], MinoruTachiki[2], ShuuichiOoi[2] and HiroshiKawarada[1,3]; [1]Waseda University, Japan; [2]National Institute for Materials Science, Japan; [3]The Kagami Memorial Research Institute for Materials Science and Technology, Japan

Josephson junctions (JJs) are weak junctions between two superconductors and have been applied to various devices such as transmon qubits and superconducting quantum interference devices (SQUIDs). SQUIDs are extremely sensitive magnetic sensors. Typical materials for JJs, such as Nb and Al, are weak against oxidation and abrasion. In contrast, superconducting boron (B)-doped diamond has high resistance to oxidation and abrasion. So, it is expected to be applied to robust and highly resistant to degradation superconducting devices.
The first SQUID using superconducting B-doped diamond was reported by S.Mandal[1]. This SQUID using nanocrystalline diamond consists of JJs with 250 nm to 100 nm linewidth weak links. The operating temperature was 400 mK at low magnetic field and 40 mK at high magnetic field, and the maximum voltage modulations ($V_{p\text{-}p}$) to magnetic field, which is a parameter related to magnetic sensitivity, was 0.35 μV. While the first SQUID using single-crystalline diamond was constructed by JJs with a step edge structure[2].Operating temperature and $V_{p\text{-}p}$ of up to 2.6K and 1.1 μV were reported for this type SQUIDs. Single-crystalline superconducting diamonds have different superconducting transition temperatures T_c depending on the growth orientation[3]. (001) B--doped diamond with low T_c (<4.2 K) grows on the step with 230 nm slope 50° produced by etching and regrowth of un-doped diamond, and the discontinuity with the heavily boron doped (B:8 x 10^{21}cm^{-3}) (111) layer with high T_c (10 K) forms the step edge JJ.For operating temperatures above the liquid He temperature (4.2 K), it was necessary to fabricate JJs and SQUIDs using only the heavily B-doped (111) layer. SQUIDs consisting of trench-type JJs with the boundaries of discontinuous (111) sectors on trenches formed by focused ion beam (FIB) operated at 10 K and the maximum $V_{p\text{-}p}$ was 4.0 μV [4]. However, the trench shape formed by FIB was unstable, and it was difficult to obtain uniform JJs characteristics. Therefore, JJs with a single-step structure, consisting of a discontinuity in the heavily B-doped (111) layer deposited on top of a minute step of about 40 nm formed by reactive ion etching (RIE), has been proposed[4][5]. SQUID with single-step JJs is simple and highly reproducible, and operation at 9.5 K has been achieved. However, the $V_{p\text{-}p}$ of single-crystal diamond SQUIDs was still small compared to SQUIDs made of other materials. Therefore, we have tried to improve $V_{p\text{-}p}$ by increasing the normal resistance of JJs through JJ width miniaturization. For SQUIDs with single-step JJs, $V_{p\text{-}p}$ increased significantly from 1.4 μV to 47.7 μV by miniaturizing JJs width from 15um to 5um. In the JJs miniaturized down to less than 5 um, however, the etching damage

became prominent, and $V_{p\text{-}p}$ could no longer be expected to improve with this type of miniaturization.
In this study, we propose a new JJ structure, the ridge conduction structure, which is unaffected by etching damage. In ridge conduction structure JJs, first a narrow ridge structure is formed on the undoped substrate by RIE, and then the heavily B-doped diamond has been grown along the ridge. JJs with a 40 nm step as in single-step JJs are formed on top of the ridge structure. The flow path of superconducting current can be restricted on the ridgelines of (111) surface, because growth sectors different from (111) sector show low T_c superconducting on sidewalls without etching the B-doped layer. As a result, we confirmed the operation of JJs and SQUIDs with a minimum JJs width of 3 μm using this structure. Also, we confirmed that the ridge conduction structure reduces etching damage by reducing the residual resistance at 300 nm nanobridges with this structure.

Diamond Quantum Devices: Surface Termination Characterization and Methods AlastairStacey; RMIT University, Australia

Diamond quantum devices are being increasingly explored for technological applications, with a common need being quantum defects - such as NV centres - very near to the diamond surface. These surfaces are known to host crystalline defects and a range of crystal termination chemistries, all of which can affect the near-surface defect centres in a variety of ways. In this talk we will present our efforts to quantify these defects, while simultaneously engineering the diamond surface with chemical and electronic functionalities.

3:45 PM EL14:03.02
Environmental Control of Shallow Nitrogen-Vacancy Sensors in Oxygenated (100) Diamond Surface AdamGali[1,2], AntonPershin[1,2] and PeterUdvarhelyi[1,2]; [1]Wigner Research Centre for Physics, Hungary; [2]Budapest University of Technology and Economics, Hungary

Quantum sensing with nitrogen vacancy (NV) center in diamond is an emerging technology to detect nuclear spins and chemical species with nearly atomistic resolution. This is achieved by translating the magnetic- and electric-field fluctuations from the respective sources directly to an optical signal, detected by a change in the fluorescence intensity of the NV center. In this work, we develop realistic models of the diamond-solvent interfaces to elucidate new sensing applications for the NV center, which are based on the reversible variations in the surface potential. More specifically, we show that aqueous diamagnetic electrolyte solutions such as sodium chloride can be sensed by an increase of the spin relaxation time of near-surface NV-center ensembles. Our first principles calculations combined with interface modeling identify a critical role of the interfacial band bending which leads to a stabilization of fluctuating charges at the interface of an oxygen-terminated diamond. In addition, we demonstrate that aqueous environment enables to recover a contrast in the optically detected magnetic resonance experiment for the shallow NV centers at cryogenic temperatures. Both predicted phenomena were directly confirmed in experiments by observing the optically detected magnetic resonance and spin relaxation times of the ensemble and single NV-centers.

This work was supported by the National Research, Development, and Innovation Office of Hungary (NKFIH) grant No. KKP129866 of the National Excellence Program of Quantum-coherent materials project and the Quantum Information National Laboratory supported by the Ministry of Innovation and Technology of Hungary, the QuantERA II MAESTRO project, and the Horizon Europe EIC Pathfinder QuMicro project (grant No. 101046911).

4:00 PM EL14:03.03
Pick-Flip-And-Place Hybrid Integration of a Single-Crystal Diamond Nanobeam with an Ensemble of Nitrogen-Vacancy Centers RyotaKatsumi[1,2], KosukeTakada[1], ShunNaruse[1], KentaKawai[1], DaichiSato[1], TakeshiHizawa[1] and TakashiYatsui[1,2]; [1]Toyohashi University of Technology, Japan; [2]The University of Tokyo, Japan

Nitrogen-vacancy (NV) centers in single-crystal diamond have been intensively studied for various quantum applications such as quantum sensing, quantum communication, and quantum simulation. To accelerate advances in quantum technologies based on NV centers, implementing micro/nanostructures in diamonds is essential. Because of recent advancements in etching technologies for diamond photonics, various nanophotonic structures, including photonic crystals, ring resonators, and disk resonators, have been successfully fabricated to date.
Combining color centers in diamond with well-developed integrated photonics using hybrid integration techniques such as transfer printing provides a powerful route toward large-scale and multifunctional quantum devices. However, the existing etching technology for diamond photonics is inherently not compatible with reported hybrid integration approaches. For example, the bottom of a diamond nanostructure fabricated using angled etching is a triangular shape that makes it difficult to place on other substrates using conventional pick-and-place techniques. Therefore, it is significant to develop hybrid integration techniques with high yields for scalable diamond quantum photonics, irrespective of the sample structure.
In this work, we propose “pick-flip-and-place” transfer printing for the hybrid integration of a diamond NV triangular nanobeam on chip in a deterministic manner. This approach provides a flat diamond-chip interface and allows for the integration of NV centers on chip with a near-unity success rate, irrespective of the width and shape of the diamond nanostructures. In experiment, we demonstrate that an integrated diamond nanobeam containing an ensemble of NV centers can function as a nanoscale quantum sensor. We believe that the proposed approach paves the way for the realization of scalable diamond quantum photonics assisted by cutting-edge integrated photonic technologies.
We describe the basic procedure for the proposed nanofabrication and hybrid integration processes based on transfer printing. First, triangular nanobeam containing NV centers with high density (300 ppb) were prepared via vertical dry etching of diamond substrate, followed by a diamond undercut process based on angled etching. We then used transfer printing to select a suitable diamond nanostructure from the processed diamond substrate using a polydimethylsiloxane (PDMS) film with weak adhesion. This “weak” PDMS was flipped to lift off the nanostructure from the flipped film using a PDMS film with strong adhesion. This process allows for a flat interface between the diamond nanostructures and photonic chip, which is necessary for high-yield integration. Finally, the transferred diamond nanobeam was integrated by slowly peeling off the film onto an SiO_2 substrate, which is a common low-refractive-index material in integrated photonics for efficient light confinement in a waveguide. It is notable that we can perform hybrid integration irrespective of device structure and target materials by using the proposed “pick-flip-and-place” integration approach, enabling us to combine diamond quantum photonics and state-of-the-art photonic integration technology.
To experimentally show that the fabricated device could function as a nanoscale quantum sensor, we performed optically detected magnetic resonance (ODMR) measurements on integrated NV centers. We confirmed an ODMR dip at a microwave frequency of 2.88 GHz with an ODMR contrast of ~0.006 and the linewidth of 7.8 MHz, which is comparable to those measured for bulk diamond. Therefore, we, for the first time, succeeded in the hybrid integration of a diamond nanobeam with an ensemble of NV centers on a chip for quantum sensing. The proposed approach based on transfer printing provides a deterministic route toward a scalable combination of diamond quantum photonics and cutting-edge integrated photonics technologies.

4:15 PM EL14:03.04
Characterization of Nitrogen Aggregation in CVD-Grown Diamond EvelinePostelnicu[1], ChristineJilly-Rehak[1], LillianB. Hughes[2], SimonMeynell[2], HaoxueYan[1], TriNguyen[1], AniaBleszynski Jayich[2] and KunalMukherjee[1]; [1]Stanford University, United States; [2]University of California, Santa Barbara, United States

Understanding the mechanisms behind incorporation of dopants in chemical vapor deposition (CVD)-grown diamond is paramount to optimizing nitrogen vacancy (NV)-center based quantum devices and those for power electronics. The mechanism of nitrogen incorporation during CVD growth, and the resulting density and spatial distribution of the nitrogen are not well understood. In the context of limited incorporation of dopants such as nitrogen, there is evidence that features on the growth surface of diamond, like step bunching and hillocks, strongly segregate these impurities. A spatially resolved study of dopant distribution around these growth features would provide more insight into the impact on devices and point to strategies to obtain higher densities of dopants. To this end, we have studied nitrogen aggregation in hillocks formed in (100) homoepitaxial diamond grown via plasma-enhanced chemical vapor deposition (PECVD).[1] ^{15}N enriched nitrogen gas was utilized during growth to form a near-surface, 7 nm-thick delta-doped ^{15}N layer. Hillock growth has been studied extensively in diamond and has been attributed to a variety of mechanisms, including spiral growth on a screw dislocation core[2], heterogeneous nucleation at foreign crystallite sites[3] and penetration twins[4], as well as repeated 2D nucleation on miscut diamond substrates.[5] Meynell et al confirmed an inverse relationship between hillock density and substrate miscut and also observed nitrogen accumulation in hillock defects which correlated to a higher NV density.[6] Using panchromatic and spectrally resolved cathodoluminescence (CL) mapping, we observed greater NV emission from hillock edges in particular. We utilized nanoscale secondary ion mass spectrometry (nanoSIMS) to spatially resolve ^{15}N concentration (measured as the $^{12}C^{15}N^-$ ion) with ~50-70nm resolution, using a 20 pA Cs^+ ion beam and a mass resolution greater than 9000 to resolve nearby isobaric interferences. NanoSIMS confirmed ^{15}N aggregation in hillock edges, which we conclude directly correlates to an increase in NV center density. Previous broad-area SIMS measurements identified 2×10^{16} cm^{-3} ^{15}N density in the uniform regions of the delta-doped layer. By comparing the local $^{12}C^{15}N^-$ counts per volume in the hillock defect to that of the uniform regions, we identified ^{15}N density of 1.2×10^{18} cm^{-3} in the hillock defects, a nearly two order of magnitude increase compared to the delta-doped layer. We will show how volumetric SIMS scans using nitrogen as a tracer provide additional insight into the growth mechanism of these

surface features. Understanding these can lead to future NV-based device applications that intentionally harness dopant aggregation.

Two-Dimensional Spin Systems in PECVD-Grown Diamond with Tunable Density and Long Coherence for Enhanced Quantum Sensing and Simulation LillianB. Hughes[1], SimonMeynell[1], ZhiranZhang[1], WeijieWu[2], EmilyDavis[2], ZilinWang[2], BingtianYe[2], NormYao[2], KunalMukherjee[3] and AniaBleszynski Jayich[1]; [1]University of California, Santa Barbara, United States; [2]Harvard University, United States; [3]Stanford University, United States

Solid-state spins constitute a powerful platform for quantum technologies. Dense ensembles of coherent spins provide a starting point for investigating strongly interacting spin systems in which novel, many-body states can arise with applications in both quantum simulation and sensing. Dimensionality plays a critical role in the nature of many-body states, with reduced dimensionality giving access to unique phases and phenomena such as interaction-driven localization or dipolar-driven spin squeezing. For sensing applications, a dense 2D layer of sensors in close proximity to a sensing target exhibits enhanced spatial resolution (set by the depth of the layer) compared to a 3D ensemble at the same volumetric density, while benefiting from either $1/\sqrt{N}$ classical sensitivity enhancements or entanglement-driven enhancements. Lastly, dense 2D ensembles could serve as a starting point for targeted, on demand formation of individual, optically resolvable defects at specific locations, such as inside nanostructures. Altogether, creating thin spin layers with tunable density is of intense current interest but has been minimally explored in solid-state electronic spin systems to date.
Defects in diamond, such as nitrogen-vacancy (NV) centers and substitutional nitrogen (P1 centers), are particularly promising solid-state platforms to explore. However, the ability to controllably create coherent, two-dimensional spin systems and characterize their properties, such as density, depth confinement, and coherence has been an outstanding materials challenge. We present a refined approach to engineer dense (> 1 ppm*nm), 2D nitrogen and NV layers in both (100) and (111) diamond using delta-doping during plasma-enhanced chemical vapor deposition (PECVD) epitaxial growth. We employ both traditional materials techniques, *e.g.*, secondary ion mass spectrometry (SIMS), alongside NV spin decoherence-based measurements to characterize the density and dimensionality of the P1 and NV layers. We present depth confinement of the spin layer down to < 4 nm, high (up to 0.74) ratios of NV to P1 centers, and reproducibly long NV coherence times which are dominated by dipolar interactions between the engineered P1 and NV spin baths. Altogether, the results of our joint materials and qubit-based approach are key elements in the engineering of solid-state-spin systems for the next generation of quantum technologies.[1-2]

Photophysics of the SnV Center in Diamond PhilippFuchs[1], SoniyaNuchikkat[1], JanFait[1], JohannesGoerlitz[1], MichaelKieschnick[2], JanMeijer[2] and ChristophBecher[1]; [1]Universität des Saarlandes, Germany; [2]Universität Leipzig, Germany

For many applications in the field of quantum information processing stationary qubits are required, providing long-lived spin coherence and suitable level schemes for coherent control and efficient optical read out. Color centers in diamond, more specifically the group-IV-vacancy centers, have emerged as promising candidates among solid state qubits. They exhibit favorable properties such as individually addressable spins with long coherence times and bright emission of single, close to transform limited photons. Recent experiments have shown that the negatively charged tin-vacancy center (SnV) [1] combines long spin coherence times at conveniently achievable cryogenic temperatures (>1K) [2,3] with truly lifetime-limited transition linewidths down to 20 MHz [1].
However, exploiting these properties requires active stabilization of the charge state, as the SnV center upon resonant laser illumination can be easily ionized to its double negative charge state (SnV^{2-}) which is optically inactive [3]. To prevent ionization, illumination with a second light field in the blue spectral range is required. We find that the charge stabilization requires the presence of additional defects in the vicinity of the SnV center such as di-vacancies [3] in the bulk or sp^2 defects on the surface [4].
Here, we propose a simple rate equation model for the SnV center photophysics that includes this ionization process. We apply the model to an extensive set of measurements on different SnV centers, along with a thorough characterization of the efficiency of our measurement setup. We conclude that a charge-stabilized SnV^- center is a nearly ideal single photon source in terms of quantum efficiency, since we can describe any reduced photon rate by ionization to the optically inactive SnV^{2-} charge state without assuming other non-radiative decay channels. We further discuss the occurrence of fluctuating background emission, its suppression via thermal oxidation in air atmosphere and the role of surface defects in the charge transition cycle.

Disposable Electrochemical Biosensor for Ultrasensitive Detection of Salivary Cortisol on a Non-Covalently Modified Laser-Induced Graphene Surface for Stress Monitoring AtulSharma, AliaWolff, AyannaThomas and SameerR. Sonkusale; Tufts University, United States

Monitoring stress indicators (such as cortisol) is crucial for understanding and managing the root cause of several cognitive, neurological, cardiovascular and endocrinological diseases. Cortisol negatively affects the regulation of various physiological processes such as carbohydrate metabolism and blood glucose levels. Long-term stress can disrupt homeostasis in the cardiovascular, renal, skeletal, and endocrine systems, leading to the development of chronic diseases [1,2]. Because of its central role, continuous monitoring of cortisol levels in the human body is critical for health and wellness. Current diagnostic techniques are complex and performed at centralized facilities by qualified specialists rather than at the site of therapy, which is critical for real-time monitoring. Electrochemical biosensors based on graphene's conductivity and flexibility are appealing in such contexts. Towards the goal of routine stress-level monitoring, this work realizes the design and development of an ultrasensitive and disposable immunosensor based on vertically aligned laser-induced-graphene (LIG) electrodes as a transducer surface for non-invasive salivary cortisol monitoring via differential pulse voltammetry (DPV) signal transduction mechanism. The LIG electrode was used due to its wide scalability, high electrochemical stability, increased number of reaction sites, efficient electrical conduction owing to the increased surface area and structurally more uniform alignment of the graphene layer conductivity, and low cost [3]. The LIG electrodes were fabricated using a laser ablation technique (in-house). Before use, the surface of the electrode was cleaned by cyclic voltammetry in 0.50 M sulphuric acid containing 0.10 M KCl as electrolyte. Later, the LIG electrode surface was chemically functionalized with a self-assembled monolayer of pyrene-NHS (1-Pyrenebutyric acid N-hydroxy succinimide) ester incorporating an NHS-activated functional group for the receptor (antibody) immobilization. Furthermore, a monoclonal antibody to

salivary cortisol (mAb) was incubated on the Pyr-NHS-LIG electrode surface and immobilized via peptide bond formation between the carboxyl terminal of the crosslinker and the amine terminal of the antibody. This step is followed by electrode passivation to incorporate an antifouling layer. LIG's structure and electrical conductivity were preserved by using the non-covalent functionalization of Pyr-NHS ester. Cortisol complexation with immobilized mAb-Cort resulted in ferri/ferro redox electrochemistry-mediated measurement. Under optimum experimental settings, the immunosensor performance exhibited a dynamic working range from 100 $fgmL^{-1}$ to 10.0 $ngmL^{-1}$ (R^2 = 0.9982) with a detection limit of 10.0 $fgmL^{-1}$ for cortisol (n=3). The developed immunosensor was successfully deployed to assay human salivary cortisol and showed a strong correlation with established laboratory methods (e.g., ELISA). This offers great promise for point of care monitoring of diseases.

Reliable Formation of Diamond p-Type Channel by Additional Negative Ions Formed from Corona Discharge XuezhenJia[1], KentoNarita[1], KosukeOta[1,2], AkiraTakahashi[1], RyosukeYamamoto[1], AtsushiHiraiwa[1], TatsuyaFujishima[2] and HiroshiKawarada[1,2,3]; [1]School of Fundamental Science & Engineering, Waseda University, Japan; [2]Power Diamond Systems, Inc., Japan; [3]The Kagami Memorial Laboratory for Materials Science and Technology, Waseda University, Japan

The hydrogen-terminated (C-H) diamond surface has been used in diamond MOSFETs for its p-type high conductivity[1][2]. So far, we have reported diamond MOSFETs using 2-dimensional hole gas (2DHG), which is induced by the surface dipole formed by hydrogen-carbon bonds. The negatively charged adsorbates are also considered to have an important role to obtain high surface conductivity[3]. In the fabrication of diamond MOSFETs, even if C-H surface is preserved, we noticed that the surface conductivity decreases after several device processing sequences, because of different ambient and high temperature processing condition. In this work, we developed the recovering method of conductivity by irradiating extra negative ions in air on the hydrogen-carbon (C-H) surface to enhance the current density of the C-H diamond surface. The low conductivity of C-H diamond substrate was improved successfully. This result indicates the necessity of negatively charged adsorbates on the C-H diamond surface. It also makes the fabrication of C-H diamond FET more reliable by intentionally introducing additional negative ion formed by corona discharge to the C-H diamond surface.
In this study, the surface of (001) undoped diamond was hydrogen-terminated. Ti/Pt/Au (30nm/20nm/100nm) was evaporated as source/drain electrodes to define the channel length. Before introducing additional negative ion, the current density was 8 mA/mm at V_{DS} = 30 V, with L_{ch} = 5 μm, W_{ch} = 70 μm, which is more than 1 order of magnitude below the current density of C-H diamond channel reported [4]. To increase the conductivity of C-H surface, we introduced a large amount of negative ion by corona discharge near the substrate surface to provide additional negative charge on the hydrogen-carbon surface for 30 min[5]. The change of current density over time was measured. With additional negative ion in the air, the current density increased rapidly from 9 mA/mm to 164 mA/mm in 30 min and saturated. Sheet resistance decreased from 656 kΩ/sq to 38kΩ/sq. The current density maintained the maximum for more than 3 days. All the experiment and measurement were performed in regular air.
The increase of current density indicated the amount of negative charge on the C-H surface has a great influence on the density of polarization-induced 2DHG. The disorption of negatively charged adsorbates in the device processing probably leads to a low density of 2DHG,which results in low conductivity of hydrogen-terminated surface. It takes more than several hours for negatively charged adsorbates to cover the surface. This low conductivity issue can be simply improved by introducing additional negative ion to the C-H surface. This process only takes about 30 minutes in air without using toxic gas such as NO_2. Introducing additional negatively charged adsorbates in the device fabrication process is recommended to secure the higher density of polarization-induced 2DHG, higher p-type conductivity and a higher yield of C-H diamond p-FET.

High Breakdown Voltage Diamond Schottky Barrier Diode with HfO_2/ Al_2O_3 Multilayer Field Plate Structure QiLi and Hong-XingWang; Xi'an Jiaotong University, China

Diamond Schottky barrier diodes (SBDs) have been studied by many researchers because of its high current, low turn-on voltage and fast switching frequency. However, the edge electric field crowding effect will lead to premature breakdown of SBD under large reverse voltage, which will result in large leakage current. There are some termination structures have been reported to improve the blocking capacitance, such as field plates (FP), junction termination extension (JTE), metal guard rings. Among those structures, FP is the most common structure because it can alleviate the electric crowding without reducing the forward current and increasing the turn-on voltage. Al_2O_3 has been used as FP of diamond SBD because of its large band offset for oxygen-termination diamond. The HfO_2 has a high dielectric constant (k) of 25-30 and can withstand higher voltage than Al_2O_3. However, due to the large positive fixed charge density in the bulk HfO_2, the barrier between HfO_2 and diamond is low.
In order to solve the weak points of single Al_2O_3 and HfO_2 FP, we fabricated a diamond SBD with HfO_2/Al_2O_3 multilayer FP. The k value of the HfO_2/Al_2O_3 multilayer was larger than that for single Al_2O_3. The leakage current of HfO_2/Al_2O_3 multilayer FP diamond SBD was always smaller than that of single oxide FP SBD. Compared with HfO_2 FP, there was a better interface between diamond and HfO_2/Al_2O_3 multilayer FP. And the diamond SBD has higher breakdown voltage than single oxide FP SBD. We also investigated the effect of annealing on this diamond SBD. The breakdown voltage was improved and the leakage current was reduced after annealing. These results show that the HfO_2/Al_2O_3 multilayer FP and annealing can effectively improve the reverse breakdown voltage of the diamond SBD, and the forward characteristics do not decrease significantly.

Carbon Ink Printed Flexible Glove-Based Aptasensor using Zinc Nanorods for Rapid and Point of Care Detection of Chikungunya Virus PradakshinaSharma; Jamia Hamdard, India

Printed electronic technologies have sparked interest worldwide because of their capacity to transcend the limitations of existing high-cost electronics based on the fabrication of various devices deploying flexible substrates. As a crucial component of flexible electronics, electrodes fabricated on soft, stretchable, and bendable substrates are significant. Hence this study demonstrates an electrochemical flexible substrate-based aptamer sensor for CHIKV antigen over an extensive range of concentrations. In brief, ZnO nanorods were chemically synthesized and characterized by FESEM, UV-Vis spectroscopy, FTIR analysis, and X-Ray Diffraction(XRD) providing biocompatibility to the biorecognition element called aptamer. The aptasensor showed a wide dynamic range (1ng/ml-10μg/ml), employing a voltammetric identification in the presence of 10mM methylene blue act as a redox-transition substance, with an estimated detection limit in the range of 1ng/ml and 25secs as its optimal response time. The sensor's applicability was also demonstrated by introducing CHIKV-Antigen into human serum samples. The built-in sensor has a shelf-life of more than a month. A portable platform for diagnosing CHIKV-Antigen has a fast response time and high sensitivity. Therefore, this allows for the diagnosis of CHIKV in a timelier manner, allowing for more effective treatment options.

8:00 PM EL14.04.05

Investigation of Intracellular Thermogenesis Dynamics using Mitochondria-Targeted Nanodiamond Quantum Thermometry YoobeenLee[1], KihoKim[2], DohunKim[2] and Jin SeokLee[1]; [1]Hanyang University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Intracellular thermometry techniques provide valuable information into biological processes by detecting temperature variations within specific organelles under different physiological conditions. However, miniaturizing biocompatible thermometers to submicrometer sizes and attaching them to organelles pose significant challenges. In this study, we present a novel approach utilizing organelle-targeting nanodiamond quantum thermometry, using nitrogen-vacancy (NV) color centers, to monitor temperature changes during ATP generation within living human skin fibroblast cells. To enable this monitoring, we developed a microscopy system that integrates a coplanar waveguide-incubating chamber and a real-time particle tracking system, facilitating the tracking of nanodiamonds within cells while simultaneously measuring temperature. Using this system, we induced temperature rise based on the thermogenic response by inhibiting ATP synthesis, and measured the resulting changes in temperature within mitochondria, nucleus, and membrane. Our technique can achieve spatially resolved temperature measurements related to mitochondrial thermodynamic and gain insights into the distinct thermodynamic properties in specific organelles within cells.

8:00 PM EL14.04.06

Homoepitaxial Diamond Growth Initiation on Smooth CMP Surfaces at Various Mis-Cut AnglesS MAsaduzzaman and TimothyA. Grotjohn; Michigan State University, United States

Homoepitaxial diamond growth by microwave plasma-assisted CVD is used to grow both doped and intrinsic epilayers of diamond for electronic and quantum applications. Often when different doping types or concentrations are desired, the deposition is done in different diamond deposition systems due to avoiding doping memory effects in the deposition system. This requires that the growth process be re-initiated when the sample is moved to a different deposition system. The initiation of the growth process has been shown to often have defects at the growth initiation boundary as evidenced by optical microscopy, photoluminescence and/or cathodoluminescence. This study aims to investigate the growth process at the initiation of the diamond deposition to improve the boundary between different doped epilayers. An objective in many applications is to have abrupt junction between diamond doped with different concentrations or types.

Experiments were performed on the growth initiation on single crystal diamond substrates with various mis-cut angles from the (001) surface. The mis-cut angle was varied from 0 to 4 degrees as determined by X-ray diffraction measurements. To prepare the smooth diamond surface before growth the substrates were chemical mechanical polishing (CMP) polished to achieve a surface roughness of less than 0.3 nm RA. The CMP process was done by polishing the diamond substrate with a slurry of boron carbide, potassium permanganate, and phosphoric acid at a rate of about 100 nm/hr. The surface roughness was measured with AFM. Prior to CMP the substrate was mechanically polished on a Scaife, and the surface was then plasma etched to remove about 2 µm of diamond that may have polishing damage.

The diamond deposition was performed with a hydrogen, methane, and carbon dioxide feed gas mixture that gives a growth rate of 2-6 µm/hr. The diamond deposition was done with only a short time between deposition system turn on and growth initiation. This short time is important to minimize any surface etching/roughening before the growth starts. The growth was allowed to proceed for short periods of time so that 1-2 µm of diamond or less were grown. When the short growth is finished the surface is examined with AFM, optical microscopy, and SEM to look for island growth and step-terrace growth features as a function of the mis-cut angle. Also diamond deposition runs are done under the same growth conditions for various times to see how the growth surface evolves at the start.

The work has observed the smooth surface getting rougher at the initiation of the growth. We will report on the evolution of the surface versus growth time and mis-cut angle. For small mis-cut angles island-like growth occurs and we will quantify the growth of the island size versus growth time. For larger mis-cut angles the transition to step-flow growth will be quantified in terms of terrace and step size evolution. The steps will also be analyzed in terms of step facet height and direction. We will also look at the implications of the growth initiation on doping spatial uniformity in the grown layer.

8:00 PM EL14.04.07
Fabrication of Polymeric Microresonators Embedded with NV Color Centers in Nanodiamonds using Two-Photon Polymerization FilipeA. Couto, MarceloB. Andrade, AdrianoOtuka, SebastiãoPratavieira, SérgioMuniz and CleberMendonca; São Carlos Institute of Physics, University of São Paulo, Brazil

The NV-color center in diamond is a fluorescent defect that shows great potential for quantum information technologies. It acts as a single-photon emitter at room temperature, offers optical spin state preparation and readout capabilities, and exhibits long coherence time and photostability. Integration of these emitters into photonic structures is essential for various applications and can be achieved through the use of nanodiamonds as a platform. Nanodiamonds enable the incorporation of these quantum emitters into a wide variety of host materials and structures. This work focuses on the fabrication of polymeric cylindrical microresonators embedded with NV color centers using the two-photon polymerization (2PP) technique on a nanodiamond-doped photoresist. The fabricated resonators are 50 µm tall, with radii ranging from 30 µm to 15 µm, and the average size of the nanodiamonds is 40 nm. The positions of the nanodiamonds are located using laser scanning microscopy (LSM), and a homemade confocal fluorescence setup is used to map and measure the spectra of the fluorescent spots. Different concentrations of nanodiamonds were tested, and it was observed that concentrations above 0.5 wt% of nanodiamonds in the photoresist made fabrication impossible. Fabrication was achieved for concentrations ranging from 0.1 wt% to 0.01 wt%, resulting in the identification of multiple fluorescent spots in the structures. However, the quality factors of the resonators were in the range of 10^2 to 10^3. For a concentration of 0.002 wt%, resonators with quality factors in the range of 10^4 to 10^5 containing around three emitters per structure were successfully fabricated. Raman spectroscopy measurements were carried out on a previously mapped resonator, where the characteristic diamond peak at 1332 cm^{-1} could only be observed in the spots where fluorescence was previously detected, confirming the presence of nanodiamonds at specific positions within the resonators. In summary, this work highlights the utilization of the 2PP technique to fabricate polymeric microresonators embedded with fluorescent nanodiamonds. Various characterization techniques were employed to analyze the position and fluorescence of the nanodiamonds. The findings pave the way for the fabrication of photonic devices integrated with nanodiamonds for applications in sensing and quantum optics.

8:00 PM EL14.04.08
Normally-Off Hydrogen-Terminated Diamond Field Effect Transistors with Nd/NdO_X Gate Dielectric Formed by Thermal Oxidation of Nd JianingSu and Hong-XingWang; Xi'an Jiaotong University, China

Hydrogen-terminated diamond (H-diamond) with p-type conductivity, high carrier mobility and large carrier density (10^{13} cm^{-2}) accumulated on the surface which makes it can fabricate the diamond-based field effect transistor (FET). Howerer, H-diamond FET usually shows normally on operation. In terms of the consideration of fail-safe system and energy saving for the logic circuits, the normally-off H-diamond FET are urgently required.
In this work, a normally-off H-diamond FET is realized by using Nd/NdO_X gate dielectric formed by thermal oxidation of Nd. The threshold voltage of Al/Nd/NdO_X/H-diamond FET is demonstrated to be -2.3 V, indicating that this device has the normally-off characteristics. The normally-off mode could be greatly ascribed to the work function difference between Nd and H diamond, and positive fixed charge in NdO_X layer. The maximum gate leakage current density value at −7.0 V is 3.3×10^{-5} A/cm^2, which is lower than previously reported H-diamond FET with other gate dielectrics. The maximum drain-source current, maximum transconductance, current on/off ratio, and subthreshold swing are calculated to be -6.6 mA/mm, 1.8 mS/mm, 10^8, and 112 mV/dec, respectively. Additionally, the small hysteresis voltage extracted from the C-V characteristic exhibits low trapped charge density in NdO_X layer, which indicated that the Al/Nd/NdO_X/H-diamond structure has good control on the two-dimensional hole gas (2DHG) channel. This work suggests that Nd/NdO_X gate dielectric could possess a great potential to achieve a high-performance H-diamond FET and also supplies a simple approach to realize normally-off devices.

8:00 PM EL14.04.09
Detection of CA125 by Hydrogen-Diamond Solution Gate Field Effect Transistor MinghuiZhang, WeiWang and Hong-XingWang; Xi'an Jiaotong University, China

In this work, the concentration of CA125 has been detected by a hydrogen-diamond solution gate field effect transistor (H-terminated diamond SGFET). The linker molecular 1-pyrenebutyric acid-N-hydroxy succimide ester (Pyr-NHS) has been utilized to modify the H-terminated diamond surface by π-π bonding. Then, the anti-CA125 antibody has been immobilized with Pyr-NHS. Finally, the specific binding of CA125 with anti-CA125 antibody leads an obviously shift of the transfer characteristics, which exhibiting a proming application of H-terminated diamond SGFET in CA125 detection.

8:00 PM EL14.04.10
Spin-Photon Interfaces based on Spin Defects in Diamond Coupled to an Optical Microcavity AndreaCorazza, YannikFontana, ViktoriaYurgens, JoshZuber, BrendanShields, MinghaoLi, MarkKasperczyk, PatrickMaletinsky and RichardWarburton; University of Basel, Switzerland

Optically-active spins in diamond attracted considerable attention as spin-photon interfaces to establish remote spin-spin entanglement among the nodes - a key building block in a quantum network. A prominent example of a highly coherent and optically addressable electron spin is the negatively charged Nitrogen-Vacancy (NV) center. However, its long radiative lifetime, the small branching ratio into the zero-phonon-line (ZPL) of the emitted photons (2.5-3%) and the inefficient photon extraction out of the diamond limit the entanglement rates and hence the scalability to a few network nodes. We demonstrate efficient selective coupling of the ZPL transition of a coherent NV center to the optical mode of an open Fabry-Perot optical microcavity, mitigating these problems. The coupling of a solid-state spin to a microcavity acts on its radiative lifetime via the Purcell effect, on its branching ratio via the cavity coupling and it efficiently funnels the coherent photons out of the diamond [1]. We present an improved NV creation protocol, carbon implantation post-fabrication, which yields to NV centers with excellent optical coherence even in membranes thinner than 2 µm, with over 50% of the emitters showing optical linewidths below 150 MHz [2]. We then embedded one of these diamond membranes (1.6 µm thick) in an open Fabry-Perot optical microcavity. The ZPL count rates are as high as 140 kcts/s under off-resonant excitation, exceeding the state-of-the-art achieved for photonic interfaces based on solid-immersion lenses (SILs). The high photonic flux is achieved through a net Purcell enhancement of 1.8, increasing the fraction of ZPL photons from 3% to 44.7%, an improvement by a factor of 17.5 compared to the NV Debye-Waller factor of 2.55%. By efficient suppression of the resonant excitation, we measure resonance fluorescence from an NV for the first time without relying on time-bin filtering and extract an NV linewidth of 159 MHz. In two-photon protocols for spin-spin entanglement, our platform would increase the entanglement success probability by more than an order of magnitude, and by more than two orders of magnitude with feasible system improvements.
Our versatile cavity design enables us to use any optically-active spin, which ideally combines excellent optical and long spin coherences. To this regard, the neutral charge state of the Silicon-Vacancy centre emerged as a promising defect in diamond and it exhibits cardinal properties required from an optically active solid-state spin such as long spin coherence and stable, strong optical transitions thanks to its high Debye-Waller factor of and its inversion symmetry which makes it insensitive to electric field noise. While the isolation and stabilization of the neutral SiV charge state has recently been made possible using Boron doping, the method is technologically challenging as it requires careful fine-tuning of the B concentration [3]. Using a versatile approach based on hydrogen surface termination, we demonstrate that the charge state of the SiV can be switched between SiV- and SiV0 in a reliable way, even for diamond structures with low surface-to-volume ratios [4]. We present the method by creating single SiV0 centres in 0.5-3 um thin diamond membranes. These structures can be readily integrated in optical microcavities, making them a promising spin-photon interface and an ideal host for a quantum memory. In conclusion, we propose two different approaches to manipulate coherently

spin defects and to generate coherent single photons resonantly and with high probability, making our systems attractive spin-photon interfaces - an important step towards quantum networks based on spin defects in diamond.

High Lateral Breakdown Field in Ib HPHT Diamond Substrates PietroArgenton, MartinKah, DanialMajidi, MarineCouret, NicolasRouger, DavidEon and JulienPernot; CNRS, France

The efficiency of power devices is critical nowadays for the rise of renewable energy. A great effort is being put into trying to optimize both energy dissipation and blocking capability. In the latter respect the goal is to increase as much as possible the voltage breakdown of devices in the off-state. Because the breakdown voltage increases with the semiconductor bandgap, Ib HPHT diamond substrate, with a bandgap of 5.5 eV, is a candidate as the ultimate substrate for power devices. In particular Ib HPHT diamond substrates are widely used for lateral Field Effect Transistors (FET) thanks to its insulating properties at room temperature.
In this work, the blocking characteristics of diamond Ib nitrogen-doped substrates are investigated through the use of metallic contacts separated by different gap widths in order to apply large range of electric field (from V/cm to MV/cm). Thanks to the electron beam lithography technique, several metallic structures separated by different gaps down to 500 nm were deposited on an Ib HPHT diamond substrate. The I-V characteristics between two electrodes have been measured up to reach the breakdown voltage of each structures. In order to understand the breakdown mechanism underlying within the structure, electron beam induced current (EBIC) has been used in order to map the electric field between two successive electrodes. This experiment is particularly useful for voltages close to the breakdown voltage.
In the first part of this presentation, the method will be described in details. Then, the I-V characteristics for different breakdown voltages and fields up to 10 MV/cm will be reported and compared with previous theoretical and experimental results. Finally, the mechanism causing the breakdown of the material will be discussed and compared with finite element simulation.

SESSION EL14.07: Laser Processing for Novel Devices

Femtosecond Laser Writing Inside Diamond PatrickSalter[1], PilarVillar[2], CalumHenderson[3], MartaKruger[1], FernandoLloret[2], DanielReyes[2], DanielAraujo[2] and RichardB. Jackman[3]; [1]University of Oxford, United Kingdom; [2]Universidad de Cadiz, Spain; [3]University College London, United Kingdom

Laser writing with pulses of duration less than a picosecond presents a diverse platform for the functionalisation of diamond, with a range of different modification regimes for internal structuring beneath the diamond surface. The laser is tightly focused beneath the surface where non-linear absorption leads to a perturbation of the diamond structure on a scale less than a micrometre, without any damage to the surrounding material or surface. At higher laser pulse energy, the light-matter interaction breaks down the diamond to create a graphitic phase. At lower laser pulse energy, a finer process is accessible which can yield a vacancy ensemble, without breakdown of the diamond lattice. These processing regimes are applied for the fabrication of a range of devices, ranging from detectors for harsh environments, through to quantum technology and security inscription within gemstones.
We focus this talk on our new results for laser written vias passing through a diamond wafer, and the influence of laser dose on the electrical conductivity. Surprisingly, increasing the laser dose delivered to the sample causes a transition from a regime in which the written structures display ohmic conductivity into a regime which in which they are insulating in nature. We show that a combination of these regimes can be achieved with laser over-writing to give asymmetric conduction characteristics for the vias. A high-resolution structural characterisation of the laser written features by transmission electron microscopy reveals a diverse range of carbon nanostructures embedded within the diamond, and can be used to explain some of these phenomenon

Direct Laser Writing of Nanochannels Between Ultra-Thin Nanocrystalline Diamond Films and Glass Substrates StoffelD. Janssens, DavidVázquez-Cortés and EliotFried; Okinawa Institute of Science and Technology Graduate University, Japan

The fabrication of nanofluidic devices, which have one dimension below the 100 nm cornerstone, is complex, expensive, and time-consuming due to the small length scales involved. Direct femtosecond laser writing of nanochannels might overcome the inherent challenges; however, progress in this field is limited. Still, encouraging developments have been made. For example, laser writing can produce nanocavities in thin nickel films [1]. Films with such cavities may offer a wide range of possibilities for magnetism-related research but are not transparent in the visible spectrum, which excludes optical microscopy for nanofluidic research. Laser writing can also produce nanochannels in fused silica substrates [2]. These channels are usually perpendicular to the surface of the substrates, have variable diameters, are open on one side, and are typically no more than ten micrometers long.

This talk presents a method for fabricating nanofluidic devices through the direct femtosecond laser writing of arbitrary long nanochannels between nanocrystalline diamond (NCD) films and glass substrates. Laser writing transforms a portion of the sample into a nanostrip, and the nanostrip is surrounded by two nanochannels generated by film delamination. For an NCD film with an as-deposited thickness of 300 nm, the mean height and the width of a nanochannel made in this way are on the order of 30 nm and 2 μm, respectively, and are tunable to a certain extent by laser pulse energy. Experiments indicate that a nanostrip consists of NCD, non-diamond carbon, and glass particles, which might be mixed with carbon due to laser ablation. It is found that the expansion of the sample material shapes a nanostrip and causes delamination and nanochannel formation. Such an expansion happens, for example, during the transformation of diamond to carbon of other forms [3]. Since the pulse energy needed to ablate the bare glass substrate is much greater than those used for nanochannel writing, one can deduce that nanostrip formation is initiated in the NCD film near the film–substrate interface. The origin of this phenomenon might be the presence of low-quality NCD at that location, which is bound to absorb more light than high-quality NCD [4]. By fabricating a nanofluidic device and performing simulations, it is shown that the nanochannels fill with water through capillary action.

NCD is an appealing material for applications due to its biocompatible, chemical, mechanical, electrical, optical, and quantum properties. Low-cost diamond films can be achieved by plasma-assisted chemical vapor deposition with methane gas diluted in molecular hydrogen as a precursor mixture. With this deposition technique, NCD films are commonly synthesized on substrates seeded with nanodiamonds [5]. NCD can also be doped to make it electrically conductive, paving the way for various applications [6]. Being inexpensive, transparent, and chemically inert, glass is a natural choice for research in micro- and nanofluidics. The coefficient of thermal expansion can also be tuned towards that of other materials, allowing the fabrication of structures with relatively low residual stress. Since NCD films are inert to hydrofluoric acid (HF), NCD can act as an etch stop during the HF etching of glass [7]. Here, we rely on this property for fabricating the nanofluidic device.

2:30 PM EL14:07.03
Femtosecond Direct Laser Writing for Diamond NV Centers Placement CleberMendonca[1], LucasNolasco[1], FilipeCouto[1], JulianaAlmeida[2], CarlieOncebay[3] and SergioMuniz[1]; [1]University of Sao Paulo, Brazil; [2]UFSCar, Brazil; [3]National University of Engineering, Peru

The integration of devices for applications in photonics and quantum information technologies requires the development of platforms combining basic elements, such as resonators and waveguides. One promising solid-state optically active systems currently studied for such applications is the nitrogen-vacancy (NV) center in diamond, which is usually produced by irradiating diamond with beams of electrons or nitrogen ions. NV centers can be optically initialized and read out, present long coherence times at room temperature and allows creating

protocols to manipulate its spin-state by combining optical and magnetic methods. Furthermore, NV centers can also be used as quantum sensors to detect temperature and magnetic and electric fields. The controlled production and placement of NV centers in photonic structures is of high relevance to engineer devices.
In this direction, this work presents results obtained from our efforts to use of fs-laser pulses to generate active and spatially localized NV centers in CVD diamond, as well as the fabrication of polymeric optical microcavities, via two-photon polymerization, incorporated with nanodiamonts containing NV centers. Upon excitation of diamond using 150-fs pulses from a Ti:sapphire laser at 775 nm, with a repetition rate of 1 kHz, we have determined that active defects, with the least damage to the surface, can be generated using pulse fluence in the range of 11 – 34 mJ/cm^2, as observed by the typical fluorescent emission of NV center. For fluences higher than 34 mJ/cm^2 the damage on the diamond's surface started to get too severe, also resulting in lower emission. Our results also revealed that the density of NV centers grows with the number of fs-pulses. The generation process, however, is stochastic. Furthermore, fs-pulse at ~800 nm (86 MHz repetition rate) were use to fabricate, via the two-photon polymerization (2PP), cylindrical resonators incorporated with nanodiamonds presenting centers. Even though the cavity quality factor (Q) decreases with the amount of nanodiamonds, for a cavity with 0.01 wt% of nanodiamonds Q ~10^3 is achieved. More interestingly, we were able to collect the NV-center emission from specific positions in such microvities, that display the typical features of the NV-centers. In summary, The results reported here demonstrate the use of fs-laser pulses to generate localized center in diamond by using 150-fs pulses (775 nm) with fluences higher than 11 mJ/cm^2. Also 2PP was sucefully used to fabricate microresonatores containg nanodiamonds, with Q of about 10^3. The authors acknowledge FAPESP (grants 2018/11283-7, 2020/08715-2, 2019/27471-0, 2015/17058-7, 2013/07276-1, and 2009/54035-4), Air Force Office of Scientific Research, CNPq, and CAPES for financial support.

Shape Induced Enhanced Fluorescence in Fluorescent Nanodiamond Revealed by Correlative Transmission Electron Microscopy and Photoluminescence Microscopy SheryChang[1], HaotianWen[1], DavidKodahl[2] and ChristianDwyer[3]; [1]University of New South Wales, Australia; [2]Centenary College of Louisiana, United States; [3]Electron Imaging and Spectroscopy Tools, Australia

Fluorescent nanodiamonds (FNDs) are diamond nanoparticles containing color centers that emit visible light at room temperature. Among the color centers in FNDs, the nitrogen-vacancy centers (NV) have drawn the most attention due to its exceptionally stable optical properties and great prospect in sensing and biomedical diagnostic applications.

The current understanding of the optical properties of the FNDs relies largely on the optical measurement methods from either ensemble of materials or from few single particles. As most of the FND fabrication is a top-down process where larger diamond crystals are milled to desired nanometer size, FNDs generally have broad size distribution and irregular shapes. Therefore understanding of FNDs structure-property relationship using ensemble measurements only is insufficient.

We have developed a new method based on correlative transmission electron microscopy and photoluminescence (TEMPL). TEMPL allows a direct correlation of the fluorescence brightness and three-dimensional size and shape of individual nanoparticles. PL provides optical information with exquisite energy resolution, and TEM provides structural information with exquisite spatial resolution. Unsupervised machine learning (ML) with the generalized 3D shape descriptors, is used to analyse correlations between the PL brightness and 3D shape of FND particles. The automation provided by machine learning allows TEMPL to be applied to large sample areas (2-3 orders of magnitude larger than a typical TEM field of view) containing a statistically significant number of particles.

Using this new method, we directly reveal that the volume-averaged PL brightness of thin, flake-like nanodiamond particles is up to several times greater than that of three-dimensional-shaped, thicker particles provided the particle diameter is less than the sub- wavelength limit. With the assumption that the number of NVs within a particle is proportional to its volume, this implies that individual NVs within thinner particles are brighter. This experimental observation is supported by the theoretical simulations on simplified particle geometries on a range of supporting substrate and surrounding medium. The simulations indicates that the comparative brightness of thinner particles, either on a thin supporting substrate or in a low- index medium, is attributable, at least in part, to the constructive interference of partial light waves in these particles. With increasing particle thickness, such an effect becomes damped. The sub-wavelength dimension of the substrate plays an important role, as it results in higher effective reflectivity comparable to diamond particles in a low-index medium (e.g., a low- index solution).

In addition to correlative PL with TEM, we have also carried out correlative SEM and AFM for the study of FNDs supported on bulk substrate. Our overall results help to guide new routes of enhancing fluorescence brightness of FNDs for broad sensing applications.

3:45 PM EL14.08.02
Enhanced Photophysical Transition Dynamics of NV Centers in Nanodiamond on Structured Metamaterial Platforms PengZheng and IshanBarman; Johns Hopkins University, United States

While promising as photostable solid-state quantum emitters for biological sensing and imaging applications, nitrogen-vacancy (NV) centers in nanodiamond are limited by their intrinsically inefficient photon generation and extraction from excited NV centers, which restrict the achievable sensitivity and temporal resolution. To overcome these challenges, judiciously structured metamaterials are developed, which can support broadband Purcell enhancement and spatially extended local plasmonic fields for effective plasmon-NV centers coupling. With fluorescence lifetime imaging microscopy characterizations, a simultaneous amplification to the photophysical transition dynamics and emission intensity of NV centers are observed. We envision that the structured metamaterials pave the way for developing superior biological sensing platforms with enhanced sensitivity as well as augmented spatial and temporal resolution.

4:00 PM *EL14.08.03
High-Efficiency Tracible Nanodiamond-Mediated Gene Editing System Development and Application Chia-ChingChang[1,1,2], Shih-HwaChiou[3,1] and YonhuaTzeng[4]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Academia Sinica, Taiwan; [3]Taipei Veterans General Hospital, Taiwan; [4]National Cheng Kung University, Taiwan

Nanodiamonds (NDs) are biocompatible crystalline carbon nanomaterials for biomolecules or small molecules delivery into the target cells especially for NDs smaller than 5 nm. By conjugating NDs with red fluorescence protein, mCherry, the distribution of these nano-fluorescence nanoparticles (ND-mCherry) can be traced in the cells or tissues. Moreover, by conjugating linear DNA fragments with all the components of the CRISPR/Cas9 genome editing system, the NDs particles became a gene-editing device. X-linked retinoschisis (XLRS) is an inherited retinal disorder disease that leads to reduced visual acuity in affected persons. Genetic analysis indicated that XLRS is caused by mutations c.625T in the RS1 gene. Therefore, RS1 serves as a target for gene editing systems. The low transfection efficiency is one of the major challenges of conventional CRISPR/Cas9 genomic editing systems. In this study, we developed an ND-mCherry-CRISPR / Cas9 gene editing system (ND-mCherry-CRISPR / Cas9). The size of ND is approximately 3 nm, which contained both a target gene sequence and an extra green fluorescence protein gene as a gene expression reporter. This tracible ND-mediated gene editing system is not only delivered genes into hiPSCs and mouse retina but also mediates gene editing events. Therefore, the structure of the mouse photoreceptor layer was loose, and cone/rod cells were also found to be abnormal by the ND-mediated gene editing system introduced. The effective gene editing efficiency is about 10 times higher than conventional CRISPR / Cas9. Namely, ND-mediated gene editing systems can be used as a way to quickly establish animal models of hereditary diseases. Furthermore, by conjugating with the gene correction sequences and our system will be a potential medical device for disease treatment.

Controlling the Interaction of Nanodiamond Surfaces with Physiologic Environments ElisabethMayerhoefer[1], JuliaPuck[2], Daniela ElenaCostea[3], Harsh NitinDongre[3] and AnkeKrueger[1]; [1]Stuttgart University, Germany; [2]Wuerzburg University, Germany; [3]University of Bergen, Norway

The application of nanodiamond in quantum sensing, tissue engineering or drug delivery requires a highly defined interaction of the diamond surface with the surrounding medium. The uncontrolled formation of a protein corona is one of the major challenges. Furthermore, the denaturing of surface bound functional moieties as well as the attachment of serum components can lead e.g. to a loss of function, masking of functional moieties, the uncontrolled agglomeration of the particles as well as alteration in the uptake mechanism for the introduction of diamond nanoparticles into cells.[1] We have recently reported on the use of a complex zwitterionic moiety for the inhibition of the protein corona formation and the efficient uptake of such functionalized fluorescent nanodiamonds into cells.[2,3]

Here, we discuss the control of these undesired effect by the highly defined modification of the diamond surface using different zwitterionic moieties based on differently charged small peptides as well as crown ethers immobilized using short organic linker molecules.
The resulting nanodiamond conjugates have been investigated regarding their dispersibility, colloidal stability and inhibition of protein adsorption.
Uptake experiments and cell based assays confirm the low toxicity and high biocompatibility of these functionalized nanodiamonds and elucidate the efficient uptake and release into the cytosol without substantial agglomeration. The influence of differently charged surface moieties will be discussed. Such functionalized nanodiamonds are a promising tool for biomedical and sensing applications as the modular approach allows to introduce additional functional moieties, which can then be used to deliver drug molecules, provide specific interactions for targeting and tissue engineering.

Nanodiamond Facilitated Drug Delivery for Drug Resistant Breath CancersC.-Y.Huang, Y.-J.Su and Chia-LiangCheng; National Dong Hwa University, Taiwan

Nanodiamond (ND) has been considered as a biocompatible and feasible platform for efficient cancer drug delivery. Examples have been successfully demonstrated for various cellular and animal models. However, to date, very few or none studies had included the assessment on the effects and efficiency in a quantitative fashion; and the transportation of these ND-drugs to the cancer/tumor sites are still in a less understood state. In cancer therapy, drug resistance may arise due to intercellular microenvironment, cytoskeletal structure, and drug resistance genes causing limited therapeutic effect in cancer treatment.
In this study, we use nanodiamond (ND) as a carrier to improve drug delivery in the 3D cellular model which has been observed drug resistant characterization due to the structure of cellular model. The aim of this study is to compare the penetration ability of ND-drug complex and free anticancer drug treatment in 2D and 3D breast cancerous cells model (MCF-7 and MDA-MB-231). Several variations of the Multi cellular tumor spheroid (MCTS) cocultures were used to examine the effect of the extra cellular matrix (ECM) to the drug delivery and drug entering mechanisms. ND-drug complex is formed by conjugating Human Serum Albumin (HSA) and doxorubicin (DOX) with ND. Cytotoxicity of the drug complex is determined by MTT assay and Quantitative analysis in 2D cellular model. Growth inhibition assay evaluated the drug efficacy in 3D cellular model. Results show that ND-complexes are more efficient to deliver the drug in 3D cellular model.

SESSION EL14.12: Nanodiamond Synthesis and Applications

3:30 PM EL14.12.01
Nucleation Layer Formation and Properties of 5 nm Hydrogenated Boron-Doped HPHT Nanodiamonds StepanStehlik[1,2], KaterinaDragounova Aubrechtova[2], EkaterinaShagieva[2], RostislavMedlin[1], PetrBelsky[1], TomasKovarik[1], EvgenyEkimov[3], StepanPotocky[4], BohuslavRezek[4] and AlexanderKromka[2]; [1]New Technologies – Research Centre, University of West Bohemia, Czechia; [2]Institute of Physics, AS CR, Czechia; [3]Institute of High Pressure Physics, Russian Academy of Sciences, Russian Federation; [4]Faculty of Electrical Engineering, Czech Technical University in Prague, Czechia

Boron-doped diamond is an excellent electrode material due to its large potential window, robustness, and antifouling properties. While boron-doped diamond in the form of CVD-grown mono or polycrystalline diamond films is already a well-established material, reports on boron-doped nanodiamonds (BNDs) are rare, and BNDs are not broadly accessible. Yet, their potential is tremendous e.g. in (photo)catalysis and biomedicine. BNDs were at first obtained by delamination and milling of CVD films (10.1021/nn500573x), showing also some positive effect on conductivity when used for nucleation (10.1016/j.carbon.2014.07.048). A more scalable and promising technique for making of BNDs is a high-pressure high-temperature (HPHT) synthesis from organic molecular precursors. This process offers unprecedented control of the ND size, enables the dopant incorporation in a high concentration, and provides monocrystalline NDs (10.1021/acsbiomaterials.0c00505). Here we investigate whether a nucleation layer from these HPHT BNDs, can potentially lead to better quality (morphology, electrical properties) of the thin (50-200 nm) boron-doped CVD diamond films compared to the standard nucleation with detonation nanodiamonds (DNDs).
We used the BNDs that were synthesized from borabicyclo[3.3.1]nonane dimer $C_{16}H_{30}B_2$ under HPHT conditions (8-9 GPa, 1250°C). The obtained black powder was analyzed by Raman and FTIR spectroscopies, which showed relatively high sp^2-C content and an abundance of C-H_x bonds. To obtain pure BNDs, the powder was boiled under reflux in a mixture of H_2SO_4 and HNO_3 (3:1) for 6 hours until the bubbling of the mixture disappeared. Surprisingly, boiling in acids led to complete breakage of the interparticle bonds, and after the centrifugal acid removal, well-dispersed deep blue BND colloid was obtained just by gentle shaking of the sediment. Raman spectroscopy showed a spectrum typical for highly boron-doped diamond without any significant sp^2-C content. FTIR and zeta potential analysis showed an oxidized surface (presence of C-O and C=O bonds and negative zeta potential of -31 mV). To determine the BND size we used small angle X-ray scattering (SAXS) that showed the mode particle size to be 5 nm. TEM analysis confirmed well-crystalline and well-dispersed BNDs. In order to reverse the zeta potential of the BNDs to become positive, the oxidized BNDs were lyophilized and then hydrogenated at 700°C for 3h. After hydrogenation, the zeta potential of BNDs indeed became positive (44 mV), i.e., similar to the intrinsic NDs after hydrogenation which is important for the achievement of densely seeded substrates with a negative zeta potential. The nucleation layer was created on Si substrates as well as on SiO_2/Au interdigital electrodes. The morphology and density of the nucleation layers obtained with H-BNDs was investigated by AFM and SEM. Finally, boron-doped CVD diamond film was grown over the nucleation layer on both substrate types, and its morphology, structure, and electrical properties were characterized and compared to the standard nucleation obtained with DNDs.

3:45 PM EL14.12.02
Accuracy Estimation of All-Optical Thermometry Between 283–373 K using the NV^--Center Zero-Phonon Line Spectrum of Diamond Microparticles TaiichiShikama[1], TakatoWatanabe[1], MasayaZetsu[1], YoshikazuHirai[1], MazinJouda[2] and MasahiroHasuo[1]; [1]Kyoto University, Japan; [2]Karlsruhe Institute of Technology, Germany

The temperature dependences of the intensity, peak wavelength, and width of the zero-phonon line (ZPL) spectrum from diamond nanoparticles have been used for all-optical thermometry of microscale objects [1-3]. The method is especially effective when it is challenging to apply the thermometry using the optically detected magnetic resonance [4-5]. However, the ZPL spectrum shape varies particle-to-particle due to presumably the difference in the particle shape [3], which produces a different magnitude of the strain in the diamond lattice, and the variation requires calibration of the particle dependence of the three parameters mentioned above. To establish the calibration procedure and estimate the accuracy of the all-optical thermometry, we measured the particle-to-particle variation in the ZPL spectrum between 283–373 K.
In the experiments, we used commercial diamond microparticles of 150 μm and 0.75 μm average diameters (Adamas Nanotechnologies). The microparticles were used instead of nanoparticles for the ease of particle-to-particle spectroscopy. Approximately 100 particles were dispersed on a silicon wafer mounted on a temperature-controlled stage of an epifluorescent microscope. 594 nm laser was used as an excitation light source, and the photoluminescence spectrum of each particle was measured using a spectrometer (1.5 nm resolution). In the measured spectra, a wavelength range near the ZPL was fitted using an analytical function based on the theoretical shapes of the ZPL and phonon side band spectra [6].
The three parameters were evaluated from the fitting result, and we made histograms of them at every 10 K between 283–373 K. Among the three parameters, the peak wavelength has the smallest variance compared with the temperature dependence suggesting that better accuracy of the thermometry can be obtained by using the peak wavelength. We found that particles with close ZPL spectrum shape at 293 K have close temperature dependences of the peak wavelength between 283–373 K. Thus, the calibration could be done at one temperature condition by sorting particles having close ZPL spectrum shapes.

4:00 PM EL14.12.03
Enhancement of NV-Center Coherence Times via Suppression of the Surface Noise in Coated Nanodiamonds DenisR. Candido[1], UriZvi[2], PeterC. Maurer[2] and MichaelE. Flatte[1]; [1]The

University of Iowa, United States; [2]The University of Chicago, United States

The emergence of Nitrogen-Vacancy centers (NVs) as a candidate for quantum sensing and metrology has recently attracted significant attention in the quantum information science community. While it is
optimal to have shallow NV to increase its sensitivity to the external signal, this conflicts with the rapid increase of the noise near the surface – decreasing the signal-to-noise ratio. Accordingly, efforts have been devoted to explore techniques aiming to reduce the surface noise.

In this work we first model and study the interplay between bulk and surface electric and magnetic noise for NVs implanted in nanodiamonds [1]. Furthermore, we theoretically obtain the corresponding signatures of both surface and bulk noises on the evolution of NV-coherence [1,2,3]. By contrasting these findings with our experimental data, we show that while the surface noise is the dominant source in bare nanodiamonds, silica-coated nanodimamonds show a dominant bulk noise source [3]. This evidences a suppression of the surface noise via coating processes, with corresponding 3.5-fold increase in the NV-coherence time [3]. Our findings evidences the potential of engineering spin coherence using fundamental nanoscience principles to significantly improve the sensitivity of real-world nanoscale quantum sensors.

4:15 PM EL14.12.04
Growth of Nanocrystalline Diamond Thin Films from Detonation and HPHT Nanodiamonds: Correlative Microscopy Study StepanStehlik[1,2], KaterinaDragounova Aubrechtova[2], EkaterinaShagieva[2], RostislavMedlin[1], PetrBelsky[1], TomasKovarik[1], AlexanderKromka[2], StepanPotocky[3] and BohuslavRezek[3]; [1]University of West Bohemia, Czechia; [2]Czech Academy of Sciences, Czechia; [3]Czech Technical University in Prague, Czechia

The nucleation layer formed by diamond nanoparticles (nanodiamonds, NDs) is nowadays probably the most common approach how to facilitate polycrystalline diamond growth on diverse substrates by chemical vapor deposition (CVD). Yet the formation of thin and ultrathin functional diamond films [Stehlik et al., doi 10.1021/acsami.7b14436] gives rise to numerous challenges in terms of adhesion, surface uniformity, layer density, sp2/sp3 carbon phases, grain sizes, grain boundaries, etc. A recent study with oxidized nanodiamonds showed that the nanodiamond material quality (determined by origin and surface modifications) has a pronounced effect on the diamond CVD growth and resulting properties, including the brightness of SiV color centers [Zhang et al., doi 10.1039/d2tc01090a].
Thus, in this work we compare the effect of several types of hydrogenated nanodiamonds (being principally more suitable) for nucleation and growth of nanocrystalline diamond thin films with SiV centers. We employ detonation nanodiamond (DND) solutions from standard 4 nm DNDs and novel size-reduced 2 nm DNDs and 4 nm DNDs with reduced nitrogen content (< 0.05 at.%), all obtained from pre-production stock (OZM Research). We also employ HPHT NDs of 0-30 nm size (MSY30, Pureon) purified by annealing in air (450°C, 5h). All NDs were hydrogenated by annealing in a hydrogen atmosphere, providing them positive zeta potential and stability in a colloidal solution [Kolarova et al., doi 10.1016/j.diamond.2023.109754]. The nucleation solutions were prepared by sonication of 100 mg NDs in 20 mL water and subsequent centrifugation to remove larger aggregates. Nucleation layers were formed on Si substrates and Si self-sensing AFM probes which were immersed in the nucleation solution and sonicated for 10 min. We applied CVD diamond growth for 5-30 min (10 - 80 nm thickness) using microwave plasma SEKI SDS6K reactor with standard growth conditions (hydrogen 300 sccm, methane 15 sccm, 60 mbar, 3 kW, 800 °C).
We characterize the morphology, material, and functional properties of the nucleation layers and resulting CVD diamond thin films by correlative microscopy combining SEM, AFM, Raman, and photoluminescence measurements. We show the dependence of these features on the specific properties of the 4 types of employed nanodiamonds. The work has been supported by the Technology Agency of the Czech Republic (TACOM project) and the Czech Science Foundation.

Fabrication of Q-Carbon Nanostructures and Subsequent Formation of High-Quality Diamond on β-Ga_2O_3Pallab KumarSarkar, Saif Al ArafinTaqy and ArifulHaque; Texas State University, United States

The ultrawide bandgap (UWBG) oxides and nitrides, particularly beta-gallium oxide (β-Ga_2O_3), are promising material systems for next-generation power devices in commercial and military applications. For most electronic and RF applications, UWBG semiconductor-based devices, including β-Ga_2O_3, can operate at much higher voltages, frequencies, and temperatures than commercially available options, including silicon carbide and gallium nitride. However, the remarkably low anisotropic thermal conductivity of β-Ga_2O_3 (11-27 Wm^{-1} K^{-1}) is a significant bottleneck for high-power device applications as it affects the device performance and results in self-heating effects (SHE), which severely limits output power density and maximum current flow of the circuit. To address this issue, the incorporation of a diamond layer that can operate as a heat spreader in Ga_2O_3-based devices has been investigated due to its extraordinarily high thermal conductivity (~ 2000 W/m/k). The deposition of high-quality diamond coatings onto non-diamond substrates, such as β-Ga_2O_3 films, is a complex task due to several inherent nucleation, growth, stress, and adhesion-related issues. The absence of carbon solubility in β-Ga_2O_3, a large mismatch in surface energies with a significant difference in thermal expansion coefficient between β-Ga_2O_3 and diamond, and unfavorable decomposition phenomena during CVD make it difficult to achieve uniform diamond layers with suitable adhesion and nucleation density. This study introduces a novel method for depositing diamond on β-Ga_2O_3 films using a diamond-like carbon (DLC) through pulsed laser deposition (PLD) and successive pulsed laser annealing (PLA) to form a quenched carbon (Q-carbon) layer, demonstrating improved precision and control in the synthesis of diamond coatings for optoelectronic and electronic devices. In this investigation, we have created strong Q-carbon/α-carbon and Q-carbon/nanodiamond heterostructures on β-Ga_2O_3 films using laser annealing of amorphous carbon films with nanosecond laser pulses above the melt threshold. The energy density required for the PLA is calculated by modeling the laser-solid melt interaction, and a maximum melt regrowth velocity of 12.5 m/s is achieved at a laser energy density of 0.4 J/cm^2. Raman studies and X-ray photoelectron spectroscopy (XPS) demonstrate the presence of a high sp^3 content of ~ 81% in the Q-carbon region. Nanodiamonds formed by the PLA process exhibit a distinct Raman peak at 1320 cm^{-1}, with a red shift of approximately 12 cm^{-1} due to the phonon confinement effect. This research reveals a considerable increase in the nucleation density during diamond deposition by hot filament chemical vapor deposition (HFCVD). A very high seeding density with high-quality delamination-free diamond film growth is possible on the Q-carbon region of the film due to the presence of densely packed diamond tetrahedra in Q-carbon which act as nucleation sites for diamond growth. The nucleation density, diamond quality, and stress values were compared for diamonds on Q-carbon coated β-Ga_2O_3 and uncoated β-Ga_2O_3 films. The incorporation of a Q-carbon intermediate layer significantly reduces the compressive stress in diamond films on β-Ga_2O_3 to 0.37 GPa, compared to 1.23 GPa for films deposited on uncoated substrates. The phase purity of the diamond can be measured by its FWHM of signature Raman peak, with a manually calculated value that matches the direct value obtained from the deconvoluted signal. The values obtained were obtained to be 11 cm^{-1} and 16.66 cm^{-1} for Q-carbon coated β-Ga_2O_3 and uncoated β-Ga_2O_3, respectively. Thus, this study addresses the critical challenges, i.e., poor adhesion and large thermal mismatch between diamonds and β-Ga_2O_3 films, which has tremendous implications in realizing efficient β-Ga_2O_3-based high power devices.

Progress on Doped Diamond Electronics AnnaM. Zaniewski, ManpuneetBenipal and JesseBrown; Advent Diamond, United States

The promise of diamond as a semiconducting material has long been understood, but this promise for commercial applications has only recently begun to be realized. Advent Diamond and collaborators have been engaging in substantial research and development efforts to bring diamond-based components to targeted applications. In this presentation, we will demonstrate how an initial focus on serving niche applications, such as a diamond-based x-ray beam monitor for scientific facilities, specialized detectors, quantum materials, and diodes, creates a platform for addressing the required technology development and the scientific advances that underpin diamond electronics development.

Current Status of Diamond Power Devices for High Voltage Applications - Prospects of Vertical Devices MarikoSuzuki; University of Cádiz, Spain

The global demand for energy savings through improved power conversion efficiency is creating a tremendous opportunity for high-performance power devices. Ultra-high-voltage and high-efficiency power devices will offer a significant reduction in size, weight, and cooling for power systems and grid-scale power conversion applications.
Diamond, an ultra-wide-bandgap semiconductor, is an ideal candidate for ultra-high-voltage devices due to its exceptional characteristics such as the high thermal conductivity, the mechanical strength, high carrier mobilities (both of electrons and holes), and the high dielectric breakdown strength. Diamond devices have been remarkably developed thanks to the establishment of microwave plasma chemical vapor deposition (MPCVD) growth techniques including doping control and characterization techniques. In this decade, several diamond power devices have exhibited excellent performances beyond other semiconductors based on the material advantages.
Vertical devices have advantages for high power devices, such as low on-resistance, high blocking voltage and high operation current. However, there are not many reports on vertical diamond power devices due to inadequate device fabrication techniques and difficulty in obtaining doped substrates especially with high-quality.
In this talk, current status and prospects of diamond power devices will be introduced focusing on vertical devices.

10^6 cm^2/(V.s) Carrier Mobility Measured in Ultra Pure Diamond by Time of Flight Electron Beam Induced Current AlexandrePortier[1,2], FabriceDonatini[2], DenisDauvergne[1], Marie LaureGallin Martel[1] and JulienPernot[2]; [1]University Grenoble Alpes, CNRS, Grenoble INP, LPSC-IN2P3, France; [2]University Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, France

Diamond is a very promising material for various applications, and understanding its basic properties is key for the development of future devices. In particular, the low-field mobility of holes has never been measured below ~80 K in ultra-pure diamond. In order to measure this mobility, we developed an innovative Time of Flight electron Beam Induced Current (ToF-eBIC) technique. A 1 ns pulsed electron beam was made to impact the diamond semiconductor, inducing charge carrier creation and motion through the 546 µm thick bulk diamond, under the influence of an applied electric field. The resulting signal was analysed using the transient time technique. Thus, the velocity of electrons and holes was assessed as a function of the temperature from 13 to 300 K and as a function of the electric field with values ranging from 1.5 to 9200 V/cm. A low-field mobility value of 1.03 x 10^6 cm^2 /(V.s) was measured for holes at 13 K, demonstrating that diamond is a suitable material to transport charge carriers in a ballistic regime at a scale of ten micrometers.

10:45 AM EL14.14.02
Effects of Modulated Boron Doping on the Carrier Transportation Characteristics of Single Crystal Diamond MOSFETs RuozhengWang, QiLi and Hong-XingWang; Xi'an Jiaotong University, China

Diamond has superior physical properties for power devices such as ultra wide band-gap (5.45eV), high breakdown field voltage (10MV/cm), high thermal conductivity (22 W/cmK) and high carrier mobility. Nowadays, Boron (B) doped diamond devices has been widely studied since boron atoms acted as a shallow acceptor impurities in diamond (0.37eV). However, the B doping concentration is hardly to be controlled becaused of the unintentional doping, leading to the poor electrical properties of devices. Delta doping technology could solve this issue by the alternating growth of heavily doped and intrinsic diamond films within the range of a few nanometers for fully activating doped carriers. However, the fabricating of high-quality delta doping diamond is rarely studied. In addition, the electrical properties of delta doping diamond film is not very high, inhibiting the practical application from materials to devices.
In this work, the high-quality growth, modulated doping and carrier transportation characteristics based on (100) single crystal diamond (SCD) boron delta doping are studied, followed by the verification of vertical structures of boron-doped diamond MOSFETs. Firstly, high quality B-doped (100) SCD has been worked out owning to the priority of high crystallinity intrinsic layer. The growth rate of B-doped layer is 3 µm/h, the RMS, Raman and XRD FWHM were 0.35 nm, 4.0 cm^{-1} and 28.4 arcsec, respectively.Then, the results of carrier concentration and mobility have been calculated for B-doped diamond at 300k by four-probe Hall tests. Then, the consecutive boron delta doping diamond film has been fabricated, adjusting the doping density of heavily (P^+,$10^{19}cm^{-3}$~$10^{20}cm^{-3}$) and lightly (P^-,10^{16}~10^{17} cm^{-3}) B-doped SCD layers. Finally, the multi-vertical structures of boron-doped diamond MOSFETs have been realized by I-V and C-V measurements. The details will be presented in the conference.

Electron Contact Strategies for Diamond Enabled with a Nitrogen Doped Nano-Carbon Interlayer GabrielB. Munro-Ludders, SaurabhVishwakarma, DavidJ. Smith, RobertJ. Nemanich and FranzKoeck; Arizona State University, United States

Ohmic metal contacts to n-type diamond have historically posed a challenge to the fabrication of diamond devices, due to the formation of a rectifying Schottky barrier, which limits the practicality and scope of diamond devices. Nitrogen-doped nanoCarbon films have recently been explored as ohmic interface layers to enable low-resistance ohmic contact with N-type diamond [1]. In this work the electronic interface between nitrogen-doped nanoCarbon interlayers and metals is investigated using photoelectron spectroscopy and transmission electron microscopy, to determine the mechanism of ohmic contact.

Titanium and molybdenum layers were deposited on nanoCarbon films, and each respective metal/nanoCarbon interface was characterized via X-ray Photoelectron Spectroscopy (XPS) and Ultraviolet Photoelectron Spectroscopy (UPS). The n-type SBH was determined to be Φ_B = 3.7 eV and Φ_B = 4.1 eV for the titanium-nanoCarbon and molybdenum-nanoCarbon interfaces, which indicates a partial pinning of the fermi level. Characterization via TEM and electron energy loss spectroscopy reveal the presence of ~4 nm diameter sp^3–bonded diamond grains surrounded by a matrix of sp^2 bonded carbon, indicating a mixed phase material with non-crystalline states. Two models of the contact mechanism, contingent on the density of unfilled surface states after metal deposition, are proposed to understand the ohmic contact mechanism. A sufficiently low surface state density coupled with a high inter-bandgap density may reduce band bending and allow for flat-band contact by filling surface states, unpinning the fermi level. Alternatively, hopping-type conduction near the Fermi level through π^*-bonded states into the conduction band may also reduce the effective SBH.

Future work will investigate the electronic interface between nanoCarbon interlayers and n-type diamond substrates, to enable ohmic contact with n-type single-crystalline diamond. Switching between pinned and unpinned contact regimes through modulating the inter-bandgap state density via modifying morphology, doping concentration, and non-carbon chemical composition in the film also presents an avenue for future investigations.

Improving Off-State Performance of Schottky Barrier Diodes Through Enhanced Apparent Schottky Barrier using Nitrogen-Doped Layers HusseinKassem, DavidEon and JulienPernot; Institut Néel, France

Diamond Schottky barrier diodes (SBDs) are commonly affected by an imperfect metal/semiconductor interface, resulting in an interface-dependent Schottky barrier height (SBH) inducing large reverse leakage current and premature breakdown voltages [1]. To remediate this issue, more advanced device structures and various metals have been explored to find the ideal trade-off between reduction of leakage current in reverse, and high current at low voltage in forward [2] [3].

The presents work aims to investigate and compare the electrical characteristics of diamond Schottky-np diode (SNPD) and classical diamond SBDs that were fabricated on the same sample. Our hypothesis is that after nitrogen-selective growth, the dopants are ionized conducting to an opposite band bending, and increasing the apparent Schottky barrier. The objective is to assess the influence of a thin nitrogen layer under the SBDs.

In advance of that, a numerical modeling study was carried out on a SNPD using nitrogen layers of different thicknesses. The aim was to evaluate the band structure and and bending at proximity of the contact, as well as to quantify the electric field at the interface. According to the simulation results, an increase in the apparent Schottky barrier ($V_b = V_{b0} + \Delta V$) was observed in front of holes in the semiconductor. We also observed that the interface electric field is increasing with the nitrogen layer thickness, which is making the sharp field peak in the material rather

than at the interface when reverse bias is applied, allowing to prevent early reverse leakage current. Further characterization with different parameters will be described.

The fabrication process involves depositing a heavily doped layer with a thickness of 500 nm and a lightly boron-doped layer with a thickness of 2.4 µm on a diamond substrate. A thin n-type layer is selectively grown on half part of the lightly boron-doped layer, followed by treating both the nitrogen-type and boron-type layers with an OH-termination process. Zirconium Schottky metal is then deposited on each layer to form the SNPDs and SBDs, respectively. The ohmic contact on the highly boron-doped layer exhibits metallic behavior.

The electrical characteristics of SNPDs and SBDs have been investigated using current voltage and capacitance-voltage methods. the forward state of SBDs in boron-type diamond showed better performance than SNPDs, while SNPDs exhibit superior performance in the reverse state. Furthermore, the comparison, of SNPDs and SBDs, fabricated on the same sample is performed in order to validate the model.

The important parameters for temperature-dependent adjustments, such as the ideality factor, apparent Schottky barrier, and serial resistance, were extracted by fitting the curve of the current density-voltage of SNPDs using the thermionic emission model. the observations indicate an increase in the barrier, which is intriguing. The overall resistance is generally low, with slight variations between the SNPDs and SBDs. However, the ideality factors are less favorable, suggesting the need for further understanding at the interface level. Therefore, to address the high ideality factor and its impact on the thermionic current reduction, a series of measures will be implemented to examine the interface quality accurately.

In conclusion, SNPD structures present a promising approach for power electronics to improve the breakdown and reduce leakage.

Improved Diamond Schottky Barrier Diode Breakdown Voltage using High Resistance and High Quality Diamond Double-Stack Field Plate Structure QiLi and Hong-XingWang; Xi'an Jiaotong University, China

The application of diamond in Schottky barrier diodes (SBD) has attracted more and more attention due to its excellent electrical and physical properties. However, because of edge electric field crowding of Schottky electrode, the breakdown electric field is far below the limit of diamond. The field plate (FP) structure is a simple method to alleviate the crowding of edge electric field, but due to the limitation of the withstand voltage capability of the FP material, the edge of the device will still be broken down in advance. Homoepitaxial diamond has the highest breakdown electric field of at least 20MV/cm, so it is suitable to choose diamond as the field plate. However, since boron atoms can diffuse from the boron-doped diamond substrate to the epitaxial layer during growth, making the epitaxial layer conductive. Therefore, we prepared high-resistance(H-R) nitrogen-doped diamond, and then grew a high-quality(H-Q) diamond protective layer as the field plate to improve the withstand voltage. The H-R and H-Q diamond is achieved by selective growth method. We have reported that the H-R diamond field plate structure can effectively increase the breakdown voltage of diamond SBDs. We reduced the thickness of the H-R layer from 800 nm to 400 nm, resulting in an increase in the breakdown voltage from 113 V to 322 V due to the introduction of fewer defects. Compared with the nitrogen-doped diamond H-R field plate, the defect density on the diamond surface will be reduced after adding the H-Q layer, thereby improving the withstand voltage. This structure will further alleviate the edge electric field crowding effect. Therefore, H-R and H-Q diamond double-stack field plate structure is expected to greatly improve the reverse breakdown characteristics of the device.

Fabrication of Diamond Membranes and Photonic Nanostructures for Integration of Color Centers JuliaHeupel, LukasWolfram and CyrilPopov; University of Kassel, Germany

Single-crystal diamond (SCD) in form of thin membranes with incorporated color centers, such as nitrogen-vacancy (NV) centers or silicon-vacancy (SiV) centers, has gained an ever-increasing interest over the years as a highly promising platform for photonic integrated devices or for envisioned applications in quantum information technologies (QITs). To achieve the desired long optical and spin coherence times for QIT applications, such membranes need to be free from lattice defects, paramagnetic impurities, and charge traps. This requires an initial removal of the damaged surface layers from the cut and polished starting material. Additionally, further processing of diamond by e.g., dry etching for fabrication of photonic structures, can lead to higher roughening of the surface due to a micro-masking effect from particles, originating from the polishing procedure. In our work we address the importance of the SCD surface preparation to overcome the above mentioned challenges, which affect the structuring process and critically influence the final quality of the membrane or structured photonic devices as well as their performance.
The fabrication process of SCD membranes with various diameters and thicknesses, exhibiting a low surface roughness down to 0.2 nm, applying inductively coupled plasma reactive ion etching (ICP-RIE) with Ar/Cl_2 and O_2 plasma will be demonstrated. By a variation of the major etching parameters, an enhanced planarization of the surface can be obtained, especially due to a low etch rate of a few nm/min and the Ar/Cl_2 chemistry. These planarized SCD membranes can be successfully bonded via van der Waals forces or via PMMA on plane cavity mirrors and optically characterized in a fiber-based Fabry–Pérot microcavity system regarding their mode structure and finesse. They can be also used as starting material for fabrication of 1D or 2D photonic crystal structures applying electron beam lithography (EBL).
The work is financially supported by the German Federal Ministry of Education and Research (BMBF) under the Project "Quantenrepeater.Link" (QR.X).

2:00 PM EL14.15.02
The Highest Concentration NV Ensembles Formed by Heavily Nitrogen-Doping CVD System with Plasma Confinement and High Density Vacancy Formation by Focused Electron Beam Irradiation YudaiAsano[1], KyosukeHayasaka[1], MayuUeda[1], KyotaroKanehisa[1], KosukeKimura[2], TakashiTanii[1], ShinobuOnoda[2], ShinpeiEnomoto[3] and HiroshiKawarada[1,3]; [1]Waseda University, Japan; [2]National Institutes for Quantum Science and Technology, Japan; [3]Waseda University, Japan

Highly concentrated NV ensembles are expected to be applied to magnetic sensing.Only method for high concentration of nitrogen above 10^{20} cm^{-3} in diamond is limited to CVD method, because the damage of heavily implanted diamond cannot recover easily.
We have successfully fabricated diamond thin films with the world's highest nitrogen concentration of 8.0×10^{20} cm^{-3}[1] using a microwave plasma chemical vapor deposition (MPCVD) system that is specially designed to confine plasma to the thickness of a microwave waveguide. This method can also introduce 1×10^{22} cm^{-3} of boron, and diamond with the world's highest superconducting transition temperature has been synthesized. HPHT synthetic (111)-oriented diamond substrates were used. That's because (111) diamond substrate have the high impurity incorporation efficiency [2].These CVD films exhibit extremely high crystallinity, as indicated by the Raman spectrum measurement (Laser 532nm), which shows a diamond peak FWHM of 8.6 cm^{-1}, comparable to HPHT diamonds. After fabricating the films, we performed electron beam irradiation using a 300 keV TEM with an electron fluence of $10^{18\sim22}$ cm^{-2}, resulting in the world's highest NV concentration of 8.5×10^{18} cm^{-3} [3]. This method is necessary for electron irradiation for high density nitrogen above 1×10^{20} cm^{-3}. The quantification of NV concentration was done using the DEER(Double Electron-Electron Resonance) based on NV interactions. DEER is a method of measuring NV concentration from the magnetic dipole interaction strength between NV's four orientation groups by applying microwaves simultaneously to groups of each different resonance frequencies, so this method utilizes the fact that the decay rate of coherence time is proportional to the number of resonant NV groups in the concentration range of $8.5 \times 10^{17} \sim 1.7 \times 10^{19}$ cm^{-3},as confirmed by simulations and experiments [4]. By manipulating the number of resonant NV groups, we determined the NV concentration [3]. Previously, the concentration was estimated from the emission intensity, but when the NV concentration exceeded 10^{18} cm^{-3}, the saturation of NV concentration occurred without an increase in irradiation fluence. As a result, the estimated values from the emission intensity using the DEER method were higher than those estimated from the emission intensity. However, the obtained NV concentration of 1.0×10^{18} cm^{-3} is only about 1% yield relative to the nitrogen concentration. Understanding the behavior of nitrogen in CVD diamond could potentially lead to higher NV concentrations. Despite such a high nitrogen concentration, the T_2^* was 50 ns, and T_2 remained at 0.5 µs measured by Ramsey and Hahn echo, respectively. This value is long compared to experimentally reported values [5]. This is because many reports showed that coherence time is inversely proportional to nitrogen concentration between 2×10^{16} and $1 \times 10^{20}$$cm^{-3}$. At the nitrogen concentration of our nitrogen-doped CVD diamond ([N] = 8.0×10^{20} cm^{-3}), the coherence time is calculated to be approximately 0.03 µs, which is much shorter than our measured value, suggesting that CVD diamond has advantages for high-density NV ensemble.

Exploring Magnetism in Multiferroics with Scanning NV Magnetometry PaulStevenson[1], PeterMeisenheimer[2], HongruiZhang[2] and RamamoorthyRamesh[3]; [1]Northeastern University, United States; [2]University of California, Berkeley, United States; [3]Rice University, United States

Multiferroic materials hold great promise for next-generation devices, offering a route towards low-power, voltage-based control of magnetic ordering. Realizing this potential, however, requires understanding the coupling between magnetic and ferroelectric degrees of freedom. Using scanning NV magnetometry (SNVM), we are able to resolve the wide range of antiferromagnetic textures in the multiferroic $BiFeO_3$, revealing previously hidden heterogeneity and allowing us to directly image the effect of applied electric fields.

We also show how SNVM can be used to image multiple field components simultaneously – without ambiguities normally present in reconstructions – by optimizing magnetic field conditions, and how local variations in the refractive index of $BiFeO_3$ can be imaged below the diffraction limit. These new capabilities demonstrate the broad utility of SNVM for exploring magnetic textures in multiferroic materials.

2:30 PM EL14.15.04
Analysis of Ferro- and Antiferromagnetic Memory Bits by Scanning NV Magnetometry PeterRickhaus[1], VicentBorras[1], RobertCarpenter[2], SebastienCouet[2], LizaZaper[1,3], AlexanderStark[1], MathieuMunsch[1], MarcoNordmann[1], PaulLehmann[3], KaiWagner[3], ChristophAdelmann[2], OleksandrPylypovskyi[4], Paulvan der Heide[2], DenysMakarov[4] and PatrickMaletinsky[3,1]; [1]Qnami AG, Switzerland; [2]Imec, Belgium; [3]University of Basel, Switzerland; [4]Helmholtz-Zentrum Dresden-Rossendorf, Germany

Storing information in magnetic bits requires excellent control over their nanoscale magneticproperties. A prime example of this challenge are STT-MRAM (spin transfer torque magnetic random accessmemory) devices - which have rather high failure rates. In order to investigate the sources of potential failure, atechnique that can resolve small magnetic fields with high spatial resolution is required. The request is evenmore urgent for next-generation magnetic memory materials, such as antiferromagnets, which generate evensmaller magnetic signals.
Scanning NV magnetometry (SNVM) is an emerging quantum sensing technique that offers the requiredsensitivity. Here, we will look at the local magnetic properties of bits in state-of-the-art STT-MRAM devicesusing scanning-NV magnetometry [1]. Furthermore, we will demonstrate magnetic images of a few hotcandidate materials for future magnetic memory devices including antiferromagnetic chromia, BFO [2] andultra-scaled CoFeB nanowires [3]. We will reveal magnetic textures that are undetectable with more standardcharacterization techniques and discuss implications on device fabrication.

An Ultra-Sensitive Biosensor Based on Mid-Infrared Diamond Waveguide Spectroscopy PontusForsberg and MikaelKarlsson; Uppsala University, Sweden

In this presentation, our latest work in the development and the use of an ultra-sensitive biosensor based on diamond waveguides will be highlighted. We have during the last years been working on the design and fabrication of mid-infrared (MIR) diamond waveguides. The diamond MIR waveguides together with a broadband tunable quantum cascade laser (QCL), emitting in the so called molecular fingerprint region, are the two key elements in our newly developed label free MIR biosensor. In our approach MIR light is coupled into microfabricated diamond waveguide structures, which are purposefully designed to sustain single or multimode standing waves. The associated evanescent waves that are created at the waveguide surface will extend into the surrounding media and interact with the analyte thus provide the sensing volume. In existing commercial technologies, attenuated total reflection IR (ATR-IR) spectroscopy, IR light from a thermal emitter is coupled through a millimeter sized diamond crystal, with up to 10 internal reflections in the diamond crystal. This is a powerful technology and is today used for i.e. quality control in medical and food industry, protein analysis, forensics, etc. However, the relatively low sensitivity of this technique hinders its use in many applications. Our biosensor achieves unsurpassed sensitivity due to the large number of standing waves nodes created in our waveguides which roughly can be translated to the number of internal reflections per length unit is maximized. Moreover, the use of a bright QCL laser as a light source further increases the sensitivity of our biosensor – therefore an ultra-sensitive sensor is realized. Finally, the diamond waveguide material facilitates further functionalization by means of organic chemistry thus extending the capabilities of traditional silicon or gold based biosensor technologies, and we demonstrate here one possible route to fabricate selective affinity layers for protein fishing from complex mixtures.
Several designs of diamond waveguides are discussed, ranging from thin film diamond slab waveguides, rib waveguides, to microfabricated free hanging diamond waveguides. We have recently showed how AlN can be used as cladding layer to overcome earlier difficulties in guiding light at longer wavelengths (5-10 µm). We will also present how we significantly can increase the sensitivity of the diamond waveguide sensor by depositing a high index film on the diamond waveguide. Using silicon as the high index film also opens up for easy functionalization of the sensor.
The diamond waveguide sensor has been tested on different analytes, such as acetone and isopropanol, showing a very stable performance and very high sensitivity. We have therefore starting to work on “real-world” chemical sensing applications. Currently, we are analyzing different forms of the protein alpha-synuclein, which is relevant in understanding the mechanism behind Parkinson’s disease. We have previously shown that ATR-IR spectroscopy can be used to analyze the secondary structure of different alpha-synuclein aggregates. Moreover, it is also possible to see the difference in the IR-spectra between the native state and the neurotoxic misfolded state of the protein. However, the ATR element is impractical to functionalize and the sensitivity of the ATR-IR spectroscopy is too low to be used on relevant samples from patients. In contrast, our diamond waveguide biosensor exhibits the desired key properties to analyze the secondary structure of alpha-synuclein at biologically relevant concentrations. Future work includes the functionalization of the diamond waveguide sensor surface to selectively adsorb alpha-synuclein from cerebrospinal fluid, with the ultimate goal to detect Parkinson’s disease at an early stage.

3:45 PM *EL14.16.02
Electronic Properties and Memristive Behavior in Undoped Diamond Foils for Artificial Neurons-On-A-Chip Application AdrianNosek[1], AdrianOlejnik[2], MarcBockrath[3] and RobertBogdanowicz[2]; [1]University of California Riverside, United States; [2]Gdansk University of Technology, Poland; [3]The Ohio State University, United States

The electronic properties of chemical vapor deposited undoped polycrystalline diamond foils are investigated via continuous and pulsed mode measurements. In continuous mode, our diamond thin foil operates as a bipolar memristor with a variable onset voltage and internal nanobattery effect. We attribute the memristive properties to a filamentary redox-based resistive switching mechanism with ionic and electronic charge transport within our diamond foil. In order to explain the occurrence of this dip, we consider the hydrogen redox-based switching model. In this model, hydrogen ions are separated from the conductive filament and migrate towards the negatively charged electrode through atomic vacancies and produce a build-up internal nanobattery voltage. This diffusion process is accelerated by local high temperatures produced by the current carrying filament. While current compliance is not necessary for this effect to occur, it is certainly beneficial because a fixed part of the voltage drop occurs due to electrons travelling towards the positive electrode and the rest of the voltage drop occurs due to protons migrating and accumulating at the negative electrode. After the pulse is turned off, a current in reverse direction flows due to the build-up internal voltage as well as repulsion of accumulated positive charge carriers. In pulsed mode operation, our diamond foils exhibit synaptic behavior, similar to the interface between two neurons. Our memristors exhibits high retention times with high on/off ratios up to 10^4 required for logic operations. As an inorganic synapse, our foil exhibits sensory, short-term, and long-term memory effects according to a psychological human

memory model. Spike-timing dependent plasticity supports our findings. Furthermore, we observe functionalities commonly found in neurons, such as a mimicked refractory period where our conductive filament corresponds to an axon. We anticipate that our study paves the way for future artificial-neurons-on-a-chip application. Our research findings constitute an important step towards artificial-neurons-on-a-chip application, as well as organic-inorganic brain-electronics interfaces.

Rapid Measurement of Plasma Molecular-Targeted Drug Concentration with Boron-Doped Diamond Electrode GenkiOgata[1], TakuroSaiki[2], YasuoSaio[2], YasuakiEinaga[1] and HiroshiHibino[3,4]; [1]Keio University, Japan; [2]Niigata University, Japan; [3]Osaka University, Japan; [4]AMED, Japan

Compared to conventional cytotoxic anti-cancer drugs, molecular-targeted medications exhibit reduced toxicity. These drugs are administered to patients at fixed doses, without the need for adjustments based on biomedical indices such as body surface area. However, this therapeutic approach leads to considerable variability in plasma concentration among individuals, often resulting in significant adverse events that necessitate dosage reduction. Recent clinical studies have sought to quantify the correlation between drug concentration and clinical efficacy or toxicity. To enable personalized administration of molecular-targeted drugs, it is imperative to determine plasma concentrations directly at the clinical site. In recent years, advancements in medical engineering have yielded various portable or wearable biosensors capable of rapid on-site monitoring. Nonetheless, the widespread utilization of these devices has been hindered by insufficient evaluation of accuracy using clinical samples, variability between sensors, and the need for complex and costly fabrication processes. To overcome these challenges, we propose a straightforward approach utilizing untreated boron-doped diamond (BDD), an electrochemical material known for its sustainability. As a proof-of-concept, we selected pazopanib, a molecular-targeting anticancer drug recommended for monitoring. By employing a BDD plate chip measuring approximately 1 cm^2, our sensing system accurately detected pazopanib concentrations in rat plasma samples within the clinically relevant range. Furthermore, the response of the chip remained stable throughout 60 consecutive measurements, demonstrating its excellent repeatability. When we examined plasma samples collected from orally administered healthy rats and cancer patients using our system, the measured concentrations closely matched those obtained through liquid chromatography with mass spectrometry. Additionally, we evaluated the reproducibility of the BDD chips. Finally, we constructed a portable system featuring a palm-sized sensor housing a chip to facilitate practical implementation. This setup successfully determined drug concentrations from approximately 40 µL of whole blood obtained from dosed rats within a short turnaround time of approximately 10 minutes. By employing this "reusable" sensor-based approach, we can accelerate point-of-care drug monitoring, advance personalized medicine, and potentially reduce medical expenses.

Fabrication of Diamond/Metal Oxide Hybrid Structures: Towards Gas Sensors with Enhanced Sensitivity and Selectivity PetrAshcheulov[1], MarinaDavydova[1], AndrewTaylor[1], NedaNeykova[1], AlexandrLaposa[2], JaromírKopeček[1] and PavelHubík[1]; [1]FZU, Czechia; [2]CVUT, Czechia

The release of hazardous compounds such as NOx, SOx, CO, NH_3, other nitrogen or sulfur-containing compounds, and volatile organic compounds (benzene, toluene, methanol, etc.) in the atmosphere is of significant concern for human health. Therefore, there is a rising demand for advanced chemiresistor sensors, which need to satisfy the following requirements: high sensitivity, selectivity, stability and reproducibility. In recent years, various metal oxides (e.g., ZnO, SnO_2, CeO_2) have been recognized as promising materials for the detection/sensing of toxic pollutants and hazardous gases. Yet, chemiresistor sensors based on metal oxides have exhibited rather poor selectivity (i.e., simultaneous sensitivity to reducing and oxidizing gases) along with the necessity of high temperature (> 300 °C) operation.
In this work we demonstrate fabrication of hybrid structures based on diamond (intrinsic and boron-doped) and metal oxides (MOx) for their application as active components in gas chemiresistor sensors. We investigate the effect of doping and the diamond structure (planar and/or 3D geometries) on the sensing characteristics of hybrid structures (e.g., sensitivity and selectivity) towards various gases. Fabricated diamond/MOx structures were characterized via various microscopic and spectroscopic techniques, and the effect of their electrical characteristics on the sensing properties is discussed.
This work was supported by the Czech Science Foundation grant GACR 22-04533S.

Normally-Off Vertical Diamond MOSFETs with Drain Current Density over 200 mA/mm using Oxidized Si Terminated Diamond Channel Formed by Si Molecular Beam Deposition Approaches KentoNarita[1], KosukeOta[1,2], YuFu[1], ChiyukiWakabayashi[1], AtsushiHiraiwa[1], TatsuyaFujishima[2] and HiroshiKawarada[1,2,3]; [1]Waseda University, Japan; [2]Power Diamond Systems, Inc., Japan; [3]The Kagami Memorial Research Institute for Materials Science and Technology, Japan

For realization of high-power high-speed miniaturized complementary inverters [1], development of p-type field-effect transistors (p-FETs) corresponding to SiC or GaN n-FETs is essential. Normally-off operation with threshold voltages (V_{th}) more negative than −3 V are required for power devices with operating voltage above 500 V, but the conventional vertical diamond FETs are normally-on operation (V_{th}: +15 ~ +30 V) using hydrogen-terminated diamond (C-H) channel [2,3]. In contrast, we have fabricated (001) vertical diamond MOSFETs with oxidized Si terminated diamond (C-Si-O) channel by the reaction of chemical vapor deposition (CVD) SiO_2 with diamond and achieved the first normally-off operation (V_{th}: −9.0 V) in vertical diamond FETs with a maximum drain current density ($I_{D,max}$) of 108 mA/mm[4]. In this study, by Si molecular beam deposition (MBD) method, we fabricated C-Si-O side-wall channel in vertical diamond MOSFETs for the first time. We obtained the V_{th} of −4.5 V and the $I_{D,max}$ of 214 mA/mm, which is the highest $I_{D,max}$ among the normally-off vertical diamond FETs.
The C-Si-O channel formation method is as follows. After 200 nm regrown undoped layer was deposited by microwave plasma CVD, SiO_2 was deposited 400 nm as a mask by tetraethyl orthosilicate based plasma-enhanced CVD. A p^{++} layer ([B]: 1×10^{21} cm^{-3}) was selectively deposited by MPCVD after etching 400 nm of the SiO_2 mask and 40 nm of the regrown undoped layer by inductively coupled plasma reactive ion etching. After SiO_2 mask removal, the diamond surface was treated with hydrogen termination. 0.5 nm-silicon was deposited and followed by in-situ annealing at 1193 K for 15 min in the MBD apparatus. During the annealing in high vacuum, the reaction between C-H and Si occurred and C-Si- happened [5,6]. The C-Si- surface was naturally oxidized and transformed to C-Si-O after the C-Si- channel was exposed to air [7].
The vertical device dimensions for source-source length (L_{SS}), effective channel length (L_{ch}), trench width (W_T), gate-drain length (L_{GD}), trench depth (D_T) and gate width (W_G) are 8 µm, 5.2 µm, 4 µm, 0.4 µm, 3 µm and 25 µm, respectively. The $I_{D,max}$ normalized by the W_G was 214 mA/mm, and the $I_{D,max}$ normalized by the active area ($L_{SS}\times W_G$: 2.0×10^{-6} cm^2) was 5350 A/cm^2 at V_{DS}: −45 V and V_{GS}: −40 V, and the on-resistance (R_{on}) was 8.1 mΩcm^2. The on/off ratio was 10^7 and gate leakage current was less than 10^{-5} mA/mm at V_{DS}: −10 V. The maximum transconductance ($g_{m.max}$) was 15 mS/mm, and the maximum field-effect mobility ($\mu_{FE,max}$) was 68 cm^2/Vs. The V_{th} was −4.5 V at V_{DS}: −10 V. As a result, we achieved the normally-off operation of $|V_{th}| > 3$ V, and the $I_{D,max}$ of over 200 mA/mm. The V_{th} shifted more than 20 V in the negative direction compared to conventional C-H channel vertical diamond FETs [2,3]. The negative electron affinity of C-Si-O surface (−0.25 eV) [7] is weaker than that of C-H surface (−1.3 eV) [8] and the negative fixed charge of Al_2O_3 on the C-Si-O interface is less than that on the C-H interface. The large negative shift of V_{th} is due to the smaller band offset and the smaller band bending between diamond and Al_2O_3 in the C-Si-O channel than in the C-H channel. In the near future, by introducing a p^--drift layer, and C-Si-O channel only on the sidewalls, we will realize vertical diamond devices with high breakdown voltage over 1000 V and normally-off operation.

Atomic Hydrogen Effects on Chemical Bonding of Diamond-Like Carbon Films Prepared by Pulsed Laser Deposition TakahiroKawabata; Public University Corporation Toyama Prefectural University, Japan

1. Introduction

Tetrahedral amorphous carbon (ta-C) films have been prepared by pulsed laser deposition (PLD) [1-4]. Stock et al. [1] reported that the sp^3 carbon ratio [sp^3 C/(sp^3 C + sp^2 C)] in the ta-C film prepared using an ArF excimer laser (198 nm) was 80% or more, which was higher than the sp^3 ratio (~60%) in the film deposited using a KrF excimer laser (248 nm). Yoshitake et al. [2] reported that the ta-C film prepared in a hydrogen atmosphere had a higher sp^3 ratio than the film deposited in an oxygen atmosphere. Cheng et al. [3,4] performed postdeposition-annealing of ta-C with atomic hydrogen irradiation and found that atomic hydrogen etching accelerated crystallization of micro/nano graphite as the annealing temperature rose. In this study, we have deposited diamond-like carbon (DLC) films by PLD using a KrF excimer laser and investigated atomic hydrogen effects on the chemical bonding of the DLC films. We clarified the optimum deposition conditions to promote sp^3-bonded carbon atoms in the films. The novelty of this study is that the hydrogen effects were investigated by varying the deposition parameters systematically.

2. Experimental methods

DLC films were prepared on Si(100) substrates by PLD using a KrF excimer laser with a wavelength of 248 nm. The DLC film was deposited at a substrate temperature of RT, a laser repetition rate of 20 Hz, a laser intensity of 0.25 J/pulse using an atomic hydrogen source (hydrogen pressure: 0.01 Pa, tungsten filament current: 4 A) for 60 min as a standard sample. One of the substrate temperature, laser repetition rate, hydrogen pressure, and filament current was varied with the other parameters fixed. The sp^3 ratio [sp^3 C/(sp^3 C + sp^2 C)] was determined from C 1s core-level spectra obtained by X-ray photoelectron spectroscopy (XPS).

3. Results and discussion

The DLC films prepared with atomic hydrogen irradiation had higher sp^3 ratios than those prepared in a vacuum. Especially, the DLC film deposited at a filament current of 4 A exhibited the highest sp^3 ratio. The hydrogen pressure at which the sp^3 ratio reached a maximum was found to be 0.01 Pa. When the substrate temperature was increased from RT to 700 °C, the sp^3 ratio decreased. It was found that the sp^3 ratio in the film deposited at a repetition rate of 20 Hz was higher than that in the film deposited at 10 Hz. The maximum sp^3 ratio of 57% was obtained in this study, which was close to that reported in Ref. 1, in which PLD using a KrF excimer laser was employed.

Yasui et al. [5] have reported that the amount of atomic hydrogen generated using a tungsten filament source increases with the filament temperature. C.-L. Cheng et al. [3] have shown that hydrogenated, disordered carbon films are deposited at RT, whereas the graphitization of the films occurs at substrate temperatures above 500 °C, which is facilitated by hydrogen etching. When the filament temperature and hydrogen pressure increase, the amount of atomic hydrogen increases, leading to the acceleration of the formation of C–H bonds and selective etching of sp^2-bonded carbons by atomic hydrogen. When the substrate temperature decreases or the repetition rate (the flux of C atoms) increases, the surface diffusion length of C atoms decreases. In this case, C atoms adsorbed on the surfaces are not able to arrive at stable sites, and the film becomes a metastable form of amorphous carbon.

4. Summary

The maximum sp^3 ratio of 57% was obtained when the hydrogen pressure, substrate temperature, laser intensity, and laser repetition rate were 0.01 Pa, RT, 0.25 J/pulse, and 20 Hz, respectively.

All-Optical Modulation of Fluorescent Nanodiamonds for Practical Applications LingzhiWang and ZhiqinChu; The University of Hong Kong, Hong Kong

Because of ultrahigh photostability, nanoscale volume emitting strong fluorescent signal, and low cytotoxicity, fluorescent nanodiamonds (FND) containing nitrogen vacancy (NV) centers are regarded as promising fluorescent markers in various applications. Here, based on optical polarization-selective excitation phenomenon of NV centers, we provided FNDs with more useful functions, including orientation measurement and providing high-dimensional anticounterfeiting information. Particularly, our scheme showed two characteristics: 1) easy-to-implement solution; 2) useful functions. Specifically, our scheme can be conveniently achieved based on mature commercial sample and common microscope with slight modification. Utilizing the orientation measurement of FNDs, we provided the information for cell traction force in a new dimension (rotational dimension). Based on the 3D anticounterfeiting information from FNDs, we achieved physical unclonable function labels, well satisfying common commercial and anticounterfeiting requirements. In above application scenarios, our scheme has little negative influence due to all-optical manipulation.

Non-Invasive Quantum Sensing and Coherent Control of Surface-Supported Spin Systems AparajitaSingha; Max Planck Institute for Solid State Research, Germany

Controlling individual atoms and molecules at their native spatio-temporal limit has an indispensable appeal that has driven fundamental research for decades. Atomic-scale interactions and correlations are also the basis of all timeless technological progress, ranging from nanoelectronics to information processing. In particular, a new attractive avenue has recently emerged for nanoscale quantum bits made of individual lanthanide atoms and molecules. The intrinsic large magnetic moment, nontrivial intra- as well as inter-atomic electron correlations, and long-term quantum coherence in these model systems altogether offer a myriad of new exciting possibilities across molecular magnetism and quantum computing research.

My present scientific effort is devoted to understand and control quantum mechanical properties of such smallest building blocks of matter, especially by probing them in the least invasive manner. However, addressing the spin states in such quantum systems is an extremely challenging task. So far, only scanning tunneling microscopy (STM) with subatomic spatial resolution is capable of achieving this, albeit being highly invasive and limited with the scope of operational temperature (< 4 K). Atomic force microscopy (AFM) using novel defect centers in diamond (NV) has the potential to overcome these limitations, given their unparalleled magnetic sensing capability, high-fidelity optical readout, and broad operational range of temperature. However, this method currently suffers from insufficient resolving power (tens of nm) primarily due to fluorescence quenching in so-called shallow NV centers. In this talk, I will discuss each of these techniques in view of access and quantum control at the atomic scale, highlighting our efforts to surpass the current capabilities of STM in this context, while simultaneously generalizing the scopes of scanning NV-magnetometry for addressing solid-state spin systems.

Room Temperature sub-THz (300 GHz) Plasma Wave Generation in p-Diamond TeraFET Muhammad MahmudulHasan[1], NezihPala[1] and MichaelShur[2]; [1]Florida International University, United States; [2]Rensselaer Polytechnic Institute, United States

The growing demand for efficient and compact terahertz (THz) sources operating at room temperature is driven by their wide-ranging applications in spectroscopy, imaging, and communication systems. Hydrodynamic transport modeling of TeraFETs (Terahertz Field-Effect Transistors) has revealed that p-diamond is a promising material for sub-THz applications beyond 5G. P-diamond, characterized by its large carrier effective mass, exhibits longer momentum relaxation times compared to other semiconductor materials, rendering it advantageous for generating THz radiation at lower frequencies. This paper presents a comprehensive hydrodynamic modeling study of a p-diamond-based TeraFET acting as a THz source. Our simulations show that p-diamond TeraFETs could support channel carrier oscillations at THz frequencies below 1 THz at room temperature operating as THz sources enabled by the Dyakonov-Shur instability.

To investigate the performance of the p-diamond TeraFETs, we conducted a thorough numerical analysis using a 1D hydrodynamic model. This model incorporates viscosity effects and considers damping resulting from electron scattering by impurities and phonons. Our simulations conclusively demonstrate the efficacy of the p-diamond TeraFET in emitting resonant THz radiation at a frequency of 300 GHz at room temperature when biased by a DC current. We explored the dependencies of the resonant oscillations on the channel length, drift velocity, and gate bias. These dependencies guide precise tuning of the emitted THz radiation. Our analysis predicts the minimum drift velocity necessary to overcome the decay factor caused by scattering and viscosity effects, ensuring robust resonant oscillation. These findings shed light on the p-diamond TeraFET's operation and aid in optimizing its performance as a sub-THz source.

Iodine Doping in Tetrathiafulvalene Twisted Crystals St. JohnWhittaker, MerrittC. McDowell, ShinKim, BartKahr and StephanieLee; New York University, United States

Tetrathiafulvalene (TTF), a workhorse of the organic electronics community since it's superconductor tetracyano-p-quinodimethane co-crystal was discovered in 1973,[1] is an optically inactive centrosymmetric molecule that crystallizes in an optically inactive centrosymmetric space group *P*-1 when grown from the melt. We recently discovered that growth-actuated crystal twisting breaks this symmetry to render TTF twisted crystals optically active and thus promising candidates for chiroptoelectronics.[2] In this work, tetrathiafulvalene (TTF) banded spherulites comprising helicoidal fibrils are doped with iodine to improve their conductivity for (chir)optoelectronics. Within five minutes of exposure to iodine vapor, TTF film conductivity increased by six orders of magnitude, from 100 pA to 100 µA, accompanied by a color change from pale yellow to dark red. Grazing incidence x-ray diffraction patterns also revealed a change in crystal structure upon iodine doping. The rate of iodine doping was found to depend on the local crystal face presented at the film surface, which alternates between faces as the crystalline fibrils twist about the growth direction, forming concentric "bands" surrounding the spherulite center. Crystal face-dependent iodine intercalation was observed by optical microscopy, light absorbance spectroscopy, and electron dispersive x-ray spectroscopy. Faces corresponding to fast iodine intercalation were previously identified as the 1-11 face.[3] Mueller Matrix imaging revealed that crystal twisting is not disrupted by iodine intercalation, with circular dichroism and birefringence retained after five minutes of film exposure to iodine vapor. Combined with the orders of magnitude improvement in electrical conductivity, optically active doped TTF banded spherulites will provide a platform to examine chiral-induced anisotropies in electron and photon interactions in molecular semiconductor twisted crystals.

Blending Chiral Small Molecules to Achiral DPP-Based Conjugated Polymer to Induce Chiroptical Properties JeongwooBeak, YinaMoon, JeongjinHong and Dong-YuKim; Gwangju Institute of Science and Technology, Korea (the Republic of)

Conjugated polymers have been developing due to their electrical and optical properties. Furthermore, the chiroptical properties with conjugated polymer have distinguished characteristics of selectivity based on handedness. There are many methods to induce chirality to conjugated polymers, but blending chiral small molecules to achiral conjugated polymers is one of promising and simple methods via supramolecular interactions. By utilizing this method, the induced chirality to conjugated polymer can be applied to optoelectronic devices for multiple signal due to differences in absorption depending on right or left circularly polarized light at the same wavelength.
In this study, diketopyrrolopyrrole(DPP) based polymers with charge transport, NIR absorption property, PDVT-10 is blended with chiral small molecules, (*R*)- or (*S*)-1,1′-Binaphthyl-2,2′-diamine((*R*)- or (*S*)-BN). The chiroptical characteristics are based on the blending ratio and opposite properties between (*R*)- and (*S*)-BN with PDVT-10 in solution. In thin films, the presence of (*R*)- or (*S*)-BN affects PDVT-10, leading to the emergence of a new peak in circular dichroism on near-infrared range and a peak shift in UV-Vis spectrometer. Moreover, it is possible to invert the absorption of circular dichroism and shift UV-Vis peaks through annealing condition. The formation of helical structures through supramolecular assembly on blended films is observed on AFM images and the chiral orientation of BN is transferred to the morphology of PDVT-10 confirmed by 2D-GIWAXS analysis. Moreover, a phototransistor based on an organic field-effect transistor (OFET) demonstrates difference sensitivity to right or left circularly polarized light with a wavelength of 850 nm in the near-infrared range. In particular, the optical activity of semiconductors in the near-infrared range, combined with chirality, is significantly important due to their ability for long-range optical communication, skin penetration, and night vision. In conclusion, this blending method could be proposed as a simple and straightforward approach to induce new chiroptical properties to achiral conjugated polymers.

Twisted Hydrogen-Bonded Frameworks RochelleB. Spencer, AnnaYusov, AlexandraDillon, WantongWu, BartKahr, MichaelD. Ward and StephanieLee; New York University, United States

Directing the assembly of molecules within hydrogen-bonded frameworks is being extensively explored as a modular crystal engineering strategy to access novel molecular packing arrangements of target molecules. Crystal twisting, a common but little-known phenomenon in molecular crystals, of these frameworks provides an additional handle to not only interrogate crystal orientation-dependent properties but also to impart chirality for chiroptoelectronics. Here, we demonstrate crystal twisting in solution-processed bis(guanidinium) naphthalene-1,5-disulfonate $(G)_2$(1,5-NDS) films in which molecular assembly is driven by hydrogen bonding between guanidinium and sulfonate moieties. When deposited from ethanol in conditions that

favor low nucleation densities but high branching rates, $(G)_2$(1,5-NDS) crystallizes as banded spherulites of helicoidal fibrils emanating radially from a single nucleation center and twisting in concert with one another about the growth direction. Scanning electron micrographs (SEMs) reveal tightly packed fibrils that alternate between flat-on and edge-on orientations with respect to the substrate surface with a twisting pitch of ~ 3 - 4 μm. 2D x-ray diffraction (XRD) patterns collected on $(G)_2$(1,5-NDS) banded spherulites confirm that the crystals adopt a bilayer packing motif with ethanol as guest molecules. These banded spherulites further exhibit band-dependent linear dichroism and birefringence, as well as circular dichroism and birefringence as a consequence of twist-induced loss of symmetry. Given the modular nature of these hydrogen-bonded frameworks to incorporate a broad range of molecular pillars and guests, combining hydrogen bond-directed assembly with crystal twisting will open unexplored avenues in the design of chiroptoelectronic materials.

11:15 AM EL15.01.04
Spinning Around You: Using Organic Doublet Systems with Rotameric Chirality to Your Benefit in Optoelectronics and Spintronics RituparnoChowdhury[1], PetriMurto[2], CraigYu[2], PratyushGhosh[1], YaoFu[2], ClareP. Grey[2], AkshayRao[1], HugoBronstein[2] and RichardFriend[1]; [1]The University of Cambridge, United Kingdom; [2]University of Cambridge, United Kingdom

Over the last decade a large fraction of materials and optoelectronics research has been focussed on the development of methods to mitigate and manage triplet states in organic optoelectronics devices while a comparably large effort is also ongoing in engineering the spin-optical interface for the deisgn of molecular qubit systems. Intermediate exchange-coupled high spin states are very counter-productive to the optical activity of a material, but they turn out as a hero instead of a villain if you want to make quantum computing units out of them. The discovery of the CISS effect was pivotal in showing a chirality mediated effect in light elements that can serve as a proxy to spin-orbit coupling without the presence of any heavy atom has now allowed us to access exotic spintronic properties which would otherwise remain untapped in chiral organic molecules. Even better, this opens up further possibilities to utilise chiral molecules with an open shell ground state. In this work I will walk you thorugh the many ways that we are doing so with carbon centered tris(2,6-chloro-4-mesitylphenyl)methyl(MTTM) radicals. We first start off simple by showing that doublet organic molecules can achieve deep red, NIR-1 and NIR-2 photoluminescence with high quantum efficiency. We then address the topic of redox stability, a big issue in standard open shell molecules, and we show succesfully that these doublet materials are exceptionally redox stable and redox reversible. Finally we dive deeper into the magnetic properties of the doublets when connected in different ways and show how this can interchange the spin multiplicity of the ground state and allow exceptional control of both the ground and excited state exchange couplings. We finally embark on the journey to unravel how chirality plays a role in these systems bearing in mind that all along chirality was inherent to these systems by virtue of the rotameric bond joining the donor and acceptor fragments of these molecules, this inherent chirality gives the possibility to design all-organic spin valves, which would be an unprecedented achievement. By taking you through this story I aim to show you the versatility of our materials and their potential for extensive application in quantum information sciences and spintronics setting the stage for an era of radical organic semiconductors.

Chiral Organic Semiconductors – Lending a Hand in Photocatalysis AishaMumtaz, RebeccaIngle and BobSchroeder; University College London, United Kingdom

Society’s ever-growing energy demands and simultaneous rapid depletion of current greenhouse gas-emitting resources showcase the need to find clean, renewable alternatives. Generation of hydrogen through the combined action of sunlight, water and a photocatalyst, the water splitting reaction (WSR), offers a promising solution to this long-standing problem. However, the WSR suffers from uncontrolled spin alignment of OH radicals, producing hydrogen peroxide (H_2O_2) as a by-product, which greatly hinders the efficacy and scalability of this process.[1] As chiral molecules are sensitive to electron spin orientation, due to the Chiral Induced Spin Selectivity (CISS) effect, they could behave as spin filters in photocatalysis, thus providing a unique pathway to cleaner energy by impeding hydrogen peroxide formation.[1],[2]

Conjugated polymers are a class of material that have gained increasing attention due to their applications in many electronic devices such as transistors, organic light emitting diodes (OLEDs) and flexible organic photovoltaics (OPVs). This is owing to their tuneable optoelectronic properties, intrinsic flexibility, solution-processability, low cost and abundance. Application of these features to photocatalysis, in combination with the spin selectivity of chiral molecules, could result in efficient, scalable production of hydrogen for clean energy resources.[2],[3]

This work focuses on the synthesis and spectroscopic characterisation of a series of novel, chiral conjugated polymers to generate the desired CISS effect for the suppression of H_2O_2 in the WSR. Development of these systems relies on gaining a deeper understanding on how the nanoscale chirality impacts the overall chiral expression. We therefore investigate the effect of chiral centre positioning on the polymer microstructure. In addition to pursuing renewable, cleaner energy for society, this work could also have a profound impact on our understanding between the interplay of chiral centres and polymer microstructure.

Can We Still Measure Circular Dichroism with Circular Dichroism Spectrometers: Anisotropic Artifacts in Multiscale Hierarchically Structured Films from Magic-Sized Clusters ThomasJ. Ugras[1], YuanYao[1], TalisiMeyer[1], DaWang[2], ArantxaArbe[3], SaraBals[2], BartKahr[4] and RichardRobinson[1]; [1]Cornell University, United States; [2]University of Antwerp, Belgium; [3]Spanish National Research Council, Spain; [4]New York University,, United States

Chiral materials with strong linear anisotropies are difficult to accurately characterize with circular dichroism (CD) because of artifactual contributions to their spectra from linear dichroism (LD) and birefringence (LB). Recently, we have discovered that CdS magic-sized clusters (MSC) can self-assemble into ordered films that have a hierarchical structure spanning seven orders of length-scale [1]. Because of the small size of MSCs and because of their high organic-ligand/core ratio, these hybrid materials have “softer” inter-particle interactions, with access to a richer phase diagram beyond the classical close packed structures seen with larger nanoparticles, resulting in self-organization into anisotropic patterns. These films have a strong CD response, but the chiral origins are obfuscated by the hierarchical architecture and LDLB contributions. Here, we derive and demonstrate a method for extracting the “chiroptic” CD signal (CD generated by structural dissymmetry) from hierarchical MSC films and identify the chiral origin [2]. The theory behind the method is derived using Mueller matrix and Stokes vector conventions, making use of a second-order Taylor series expansion to extract the CD. The method is verified experimentally before it is applied to hierarchical MSC and nanoparticle films with varying macroscopic orderings. Each film’s extracted chiroptic CD shares a bisignate profile aligned with the exciton peak, indicating the assemblies adopt a chiral arrangement and form an exciton coupled system. Interestingly, linearly aligned MSC films possess one of the highest g-factors (0.05) among semiconducting nanostructures reported. Further, we derive an expression to model the measured CD using a third order Taylor series expansion which introduces "pairwise interference" contributions to CD spectra that, unlike LDLB contributions, cannot be averaged out of the signal. We find that the third order pairwise interference terms can make noticeable contributions to the simulated CD spectra. Using numerical simulations of the measured CD across a broad range of linear and chiral anisotropy parameters, the LDLB interactions are most prominent in samples that have strong linear anisotropies (LD, LB) but negligible chiral anisotropies, where the measured CD strays from the chiroptic CD by factors greater than 10^3. Media with moderate-to-strong linear anisotropy are in great danger of having their CD altered by these effects in subtle manners. These experimental and theoretical studies provide a simple means to extract the chiroptic CD from spectra anisotropically structured samples and highlight the significance of considering distortions in CD measurements through higher order interference effects in highly anisotropic nanomaterials.

Chirality-Induced Quantum and Topological Properties in 2D Tellurium ChangNiu and PeideP. Ye; Purdue University, United States

Chirality is increasingly recognized as a critical property in various aspects of human life, spanning fields such as biological chemistry and physics. The disruption of chiral symmetry significantly influences the properties of matter, particularly in pharmaceuticals, biochemistry, and materials science. Thus, a comprehensive understanding and manipulation of chiral materials are crucial for advancing cutting-edge technologies, including chirality-based sensors, optical devices, and electronic systems.
Trigonal Tellurium (Te) possesses one of the simplest crystal structures, consisting of a unit cell where three Te atoms form a covalently bonded spiral chain. The chirality of the Te crystal is determined by the helicity of these atomic Te chains, classified into different space groups: $P3_121$ (right-handed) and $P3_221$ (left-handed). Recently, hydrothermally grown two-dimensional (2D) Tellurium (Te) with a thickness of about 10 nanometers has attracted considerable attention due to its excellent electrical, thermal, and optical properties. The chemical potential of 2D Te can be electrostatically tuned by applying a gate voltage, enabling systematic studies of the quantum and topological properties induced by chirality.
Under ambient pressure, the conduction band minimum and valence band maximum of Te are located at the H(H') point in the first Brillouin zone. Due to Te atoms' strong spin-orbit interaction and the unique chiral crystal structure characterized by three-fold screw symmetry, the conduction bands split and cross at the H(H') point, leading to a Weyl node. This node produces a radial-like spin texture in k-space, where spin polarization aligns parallel to the direction of electron momentum. This characteristic distinguishes it from the spin texture observed in Rashba semiconductors or the surface states of topological insulators, where the spin polarization is perpendicular to the electron momentum direction. Importantly, the spin polarization and charge of the Weyl nodes reverse in different enantiomers, a consequence of the mirror symmetry of left- and right-handed Te crystals.
Our investigations of the chirality-induced properties in 2D Te involved electrical and photoelectric responses. The chirality of 2D Te flakes was determined and verified using hot sulfuric acid etch pits and high-angle tilted high-resolution scanning transmission electron microscopy (HR-STEM). At low temperatures (0.3 K), we observed gate-tunable nonlinear electrical responses in 2D Te, including nonreciprocal electrical transport along the longitudinal direction and a nonlinear planar Hall effect along the transverse direction when subjected to a magnetic field. At room temperature, we discovered tunable chirality-dependent circular photogalvanic and photovoltaic effects, stemming from the interaction between circular-polarized light and the chiral crystal structure of 2D Te. These findings highlight the ability to control and manipulate the degree of chirality in materials.

Nonlocal Spin Transport Property of Chemical Vapor Deposition - Grown Tellurium Crystal ZixuWang and JianShi; Rensselaer Polytechnic Institute, United States

Chiral crystalline materials have a unique and robust spin-momentum relation allowing the design of energy-efficient spintronic devices. For example, when electrons flow in chiral materials, the electron spin is polarized either parallel or antiparallel to the current direction. In this work, we report the nonlocal spin transport characteristics of chemical vapor deposition - synthesized single crystalline Te crystal. We apply inversion spin hall effect to measure the current-induced spin in Te crystal. We find that the spin polarization can transport several hundreds of micrometers at room temperature. This work provides resilient testbeds for future development of practical spintronic devices.

Anisotropic and Bilinear Magnetoresistance of Bulk Doped GaAs ZhizhuoLiang and JianShi; Rensselaer Polytechnic Institute, United States

Basic understanding of the anisotropic and bilinear magnetoresistance (BMR) of GaAs is crucial for the design of spin-active devices. For BMR, it shows a linear dependence on the electric current and the magnetic field. BMR has been reported in topological insulators, two-dimensional electron gas, topological semimetals, 3D Rashba materials, etc. Here we report the observation of BMR in bulk n-type GaAs with a doping concentration of $1x10^{18}$ cm^{-3}. We measure the anisotropic magnetoresistance and BMR at 2.4 K, 4 K, and 10 K. During measurement, we vary the magnetic field from -14 T to 14 T. Magnetoresistance dependency on the current intensity, the magnetic field strength, direction of the magnetic field, and angle between the magnetic field and the current are studied. The work suggests the existence of non-trivial BMR in bulk GaAs.

Novel Topological Chiral Materials and Quantum PropertiesM. ZahidHasan; Princeton University, United States

Abstract Body: In this talk I present experimental realizations and properties of several chiral topological materials in novel Weyl, Dirac and Kagome systems building up on earlier results on topological insulators (Hasan & Kane, RMP 2010) and "Topological quantum properties of chiral crystals" (Nature Materials (2018); "Topological Hopf and Chain Link Semimetal States" (Physical Review Letters 119, 156401 (2017)); "Magnetic Weyl fermion semimetals in the R-AlGe family of compounds" (Physical Review B (2018)); "Giant and anisotropic many-body spin–orbit tunability in a strongly correlated kagome magnet" (Nature 562, 91–95 (2018)), Chern magnets (Nature 2020, Nature Physics 2020) and "Unconventional chiral charge order (magnetic) in the normal state of kagome superconductor KV3Sb5" (Nature Materials 2021). I conclude by indicating the new frontiers of research opened by the discovery some of these chiral materials.

Atomically Sharp Internal Interface in a Chiral Weyl Semimetal Nanowire NitishMathur[1], FangYuan[1], GuangmingCheng[2], SahalKaushik[3], InigoRobredo[4], MaiaG. Vergniory[4], JenniferCano[5,6], NanYao[2], SongJin[7] and LeslieSchoop[1]; [1]Princeton University, United States; [2]Princeton Institute for Science and Technology of Materials, United States; [3]Nordita, Stockholm University and KTH Royal Institute of Technology, Sweden; [4]Max Planck Institute for Chemical Physics of Solids, Germany; [5]Department of Physics and Astronomy, Stony Brook University, United States; [6]Center for Computational Quantum Physics, Flatiron Institute, United States; [7]University of Wisconsin--Madison, United States

Internal interfaces in Weyl semimetals (WSMs) are predicted to host distinct topological features that are different from the commonly studied external interfaces (crystal-to-vacuum boundaries). However, the lack of atomically sharp and crystallographically oriented internal interfaces in WSMs makes it difficult to experimentally investigate hidden topological states buried inside the material. In this talk, I will first discuss the presence of a unique internal interface known as *merohedral* twin boundary in chemically synthesized single-crystal nanowires (NWs) of CoSi, a chiral WSM of space group $P2_13$ (No. 198). Secondly, I will show the material characterization techniques to confirm the nature of lattice symmetry breaking inside the CoSi NWs due to the presence of this internal interface. Finally, I will conclude with showing why these interfaces are topologically relevant and how these *merohedrally* twined NWs could be ideal material systems to probe unexplored topological properties associated with internal interfaces in chiral nanostructures.

A Room-Temperature Polar Magnetic Metal HongruiZhang[1] and RamamoorthyRamesh[1,2,3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Rice University, United States

Multiferroic (-like) materials-based electric/magnetic devices hold great promise for the realization of ultra-low power logic-memory elements.[1] However, multiferroic (like) materials are elusive.[2] In this talk, we present the successful synthesis of a room-temperature polar magnetic metal, $Fe_{2.5}Co_{2.5}GeTe_2$ (FCGT).[3] The breaking inversion symmetry in FCGT induces an in-plane Dzyaloshinskii-Moriya interaction and spin-orbit torque when a charge current is applied. Thus, the FCGT system with perpendicular magnetic anisotropy demonstrates various novel magnetic properties that hold potential for spintronics devices. Our experimental results demonstrate the observation of a Néel-type skyrmion lattice at room temperature and zero field [4]. Additionally, by utilizing the confinement effect through stacking two flakes, we created an ordered skyrmion lattice [5]. Furthermore, we achieved current-induced magnetization self-switching in a few-layered flake at room temperature. This discovery of a non-centrosymmetric layered magnet operating at room temperature opens up new possibilities for layered spintronics device applications.

Inorganic Chiral Nanoparticles—A Promising Chiral Trigger to Induce Homochirality ZhifengHuang; The Chinese University of Hong Kong, Hong Kong

Origin of homochirality is a fundamentally important but yet unanswered question. One of the keys to answer this question is to understand external chiral forces to trigger symmetry breaking, which has been believed to induce the homochirality. Diverse chiral forces have been proposed, but one is missing: inorganic chiral surfaces have an enantiospecific interaction with prochiral molecules, considering the fact when the Earth formed about 4.5 billion years ago, it was prebiotically composed of inorganic minerals, mostly crystalline in nature and some are chiral, followed by the existence of organic life. We are studying chiral forces contributed from inorganic atomically chiral surfaces.

We use glancing angle physical vapour deposition to fabricate inorganic chiral nanoparticles (or CNPs), which have adjustable optical activities in the UV-visible-near infrared region. Inorganic CNPs are made of diverse metals, alloys and oxides, and composed of chiral structures at the atomic scale, including chiral twisting of multi-layers of achiral facets, high-index chiral facets, and chiral defects. Inorganic CNPs enantiospecifically interact with prochiral molecules, leading to an enantiospecific amplification of molecular optical activity, an enantioselective photoinduced cyclodimerization of a prochiral anthracene derivative, and reliable manipulation of symmetry breaking of prochiral helicenes. Our works shed light on the origin of homochirality (or life) stemming from the atomically chiral surfaces of minerals through the enantiospecific interactions with prochiral molecules.

Origins of Chirality in II-VI Semiconductor Nanoclusters via Symmetry Breaking ChenjieZeng; University of Florida, United States

Chiral semiconductor nanostructures have potential applications in chiral optoelectronics, spintronics, sensors, and catalysis. Compared to organic molecules, the origins of chirality in semiconductor nanomaterials are less understood due to many possible chiral geometries at hierarchical levels. Here, we unveil the intrinsic origins of chirality in II-VI semiconductor nanoclusters by achieving atomic precision in a tetrahedral-shaped CdSe nanocluster and X-ray crystallographic analysis. We show that the chirality emerges from the incorporation of tetrahedral coordination of individual ions into the icosahedral packing of the lattices, breaking the symmetry of the inorganic core from an achiral I_h to a chiral T. The chirality in the CdSe core further propagates to the metal-ligand interface, as manifested in the clockwise and counter-clockwise rotations of the interfacial coordination patterns. The asymmetric assembly of ligands on the tetrahedral facets further breaks the cluster symmetry from T to C_3. The left- and right-handed enantiomers are co-crystallized as a 1:1 racemic mixture. The resolved atomic structure of the chiral CdSe clusters shed light on the chiral structures observed in the larger semiconductor nanocrystals and their assemblies.

Inducing Chiral Photoluminescence in Single Photon Quantum Emitters using Chiral Induced Spin Selectivity Effects. SuryakantMishra, JenniferHollingsworth, EricBowes, HanHtoon and AndrewC. Jones; Los Alamos National Laboratory, United States

Chiral quantum emitters or non-reciprocal single photon devices have the potential for playing a significant role in future quantum communication-based infrastructure. To date, the realization of circularly polarized quantum emitters generally requires complex and bulky experimental infrastructures such as high magnetic/electric fields and cryogenic-temperatures. One potential means of realizing chiral quantum emission in solid-state systems is Chiral-Induced Spin Selectivity (CISS). This effect is a well-known physical phenomena known to enable control over electronic spins via the asymmetric transport of electronic spins in chiral organic and inorganic systems. We have explored the utilization of CISS effects as a means of manipulating the circular polarization of photoluminescence from single quantum emitters. Here, cadmium selenide-quantum dots are immobilized on a chiral surface prepared using electrodeposition of aniline. We observe both the inducement a significant degree of circular polarized photoluminescence emission and a magnetization-dependent photoluminescence quenching by using a ferromagnet valve in the chiral substrate. These observations illustrate the potential of a CISS-based mechanisms for realizing chiral single photon emission sources in solid-state material devices. By further exploring the dependence of circularly polarized emission on the quantum dot shell thickness and the thickness of the chiral films, we develop and demonstrate a model for the energy transfer pathways experienced by differing spin orientations in this system.

9:00 AM EL15.03.04
Structure-Property Relationships of Electrospun CdS Quantum Dot Fibers with Mechanically Modulated Reversible Chirality HansadiJayamaha, ThomasJ. Ugras, TobiasHanrath, RichardRobinson and LarissaShepherd; Cornell University, United States

Over the last three decades, electrospinning has gained increasing interest as a synthesis technique for micro and nano fibers due to its tunability and versatility. For the first time, electrospinning induced self-assembly of Cadmium Sulfide (CdS) magic sized clusters (MSCs) and their resulting chiroptical properties are discussed. The MSCs assemble into hexagonal mesophase during synthesis and the higher-level structures arise during the evaporation process. Through electrospinning, multiple hexagonal mesophase bundles are postulated to form twisted nanofibrils. These nanofibrils collectively constitute the microfiber as the result of self-assembly. Using Field emission scanning electron microscopy (FE-SEM), and atomic force microscopy (AFM) the morphology of the microfibers and the arrangement of the observed fibrillar structures are studied. The chiroptical properties of the fiber mats are extensively studied using Circular dichroism (CD) spectroscopy.

We improve the uniaxial fiber orientation, thereby synthesizing chiral microfibers with high dissymmetric factors ((~0.02) and linear dichroism (LD), comparable to thin films of the same material. Reversible changes in CD signals and reduced electron dipole alignment (i.e., LD) occur on stretching of the fibers embedded in elastomeric films. To study the alignment of the mesophase filaments and inter-filament distance upon stretching, Synchrotron based small angle X-ray scattering (SAXS) was used. We confirm a 4-scan method for removing Linear Dichroism-Linear Birefringence (LD-LB) and photo elastic modulator contributions and isolating true CD is applicable for such fibrous webs. This work provides the groundwork for further study of electrospun chiral fibers by bringing forth new research questions regarding the assembly of MSCs into fibrous structures.

Room-Temperature Electrically Switchable Rashba-Dresselhaus Effect in a Van Der Waals Ferroelectric Crystal with Persistent Spin Helix JianShi; Rensselaer Polytechnic Institute, United States

Here we show the discovery of the persistent spin helix in an organic–inorganic hybrid ferroelectric halide perovskite whose layered nature makes it intrinsically like a quantum well. We demonstrate that the spin-polarized band structure is switchable at room temperature via an intrinsic ferroelectric field. We reveal valley–spin coupling through a circular photogalvanic effect in single-crystalline bulk crystals. The favoured short spin helix wavelength (three orders of magnitude shorter than in III–V materials), room-temperature operation and non-volatility make the hybrid perovskite an ideal platform for understanding symmetry-tuned spin dynamics, towards designing practical spintronic materials and devices that can resolve the control-relaxation dilemma.

10:00 AM *EL15.03.06
Noncentrosymmetric and Chiral 2D Quantum Materials Through Screw Dislocations and Structural Tuning SongJin; University of Wisconsin--Madison, United States

Rationally controlling the structures of two-dimensional (2D) layered materials allows us to tune the electronic structures and quantum states of matter, discover new physical properties, thus enable new applications. We show how the phase, layer stacking and thus physical properties of 2D MX_2 materials can be influenced by screw dislocations. Noncentrymmetry of these MX_2 materials and 2D Ruddlesden-Popper (RP) lead halide perovskites could be enabled at the monolayer and bulk crystal structure level by structural tuning and screw dislocations. Furthermore, chiral microplates of MX_2 and 2D RP perovskites can be produced via a screw dislocation growth mechanism and the resulting chiroptical properties of individual chiral objects are studied using fluorescence detected circular dichroism (FDCD) microscopy and other polarized spectroscopic/nonlinear optical techniques. Moreover, we achieved systematic interlayer twisting of MX_2 spiral layers grown via screw dislocations due to mismatched geometry between Euclidean crystal lattices and non-Euclidean (curved) surfaces to form moiré superlattices, which could lead to novel quantum phenomena. The ability to enable and control noncentrosymmetry, chirality, and twisting of 2D materials open up new dimensions of quantum materials for the study of nonlinear and chiral optical properties, valleytronics and twistronics.

10:30 AM EL15.03.07

Enabling Chiroptical Properties in Achiral 2D Perovskites via Spiral Morphology WillaMihalyi-Koch, KatherineParrish, RandallH. Goldsmith and SongJin; University of Wisconsin–Madison, United States

Chiral 2D halide perovskites are promising semiconducting materials for chiroptoelectronic and spintronic applications. Chirality is typically imparted into 2D perovskites through the incorporation of chiral ammonium spacer cations, resulting in a chiral crystal structure. However, the extent of chirality transfer from the chiral organic cations to the inorganic perovskite network remains debated. In this work, we present another approach to introduce chirality and chiroptical properties into 2D perovskites through nanostructure morphology. By tuning crystallization conditions at an air-water interface, a large family of 2D perovskites with achiral crystal structures can be directly grown into spiral microplates via a screw dislocation growth mechanism. We demonstrated the versatility of this method by synthesizing spiral microplates of 10 different 2D Ruddlesden-Popper lead halide perovskites with various spacer cations, A-site cations, *n* number, and halide anions. The microplates can then be transferred to arbitrary substrates and characterization with atomic force microscopy clearly revealed the spiral centers. Fluorescence-detected circular dichroism (FDCD) microscopy was used to investigate the resulting chiroptical properties of individual chiral objects and large, spatially dependent g-factors on the order of 10^{-3} were observed from $(BA)_2(MA)_2Pb_3I_{10}$ spiral microplates. These results show that screw dislocation-driven growth can be used as a generally applicable method for enabling chirality and chiroptical properties in 2D perovskites without the need for chiral cations.

10:45 AM EL15.03.08

Ligand-Induced Chirality in Zig-Zag Topography of Two-Dimensional Iron Hydroxide for Spin-Polarized Photon Absorption Control BumchulPark[1,1], Sung-ChulKim[2], Dae BeomLee[3], JunLu[1,1], Ji-YoungKim[1,1], Sang HyunLee[1,1], Young KeunKim[3] and NicholasA. Kotov[1,1]; [1]University of Michigan–Ann Arbor, United States; [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Korea University, Korea (the Republic of)

Chiromagnetic nanomaterials capable of combining magnetism and chirality are of the cutting-edge engineering for spin-polarized light-matter interaction because they can modulate circularly polarized light through a magnetic field or conversely modulate the excited state and spin state of a material with circularly polarized light. However, most chiral nanomaterials, including noble metals, semiconductors, and ceramics, have a strong chiroptical response but a weak net magnetic moment, limiting to induce strong coupling with the magnetic field of photons in polarized light-matter interaction. Transition metal oxides such as Co, Fe, Ni, and Mn can offer a strong magnetic dipole moment from the exchange coupling of 3d electron spins but rarely have optical activity in the UV-Vis range. Antiferromagnet has been marginalized in spin-polarized light modulation because the net magnetic moment is canceled out by antiparallel spin sublattice leading to negligible Zeeman effect. However, unlike ferromagnetism, which is usually limited to metals, antiferromagnets offer a much greater degree of freedom to control atomic topography and spin configuration.
Here, we identified that previously unknown two-dimensional (2D) topography of iron oxyhydroxide enables the arrangement of low-dimensional antiferromagnet spin chains, which can be leveraged in a magnetically tunable spin-polarized photon absorption. We found a new type of nanoscale iron oxyhydroxide, layered ferric rust (LFR), with a monoclinic structure forming in the crystallization in the presence of acetate anion. The acid ligands coordinating iron atoms induce an unexpected zig-zag stacking of dimerized FeO octahedra, leading to a layered crystal structure with extended interlayer spacing. Topotactic intercalation of enantiomeric amino acids between the sheets breaks mirror symmetry in the crystal lattice and introduces screw axis symmetry, enabling transfer chirality of amino acid to LFR crystallization, producing chiroptical active LFRs. Achiral and chiral LFRs reserve low dimensional antiferromagnet spin chains where some portion of spins can be excited into parrell spin arrangement even under low external magnetic fields at room temperature. Therefore, the chiral LFR enables spin-polarized photon absorption in the UV-Vis wavelength range by the Zeeman effect in addition to the chiroptical activity contributed by the ligand-induced mirror symmetry breaking, as manifested by magnetic circular dichroism measurement. We believe our results would be a cornerstone for designing inorganic-organic hybrid two-dimensional nanomaterials for the various chiral spintronics, optoelectronics, and catalyst fields.

11:00 AM EL15.03.09

Exceptionally Large Chiroptic Dissymmetry Factors in Films of Supramolecular Magic-Sized Clusters ThomasJ. Ugras, YuanYao, ReillyLynch and RichardRobinson; Cornell University, United States

A key goal of optical materials science is to develop self-assembling hierarchical materials from nanoparticle building blocks with interesting properties. Understanding the structure-property relationships within these systems will enable the rational design of advanced optical devices. Recently, our group has discovered that CdS magic-sized clusters organize into hexagonal fibers which can self-assemble into ordered films that have a hierarchical structure spanning seven orders of length-scale[1]. These films have demonstrated strong linear and circular dichroism (LD, CD) responses originating from transition dipole alignment and cluster-to-cluster coupling, respectively, but further characterization of the optical properties using lab-based measurements are obfuscated by the samples' mixed linear and chiral anisotropies[2, 3]. In this work, we pair two synchrotron techniques, microfocussed small-angle x-ray scattering (SAXS) and synchrotron radiation Mueller Matrix polarimetry (MMP) mapping, to unravel the structural and optical anisotropies present in the self-assembled nanocrystal films. These studies have revealed local chiroptical properties stronger than previous measurements from lab instruments; in fact, our measured dissymmetry factors (i.e., absorption g-factor) are the largest reported for inorganic semiconductors, and only an order of magnitude smaller than the theoretical maximum limit of 2. The MMP mapping reveals that the self-organized films contain millimeter-scale domains with a constant CD magnitude and handedness, whereas isotropic films (non-self-assembled) present much smaller micron-scale domains. Further, MMP and SAXS measurements show that within self-assembled, anisotropic films the transition dipoles of the clusters are macroscopically oriented in the same direction as the nm-scale fibers. In summary, these experiments have revealed a relationship between the self-assembly process, the orientation of supramolecular nanocrystal fibers, and the handedness of a film's response. These results - anomalously large chiral anisotropy, orientational control of the clusters and their transition dipoles, and enantiomeric control of chiral domains within nanocrystal films - enable chiral light control for a range of emerging technologies.

11:15 AM EL15.03.10

Decomposition of Layered Double Hydroxides for Accessing Chiral Metal OxidesÁineCoogan[1], LuciaHughes[1,1,1], FinnPurcell-Milton[1,2,3], SeánCardiff[1,1], ValeriaNicolosi[1,1,1] and YuriiK. Gun'ko[1,3,1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Technological University Dublin, Ireland; [3]University College Dublin, Ireland

In recent years, significant research efforts have been directed towards the developmemt of chiral and chiroptically active inorganic nanomaterials, resulting in many new nanomaterials of various forms and morphologies, including quantum dots, nanowires, and tetrapods, among others.[1-3] Layered double hydroxides (LDHs) have emerged as a distinct class of ionic two-dimensional (2D) nanomaterials, renowned for their exceptional anion exchange properties, allowing for the incorporation of diverse species within their interlayer spaces, including chiral molecules. Surprisingly, despite this unique characteristic, there is a notable absence of reported studies exploring the utilisation of LDHs treated with chiral ligands to induce chiroptical activity.
While chiral copper (II) oxide (CuO) nanostructures have previously been documented in literature, their synthesis often requires harsh, high-temperature synthetic conditions and the inclusion of expensive surfactants and symmetry-breaking agents to induce circular dichroism (CD) responses in the visible range.[4-5] Prior to this work, the room temperature synthesis of chiral CuO has remained un-explored to the best of our knowledge. Additionally, the potential for chirality transfer from chiral ligands to LDH-based nanostructures has not been reported. Herein, we present the unique facile approach to the synthesis of chiral CuO nanostructures through an alkaline room-temperature, aqueous treatment of carbonate-intercalated copper-aluminium LDHs (CuAl-CO_3 LDHs) with L- and D-Phenylalanine (L- and D-Phe). The resulting 2D CuO nanosheet bundles display remarkable chiroptical activity, with *g*-factors up to 0.0035. Time-dependent circular dichroism (CD), powder X-ray diffraction (pXRD) and Fourier transform infrared spectroscopy (FT-IR) studies reveal that the initial chirality transfer arises from Phe coordination to the Cu^{2+} sites, leading to decomposition of the CuAl-CO_3 LDH to CuO. Self-assembly of the Phe-functionalised CuO nanosheets results in enhancement of the chiroptical activity. This work represents a novel, facile route of accessing chiral metal oxides through decomposition of LDH precursors. The ease of synthesis and induction of strong chiroptical activity in the visible range (400-800 nm) highlights the significance of this work. The resultant new chiral metal oxides hold promise for potential applications in enantiomeric separation and asymmetric catalysis, paving the way for advancements in chiral nanomaterial research.[6]

DNA-Templated Silver Nanoclusters with Strong Chiroptical Response in the Visible Spectral Region RweetuparnaGuha, AnnaGonzalez Rosell, MalakRafik and StacyCopp; University of California, Irvine, United States

DNA can template the chemical synthesis of few-atom silver nanoclusters with defined chiralities and strong electronic circular dichroism (CD) response. These "Ag_N-DNAs" have a diversity of sizes, shapes, and optical properties that are selected by the nucleobase sequence of their DNA ligands. Composed of just 10-30 Ag atoms and 1-3 short DNA oligomers, most studies of Ag_N-DNAs have focused on their bright visible to near-infrared fluorescence. The DNA sequence-selected chiroptical properties of Ag_N-DNAs are also of both fundamental and applied interest and have been far less studied. As an inherently chiral ligand, DNA selects for nanocluster chirality without the need for intensive separation techniques that are typically required for metal nanocluster enantiomer separation, such as chiral chromatography. The chiral properties of Ag_N-DNAs hold promise for biomolecular sensing and nanophotonics applications. However, studies of the chirality of Ag_N-DNAs prepared to atomic precision are limited to date, and few X-ray crystallographic structures have been reported.

To understand the chiral properties of Ag_N-DNAs, we investigated a large set of 19 different atomically precise Ag_N-DNA species with emission at the far red/NIR spectral border [1]. The molecular formula of each purified species is determined by high-resolution mass spectrometry and correlated to its optical absorbance, emission, and CD spectra. We find that these Ag_N-DNAs are either 6-electron clusters or 8-electron clusters (corresponding to the oxidation state of the silver nanocluster), with distinct absorbance and CD spectral features for these two classes of nanoclusters. 8-electron Ag_N-DNAs are stabilized by two DNA oligomer copies and display complex CD spectra with multiple distinct UV and visible transitions. The electron count of these "magic-sized" 8-electron nanoclusters suggests quasispherical geometries. 6-electron Ag_N-DNAs, which past studies support have rod-like shapes, exhibit three different ligand compositions, each with its own characteristic CD signatures. Ag_N-DNAs stabilized by two oligomer copies exhibit a distinct positive or negative monosignate CD signature aligned with the longest visible absorbance peak of the nanocluster, suggesting a chiral nanocluster core whose handedness is selected by the specific DNA template sequence. Ag_N-DNAs stabilized by three oligomer copies exhibit the same visible CD signature but distinct UV CD signatures, suggesting that DNA ligands adopt similar conformations around nanoclusters with three DNA ligands. Finally, Ag_N-DNAs stabilized by two oligomer copies and additional chlorido ligands exhibit significantly suppressed visible CD signatures, supporting that the additional atomic ligands suppresses nanocluster chirality. The distinct chiroptical signatures and compositions of these four classes of Ag_N-DNAs also correlate to distinct excited state emission properties, suggesting that nanocluster electron count and chirality influences both ground and excited state processes in these emitters. This study illustrates the diversity of structure-property relationships for NIR-emissive Ag_N-DNAs, which could be harnessed to precisely tune these emitters for applications that exploit their DNA sequence-selected chiral properties. Moreover, the results show that the chiroptical properties of Ag_N-DNAs are highly sensitive to nanocluster composition and ligand conformation.

SESSION EL15.04: Interaction Between Spin and Structural Chirality in Materials
Session Chairs: Matthew Beard and Hanyu Zhu
Tuesday Afternoon, November28, 2023
Hynes, Level 2, Room 207

1:30 PM *EL15.04.01
Magnetic Chirality Sang WookCheong and XianghanXu; Rutgers University, United States

Chirality, which arises from the breaking of mirror symmetries combined with any spatial rotations, is a fundamental concept that plays a pervasive role in a wide range of phenomena from the functionality of DNA, vine climbing to the piezoelectricity of quartz crystals. It is worth noting that chirality does not always involve a twisting resembling a screw. In the context of magnetic systems, chirality refers to the presence of chirality in spin ordered states or mesoscopic spin textures. The term "chirality" has been extensively used in the physics community in recent years, often leading to confusion due to its various interpretations. To provide clarity, we define that in steady states, chirality (C) remains unchanged under time-reversal operations, whereas chirality prime (C¢) represents the breaking of both time-reversal and mirror symmetries combined with spatial rotations. This colloquium aims to explore different examples of magnetic chirality and chirality prime, along with the emergent phenomena associated with them. These phenomena include self-inductance, directional nonreciprocity in magnetic fields, current-induced magnetization, chirality-selective spin-polarized current, Schwinger scattering, magneto-optical Kerr effect, and linear magnetoelectricity. While some of these exotic phenomena have been recently observed, many others still require experimental confirmation in the future.

Chiral States of Electrons and Spins and Their Electromagnetic Signatures JoelMoore[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Chiral crystal structures allow optical effects such as natural optical activity, which has long been used to identify chirality. While the symmetry analysis of structural chirality and optical response was carried out many years ago, the details of how microscopic electron wavefunctions generate observed chirality were not completely understood even in the linear case. Studies motivated by the experimental discovery of Weyl semimetals clarified the orgiin of chirality at low frequency in all chiral metals (the chiral or gyrotropic magnetic effects) and the importance of the orbital magnetic moment. Weyl semimetals are more unique in their *nonlinear* optical properties, where chiral Weyl semimetals show an exciting kind of quantization in their chiral photocurrent or chiral magnetic effect at the non-interacting level. The second part of the talk concerns how interactions between electrons or spins can lead to the spontaneous development of a chiral order parameter. The specific example discussed in detail is the behavior of triangular lattice Mott insulators, where a chiral spin liquid is shown numerically and analytically to be a competitive state arising near the Mott transition. Experimental signatures of this state, and the rapidly developing experimental sitaution of triangular lattice compounds, are discussed as an example of how new techniques allow greater understanding of correlated lattice problems.

Chiral Magneto-Optical Properties and Chiral Spintronics Based on Chiral Halide Perovskites Lan-ShengYang, Pei-HsuanLo, Chin-AnHsu, Yi-HsiuHua and Yu-ChiangChao; National Taiwan Normal University, Taiwan

Chiral halide perovskites can be prepared by solution processing using a mixture of a lead halide and a chiral organic halide as a precursor. Examples of chiral organic halides are *R*- and *S*-methylbenzylammonium halide and *R*- and *S*- 1-(2-naphthyl)ethylammonium halide. In this presentation, we will present the chemical composition, morphology, absorption, photoluminescence, quantum yield and carrier lifetime of chiral perovskite films prepared from precursor solutions with different stoichiometric ratios and different halide ratios. The chiral halide perovskite films exhibit chiroptical properties, such as circular dichroism and circularly polarized luminescence, in the absence of an external magnetic field. Symmetrical circular dichroism spectra were obtained. The energy level splitting induced by chiral molecules was estimated by using multiple Gaussian fitting. Once the magnetic field is applied, the magnetic field-induced CD features are superimposed on the intrinsic chirality-induced CD features. In addition, spin organic light-emitting diodes were realized by using chiral halide perovskite film as the spin-polarized hole transport layer. At room temperature, circularly polarized electroluminescence was observed from the spin organic light-emitting diodes in the absence of an external magnetic field.

2:45 PM EL15.04.04
Evaluation of the Spin Splitting of Chiral Perovskites via Circular Photogalvanic Effect TaishiNoma[1] and DaigoMiyajima[1,2,3]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan; [3]The Chinese University of Hong Kong, China

In materials that exhibit spin splitting, a zero-bias photocurrent can be generated by circularly polarized light. This phenomenon is called circular photogalvanic effect (CPGE), and CPGE had been investigated exclusively in inorganic materials.[1] However, recently, CPGE has been observed also in chiral perovskites, where chiral organic molecules are incorporated into inorganic

perovskite frameworks.[2,3] It is reported that the direction of the CPGE current in chiral perovskites is reversed depending on the chirality, which could provide novel functionalities for spintronic devices. Nevertheless, the CPGE of chiral perovskites has not been well investigated. The chirality-dependent CPGE of chiral perovskites originates from Dresselhaus effect, which is caused by the inversion asymmetry at crystal structures. However, Rashba effect, which is caused by the inversion asymmetry at surfaces or interfaces, can also occur in chiral perovskites with strong spin-orbit coupling (SOC). Rashba effect is promising for spintronic application because the strength of SOC can be tuned by external voltages. Therefore, it is of great importance to clarify the contribution of Rashba and Dresselhaus effects in the observed CPGE currents. In this study, we observe the CPGE of ((*R*/*S*)-(-)-1-cyclohexylethylamine (*R*/*S*-CYHEA))$_8$Pb$_3$I$_{14}$ single crystals possessing chiral-polar crystal structures (space group is $P2_1$), and evaluate the contribution of Rashba and Dresselhaus effects.

To evaluate the contribution of Rashba and Dresselhaus effects, we compared the CPGE currents of (*R*-CYHEA)$_8$Pb$_3$I$_{14}$ and (*S*-CYHEA)$_8$Pb$_3$I$_{14}$, generated along the nonpolar axis in the crystals. As reported in our previous work,[3] we observed the chirality-dependent CPGE current of the (*R*/*S*-CYHEA)$_8$Pb$_3$I$_{14}$ based on the Dresselhaus effect, by obliquely irradiating light in the incident plane parallel to the measurement direction of photocurrent. In our experiment, in theory, the CPGE current based on Dresselhaus effect can be generated regardless of the incident planes of light, whereas the CPGE current based on Rashba effect can be generated only in the direction perpendicular to the incident plane of light. Therefore, by obliquely irradiating light in the incident plane perpendicular to the measurement direction of photocurrent, it is possible that we can observe the CPGE current induced by both Rashba and Dresselhaus effects. Results showed that the CPGE of (*R*-CYHEA)$_8$Pb$_3$I$_{14}$ was negligibly small, whereas that of (*S*-CYHEA)$_8$Pb$_3$I$_{14}$ was significantly large. Importantly, the direction of the CPGE current based on the Rashba effect is identical regardless of the chirality, which is in contrast to that based on the Dresselhaus effect. Hence, it could be reasonable that the magnitudes of the CPGE currents of (*R*-CYHEA)$_8$Pb$_3$I$_{14}$ and (*S*-CYHEA)$_8$Pb$_3$I$_{14}$ were significantly different due to the contribution of both Rashba and Dresselhaus effects.

We investigated the contribution of Rashba and Dresselhaus effects to the CPGE of chiral perovskites. In the presentation, we will quantitatively discuss the contribution of Rashba and Dresselhaus effects.

Chiral Discrimination and Dispersion Intermolecular Forces VladimiroMujica[1] and RafaelGutierrez[2]; [1]Arizona State University, United States; [2]Dresden University of Technology, Germany

Intermolecular London dispersion forces, responsible for van der Waals (vdW) interactions, are due to induced-electric dipole induced-electric dipole interaction. They can be affected by molecular chirality in an unexpected way that is connected to the Chiral-Induced Spin Selectivity (CISS) effect, which provides a physical mechanism for the onset of an effective vdW interaction that depends on the relative orientation of the two enantiomers associated to a chiral molecule. This argument provides a path for chiral discrimination, which plays a fundamental role in molecular recognition of bio-molecules and the design of chiral material inerfaces.

In this contribution, we will explicitly describe a simple model to explore the influence of the CISS effect in vdW forces, and the way this leads to molecular chiral discrimination.

Theoretical Perspective on Chirality-Induced Spin Selectivity and Chiroptical Properties in Layered Halide Perovskites MikaelKepenekian[1], ClaudineKatan[1], SimonThébaud[2], JackyEven[2], ShangpuLiu[3], FelixDeschler[3], AlexandreAbhervé[4] and NicolasMercier[4]; [1]University of Rennes, France; [2]INSA Rennes, France; [3]Heidelberg University, Germany; [4]University of Angers, France

3-dimensional (3D) halide perovskites AMX_3 (A: organic cation, M: metal ion, X: halide) have shown spectacular results in optoelectronic devices. However, they offer limited choice of metals and organic cations, which limits the chemical design of optimal materials. This is not the case of lower dimensional materials, e.g. layered (2D) halide perovskites (LHPs) [1], that impose far less constraints over the organic spacer. It then become possible to associate the exceptional optoelectronic properties of halide perovskites with chiral cations to reach promising materials for chiroptical and magnetochiral applications [2].
Here, we report joint experimental and theoretical investigations of LHPs with exceptional (i) chiroptical, and (ii) magnetochiral properties. Firstly, the enantiopure 3BrMBA$_2$PbI$_4$ (MBA = methylbenzylammonium) perovskite thin films exhibit external photoluminescence quantum efficiency as high as 39% and circularly polarized photoluminescence up to 52%, at room temperature [3]. Next, we consider a series of chiral lead-bromide networks which crystallize in enantiomorphic polar space groups $P4_12_12$ and $P4_32_12$ for the R and S enantiomers, respectively [4]. Chirality-induced spin selectivity (CISS) effect measurements performed over those materials by magnetic conducting-probe atomic force microscopy (mc-AFM) reveal a spin polarization of about 40% [4].
We use a set of experimental characterizations (e.g. single-crystal x-ray diffraction), and theoretical tools (semi-empirical modeling and density-functional theory based calculations) to describe the chiral-related properties of these LHPs and help the cation engineering of efficient chiral halide perovskites.

Spin Polarized Current Injection from Chiral Halide Perovskites into III-V LEDs MatthewHautzinger, KirstinM. Alberi and MatthewC. Beard; National Renewable Energy Laboratory, United States

Spintronic applications integrating conventional group IV and III-V semiconductors suffer from a lack of efficient spin injection techniques. Most works rely on a ferromagnetic layer in combination with a tunnel oxide barrier, to avoid the conductivity mismatch, to inject spin polarized current into the semiconductor. These complicated interfaces are susceptible to defect chemistries inhibiting efficient spin polarized carrier injection. Here, we integrate semiconducting chiral halide perovskite, (R/S-MBA)$_2$PbI$_4$ (MBA = alpha-methylbenzylammonium) with III-V AlGaInP LEDs. The semiconducting (R/S-MBA)$_2$PbI$_4$ injects spin polarized current into the AlGaInP via the chirality induced spin selectivity effect. The spin polarized current produces circularly polarized electroluminescence, with efficiencies regularly achieved of 10 +- 3% at room temperature and no external magnetic field applied. This remarkable efficiency is due to the pristine semiconductor-semiconductor interface between the (R/S-MBA)$_2$PbI$_4$ and AlGaInP which avoids the problematic conductivity mismatch of ferromagnetic-semiconductor interfaces. We characterized this interface with TEM, XPS, and cross sectional KPFM to show it has excellent interfacial properties with no unintentional barriers introduced. We further prove the circularly polarized emission is the result of spin polarized current injection by measuring the Hanle effect. We observe a decrease in circularly polarized light emission with the application of a magnetic field, as expected from spin polarized current injection. These results present a new method of spin polarized current injection, enabled by a semiconducting CISS layer, which can be applied to numerous spintronic applications.

9:00 AM *EL15.05.01
Structure-Property Tunability using Chirality and Symmetry Breaking in Hybrid 2D Perovskites DavidB. Mitzi; Duke University, United States

Hybrid organic-inorganic perovskite (HOIP) semiconductors based on metal halide frameworks offer unprecedented opportunity to tailor structural and materials properties using the full flexibility afforded by the associated inorganic and organic components,[1] and such tunability offers wide-ranging potential for applications including solar cells, light-emitting devices, detectors, transistors and advanced computing devices. In this talk we will focus on examining the role that the organic cation can play in introducing or impacting chirality, symmetry breaking and associated phase transitions within HOIPs, as well as on the resulting chiroptical (e.g., circularly dichroism),[2] spin-selective charge transport (e.g., chirality-induced spin selectivity),[3] and electronic structure (e.g., spin splitting of the conduction band)[4] characteristics of these systems. Recent examples of such symmetry-related tunability highlight the promise of using the organic component to control light, charge and spin within the wide-ranging HOIP family.

Proximity-Effect-Induced Remote Chirality Transfer in Halide Perovskites Md AzimulHaque[1], RomanBrunecky[1], JunxiangZhang[2], YifanDong[1], MatthewP. Hautzinger[1], StevenP. Harvey[1], SethR. Marder[2], MatthewC. Beard[1] and JosephLuther[1]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

Hybrid organic/inorganic halide perovskites are intriguing chiral material systems owing to their excellent optoelectronic properties and potential to impart chirality with the organic A-site cation. Typically, chiroptical properties arise due to structural symmetry breaking from chiral A-site organic cation to the inorganic framework. In the present work, we demonstrate a proximity effect of remote chirality transfer to induce chirality in otherwise *achiral* 2D halide perovskites. A chiral organic ligand is introduced in the perovskite lattice without altering the structure, thus introducing chirality into existing 2D perovskites. Furthermore, we construct a chirality-composition library with varying the A, B, X-sites, along with the dimensionality, revealing the essential role of each atomic component in the perovskite structure. This approach of remote chirality transfer in halide perovskites could lead to new prospects in terms of composition, spin transport properties, and devices without extensive chemical modifications.

9:45 AM EL15.05.03
The Real Origin of Apparent Circular Dichroism in Chiral Perovskites SunihlMa[1], BumchulPark[1], Sang HyunLee[1], JoohoMoon[2] and NicholasA. Kotov[1]; [1]University of Michigan–Ann Arbor, United States; [2]Yonsei University, Korea (the Republic of)

Chirality, a fundamental concept for matters that cannot be super-imposed with their mirror images, is ubiquitous in almost all branches of natural science. Due to significance of chirality and wide versatility of chiral materials, in recent years, the concept of chirality can be successfully expanded to variety of different material including quantum dots, liquid crystals, and organic-inorganic hybrid system. Especially, chiral perovskite materials have attracted unprecedent attention as a new type of chiral semiconductors since the first report of chiroptical response in 2017. Different from the inherent chiral organic materials, chirality transfer from chiral organic spacer to achiral inorganic frameworks should be preceded to achieve chiroptical activity in chiral perovskite. Although extensive studies have reported the circular dichroism (CD) in chiral perovskite, the origin of chiroptical response in chiral perovskite ambiguous. Furthermore, several groups reported CD sign inversion behavior when flipping thin films samples, implying that the observed CD signal from chiral perovskite thin films might be originated from linear effects. However, due to the poor understanding of CD mechanism and inherent limitation of commercial CD spectrometers, the macroscopic origin of apparent CD behavior has been incorrectly interpreted. From this point of view, we investigate the real origin of apparent and genuine CD response in chiral perovskite thin films by using our home-made Mueller matrix polarimeter (MMP). Interestingly, based on experimental results from MMP and theoretical decomposition of Mueller matrix parameters, we found that apparent CD behavior is primarily originated from linear birefringence (LB) effects rather than linear dichroism (LD) behavior which is attributed to microscopy preferred orientation of thin films. Furthermore, polarization optical microscopy confirmed that LB effect is closely related with second-order ferroelectric phase transition behavior. To the best of our knowledge, this is first systematic study to clarify the real origin of apparent CD behavior based on the decomposition of Mueller matrix parameter, which is different from the interpretation based on ambiguous LDLB effect. Our study unveils the importance of the LB effect on the CD behavior of thin films and provide an in-depth understanding between ferroelectricity and chiroptical response.

10:30 AM EL15.05.04
Fluorinated Structural Isomers in 2D Chiral Perovskites Enabling Efficient Stable Spin-Dependent Oxygen Evolution Reaction JaehyunSon[1], SunihlMa[2], HyungsooLee[1], GyuminJang[1], Chan UkLee[1], SeongyeonYang[1], SubinMoon[1], JunwooLee[1], WooyongJeong[1] and JoohoMoon[1]; [1]Yonsei University, Korea (the Republic of); [2]University of Michigan–Ann Arbor, United States

Spin-dependent electrochemistry is introduced as an innovative concept for boosting overall photoelectrochemical (PEC) efficiency. Especially, the performance of oxygen evolution reaction (OER) can be improved by the chirality-induced spin-selectivity (CISS) phenomenon based on chiral materials. The CISS can effectively reduce the overpotential of the OER process by aligning the electron spins with specific directions. The parallel-aligned electron spins favor the generation of triplet oxygen ($^3O_2$), which is energetically more stable than the singlet oxygen state ($^1O_2$), while refraining from the formation of competitive by-product of hydrogen peroxide. In this regard, the chiral 2D organic-inorganic hybrid perovskites (OIHP) are considered as a promising spin filter due to their exceptional spin-polarization capability of over 80%. However, there are still underlying intrinsic obstacles to exploit chiral 2D OIHPs as spin filters for OER devices. The 2D OIHPs structures have poor conductivity along with out-of-plane direction where multiple spin-alignment occurs, which restricts further enhancement of OER performance. Such a problem stems from the multi-quantum well structures of OIHPs composed of two repeating building blocks, namely organic cations and inorganic frameworks. In addition, the vulnerability of 2D OIHPs to water is attributed to the hygroscopic nature of the organic cations, which becomes another hindrance to accomplishing the long-term operational stability of OER devices. Therefore, it is essentially necessary to develop groundbreaking materials that can promote electrical properties and moisture instability while maintaining the chirality of OIHPs.
Herein, we introduce chiral 2D OIHPs fluorinated methyl-benzylamine (F-MBA) chiral structural isomer cations, which have different structures according to the fluorine location of ortho-, meta-, and para- on the benzene ring. The chirality of the 2D OIHPs can be augmented according to the specific chiral cation structures originating from the intensified organic-inorganic halogen-halogen interactions. Moreover, the fluorinated chiral organic cations can not only endow hydrophobic characteristics to OIHP systems but also enhance the out-of-plane conductivity by reducing the exciton binding energy. As a result, we have implemented the fluorinated 2D OIHPs film on top of $BiVO_4$ photoanode for oxygen production. The fluorinated OIHPs spin filter dramatically reduces the overpotential with improved operational stability. Our results suggest a promising material design rule to fabricate stable and efficient chiral 2D OIHPs spin filter for spin-dependent applications.

10:45 AM EL15.05.05
Chiral Cation Doping for Modulating Structural Symmetry of 2D Perovskites YiXie[1,1], JackMorgenstein[1], BenjaminBobay[1], RuyiSong[1], NaidelCaturello[2], PeterC. Sercel[3], VolkerBlum[1,1] and DavidB. Mitzi[1,1]; [1]Duke University, United States; [2]Federal University of ABC, Brazil; [3]Center for Hybrid Organic Inorganic Semiconductors for Energy, United States

Cation-mixing in two-dimensional (2D) hybrid organic-inorganic perovskite (HOIP) structures represents an important degree of freedom for modifying organic templating effects and tailoring inorganic structures. However, the limited number of known cation-mixed 2D HOIP systems generally employ a 1:1 ratio of cations for stabilizing the 2D perovskite structure. Achieving more general cation mixing ratios should allow greater control over accessing lower symmetry structures and therefore opportunities for modulating and enhancing emergent symmetry-sensitive properties. Here we demonstrated a chiral-chiral mixed-cation system wherein a controlled small amount (<5 %) of chiral cation S-2-MeBA (S-2-MeBA = (S)-(-)-2-methylbutylammonium) can be doped into $(S\text{-}BrMBA)_2PbI_4$ (S-BrMBA = (S)-(−)-4-bromo-α-methylbenzylammonium), modulating the structural symmetry from a higher symmetry (*C*2) to the lowest symmetry state (*P*1). This structural change occurs when the concentration of S-2-MeBA, measured by solution nuclear magnetic resonance, exceeds a critical level—specifically, for 1.4 ± 0.6 %, the structure remains as *C*2, whereas 3.9 ± 1.4 % substitution induces the structure change to *P*1. Atomic occupancy analysis suggests that one specific S-BrMBA cation site is preferentially substituted by S-2-MeBA in the unit cell, which rearranges the organic layer to break C_2 rotational symmetry. Density-functional theory calculations indicate that the spin splitting along different k-paths can be modulated by cation doping. A true circular dichroism band at the exciton energy of the 3.9% doping phase shows polarity inversion and a ~45 meV blue shift of the Cotton-effect-type line-shape relative to $(S\text{-}BrMBA)_2PbI_4$. A trend toward suppressed melting temperature with higher doping concentration was observed. The chiral cation doping system and the associated doping-concentration-dependent structural transition provide a material design strategy for controlling and enhancing symmetry-related properties, such as chiroptical, non-linear optical, spin-related, and ferroelectric properties.

11:00 AM EL15.05.06
Boosting Non-Centrosymmetric Distortion and Magnetic Properties in Chiral Metal Halide Perovskites SanghyunNam[1], JaewoookAn[2], In HyeokPark[2] and Young HoonKim[1]; [1]Hanyang University, Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of)

Control of spin-polarized currents and magnetic properties in materials are important to demonstrate various spintronic applications such as MRAM and spin LEDs. In conventional semiconductors and metals, spin polarization and magnetization occur by the application of external magnetic fields or fabrication of ultra-thin (<5 nm) layer of the materials, which complicate the fabrication process and device structure. Here, we report novel materials system, hybrid chiral metal-halide perovskites (MHPs), which can control the spin polarization and magnetic properties via simple solution process. MHPs consist of three different atoms or molecules in various crystal structures (representations are ABX_3 and A_2BX_4 where A is an organic ammonium, B is a transition metal cation and X is a halide anion). First, we synthesize chiral lead (Pb)-based MHPs ($(R\text{-/S-MBA})_2PbI_4$ where MBA is methylbenzylammonium) and find that R-/S-MBA cations transfer the chirality to the inorganic metal-halide octahedra (PbI_6) by the asymmetric electrostatic interaction between ammonium group in MBA and halide in inorganic octahedra. $(R\text{-/S-MBA})_2PbI_4$ polycrystalline thin films show circular dichroism (CD) signals with opposite directions which are dependent on the chiral direction of MBA. Furthermore, $(R\text{-/S-MBA})_2PbI_4$ show efficient spin selectivity > 80% without external magnetic fields by the chiral-induced spin selectivity (CISS) effect. Second, to solve the toxic problem in Pb-based MHPs, we synthesize Pb-free chiral MHPs that use palladium (Pd) in B site cation. Pd-based MHPs have 0-dimensional orientation of Pd-halide square-planar, where the direction of the orientation depends on the chiral direction in A-site cation, and increased CD signals when mixed halides are used in X-site (anisotropy g-factor (g_{CD}) = 3.3×10^{-3} in pure chloride, 1.2×10^{-2} in pure bromide, 1.8×10^{-2} when $Br_{0.5}Cl_{0.5}$). We also measured the spin selectivity in Pd-based chiral MHPs. Third, to induce magnetic properties in MHPs in addition to the chirality, we synthesize iron (Fe)-based chiral MHPs with different Fe compositions. Fe-based chiral MHPs show CD signals in the absorption range of metal-halide tetrahedra, which clarify that R-/S-MBA transfers its chirality to the metal-halide tetrahedra. Furthermore Fe-based chiral MHPs exhibit paramagnetism at low temperature, which demonstrate the potential of future MHP materials which have both chirality and magnetic properties.

11:15 AM EL15.05.07
Highly Efficient Chiral 2D/3D Perovskite Artificial Leaf for Spin-Dependent Photoelectrochemical Overall Water Splitting HyungsooLee, Chan UkLee, JuwonYun, WooyongJeong, Chang-SeopJong, JaehyunSon, Young SunPark, SubinMoon and JoohoMoon; Yonsei University, Korea (the Republic of)

The intricate nature of the multi-step oxygen evolution reaction (OER) continues to pose a challenge in achieving bias-free photoelectrochemical water-splitting systems. Several theoretical and experimental studies have suggested that OER efficiency can be significantly improved in chiral material-based photoanodes by utilizing the chirality-induced spin selectivity (CISS) phenomenon. The final product at the photoanode is the oxygen molecules, where the spin alignment of intermediate radicals is favorable to the generation of triplet $^3O_2$ (most stable molecular oxygen species). Considering the energy difference between a singlet $^1O_2$ and triplet $^3O_2$ (the energy of a singlet $^1O_2$ is approximately 100 kJ mol^{-1} higher than that of triplet $^3O_2$), spin-dependent chemical reactions combined with the CISS phenomenon can play a crucial role in facilitating the OER process. Especially, by promptly aligning the spin distribution of photo-generated charges within the absorber, it could effectively prevent the formation of hydrogen peroxide, leading to a dramatic reduction in overpotential. In this regard, the incorporation of a chiral spin-filter layer on top of the absorber has been recognized as a promising strategy to achieve a significant enhancement on the PEC performance of the solar-driven water splitting system.
Chiral 2D OIHPs have been conventionally employed as spin-filter layer with two distinct enantiomers, namely *R*- and *S*-methyl benzylamine (*R*- and *S*-MBA). Owing to the weak π-π interaction of the MBA organic cation, however, the coupling effect between the π-electron and p-orbital of the halide in the inorganic framework is relatively weak in chiral 2D OIHPs. To reinforce the coupling effect of chiral 2D OIHPs, we utilized naphthyl ethylamine (NEA) capable of stronger π–π stacking interaction between naphthalene rings. Moreover, the introduction of NEA organic cations can simplify the molecular arrangement of chiral 2D OIHPs, leading to enhanced film crystallinity and improved chiroptical properties. Herein, we demonstrated that the CISS phenomena can become a remarkable approach by adopting NEA-based chiral 2D OIHPs as a spin-filtering layer on the 3D OIHPs photoanode. Our chiral 2D OIHPs exhibited an impressive CISS efficiency of approximately 95%, indicating a remarkable achievement in spin controlling when compared to other chiral materials. Moreover, chiral 2D/3D OIHPs-based water-splitting device achieved enhanced oxygen evolution performance with a reduced overpotential of 0.2 V, high fill factor, and increased photocurrent of 22 mA cm^{-2} at 1.2 V_{RHE} compared to a device without a spin-filtering layer. For unbiased water splitting, a perovskite-based photocathode decorated with a spatially decoupled hydrogen evolution reaction catalyst was fabricated. This decoupled geometry was adopted to enable the physical protection of the perovskite layer from the electrolyte, thus allowing excellent stability for over 100 h. To implement the bias-free water splitting performance, this perovskite photocathode was connected in parallel with spin-filtering layer adopted 2D/3D OIHPs-based photoanode. Overall solar-driven water splitting was achieved using all the OIHP photoelectrodes, resulting in a remarkable unassisted solar-to-hydrogen efficiency of ~13% and a continuous 100 h stable operation.

SESSION EL15.06: Chiral Photonic and Optoelectronic Materials
Session Chairs: Jian Shi and Hanyu Zhu

Leveraging Chirality for Extreme Control of Light AndreaAlu; City University of New York, United States

In this talk, I will discuss our recent progress in tailored broken geometrical symmetries to control the interaction of light with structured materials and metasurfaces. In particular, I will discuss our theoretical and experimental work on nonlocal metasurfaces supporting chiral eigenstates, locally structured with subwavelength resolution. I will also discuss the unique opportunities that chirality and rotational broken symmetry enables in the context of polaritonic systems and time metamaterials.

2:00 PM EL15.06.02
Active Chiral Plasmonic Metasurfaces JuhwanKim, Jang-HwanHan, GyurinKim and Hyeon-HoJeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Chiral plasmonics offers a powerful means to control light-matter interactions based on their unique polarization-sensitive chiroptical characteristics, enabling a wide range of applications, including molecular sensing, holographic encryption, and optical filters.[1] In order to fully exploit the potential of chiral plasmonics for industrial applications, it is crucial to develop their active system that can respond to external stimuli and thus allow us to dynamically control their chiroptical responses. However, such active chiral plasmonics are still in their early stages of development.
Here, we present an active chiral plasmonic metasurface capable of dynamically controlling the chiroptical response through combinatorial modulation of both the state of light polarization and an external electrical input. The metasurface consists of a wafer-scale array of chiral nanohelices grown using a physical shadow growth technique, with a conductive polymer shell polymerized around the entire surface of helices. The intrinsic dissymmetry factor of this chiral plasmonic metasurface exceeds 0.1, leading to rich polarization-dependent colors. To achieve further extended color dynamics, we electrochemically control the redox state (i.e., refractive index) of the conductive polymer shell, thereby inducing changes in the plasmonically resonating colors of the nanohelices.[2] Remarkably, in conjunction with controlling the state of the light polarization, we achieve full-color dynamics from the single chiral plasmonic metasurface, driven by just input voltages of less than 1 V, highlighting its potential applications in electrochromic displays and filters.
In this presentation, we will discuss the successful fabrication of these chiral plasmonic metasurfaces and provide a comprehensive characterization of their active chiroptical properties. The proof-of-concept applications will also be presented, featuring their impressive fidelity for active coloration.

Chirality Induced Second Harmonic Generation in Aligned and Enantiomer Enriched Carbon Nanotubes RuiXu[1], YuanTian[2], JacquesDoumani[1], AndreyBaydin[1], WeiranTu[1], YoheiYomogida[3], FuyangTay[1], JiamingLuo[1], JunLou[1], KazuhiroYanagi[3], RiichiroSaito[2], JunichiroKono[1] and HanyuZhu[1]; [1]Rice University, United States; [2]Tohoku University, Japan; [3]Tokyo Metropolitan University, Japan

Aligned assemblies of single-chirality semiconducting carbon nanotubes (CNTs) are ideal materials for developing nanoelectronic, optoelectronic, and quantum photonic devices. Although left- and right-handed CNTs have identical properties in many aspects, enantiomer-dependent properties can manifest in magneto-transport, optical polarization selection, and nonlinear optics. For example, theoretical studies have predicted a large, resonance-enhanced second-order nonlinear optical susceptibility up to nm/V in perfect chiral CNT ensembles, but the value has never been experimentally verified due to mixed chirality components, poor alignment, and low densities. Here, we report the synthesis of centimeter-scale single-enantiomer, highly packed, and

aligned (11,-5) CNT thin films using the controlled vacuum filtration method. We observed giant second harmonic generation (SHG) from the samples with effective second-order nonlinear optical susceptibility up to 70 pm/V, which corresponds to 350 pm/V for an enantiomerically pure, densely packed and perfectly aligned solid as predicted when the fundamental frequency resonates with the transition of the CNTs at 1000 nm. We confirmed that the SHG signal originates from the inversion symmetry breaking from the intrinsic chirality of the film, instead of surface defects, by angle and polarization dependent SHG measurements. Our findings provide a fast and scalable method for characterizing the alignment and enantiomer purity of CNT films, and establish them as an excellent material for nonlinear optical studies and applications.

Chiral Materials from Perylene Diimide Building Blocks: Twistacenes and Helicenes ColinNuckolls; Columbia University, United States

This presentation will detail our efforts to create materials from contorted aromatic molecules. In particular, I will discuss how to create helicenes and twistacenes from perylene diimide building blocks. These materials have extraordinary properties as materials. The helicenes have the largest chiroptic response of any molecular species. The twistacenes helicity is dynamic and can be controlled by light and chemical/electrochemical reductions. These materials excel as photovoltaics, photodetectors, batteries, and pseudocapacitors. The presentation will discuss these opportunities.

4:00 PM EL15.06.05
Bringing Sensitive Circularly Polarized Luminescence Spectroscopy to the Time Domain Antti-PekkaM. Reponen[1], MarcelMattes[1], WinaldKitzmann[2] and SaschaFeldmann[1]; [1]Harvard University, United States; [2]Johannes Gutenberg-Universität, Germany

Materials capable of emitting circularly polarized light (CPL) are promising for breaking efficiency limits in existing optoelectronic applications and may enable entirely new photonic and spintronic technologies [1]. However, reliably detecting CPL with the necessary sensitivity to quantify low dissymmetry factors, while being able to identify and ideally circumvent artefacts arising from linear dichroism, linear birefringence or linearly polarized emitted or scattered light is experimentally challenging [2].

Here we report on our recent efforts to develop CPL detection with the additional dimension of time evolution to achieve broadband, calibration-free CPL spectroscopy with nanosecond time resolution [3]. This technique will serve as a powerful tool to study the dynamics of chiral emitters and to understand how chirality evolves in the excited state.

4:15 PM EL15.06.06
Twisting Photons with Chiral Metal-Halide Semiconductors HaipengLu; The Hong Kong University of Science and Technology, Hong Kong

Chiral metal-halide semiconductors (MHS) have recently developed as promising candidates for spin- and polarization-resolved optoelectronic devices. Although several chiral MHS with rich chemical and structural diversity have been reported lately, the fundamental mechanisms governing their chiroptical activity, namely, circularly polarized absorption and emission, remain elusive. In this talk, I will discuss our recent progress in understanding and tuning the chiroptical activity in chiral MHS. I will first discuss how the chirality is transferred from organic to inorganic component through asymmetric covalent bonding interactions. Their endowed molecular chirality was then studied by circular dichroism (CD). However, we found that the previously reported “apparent” CD in chiral MHS thin films is not an intrinsic chiroptical property, but rather, arising from an interference between the film’s linear birefringence and linear dichroism. We verify the presence of LB and LD effects in both one-dimensional and zero-dimensional chiral MHS thin films. We then establish spectroscopic methods to decouple the genuine CD from other spurious contributions, which allows a quantitative comparison of the intrinsic chiroptical activity across different chiral MHS. The relationship between the structure and the genuine chiroptical activity is then uncovered, which is well described by the chirality-induced spin–orbit coupling in the chiral structures. Meanwhile, we found that high CD signals do not necessarily lead to high circularly polarized luminescence as most of the current chiral MHS display very low photoluminescence quantum yields (PLQY). We will then discuss the reasons of low PLQY in these materials. Finally, we will show our strategies to turn on the circularly polarized luminescence by introducing extrinsic self-trapped excitons in a 0D chiral MHS, and by tuning the inorganic layer thickness in perovskite nanoplatelets.

4:30 PM EL15.06.07
Twisted Organic Semiconductor Crystals for Chiroptoelectronics SeheeJeong, St. JohnWhittaker, YongfanYang, AkashTiwari, AlexanderShtukenberg, BartKahr and StephanieLee; New York University, United States

We present crystal twisting, a common albeit little known phenomenon in molecular crystals, as a generalizable strategy to repurpose optically inactive organic semiconductors for chiroptoelectronics. This phenomenon is not limited to specific chemical structures or crystal space groups - twisting has been observed in inorganic, polymer, and small molecule crystals grown from vapor, solutions and melts. Because crystal twisting introduces repeating patterns of crystal orientations perpendicular to the substrate surface as crystals twist about the fast growth direction, <hkl>-dependent material properties are likewise patterned on the microns to millimeter length scale. Twisting also imparts chirality - crystals twist either clockwise or counterclockwise about the growth direction - rendering them optically active. The commonality of crystal twisting enables potentially hundreds of centrosymmetric organic semiconductors designed over the past fifty years to be incorporated into devices that discriminately transmit, emit and detect circularly polarized light. Here we characterize the (chir)optoelectronic properties of several molecular semiconductors, including triisopropylsilylethynyl anthradithiophene (TIPS ADT) and tetrathiafulvalene (TTF), and test their performance in resistors, transistors and photodetectors.

4:45 PM EL15.06.08
Chiroptical Synaptic Heterojunction Phototransistors: Noise-Reduced Detection of Circularly Polarized Light via Self-Assembled Supramolecular Nanohelix of π-Conjugated Molecules Jung AhLim[1], HannaLee[1], ChangsoonChoi[1] and EunjiLee[2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)

Chiroptical photodetectors have become increasingly important in a range of fields, including chiral imaging, spintronics, and quantum optics. To enable practical chiroptical optoelectronics, it is essential to develop high-performance chiroptical photodetectors with high responsivity, sensitivity, polarization direction identification, and device integration feasibility. This study presents the successful demonstration of high-performance chiroptical synaptic phototransistors utilizing heterojunctions comprising a self-assembled nanohelix of a π-conjugated molecule and a metal oxide semiconductor. In this work, heterojunction devices consisting of a chiral nanomaterial and semiconductor offer a promising strategy for developing high-performance chiral optoelectronic devices. To impart strong chiroptical activity, a novel diketopyrrolopyrrole-based, donor-acceptor type π-conjugated molecule decorated with chiral glutamic acid was newly synthesized, capable of supramolecular self-assembly through noncovalent intermolecular interactions. Through hydrogen-bonding-driven, gelation-assisted self-assembly, we obtained supramolecular nanohelix structure consisting of intertwining fibers with strong and stable chiroptical activity in solid-film form. Phototransistors based on interfacial charge transfer at the heterojunction from the chiroptical nanohelix to the metal oxide semiconductor exhibited exceptional chiroptical detection, with a high photocurrent dissymmetry factor and remarkable photoresponsivity. Interestingly, the chiroptical phototransistor displayed photonic synapse-like behavior, generating time-dependent photocurrents and persistent photoconductivity attributed to interfacial charge trapping. Leveraging the synaptic functionality advantage, a trained convolutional neural network achieved over 89 % accuracy in recognizing noise-reduced circularly polarized images of handwritten alphabetic characters.

5:00 PM EL15.06.09
Ionically Modified Cellulose Nanocrystals Chiral Structures for Electronics DianaGaspar[1], PaulGrey[2], BrunoMendes[2], MadalenaRoque[2], RodrigoF. Martins[2] and LuisPereira[1,2]; [1]AlmaScience, Portugal; [2]Cenimat|i3N, School of Science and Technology (FCT-NOVA), Universidade NOVA de Lisboa and CEMOP/UNINOVA, Portugal

Many approaches exist in the quest for efficient, abundant, cheap and eco-friendly photonics that can be easily integrated with other platforms for practical applications.
Approaches using 3D metamaterials, mesoporous semiconductors, or plasmonics are promising. Nevertheless, these methods often involve complicated fabrication processes that need high energy consumption (such as vacuum and physical vapour deposition) to deposit these materials, which are often not so green, sustainable, typically expensive, and colour-limited.
Researchers have sought eco-friendly materials with similar performance and lower energy costs during the past few years, and Nature offers many examples of such materials for our innovation. Natural micro and nanostructures, such as the ones found in beetles or butterflies, have evolved over millions of years to produce periodic patterns that can reflect light. These structures served as inspiration to create artificial analogues using cellulose nanocrystals (CNCs), which can form a chiral nematic liquid crystalline phase when dispersed in water. The chiral order is preserved as the water evaporates, and solid films with 1D photonic crystal properties and iridescent colours are obtained. The intrinsic left-handedness of such structures can interact

selectively with left and right-circular polarized light (LCPL and RCPL).
The pitch control and, therefore, the reflected colour is particularly interesting. This manipulation can be done using external stimuli such as magnetic and electric fields, drying processes with different interfaces or playing with the chemistry behind the acid hydrolysis. With this work, we demonstrate that CNC suspensions with low concentrations (~4-5wt.%) with proper evaporation-induced self-assembly conditions lead to the formation of films with interesting photonic properties with a left-handed twisted arrangement. The use of strong acid cation resins to mediate the counterion exchange on commercial CNCs. It was observed that adding different alkali salts to the CNCs anisotropic suspension results in a blue shift of the photonic bandgap with higher salt concentrations and proper distinction between LCPL and RCPL ($\Delta CPL \approx 42\%$).
Combining the photonic character of the tailored CNC films, whose photonic bandgap can be matched with the bandgap of light sensitivity of semiconductors, it will be possible to create devices capable of discrimination between LCPL and RCPL signals in the blue region.

SESSION EL15.07: Poster Session: Chiral Materials with Novel Properties

8:00 PM EL15.07.01
Anisotropic Circular Photogalvanic Response in Chiral Weyl Semimetal RhSi ByunghoonKim[1], TylerCochran[1], Zi-JiaCheng[1], Gyu-HeeKim[2], XianYang[1], Doo-HyunKo[2], PrashantPadmanabhan[3] and M. ZahidHasan[1]; [1]Princeton University, United States; [2]Sungkyunkwan University, Korea (the Republic of); [3]Los Alamos National Laboratory, United States

Weyl semimetals have been a hot topic in the condensed matter physics community due to their unconventional linear band crossing from the bulk characters. Breaking of time-reversal or inversion symmetry allows Dirac fermions to split into a pair of Weyl fermions with an opposite chirality at a non-high symmetry point in momentum space. The circular photogalvanic effect in which the incident helicity determines the generated current vector is direct evidence from the topology and band structure of the chiral Weyl semimetals. Notably, in optical transition near a Weyl node, it has recently been predicted that the magnitude of the CPGE is associated with its monopole charge. Since the nodes with opposite charges are nondegenerate, it also hints at the CPGE response stemming from the Berry monopole charge. Here, we explore the helicity-dependent optoelectronic response of the topological/Weyl semimetal RhSi via time-domain terahertz emission spectroscopy. The remarkable CPGE behavior in in-plane mode was experimentally demonstrated, whereas it did not exhibit notable signatures in out-of-plane mode. We further perform the photoemission measurement, together with optical simulation, to investigate the physical properties of chiral Weyl semimetal RhSi.

8:00 PM EL15.07.02
Chiral Pyrrole-Based Polyaromatics AbdusalomA. Suleymanov and TimothyM. Swager; Massachusetts Institute of Technology, United States

In recent years, there has been significant interest in incorporating heteroatoms into polycyclic aromatic hydrocarbons (PAHs). This exploration of heteroatom-doped variants of extended π-conjugated materials has revealed their distinct and enhanced electronic and photophysical properties. Among the various five-membered aromatic heterocycles, pyrrole stands out as the most electron-rich when compared to its isoelectronic counterparts, furan and thiophene. The synthetic versatility and strong redox activity of pyrrole enable the creation of synthetic frameworks with enhanced p-doping and other desirable material properties.
Our research has focused on the synthesis and characterization of novel chiral pyrrole-based PAHs. These include twisted azacoronenes and helicenes incorporating pyrrole units. We are currently investigating their chiroptical, electrochemical, and magnetooptical properties.

8:00 PM EL15.07.03
Chiral Phonons in α-HgS Nanocrystal Sang HyunLee, BumchulPark and NicholasA. Kotov; University of Michigan, Ann Arbor, United States

Chiral phonon is a quantized particle that represent collective atomic motions with broken reflection and inversion symmetries. Chiral phonons have gathered significant interest due to their unique properties observed in various types of materials such as two-dimensional (2D) materials, biomolecular complexes, and inorganic chiral crystals [1,2,3]. Here, we observe chiral phonons in mercury sulfide cinnabar (α-HgS) nanocrystals with terahertz time-domain polarimetry (THz-TDP). α-HgS has two enantiomeric crystal structure that belongs to space group $P3_121$ or $P3_221$ depending on the rotational direction of the helical crystal lattice. By employing phonon dispersion calculations, we identify the IR active phonon modes in α-HgS that lies in the spectral range of 1 ~ 10 meV, specifically the A_2 (1.16 THz) and E modes (1.3 THz), which can be experimentally measured using THz-TDP. Mirror-symmetrically synthesized P/M α-HgS nanocrystals show identical THz absorption (TA) peaks, while their THz circular dichroism (TCD)/THz optical rotary dispersion (TORD) signals exhibit opposite caracteristics, corresponding to the A_2 phonon mode. This clearly proves the existence of chiral phonons in α-HgS nanocrystals. Moreover, it is important to mention that strong TCD signals can be measured despite the substantial disparity in scales between the THz wavelength (~300 μm) and α-HgS nanocrystals (~20 nm). Chiral phonons of α-HgS nanocrystals within the THz range not only provide new insights for THz photonics/phononics, but also bridges the gap between THz photonics and nano-engineering, opening a new door for various applications.

8:00 PM EL15.07.04
Banded Spherulite Formation in Chiral Halide Perovskites MatthewHautzinger, QiutongGe and MatthewC. Beard; National Renewable Energy Laboratory, United States

Halide perovskites containing chiral organic moieties have been recognized recently for their remarkable chirality induced spin selectivity properties. Notably, the compounds exhibit chirality transfer from the chiral organic to the inorganic metal halide components. Here, we investigate the growth of the chiral halide perovskites as textured thin films containing banded spherulite structures. The compound, (S-NPB)2PbBr4 in particular, exhibits robust banded spherulite formation when the processing conditions are optimized. These banded spherulites containing extrinsic chirality of helical twists in them leading to their mesoscopic structure. We show the temperature control over these structures during the growth and characterize the pitch and growth of the helical twists within these films. The results presented here have implications for the chirality induced spin selectivity of these materials, as the compound contains meta chirality, not only in the crystallographic structure, but also in the mesoscale banded spherulites formed.

8:00 PM EL15.07.05
Growth-Actuated Twisting of Photochromic Crystals MerrittC. McDowell[1], NaterciaBarbosa[2], HelenZardus[1], AlexanderShtukenberg[1], JohannaBrazard[2], BartKahr[1], TakujiAdachi[2], St. JohnWhittaker[1] and StephanieLee[1]; [1]New York University, United States; [2]University of Geneva, Switzerland

1,2-bis(2-methyl-5-phenyl-3-thienyl)perfluorocyclopentene (BpFCP) single crystals grown from the vapor phase were previously discovered to dynamically twist and coil when irradiated with UV light due to mechanical strain associated with a reversible, light-induced ring closure [1]. Here, we form BpFCP twisted crystals through growth-actuated twisting during crystallization from the melt. At high undercoolings, i.e. large crystallographic driving forces, BpFCP forms banded spherulites comprising helicoidal fibrils that twist in concert with one another as they grow radially from the spherulitic nucleation center. As-crystallized films appear transparent when viewed using unpolarized light. When imaged between crossed polarizers, on the other hand, concentric bands of interference colors are visible due to continuously rotating refractive indices as the crystals twist about the growth direction. Upon irradiation with UV light to induce the photochromic ring closure, alternating bands in BpFCP spherulites turn dark blue, creating a vibrant stripe pattern. Local Raman spectroscopy on adjacent bands revealed this patterning to be a result of orientation-dependent dichroism of photocyclized crystals, as opposed to orientation-dependent photoreactivity. Film cracking upon UV light exposure suggests that fibrils experience internal stress from photoisomerization-induced shifts in crystal lattice parameters. Mueller Matrix imaging further revealed strong circular dichroism (CD) and birefringence (CB) in BpFCP banded spherulites, with local CD and CB signals changing dynamically during photocyclization. Because banded spherulites expose different crystal orientations at the film surface, they provide a unique opportunity to investigate orientation-dependent chiroptoelectronic properties in these dynamic crystals.

8:00 PM EL15.07.06
Supramolecular Chirality Induced by Self-Assembly in Novel Quinoid Conjugated Molecules JeongjinHong, YeonsuChoi, yunseulKim, YinaMoon, JeongwooBeak and Dong-YuKim; Gwangju Institute of Science and Technology, Korea (the Republic of)

Molecular assemblies with supramolecular chirality have been developed for decades due to their distinctive chiroptical properties. Among the versatile approaches to induce supramolecular chirality, self-assemblies using non-covalent interactions have considered as a great potential for applying biological field and chiroptical devices owing to their high tunability and controllability.

In this work, we designed and synthesized novel quinoid conjugated molecules QuEDOT-(S)-Cn and QuPheDOT-(S)-Cn employing enantiopure alkyl side chains. Quinoidal moieties are suitable for constructing supramolecular chirality through self-assembly due to their strong π-π stacking property of highly planar structure. QuEDOT-(S)-Cn and QuPheDOT-(S)-Cn had different chiroptical properties in solution and film states depending on the external stimuli (solvents, temp) as well as different chemical structures. Then we conducted diverse analyses such as AFM, POM, SEM, CD, GIWAXS to determine the reason for the difference in anisotropic factors between two molecules. We will explain and discuss the relationship between the behavior of supramolecular chirality and chemical structures. These results suggest chemical designing strategies of organic semiconducting materials in forming supramolecular chirality using self-assembly.

8:00 PM EL15.07.07
Chiral-Induced Surface-Enhanced Raman Optical Activity on Nanoparticle-On-Mirror Substrate Sung GunLee; Seoul National University, Korea (the Republic of)

Raman Optical Activity (ROA) has emerged as a valuable tool for characterizing stereostructural changes in both organic and inorganic compounds, offering complementary steric information to traditional spectroscopic methods. In particular, ROA has garnered attention as a chiral-selective method for analyzing biomolecules such as nucleic acids, and peptides, overcoming the limitations of conventional spectroscopy. However, due to the inherently low cross-section of ROA, which is three to five orders of magnitude lower than typical Raman, achieving sufficient signal sensitivity remains a challenge. To address this issue, efforts have been made to measure ROA signals using SERS, which utilizes plasmonic materials to enhance the Raman signal of analytes via the electric field concentrated around nanoparticles (SEROA). However, biomolecules typically have low Raman cross-sections and poor signal stability at high laser intensity and long measuring times, limiting the utility of SEROA. Recently, chiral-induced ROA has been proposed as a breakthrough, leveraging the "sergeants-and-soldiers" principle to induce chirality in a trace chiral compound, enabling the measurement of chirality with shorter measuring times and lower laser intensities.
This study demonstrates the possibility of a nanoparticle-on-mirror (NPoM) substrate and measurement configuration for ROA, which isolates hotspots from particle aggregation. To confirm the reliability of the NPoM configuration for ROA, chirality was induced in a self-assembled monolayer of 4-mercaptopyridine on a gold nanofilm surface.

SESSION EL15.08: Tunable Structural Chirality in Materials

Bio-Enabled Chiral Flexible Nanomaterials—From Chiral Emitting Sources to Photonically-Assisted Multilevel Logic VladimirTsukruk[1,2]; [1]Georgia Institute of Technology, United States; [2]Institute for Human and Machine Cognition, United States

Bio-enabled hybrid nanomaterials represent a novel class of functional materials, which uses bio-derived materials, bioinspiration and biomimetic approaches to design functional nanomaterials and structures with co-assembled biological and synthetic components to bring best of two worlds: adaptive photonic functions and chiroptical activity, flexibility and mechanical strength, potential sustainability and scalability [1]. Here, we summarize our recent results on functional bio-derived chiral nematic polysaccharides co-assembled with graphene oxides, organic semiconductors, magnetic nanoparticles, and quantum dots for adaptive chiroptical materials, magnetic materials and photonic multi-value logic thin film electronics.

Firstly, we discuss robust photonic nanomaterials from cellulose nanocrystals and nanofibers decorated with highly photoluminescent organic dyes, quantum dots and quantum nanowires for tailored emission of linear and circular polarized light [2, 3]. Secondly, we present results on magnetically steerable uniform photonic organization of cellulose nanocrystals decorated with superparamagnetic nanoparticles to achieve uniform organization [4]. Assembly under weak magnetic field gradients enables transformation from helicoidal cholesteric to uniaxial nematic phase with near-perfect orientation order parameter was achieved across large areas, enhanced mechanical robustness, and fast actuation ability. Finally, we demonstrate biophotonic field effect transistors mediated by circularly polarized excitation with multi-valued logic elements for dramatically elevated encryption ability [5].

Switching Chirality in Microarrays Enabled by Shape-Reconfigurable Spindle Microparticles MingzhuLiu, XingyueHan, So HeeNah, TianweiWu, YuchenWang, LiangFeng, LiangWu and ShuYang; University of Pennsylvania, United States

Giant circular photo-galvanic effect has been realized in chiral metals when illuminated by the circularly polarized light. However, the structure itself is not reconfigurable nor can we tune the crystal chirality in the adjacent domains. Here we synthesize spindle-shaped liquid crystalline elastomer microparticles that can continuously change shape from prolate to spherical to oblate upon heating above the nematic to isotropic transition temperature. The shapes are reversed upon cooling. When arranged the microparticles in a honeycomb lattice, the lattice can be switched from a right-handed chiral state to achiral one, then to a left-handed chiral state, without breaking the translational symmetry. Accordingly, the sign of rotation of the polarized light passing through the lattices changes as measured by time-domain terahertz (THz) spectroscopy. Further, we can locally alter the chirality in the adjacent domains using near-infrared (NIR) light illumination. The ability to controllably create chiral states at the boundary of the achiral/chiral domains will allow us to explore complex structures through the interplay of symmetry and topology.

Artificial Photosynthesis Empowered by PSII-Inspired Supramolecular Quantasomes with Chiral Architectures MarcellaBonchio[1,2,3]; [1]University of Padova, Italy; [2]INSTM, Italy; [3]ITM-CNR, Italy

Being the natural-born photoelectrolyzer for oxygen delivery, Photosystem II (PSII) is hardly replicated with man-made constructs. In particular, the PSII organization in natural thylakoids sets key guidelines to rethink the molecular design of groundbreaking artificial photo-electrolysers. Building on the early “quantasome” hypothesis (*Science 1964, 144, 1009-1011*), PSII mimicry can be pared down to essentials by shaping a photocatalytic ensemble (from the Greek term ”soma”= body) where light-quanta trigger water oxidation. We have recently reported on PSII-inspired nanodimensional quantasomes (QS) that readily self-assemble into hierarchical photosynthetic nano-stacks, made of bis-cationic perylenebisimides (PBI^{2+}) as chromophores and deca-anionic tetraruthenate polyoxometalates (Ru4POM) as water oxidation catalysts (*Nature Chem.* 2019, 11, 146–153). A combined supramolecular and click-chemistry strategy allows to interlock the multi-lamellar architecture emerging from the perylene aromatic stacking in water, while installing tetraethylene glycol (TEG) cross-linkers thus enhancing water harvesting and transport in proximity of the oxygen evolving center (*J. Am. Chem. Soc.* 2022, 144, 14021-14025). *Our breaking new results deal with the introduction of sugar-based substituents as asymmetry effectors for the assembly of chiral quantasomes* evolving oxygen using low energy green photons ($\lambda > 450$ nm, $FEO_2 > 95$ %). Action spectra, mass-activity, light-management, photoelectrochemical impedance spectros-copy (PEIS) together with Raman mapping of hydration shells, point to a key role of the supramolecular structure nano-arrays, where the interplay of hydrophilic, hydrophobic and chiral domains is reminiscent of PSII-rich natural thylakoids.

A Multi-Functional Full-Polarized Light Emitting and Controlling Device JiaweiLyu and Ki TaeNam; Seoul National University, China

Nanomaterials emitting polarized light directly without using the traditional polarizers are believed to simplify the design of polarization optics and afford higher efficiency, showing great potential in practical applications such as 3D display, hologram, anti-counterfeiting and light communication. While most efforts are focused on improving the polarized light emission performance of specific nanomaterials, of paramount importance is to interface these excellent materials with state-of-the-art industrial technology to make functional devices. Herein, we propose and demonstrate an efficient route to fabricate full-polarized emitting and controlling devices via integrating 3D printing technique with the (micro) LED display technology. We achieved an extraordinarily high degree of linearly and circularly polarized luminescence (CPL) through precise control of the nanomaterial assembly structure. Moreover, we realized efficient spatio-temporal modulation of various polarization states. These features enable multiple applications including a secured visible light communication (VLC) system and polarization-based multichannel displays.

Solution Synthesis of Halide Chiral Crystal with Controlled Dimension and Morphology ZhihaoZhang; Rensselaer Polytechnic Institude, United States

Recently, there has been a surge of research interest in understanding the intriguing spin-related phenomena in chiral materials. In this work, we present a solution-based approach for growing ferromagnetic chiral halide crystal. By tuning the temperature, growth time and concentration, we optimize the growth morphologies. We use X-ray diffraction and Raman spectroscopy to characterize the crystal structure and phase. The chirality is investigated by circular dichroism spectroscopy. The integration of ferromagnetism and chirality in the same crystal provides a rich platform for understanding spintronic phenomena.

11:00 AM EL15.08.06
Unprecedented Intrinsic Chirality in CsPbBr3 Nanoplatelets Tunable Through Synthetic Conditions PrognaBanerjee, Jia-ShiangChen, XuedanMa and ElenaShevchenko; Argonne National Laboratory, Center for Nanoscale Materials, United States

This work reports on the intrinsic chiral behavior in colloidal ultrathin CsPbBr3 nanoplatelets with unprecedent quantitative s-handed value as studied using circular dichroism measurements. Through adjusting various synthetic parameters, such as temperature, Cs and Pb reagent ratios, reaction solvents and stirring direction, we are able to tune the quantitative chiral properties in these nanomaterials. Additionally, the functional aspects such as the handedness of these nanoplatelets can be tuned using brominated methylbenzylamines with suitable r/s chirality. We utilize the advantageous procedure of single particle photoluminescence studies to attain insights into the lifetimes and correlate them with the presence and the type of ligands. We reach qualitative arguments based on surface defects and Pb extraction through selected area electron microscopy, and rigorous x-ray diffraction accompanied with Rietveld refinement analyses- to explain the atomic arrangements at the surface of these nanoplatelets which can be tuned through synthetic factors. Optical characterization by absorption and circular dichroism extends these ideas into correlation with microscopy and diffraction results. These remarkable control of chiral parameters without external stimuli in untreated/as prepared nanoplatelets; and through choice of the ligation combinations hence accomplished highlight the suitability of these ultrathin CsPbBr3 nanoplatelets for applications in a wide range of optical and mechanical applications including chiral superstructures.

Tuning Chiroptical Properties of Chiral 2D Hybrid Organic-Inorganic Perovskites Through Mixing Halogen Lan-ShengYang, Chun-YaoHuang and Yu-ChiangChao; National Taiwan Normal University, Taiwan

Chiral 2D halide perovskites have attracted increasing attention due to their exceptional photoluminescence properties, tunable bandgap, and various crystallized structure. However, tuning chiroptical properties of chiral 2D hybrid halide organic-inorganic perovskites have not yet been extensively studied. Here, we report the chirality of chiral 2D halide perovskites through circular dichroism(CD) and circularly polarized photoluminescence(CPL). By varying the mixing ratio of chlorine, bromide, and iodide anions in S- or R-(MBA)2 PbI4(1−x)Br4x or S- or R-(MBA)2 PbBr4(1−y)Cl4y, the mixing of halide ions allows a tunable band gap of the chiral OIHPs, leading to a shift of the CD signal from 495 to 320 nm and the CPL signal from 530 to 485nm. Moreover, it is noticed that the CD signal ascends from x=0 to x=1 and descends from x=1 to x=4. Successively, the CD signal ascends from y=0 to y=4. This difference can be explained that the phase transition of the crystalline structure occurred. Chiral optical asymmetry (g-factor) at y=4 has a maximum value of 0.015 compared to other mixing ratios. The CPL signal becomes greatly small after the phase transition because of structural distortion in the inorganic framework and instability. Additionally, the CD sign conversion is discovered as well through mixing halogen. These properties can take advantage of the structural engineering of high-performance chiroptical materials for spin-polarized light-emitting devices. Spin organic light-emitting diodes were achieved by using chiral 2D hybrid halide perovskites film as the spin filter layer. Circularly polarized electroluminescence was observed at room temperature in the absence of an external magnetic field.

11:30 AM EL15.08.08
Telling Left From Right using Electron Microscopes AssafBen Moshe; Bar Ilan University, Israel

In 1848 Louis Pasteur reported his findings on the separation of a racemic mixture of chiral molecules during their crystallization from the solution phase. Left and right molecules crystallized separately in crystals that exhibited left- and right- handedness at the macroscopic level, as portrayed by their overall chiral habit. This monumental experiment is considered by many to have helped setting the foundations of modern stereochemistry.

Determination of absolute configurations of molecules, and relation between microscopic and macroscopic handedness in chiral crystals became a key challenge. This is often addressed using chemical assays with chiral additives, x-ray crystallography and chiroptical spectroscopy. At a later stage in history the advent of electron microscopy led to many studies of (nano)crystals using powerful high-resolution techniques, yet the problem of handedness determination often remains untreated and elusive.

In this project a nanoscale crystalline system that exhibits chirality at the atomic arrangement, as well as its overall habit was studied.[1] We showed that the mechanism that determines shape chirality in this material is not trivial, and is not the result of the chiral crystallographic symmetry of the crystal. While doing so, we also developed approaches for determination of shape and crystal structure handedness using electron microscopy.

Leveraging The Preferences in Transition Metal-P/Si Bonding to Design Novel Chiral Materials KirillKovnir; Iowa State University, United States

Non-centrosymmetric chiral intermetallic compounds with antisymmetric spin-orbit coupling exhibit a plethora of emergent properties. Chemical bonding preferences in the transition metal silicon-phosphides TM-Si-P create the asymmetric environment around metal atoms resulting in high abundance of non-centrosymmetric chiral and polar crystal structures. The synthesis of those phases is hampered by inertness of TM and Si in contrast to high reactivity and vapor pressure of phosphorus. We developed a comprehensive synthetic strategy allowing to produce single crystals and phase-pure polycrystalline samples of metal tetrel-pnictides. The correlation between the crystal structure, chemical bonding, and optical and properties will be discussed with focus of earth abundant TM for applications.

Chirality-Induced Spin Selectivity Effect in 2D Chiral Hybrid Perovskites: Chiral-Phonon-Activated Spin Seebeck Effect DaliSun; North Carolina State University, United States

The Chirality-Induced Spin Selectivity (CISS) effect, a unique 'spin filtering' effect arising from the structural handedness of organic compounds (i.e., chirality) and their assemblies that lack inversion symmetry [1]. It utilizes chirality to generate robust spin information from chiral (left- (S) or right-handed (R)) molecules without the need for common magnetic elements. The CISS effect provides a strong coupling between spin and electronic properties without the need for magnetic ordering. Recently, the CISS effect has been reported in 2D chiral hybrid perovskites (2D-chiral-HOIPs), a resurgent class of solution-processed hybrid semiconductors consisting of alternating layers of chiral organic compounds and inorganic framework of corner-sharing metal halide octahedra. Although considerable progress has been made in understanding many features of the CISS response in chiral-HOPs [2,3] and other chiral materials, an adequate quantitative description of (i) the CISS effect, (ii) its strong manifestation for spin selectivity at ambient temperatures, and (iii) its mechanistic origins, is still lacking. It comes to our attentions that angular momentum in condensed matter systems, including rigid rotation and elastic deformation, can be viewed as an information vector [4]. At the microscopic scale, the lattice vibrations, i.e., phonons, can carry angular momentum and mimic the well-known information-carrying photons [5]. This phonon angular momentum, i.e., *chiral phonon* displays a non-zero phonon angular momentum when the system is displaced from equilibrium, offering a high potential for producing the CISS effect at elevated temperatures. Here we show the observation of spin currents generated by chiral phonons in a 2D chiral HOIP implanted with chiral cations when subjected to a thermal gradient [6]. The generated spin current shows a strong dependence on the chirality of the film and external magnetic fields, of which the coefficient is orders of magnitude larger than that produced by the reported spin Seebeck effect. Our findings indicate the potential of chiral phonons for spin caloritronic applications and offer a new route toward spin generation in the absence of magnetic materials. Demonstration of the chiral-phonon-activated spin Seebeck effect in 2D chiral HOIPs may aid in solving the paradoxical diversity of CISS models, shedding light on CISS-related responses observed in a wide variety of chiral systems.

Chiral Phonon-Induced Spin Polarization HanyuZhu, JiamingLuo, TongLin, JunjieZhang, XiaotongChen, ElizabethBlackert, RuiXu and BorisI. Yakobson; Rice University, United States

Controlling spins on very short time scales may enable novel non-equilibrium magnetic physics as well as ultrafast spintronics for energy-efficient information processing. Chiral phonons, where atoms rotation unidirectionally around the equilibrium position inside crystalline lattice, break time reversal symmetry and are expected to directly couple with magnetization. We excited chiral phonons using circular-polarized terahertz pulses and observed a prominent transient magneto-optic Kerr effect in rare-earth trihalides. The effective magnetic field needed to polarize the paramagnetic spins is on the order of 1 T under very moderate pump fluence of 0.2 mJ/cm2. The temperature dependence of the spin dynamics indicates the magnetic field indeed is generated by the phonons, as opposed to a pure electromagnetic inverse Faraday effect. Our result may open a new route to investigate spin-phonon interaction in ultrafast magnetism and chiral transport properties for quantum devices.

2:15 PM EL15.09.03
Terahertz Excitation of Chiral Phonons to Induce Dynamical Multiferroicity MeganNielson, Enoch (Sin Hang)Ho, AldairAlejandro, MatthewLutz, ClaytonMoss and JeremyA. Johnson; Brigham Young University, United States

Circular motion of ions in solid materials has been posited as a means to dynamically induce or control magnetic properties. This circular motion fundamentally requires the excitation of "chiral" phonon modes, and the ability to excite and control transient crystal chirality could have a significant impact on condensed matter physics.

Pairs of phonon modes in ferroelectric materials can be excited to create circular or elliptical motion of ions. Depending on the charge of the ions and magnitude of their motions, these ion loops with right or left handedness can induce a magnetic moment, even in originally non-magnetic materials. Therefore, exciting ion loops in ferroelectric solids to dynamically induce magnetic ordering, will make them transiently multiferroic.

We have recently had much success in controlling the waveform and polarization of high-field, broadband terahertz (THz) pulses. This waveform control is driven by the capability to perform two-dimensional (2D) THz spectroscopy, including the ability to create circularly polarized THz pump pulses. In this presentation, we report how we generated intense pulses of circularly polarized THz light to excite pairs of degenerate phonon modes. As the phonon modes are excited with proper relative phase (provided by the circularly polarized THz pulses), circular phonon motion results. The transient magnetic moment induced by these excited ions loops is then measured with the ultrafast Faraday effect.
To generate circularly polarized light, we combine two linearly polarized THz pulses with adjustable relative delay. A differential chopping scheme enables us to readily measure the sample response from a single (vertically polarized) THz pulse, the other individual (horizontally polarized) THz pulse, and the combined THz pulse with controllable polarization state, all in a succession of four laser shots; the probe response in the absence of a THz pump pulse is measured with the fourth laser shot.

To probe the sample response, we direct an 800-nm probe pulse through the excited region of the sample and measure the modification of the probe polarization with a transient birefringence detection scheme. This allows us to measure the transient Faraday effect to detect the creation of an ultrafast magnetic moment. However, it can also measure other ultrafast birefringence signals, like the THz Kerr effect. Fortunately, by controlling the relative polarization angles between THz and probe pulses, we can isolate the Faraday signal from the Kerr signal.

With circularly polarized THz pulses, we excite a z-cut sample of $LiNbO_3$. The lowest frequency E symmetry phonon modes are doubly-degenerate with perpendicular mode effective charge vectors that can be driven with THz pulses polarized along the crystallographic x and y directions. Exciting pairs of E-modes with circularly polarized THz pump pulses induces ion-loop motion, leading to a transient magnetic moment in $LiNbO_3$. While the chiral phonon motion takes place, a transient magnetic moment is induced that can be detected with the Faraday rotation of a probe pulse. We observe a transient signal persisting for ~3 ps, which is longer than the THz pump pulse duration (<1 ps), confirming that this isn't just the THz inverse Faraday effect. The magnetic moment signal also switches sign as the THz polarization and subsequent chiral phonon motion changes handedness.

In summary, using a 2D THz experimental setup, we can create high-field circularly polarized THz pulses. These circularly polarized THz pulses excite chiral phonon motion in $LiNbO_3$, transiently inducing a magnetic moment that persists longer than the THz excitation pulses. Isolating the Faraday signal from the Kerr signal confirms that the excited chiral phonon motion, so-called ion loops, induces magnetic ordering in non-magnetic $LiNbO_3$. The ability to use circularly polarized THz pulses to control chiral phonon motion will provide many new avenues in the study of condensed matter systems.

Phonons and Phase Symmetries in Non-Symmorphic Twisted and Layered Materials LucasLindsay; Oak Ridge National Laboratory, United States

Structural complexity underlies a variety of novel quasiparticle behaviors that can have profound impacts on material functionalities. Here I will discuss the role of structural twisting and translational symmetries in determining the vibrational behaviors of non-symmorphic chiral and achiral materials and how these translate into spectral features and functionalities. We advance

a dynamical theory that incorporates the various symmetries internal to the lattice unit cell directly into the description of the phonon frequencies and eigenvectors. This naturally elucidates phase conservation relations in twisted structures and layered materials. We apply this theory to build insights into vibrational dynamical structure factors and spectral observations from inelastic neutron and x-ray scattering experiments, and provide a fresh perspective on symmetry-enforced crossings, quasiparticle interactions, and band topologies.

Towards Chiral Acoustoplasmonics BeatrizCastillo Lopez de Larrinzar[1], ChushuangXiang[2], Edson RafaelCardozo de Oliveira[2], Norberto DanielLanzillotti-Kimura[2] and AntonioGarcia-Martin[1]; [1]Instituto de Micro y Nanotecnologia, CSIC, Spain; [2]Centre de Nanosciences et de Nanotechnologies (C2N), France

The possibility of creating and manipulating nanostructured materials encouraged the exploration of new strategies to control electromagnetic properties. Among the most intriguing nanostructures are those that respond differently to helical polarization, i.e., exhibit chirality.[1] Circularly polarized light can be used to probe and determine the chiral nature of a plasmonic structure, which is usually reflected as quantitative differences in the values of the absorption or scattering cross-sections. However, reaching maximum absorption and minimum scattering for one helicity, and the opposite for the other is not usually found to occur at the same wavelength.[2]
In the present work, we propose a simple chiral plasmonic structure based on crossed elongated bars where light-handedness defines the dominating cross-section absorption or scattering, as it identifies the two different enantiomers in a chiral structure which determine how the system interacts with its environment. The system is yet maintained simple enough to understand the actual nature of the response observed, be open to future developments, and warrant fabrication for future experimental verification [3,4]. Based on this structure, our work demonstrate that, not only through the interactions between different elements it is possible to make the absorption and scattering cross-sections radically and qualitatively different for the two circular polarizations, but also that the dominating cross-section can be switched from absorption to scattering by simply changing the polarization of the impinging beam. Also, we theoretically propose a simple pump-probe experiment using circularly polarized light. [5] In the reported structures, the generation of acoustic phonons is optimized by maximizing the absorption, while the detection is enhanced at the same wavelength -and different helicity- by engineering the scattering properties [6]. Thus, the presented results constitute one of the first steps towards harvesting chirality effects in the design and optimization of efficient and versatile acoustoplasmonic transducers.

Preparation and Characterization of Chiral Mechanical Metamaterials WenbingWu and NicholasA. Kotov; University of Michigan, United States

Chirality of nanostructures and nanocomposites have been instinctively associated with their chiroptical activities, *e.g.*, circular dichroism and optical rotation. Chiral effects have also been predicted to exist in the mechanics of materials by theories more than 50 years ago.[1]Two key phenomena have been identified: 1) A chiral material can rotate the linear polarization plane of a transverse mechanical wave, analogous to the optical rotation of electromagnetic waves. 2) A moment is induced when a chiral solid is subjected to longitudinal stress. Notwithstanding the theoretical achievements, it has only been recently that a few experimental progresses have emerged, because challenges remain in both the preparation and characterization of such materials. The goal of this talk is to present our most recent work in addressing these two challenges.
Currently reported chiral mechanical structures were mostly created via 3D printing. We propose a material engineering strategy to fabricate chiral mechanical composites with helical inclusions. A variety of chiral nano- and micro-particles and assemblies can be obtained self-assembly methods.[2] The morphology of these particles, including their size and twisting pattern, can be tuned by the self-assembly process. The chiral particles are then included in an aerogel matrix of aramid nanofibers.[3] The micro-rotation of the particles, induced by external linear mechanical waves, transmits through the nanofiber network and couples into a collective macroscopic rotation, which can be experimentally measured.
In contrast to electromagnetics, there are few commercially available tools for the detection of the polarization of mechanical waves. We built up a digital image correlation (DIC) system that enables the measurements of the displacement vector of a surface with nanometer resolution.[4] A piezoelectric transducer, on which a chiral solid is mounted, produces a linear transverse mechanical wave up to 250 kHz. The DIC measurements are used to identify the polarization directions of the transvers waves on the piezoelectric transducer and the sample surface. The twisting angle between the two directions is an indication of the mechanical chirality of the solids. This presentation outlines our ongoing efforts on the preparation and characterization of chiral mechanical effects in self-assembled composite metamaterials.

The Interplay Between Dopants and Charge Carriers in Organic Semiconductors Lambert Jan AntonKoster; University of Groningen, Netherlands

In order to make rational improvements of the charge transport properties of doped organic semiconductors, a thorough understanding of this rather complex process is needed. The efficacy of doping is governed by a multitude of steps, including the interactions between (ionized) dopants and charge carriers. In this contribution, we explore the effects of carrier-dopant and carrier-carrier interactions and strategies to mitigate them.

We use kinetic Monte-Carlo simulations to better understand the effects of carrier-dopant and carrier-carrier interactions. Such simulations predict that a lager host-dopant distance can result in a higher Seebeck coefficient for a given electrical conductivity. In order to realize such a system, we use amphipathic side chains in an n-type donor-acceptor copolymer. The amphipathic side chain contains an alkyl chain segment that acts as a spacer between the polymer backbone and an ethylene glycol type chain segment. The use of this alkyl spacer can not only reduce the energetic disorder in the conjugated polymer film but can also properly control the dopant sites away from the backbone, which minimizes the adverse influence of counterions. We find that this selectively increases the Seebeck coefficient and the power factor by a factor of ~ 5.

While it has been recognised that Coulomb interactions between dopants and charge carriers are important, carrier-carrier interactions—interactions among charge carriers—in doped organics have received less attention. In a doped organic semiconductor, however, the number of (free and bound) charge carriers equals the number of reacted dopants. As a result, both types of interactions are of importance for a proper description of the transport properties of doped organic semiconductors.

To study the transport properties in the presence of dopants and including both carrier-carrier and carrier-dopant interactions we once again use kinetic Monte-Carlo simulations. While the conductivity is indeed affected by carrier-dopant interactions, the effect of carrier-carrier interactions appears to be even stronger, especially so at high doping concentrations. Experimentally, we observe that the electrical conductivity of a large number of organic semiconductors shows a maximum: Upon increased doping levels the conductivity decreases. This type of behaviour is commonly attributed to changes in the microstructure as a consequence of doping. However, we find that even when using vapour doping, where there are no observable changes in the microstructure, this behaviour persists. The experimental findings match the Monte-Carlo data very closely, which suggests that the Coulomb interactions among charge carriers is at the root of the limited conductivity at high doping densities.

Dopant-Carrier Coulomb Interactions in Organic Electronics: DOS Shape, Transport, and Carrier Screening ZlatanAksamija; University of Utah, United States

Organic electronic materials, specifically conjugated polymers, are a cost-effective and environmentally friendly alternative to inorganics. However, they do not possess intrinsic free carriers, which means they must be doped to increase the number of free carriers and boost conductivity. Simultaneously, their low dielectric constant means electrostatic Coulomb interactions between free carriers and dopant counterions are poorly screened. These dopant-carrier interactions dramatically alter the energetics of the states available for transport as well as the dynamics of free carriers. The importance of Coulomb interactions and their impact on the density of states (DOS) via dopant-induced disorder is now well established. In this invited talk, I will discuss our results arising from coupling a model for modification of the electronic density of states (DOS) in the presence of dopants with a phonon-assisted carrier hopping simulation through those states. We expanded the model initially proposed by Arkhipov et al. to include the finite dopant size and minimum dopant-carrier separation, which limit the deepest traps in the tail of the DOS. We use the DOS model as input to the hopping transport simulation to analyze the transport properties of doped conjugated polymers and extract both conductivity and Seebeck coefficient at each doping concentration. We also vary the parameters of the dopants, including their size, energy level, and charge distribution on the dopant counterion to quantify their impact on conductivity.

However, previous studies of hopping transport within the Gaussian Disorder Model did not consider the role of screening the dielectric interactions by the carriers. In our work, we implement screening in the Debye-Hückel formalism and calculate dopant-induced disorder with the resulting electrostatic potential. For a point dopant, this gives the well-known Yukawa potential, which we generalize for dopant charge distributions other than the point charge. Then we solve Pauli Master Equation with Miller Abrahams hopping rates with states from the resulting screened DOS. Our results show that screening has a significant impact on the Seebeck coefficient and shape of the DOS. The thermoelectric power factor increases almost by a factor of 2 at higher doping. We also observe that the log slope of the Seebeck coefficient plotted against the electrical conductivity for different doping concentrations, which was previously thought to have a universal value (-1/4), increases for a more energetically disordered system. By including screening, we were able to reproduce and explain these curves obtained in measurements and connect the change in slope with the change in structure of the host polymer. We conclude that carrier screening of dopant Coulomb interactions plays an important role in transport and thermoelectric properties of polymers, especially at high doping concentrations. Our work refines the understanding of fundamental processes in doped polymers and enables their easier engineering for thermoelectric, photovoltaic and other applications.

The Effects of Doping on Transport in Organic Electronics: Analyzing the Dopant-Induced Disorder AndrewTolton and ZlatanAksamija; University of Utah, United States

Organic electronic materials, specifically conjugated polymers, are a cost-effective and environmentally friendly alternative to inorganics. However, their low intrinsic conductivity means they must be doped to increase the number of free carriers. Characterizing the effects of doping on organic thermoelectrics has proven to be a long-standing problem. Doping introduces both structural and energetic changes to the polymer, changing the shape of the electronic Density of States (DOS) through the creation of band tails and widening the DOS, resulting in a type of energetic disorder termed dopant-induced disorder (DID). The shape of the DOS resulting from doping can be captured through two parameters: the width of the DOS, termed energetic disorder, and the shape of the DOS, which is quantified by a shape parameter p, which can take on values of 1 for an exponential DOS to 2 for a Gaussian one. In our previous work, we showed that DID causes energetic disorder to increase while the p value simultaneously decreases from 2 to below 1 in heavily doped polymers, implying heavy tails. The resulting carrier mobility is impaired by the presence of heavy tails and the deep trap states in them. Doping then simultaneously increases DID, affecting the shape of the DOS, but fills the deepest tail states first, partially countering their effect.

To decouple the influences of each of these effects, we fix the shape of the DOS to simulate doping without DID. We then compute both conductivity and thermoelectric Seebeck coefficient at each DOS and carrier concentration using a numerical simulation of phonon-assisted carrier hopping between localized states. The simulation iteratively solves the Pauli master equation with Miller-Abrahams hopping rates. The iteration converges on an out-of-equilibrium distribution function, from which carrier and energy currents are computed, from which we extract conductivity and Seebeck coefficient, respectively. The Seebeck coefficient is a convenient and readily measurable proxy for the carrier concentration as it scales with the position of the Fermi level in the DOS. The Seebeck vs conductivity plot thus reveals the tradeoff induced by doping and captures the impact of the DOS on transport. We find distinct behavior of the Seebeck vs conductivity relation across doping regions, and these behaviors can be described in terms of carrier concentration in conjunction with the key parameters of the DOS: its width (energetic disorder) and shape parameter. The distinct regions on the Seebeck-conductivity curve come from surprisingly simple relationships between doping and several transport parameters, which also allow us to provide qualitative expressions for difficult-to-measure quantities like carrier concentration and carrier-dependent mobility. Ultimately, this analysis clearly displays the underlying effects of doping without the simultaneous obfuscation of DID, allowing us to gain a clearer understanding of the effects of both influences. This work will impact the design of polymer-dopant complexes for reaching higher carrier mobility in future organic electronics.

A New Strategy to Greatly Improve The Seebeck Coefficient and Overall Thermoelectric Properties of Conducting Polymers JianyongOuyang; National University of Singapore, Singapore

Conducting polymers emerge as the next-generation thermoelectric materials because of their merits including high conductivity, high mechanical flexilbility, low cost and solution processability. However, their Seebeck coefficient is notably lower than inorgnaic thermoelectric materials by about one order in magnitude. The conventional methods to increase the Seebeck coefficient of conducting polymers including partial dedoping with a reducing agent or base and energy filtering. Nevertheless, these methods are not very effective, and the overall thermoelectric properties of conducting polymers are not very high. Here, I will present a new strategy to greatly improve the Seebeck coefficient and thus the overall thermoelectric properties of conducting polymers. The zT value can be comparable to the best inorganic thermoelectric materials at room temperature.

SESSION EL16.02: Carrier-Dopant Interactions in Organic Semiconductors—Design and Applications

Doping-Enabled Photomultiplication in Narrowband Near-Infrared Organic Photodetectors for Enhanced Detectivity Louis ConradWinkler[1], JonasKublitski[2], JohannesBenduhn[1] and KarlLeo[1]; [1]Technische Universität Dresden, Germany; [2]Universidade Tecnológica Federal do Paraná, Brazil

Continuous monitoring of food quality, blood oxygen, or industrial processes requires high-throughput near-infrared photodetectors. Due to excellent properties like low-cost, flexibility, and narrowband response, organic photodetectors (OPDs) have vast market potential for such applications.
In this work, we utilize the emerging absorption feature of a weakly doped C60 bulk for photo-responses above 1000 nm, circumventing the difficulties of obtaining molecules with a low optical gap and low molecular mass. The unavoidable increase of band-to-band recombination for low-gap systems, which is detrimental to the external quantum efficiency (EQE), is overcome by combining two mechanisms to achieve a strong photocurrent gain. Trap-assisted accumulation, realized by very low doping, and energetic blocking of holes, are utilized to achieve a spectral response (SR) of 15 AW^{-1} at 1092 nm.
Furthermore, spatial doping variations are implemented into the device to boost the absorption within the optical cavity, resulting in a narrow response of 18 nm. This approach allows easy tuning of the resonant wavelength by bulk thickness variations and thus allows spectrally highly resolved measurements. Contrary to OPDs working in the self-powered mode, this detector is optimized for operation under reverse bias. With its high spectral response, low-cost readout circuitry based on CMOS technology could be used for signal detection.

Control of Resistance Temperature Change of Solution-Processed Conductive Polymers for Strain Sensor Applications YuKato[1], KenjiroFukuda[2,2], TakaoSomeya[1,2,2] and TomoyukiYokota[1,1]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan

Organic materials are used in flexible electronics due to their excellent flexibility and simple fabrication using solution processes. Because the resistance of organic materials changes with strain and temperature, flexible strain[1] and temperature[2] sensors using organic materials have been studied. In such sensors, control of conductivity and resistance temperature change is important. When the device is used as a strain sensor, the resistance temperature change needs to be small to make the sensor less susceptible to temperature. In contrast, when the device is used as a temperature sensor, the resistance temperature change should be large to increase sensitivity. Low conductivity makes the device more sensitive to electronic noise. In this study, we evaluated the influence of the fabrication conditions on the conductivity and temperature characteristics of devices using conductive polymers. Then, we selected a condition and applied it to a strain sensor.
Chromium and gold were evaporated on substrates as electrodes. Conductive polymers were spin-coated on the substrates followed by annealing under a nitrogen atmosphere. Conductive polymers consisted of a polymer material and a p-type dopant. The doping concentration in this experiment was 12%, which means that twelve dopant molecules were added per one hundred monomeric units of the polymer. The standard conditions in this experiment were P3HT for the polymer, BCF for the dopant, and 70 °C for the annealing temperature, and the effects of changing these conditions were evaluated. Temperature coefficient of resistance (TCR) is defined as the ratio of resistance change to temperature change. In this study, TCR was calculated using the resistances at 25 and 40 °C. When the device was applied to the strain sensor, a 1-µm-thick parylene was deposited on the device as a passivation layer. A gauge factor, defined as a ratio of resistance change to applied strain, was measured.
By adding BCF to P3HT, the conductivity increased by four orders of magnitude, and the TCR changed from -1.3%/K to -0.9%/K. Increasing the annealing temperature from 70 to 150 °C reduced the conductivity by two orders of magnitude and changed the TCR to -2.0%/K. Similar results were obtained when F4-TCNQ was used as a dopant, indicating that the influence of the dopant type on the characteristics was small. When other polymers such as DPP-DTT, PTB7 and PBDTT-DPP were mixed with F4-TCNQ, the TCRs were -2.0%/K, -2.3%/K, and -2.7%/K, respectively. Subsequently, we fabricated a strain sensor using P3HT/BCF annealed at a low temperature, which was a condition that exhibited a small resistance temperature change and high conductivity. The gauge factor of the sensor was 5.9 when a tensile strain of 6.6% was applied. The sensor was attached to an arm and detected resistance change during arm bending.

Interplay of Electrical and Mechanical Properties of Doped Conjugated Polymers ChristianMüller; Chalmers University of Technology, Sweden

Chemical and electrochemical doping are widely used to modulate the electrical properties of conjugated polymers. Doping of thin films facilitates fundamental spectroscopic studies and, ultimately, is important for the operation of devices from transistors to solar cells. However, some applications such as thermoelectrics and wearable electronics require bulk materials, which complicates doping processes and mass transport, limiting the performance of devices. This talk will explore some of the fundamentals of doping of both thin films and bulk materials. The impact of doping on the electrical as well as mechanical properties will be discussed, and it is shown how doping can be used to tune both the conductivity and stiffness of conjugated polymers. Finally, strategies are explored that permit to decouple the effect of doping on the electrical and mechanical properties, which can be used to prepare a variety conducting bulk materials, from stiff composites and foams to hydrogels and stretchable fibers.

Role of Confinement in Enhancing Electrical Transport of Conducting PolymersK.S. Narayan, SukanyaDas and ChandanPramanik; JNCASR, India

Confined conducting polymers (CPs) such as in nanocylinder geometries have been shown to exhibit enhanced conductance that is primarily attributed to factors such as chain alignment, increased crystallinity, and/or pi-pi stacking. We address the significance of these factors of polymers confined in alumina nanocylinders of diameters ranging from 20 nm to 100 nm and compare them with properties of bulk films. A conducting substrate of suitable work function and a common top contact was used to examine the macroscopic electrical transport of the CPs in these regularly patterned structures. Isolated nanopores were examined using conducting atomic force microscopy methods. A series of conducting polymers that include in-situ polymerized PEDOT:Tos, other forms of PEDOT from aqueous dispersion, and n-type doped polymers were examined. The enhanced vertical conductivity that is normally not observed in thick PEDOT films due to the transport barriers also points to the reduced degree of disorder. The difference in electrical charge transport of polymer blend PEDOT:PSS and polymer-monomer blend PEDOT:Tos in alumina scaffold in terms of σ as a function of ω and T highlights the efficacy of this approach to reduce disorder in tailored systems. The high-resolution transmission electron microscopic technique illustrates the picture of structural disorder present in the nanochannels and the variation of connecting pathways between the ordered regions on an amorphous matrix in two types of CPs with similar electronic PEDOT backbone. The confinement facilitates microstructures as the in-situ polymerization of PEDOT:Tos proceeds. The utility of these geometry-induced properties is demonstrated in the context of photodetection and thermoelectric applications.

Electric Field Induced Negative Capacitance in Semiconducting Polymer SougataMandal and ReghuMenon; Indian Institute of Science Bangalore, India

Electric field dependent capacitance and dielectric loss in poly(3-hexylthiophene) are measured by precision capacitance bridge. Carrier mobility and density are estimated from fits to current–voltage and capacitance data. The capacitance varies largely at lower frequency, and it decreases at higher electric fields. The negative capacitance at low frequency and high field is due to the negative phase angle between the dipole field and the ac signal. The intrinsic carrier density is calculated from fits to the Mott–Schottky equation, and this is consistent with I-V data analysis. At higher frequency, the carriers do not follow the ac signal and their density drops; and the flatband potential increases mainly due to the build-in potentials within ordered and amorphous regions in the sample.

A Close Look at Organic Magnetoresistance in Conjugated Polymers ZuchongYang and EmanueleOrgiu; Institut National de la Recherche Scientifique (INRS), Canada

Migratory animals in nature can amazingly sense Earth's extremely weak magnetic field (~50 micro-tesla) and use it as a compass for the precise navigation during their long-distance migration. It has been shown that this mysterious magnetoreception capability is closely related to the quantum spin dynamics of radical pairs from their magnetically sensitive proteins[1]. Intriguingly, some lab-synthesised organic semiconductors (OSCs) can also show a similar magnetic field response but to a much wider range (from sub-milli-tesla to tens of tesla), even at room temperature. The electrical current of organic-based devices can exhibit a noticeable variation when the latter ones are immersed in a magnetic field, which is called the organic magnetoresistance (OMAR). As OMAR is believed to be originated from bipolaron formation, which is intimately coupled with the charge transport, it represents an attractive playground for understanding the fundamental spin physics in OSCs and further exploring its potential for organic spintronics.

So far, most of the previous studies on OMAR have been based on limited kinds of model OSCs such as Alq_3, polyfluorene with a relatively disordered charge transport, which also serve as the active layer in the organic light-emitting diode[2]. Compared with a diode, a 3-terminal field-effect transistor (FET) adds a powerful electrical knob to tune the charge density inside the semiconductor via electrostatic doping. Furthermore, by functionalizing with different self-assembled monolayers, the structure of additional semiconductor-dielectric interface can also have an impact on the charge transport and spin dynamics through van der Waals interaction. Thus, an extensive study on state-of-the-art OSCs and more importantly, from the perspective of FET, could provide insights for understanding the effect of magnetic field-dependent spin pair configuration on charge transport. Herein, we chose three high-performance semiconducting polymers with the microstructure ranging from semi-crystalline to semi-amorphous, and representative of p-, n-, and ambipolar-type, respectively. Exploiting the transistor configuration, we studied the magnetic field effect on charge transport in these conjugated polymers under both low (100 milli-tesla) and high magnetic field (up to 9 tesla). A systematic investigation of the temperature-, electric field-, and interface-dependent magnetoresistance will be presented in detail.

Amorphous Poly-3-Hexythiophene Thin Films via Electrospray Deposition under High Vacuum ShubhamBhagat and IngoSalzmann; Concordia University, Canada

Conjugated polymers (CPs) are heavily explored for their application in flexible organic electronic devices such as- organic photovoltaics, organic light emitting diodes, organic transistors and organic thermoelectrics. This interest in CPs mainly stems from their high flexibility and ease of processibility on the large-scale by using cost-efficient solution-based techniques. Moreover, unlike their inorganic counterparts, the materials class of organic semiconductors offers the striking advantage that their optoelectronic properties can be easily tuned by their chemical structure including the chain length. However, CPs are thermally fragile thus intrinsically inhibiting vacuum deposition by thermal evaporation. Therefore, CPs are typically processed by solution-based techniques only. There, however, the extent of polymer pre-aggregation and film growth is substantially influenced by the choice of the solvent and other difficult to control experimental factors. The resulting microstructure in CP films can, in addition, not be improved by processing at elevated temperatures, which are largely inaccessible for common solvents. In contrast to conjugated organic molecules (COMs) that can be processed in-vacuo to form crystalline films of high coherence lengths, prototypical CPs such as regioregular poly(3-hexylthiophene) (P3HT) are semi-crystalline when grown from solution with the ratio of crystalline to amorphous film portion being hard to control.
For CPs, molecular doping enables tuning the thin-film conductivity over orders of magnitude. However, the film crystallinity has huge impact on the charge carrier mobility in CP heterostructures as well as pristine and doped CP films, where it has been argued that amorphous and crystalline film portions react differently to dopant exposure. Due to the intrinsic semi-crystalline nature of CPs such as P3HT in thin films, information experimentally gained comprises superimposed signatures from the crystalline and amorphous regions of the CP. Therefore, preparing amorphous CP films represents the most straightforward experimental approach to disentangle this information. In contrast to *improving* the structural properties of semi-crystalline CP films, however, deliberately *reducing* their crystallinity and achieving *amorphous* films has not been achieved so far. Here, we demonstrate that room-temperature high vacuum electrospray deposition (HV-ESD) of P3HT enables reproducibly establishing such films and provide evidence for their amorphicity by synchrotron grazing-incidence X-ray diffraction (GIXRD). In addition to details of the experimental procedure of HV-ESD and the properties of pristine P3HT films established therewith, we will discuss their doping phenomenology with the strong electron acceptor 2,3,5,6-Tetrafluoro-tetracyanoquinodimethane (F4TCNQ).

Tuning the Properties of Poly(3-alkylthiophene)s via Side Chain Engineering GenevieveSauve; Case Western Reserve University, United States

Regioregular poly(3-alkylthiophene)s (P3ATs) constitute an important class of conjugated polymers (CPs) for organic electronic applications. In particular, poly(3-hexylthiophene) (P3HT) is one of the most studied and accessible CPs due to it's simple synthesis that enables kilogram scale production. One way to potentially tune CPs properties without affecting electronic properties is to introduce functional groups several carbons away from the conjugated backbone. However, such modifications can affect CPs self-assembly, crystallinity and π–π stacking, making it challenging to optimize properties while maintaining good charge carrier mobility. It is thus essential to better understand how side chain modifications affect desirable properties. Here, we explore using side chain engineering to increase the relative dielectric constant (ε_r) and to improve the mechanical properties of P3ATs. Results give us guidelines to tune properties while maintaining favorable film morphology for charge carrier mobility.

Conjugated polymers typically have low ε_r (3-4), which limits their application. Increasing ε_r could enhance device performance by promoting exciton dissociation, reducing bimolecular charge carrier recombination, and enhance charge carrier mobility via charge screening. Here, we introduced highly polar methylsulfinyl and methylsulfonyl groups at the end of P3AT side chains. This placement should allow the polar groups to efficiently rotate and increase orientational polarization. High ε_r values were achieved for these functionalized P3ATs based on an accurate capacitance measurement using a gold/ semiconducting polymer/SiO_2/n-doped Si configuration. The ε_r at megahertz and room temperature increased from 3.8 for P3HT to 7.4 for the sulfinylated and 8.1−9.3 for sulfonylated P3ATs. These values are among the highest ε_r reported for CPs. Grazing-incident wide-angle X-ray diffraction results showed that these polar groups decreased the crystallinity for the polythiophene backbones and interfered with the π–π stacking in the crystalline structure, especially the methylsulfonyl groups. From this study, we conclude that the methylsulfinylated polymers may be promising to provide a balance between high ε_r and preserving favorable π–π stacking structure for device applications.

Like most CPs, P3ATs tend to be brittle, limiting their application. Interestingly, one of the polymers with high dielectric constant had unusual mechanical properties. We hypothesized that the improved properties were due to the ester group six carbon away from the backbone. To better understand the effect of ester groups on both mechanical and electronic properties, we synthesized two random copolymer series: poly(3-alkylthiophene-2,5-diyl)-*ran*-(3-(6-pentanoatehexyl)thiophene-2,5-diyl) where alkyl is either hexyl (P3HT series) or dodecyl (P3DDT series). In both series, the ester-functionalized side chain content was varied. The copolymer's optical, thermal, structural, electrical and mechanical properties were investigated. Optimal mechanical and electrical properties were obtained with 10% ester content, and the mechanical property improvements were maximized when the co-side chain was shorter (hexyl) than the ester-functionalized side chain. The best combination of robustness and charge carrier mobility was thus obtained for the P3HT random copolymer with 10% ester-functionalized side chain: a high fracture strain (29±6%) combined with a high tensile strength (3.9±0.6 MPa) was achieved while maintaining the same high charge carrier mobility than a similar MW P3HT ($0.12\pm0.01 cm^2/Vs$). These exciting results demonstrate the feasibility of using ester-functionality in optimizing both mechanical and electrical properties of poly(3-alkylthiophene)s.

Tuning Work Function and Device Efficiency in Nanostructured Organic Layered Interfaces—From Electrochemical Crosslinking to Hybrid Dendrimers RigobertoC. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

The introduction of organic and polymer layers in bulk heterojunction solid-state devices, displays, and transistor devices, plays a central role in mediating device performance. It is often associated with thin-layered nanostructuring and control of energy/electron transport corresponding to mobility with the active layers. In this talk, we emphasize our studies in the use of nanostructuring methods and rational electrochemically active dendrimer synthesis to fine-tune the work function in organic semiconductor devices, i.e. to increase device performance and efficiency. Several examples of this approach in exploring the role of electro-active species include 1) synthesis and electrochemical crosslinking of precursor polymers, 2) grafting of polymer brushes and patterning, 3) utilizing surface plasmon resonance spectroscopy to probe transport phenomena, and 4) LED, PV and sensor device development.

Role of Polymer-Dopant Distance on Charge Transport in Amorphous and Crystalline Domains in Doped Conjugated Polymers MichaelLu-Díaz[1], MuhamedDuhandzic[2], SubhayanSamanta[1], SimonHarrity[1], ZlatanAksamija[2] and DhandapaniVenkataraman[1]; [1]University of Massachusetts Amherst, United States; [2]The University of Utah, United States

Conjugated polymers lack free carriers and thus need to be chemically doped to increase conductivity. This process, however, introduces energetic disorder and charge traps. Therefore, there is a compelling need to identify factors that affect dopant-polymer interactions and modify them suitably for improved charge transport. The effect of Coulomb interaction of charged polymer and dopant counterion is one such factor. In literature, some studies ascribe reduced Coulomb interactions to increased counterion size while others to increased molecular ordering. We resolve this apparent conflict by evaluating the impact of doping the crystalline and amorphous domains on the density of states (DOS) and how each domain type contributes to charge transport. We measured Seebeck coefficient (α) and electrical conductivity (σ) of gradually dedoping of regioregular and regiorandom P3HT films and their blends. We used wide angle X-ray scattering and UV-Vis-near IR spectroscopy to characterize the doped P3HT films and fitted data to a phonon-assisted hopping model of charge transport to extract the dopant-induced disorder from the calculated DOS. We show that the regiorandom and regioregular domains in the doped polymer simultaneously contribute to the charge transport with their individual contribution depending on their doping level. We also show that any observable impact of counterion size or paracrystallinity on charge transport can be correlated to polymer-dopant distance, R_s. Our two-DOS model of crystalline and amorphous regions connects well to the observed trends in the α-σ curves of regiorandom and regioregular P3HT blends. Our work shows the amorphous domain encounters a larger dopant-induced disorder and also contributes to charge transport significantly. Thus, it is important to take into account the effect of dopant-induced disorder on particular structural regions while designing polymers and dopants for improved charge transport.

Enhancing the Power Factor of SWNT Thin Films for Organic Thermoelectrics SooyonChang and ZhitingTian; Cornell University, United States

Thermoelectrics are regarded as one solution that upcycles waste heat to convert it into a useful resource; electricity. A thermoelectric device utilizes the Seebeck effect across a p-type and n-type material to create a voltage difference from a temperature gradient. Unlike many developments in the area of p-type, many conventional n-type materials have been restricted to inorganics that are toxic and expensive. Here, we focus on organic n-type material through doping and post-treatment which allows us to tune the power factor (PF) even further. Organic single wall carbon nanotubes (SWNT) are known for their high electrical conductivity through electron hopping of valence electrons and have shown potential for thermoelectrics. We have fabricated micron-thick SWNT films using a surfactant to induce an n-type behavior and doped them to further increase the electrical conductivity. The films were measured over 3 months and retained a stable negative Seebeck coefficient, which proves as a promising candidate for long-term thermoelectric devices. We have found that the different annealing temperatures and doping times of the dopant resulted in a distinguished surface morphology where we could improve the electrical conductivity with no diminishing of thermopower.

8:00 PM EL16.03.03
Large Area Scalable HTL-Free Organic Solar Cells with Phosphotungstic Acid Solid Additives JahandarMuhammad, SoyeonKim and Dong ChanLim; Korea Institute of Materials Science, Korea (the Republic of)

The interfacial layers play a crucial role in enhancing the performance and stability of organic solar cells (OSCs). Despite achieving high efficiency in OSCs, the challenges associated with large-area manufacturing and the need for nanoscale uniformity during coating have hindered large-scale production. To address these issues, we propose the concept of hole transport layer (HTL)-free OSCs to simplify fabrication processes and enable more efficient production. In this study, we explore the potential of phosphotungstic acid (TWA) as a promising alternative for the HTL and as a solid additive in HTL-free OSCs to enhance device performance and scalability from cell-to-module. Remarkably, incorporating TWA as an annealing-free HTL and as a solid additive into the photo-active layer (PM6:Y6:PC71BM) significantly boosts the power conversion efficiency (PCE) up to 17.28% and 16.33%, respectively, compared to the reference device with PEDOT:PSS (15.88%). We successfully fabricated a large-area OSC module with an impressive PCE of 15.18% and an active area of 54 cm^2, achieving approximately 85% of the effectiveness of small-area OSCs. The improved performance is attributed to the enhanced transmittance, excellent carrier-dynamic capacity, suppressed carrier recombination, and reduced trap-states in the ternary-bulk heterojunction OSCs. This study demonstrates the promising versatility of TWA for OSCs, offering potential enhancements for device performance and scalability in future applications.

Stability of $FeCl_3$ as a p-Type Dopant for Semiconducting Polymers MeghnaJha, JoaquinSantiana and AdamJ. Moule; University of California, Davis, United States

Molecular doping of semiconducting polymers has garnered significant attention in the field of organic electronics. $FeCl_3$ has emerged as a promising, cost-effective p-type dopant for "hard-to-dope" polymers like DPPs. In this study, we investigate the stability of $FeCl_3$ as a dopant by cycling the doping and de-doping process. Specifically, DPP-4T is doped with $FeCl_3$ and subjected to temporal de-doping in air and darkness. Our observations reveal a degradation of neutral peaks and a subsequent reduction in absorbance during the de-doping process.
To gain deeper insights into the doping mechanism at the atomic level, we employ UV-Vis-NIR spectroscopy, Four-probe sheet resistance measurements, and X-ray absorption near-edge structure (XANES) spectroscopy. Our results indicate the involvement of two distinct Fe ions in charge transfer and charge stabilization reactions during the doping process.
Furthermore, we explore the impact of different solvents on the properties of the dopant. Our findings highlight the crucial role of solvent dielectric constant and electron donor effects in controlling the degree of polymer doping.
Additionally, we discuss the application of anion exchange doping and perform lifetime measurements to assess the long-term stability of the doped polymers. Finally, we present an analysis of the advantages and disadvantages of molecular doping, including a comparison to simple molecular doping techniques.
This study provides valuable insights into the stability of $FeCl_3$ as a dopant, elucidates the atomic-level mechanisms of the doping process, and underscores the significance of solvent choice. The findings contribute to the understanding of molecular doping in organic electronics and pave the way for further advancements in the field.

Quasi-Instantaneous Doping Mechanism of Organic Semiconductors by a Strong Lewis Acid MelissaBerteau-Rainville[1], ShubhamBhagat[2], ThomasBaumgartner[3], EmanueleOrgiu[1], ChristopherCaputo[3] and IngoSalzmann[2,2]; [1]Institut National de la Recherche Scientifique, Canada; [2]Concordia University, Canada; [3]York University, Canada

The doping of organic semiconductors (OSCs) is of crucial importance for applications in electronic devices, where it is used to alter the opto-electronic properties of OSCs. P-type doping is generally achieved via the admixture of strong electron acceptors, i.e. molecules that feature a high electron affinity, in order to remove a full electron from the OSC. Because of their typically conjugated nature such molecules tend to form supramolecular complexes with the organic semiconductor instead of promoting electron transfer, which quenches the efficiency of the dopant. Furthermore, control over structure in doped systems, which is paramount to performances in applications, is difficult to achieve because these molecules do not interact covalently.

In this light, trivalent group XIII Lewis acids (boron, aluminum centers) have been used as dopants, paired with OSCs that contain hard nitrogen atoms to which they can bind covalently. This resulted, for example, in the possibility to tune the bandgap of OSCs by employing acids of different strengths, but not in full electron transfer. In other systems where OSCs do *not* feature hard basic sites to which LAs can bind covalently, however, full electron transfers were reported, notably in the poly(3-hexylthiophene) (P3HT) - tris(pentafluorophenyl)borane (BCF) system. This came as a surprise as the electron affinity of BCF is thought to be insufficient to induce such electron transfers. As such, it was more recently proposed that this doping proceeds via a proton transfer that can be introduced by water traces even in inert environments, through a mechanism that was calculated to be highly endergonic.

Considering all these findings, we will report on the surprising observation that BCF can readily dope three different thiophene-containing OSCs of relatively low ionization energy in a quasi-instantaneous manner that is at odds with a highly endergonic mechanism. We investigated more closely the doping behavior of several Lewis acids analogous to BCF with P3HT in order to understand the factors determining the ability of Lewis acids to produce such doping. We performed supporting DFT calculations to assess the energetics involved in different possible mechanisms. Altogether, our data strongly suggest that this quasi-instantaneous doping is not mediated by a proton transfer alone, which we will discuss in the framework of the previously suggested doping processes known to be at work for organic semiconductors.

Adduct-Forming and Macromolecular Dopants for Semiconducting Polymers HowardE. Katz, JinfengHan, TushitaMukhopadhyaya, ConnorGanley and PauletteClancy; Johns Hopkins University, United States

The traditional vision of the dopant-semiconductor interaction, including organic and polymeric semiconductors, is direct electron transfer between the two, leaving a charge carrier on the semiconductor in the form of a mobile radical ion and an oppositely charged counterion. In this presentation, we explore a two-step alternative doping mechanism, by which the dopant forms a covalent adduct with a conjugated polymer segment, and that adduct subsequently participates in the electron transfer that leads to the charge carrier generation. We investigated both p-type and n-type versions of this process, using tris(pentafluorophenyl)borane (TPFB) and fluoride anion (F-), respectively, as the adduct-forming species. Many structures of conjugated segments were used as models for the polymer segments that might form adducts with TPFB or F-. Evidence that adducts could serve as dopants was obtained from conductivity and Seebeck coefficient measurements, electron paramagnetic resonance (EPR) spectroscopy, optical absorbance spectroscopy, and Density Functional Theory calculations. Furthermore, we paired the F- dopant with a pyridinium polymer to create an n-type analog of PEDOT-PSS, where the charge transporter and dopant counterion in the conducting composition are both macromolecular, and the electronic conductivity was especially high compared to that obtained from single-molecule dopants.

Inhomogeneous Dopant Distribution in Organic Semiconductors: Causes and Consequences for ChargeTtransport MartijnKemerink; University of Heidelberg, Germany

While the effect of the incorporation of dopant molecules on the microstructure of the host material has been intensely investigated, translating these results to electronic properties has received less attention. Here, we will show two case studies of inhomogeneous dopant distribution in organic semiconductors, for which we do a quantitative comparison between experimental data of dopant distributions and conductivity and numerical simulations thereof. For the latter we developed two intuitive tools to produce simplified yet realistic morphologies of doped organic polymers, accounting for the effects of (a) aggregation and phase separation in the semiconducting host material and of (b) diffusion and preferential incorporation in specific phases of the dopant. The created morphologies are then used as starting point for kinetic Monte Carlo simulations of charge transport. Importantly, the case studies can be generalized to design rules to achieve high conductivity at low dopant concentrations.

Stable and Tunable Chemical Doping for Organic Semiconductors in Aqueous Solution under Ambient Conditions MasakiIshii[1,2], YuYamashita[1,3], ShunWatanabe[3], KatsuhikoAriga[1,2,3] and JunTakeya[1,3]; [1]National Institute for Materials Science, Japan; [2]Tokyo University of Science, Japan; [3]The University of Tokyo, Japan

Doping levels in chemical doping of organic semiconductors are determined by semiconductor and dopant energy levels. While precise control of doping is required to fabricate advanced devices, as seen in silicon semiconductors, control in doping levels at a scale of thermal energy (25 meV) has been challenging for organic semiconductors. Most of dopants are unstable under ambient conditions owing to the reactivity with water or oxygen in air, which further decreases precision in doping levels. Low precision in doping levels and need for inert processing environment have been bottlenecks for developing and manufacturing advanced organic semiconductor devices employing chemical doping.
In this study, doping levels of organic semiconductors were controlled reproducibly and precisely in aqueous dopant solution under ambient conditions [1]. In our method, chemical doping is based on proton-coupled electron transfer (PCET) reactions that are widely observed in biochemistry, unlike conventional methods that employ single electron transfer reactions. Our aqueous dopant solutions contain dopant salts, pH adjusting agents and PCET-based redox couples. As a PCET-based redox agent, for instance, Benzoquinone/Hydroquinone (BQ/HQ) couple was employed. Through redox reactions, BQ gets transformed into HQ by accepting two electrons and two protons, where its redox potential depends on proton activity, pH, of the aqueous solution following the Nernst equation. A well-known p-type semiconducting polymer, poly[2,5-bis(3-tetradecylthiophen-2-yl)thieno[3,2-b]thiophene] (PBTTT), was doped by BQ/HQ doping solutions. PBTTT got oxidized when the redox potential of BQ/HQ exceeded the Fermi level of PBTTT in a low pH environment. The positive charge introduced into PBTTT was compensated by intercalation of anions in aqueous solution similarly to anion-exchange doping in organic solvents [2]. Bis(trifluoromethanesulfonyl)imide (TFSI) or bis(nonafluorobutanesulfonyl)imide (NFSI) was employed as dopant anion introduced into PBTTT, which would realize stable doped state owing to their closed-shell structures and hydrophobicity [3].
Doping level of PBTTT was controlled by the pH value of dopant aqueous solution, where the redox potential of BQ/HQ showed pH dependence of 59 mV/pH. According to the optical absorption and conductivity measurement, the doping level of PBTTT increases with decreasing solution pH. Tuning of doping levels were also confirmed by structural analysis based on X-ray diffraction and elemental analysis based on X-ray photoelectron spectroscopy measurements. Doping levels of one PBTTT film were modulated repeatedly by cycles of increase and decrease in solution pH, which demonstrates that both of oxidation and reduction of organic semiconductors take place in our system that develops chemical equilibrium. It was verified that one can control the Fermi level of organic semiconductors reproducibly with a high degree of precision, *ca.* thermal energy of 25 meV at RT, over a few hundred meV around the band edge. This is a critical range to control electronic properties of semiconductors.
Our PCET-based system provides a facile, scalable, precisely controlled, reproducible and reliable chemical doping method, which would lead to ambient processed organic electronics and bioelectronics.

Effect of Dipolar Dopants on Charge Carrier Transport in Ordered Molecular Semiconductors with Order Parameters AkiraOhno, TsukasaNakamura, YukikoTakayashiki, Jun-ichiHanna and HiroakiIino; Tokyo Institute of Technology, Japan

We have investigated the orientational and translational order effect of dipolar molecules on carrier transport. Random orientation of dipolar or polar molecules interacting with carriers provides static disorder in organic semiconductors. We examined the doping effect of dipolar dopants using liquid crystalline organic semiconductors, which provides us with a useful model system for examining the effect in both experiments and simulations: we doped molecules with electrostatic dipoles or molecular polarization in smectic liquid crystal, e.g., phenylnaphthalene derivatives, which show the layered structure and resulting 2D carrier transport. The dopants such as organic cyanides and ketones are controlled in their orientation and translational ordering in the smectic liquid crystals where they are either mixed in intralayer or microphase separated in the interlayer, while the others are inserted into the interlayer and behave in a three-dimensional random orientation and coordination in the alkyl chain of liquid crystal.
Obtained mobilities by time-of-flight experiments have characteristic temperature and field dependence and can be analyzed by Gaussian disorder formalism. These effects are successfully analyzed by using our theoretical model based on calculating the N-th moment of the total Coulomb potential contribution of dipoles for an ordered molecular alignment. We found that the dipole dopants degrade the carrier transport in the 2D-ordered layer structure and gave the additional energetic disorder σ_d proportional to a square root of the dipole concentration $\sim C^{1/2}$. Therefore, it should be noted that the carrier transport is less sensitive to the dipoles compared with that in the 3D conduction system. We also confirmed the phenomena by carrier transport simulation of kinetic Monte Calro for a snap-shot of hopping sites decided by MD simulation with generated energetic disorder landscape.
This dependence shows us that the effect on carrier transport is limited in highly ordered materials, even if there is an origin that causes a large static disorder. This gives us an insight into why the behavior of carrier transport is different between crystal and semi-ordered phases such as liquid crystals or polymers. Intrinsic mobilities measured in various liquid crystalline (LC) materials reported in the last few decades, do not change much from material to material but do change much from mesophase to mesophase: for example, typical mobility is on the order of $\sim 10^{-2}$-10^{-3} cm^2/Vs in crystal B and E phases, of $\sim 10^{-2} cm^2/Vs$ in hexatic B phase, and $10^{-3} cm^2/Vs$ in smectic A and C phases [1] regardless chemical structures of liquid crystal. On the other hand, a wide variation of mobilities from 10^{-3} to 10 cm^2/Vs depending on chemical structures is often observed in crystals. It is true even for liquid crystalline molecules, benzothienobenzothiophene (BTBT) derivatives, such as Cn-BTBT and Ph-BTBT-Cn in crystalline phase: in fact, high mobility of over 10 cm^2/Vs reported in their crystalline phase. [2] These facts indicate a clear contrast in carrier transport between the ordered and semi-ordered phases. For investigating the origin of differences, we introduced the Gaussian disorder model restricted by the order parameters as static disorder into the charge transport model with the dynamic disorder. This model can be consistently applied for both crystalline and liquid crystalline phases and made it possible to discuss the difference in carrier transport between crystal and semi-ordered materials. These fundamental studies are very important for the functional design of organic semiconductors, especially for the operation of printable electronics.

Minimizing Molecular-Dopant-Induced Disorder in Emerging Semiconductors KeehoonKang; Seoul National University, Korea (the Republic of)

Doping has been one of the most essential methods to control charge carrier concentration in semiconductors. Excess generation of charge carriers is a key route for controlling electrical

properties of semiconducting materials and typically accompanies alteration of electronic structure by the introduction of dopant impurities, both of which have played pivotal roles in making breakthroughs in inorganic microelectronic and optoelectronic devices both at research and industrial levels, especially for Si-based technology. Molecular doping is a facile and effective doping method for various semiconducting materials since it is relatively non-invasive compared to high-energy implantation of ionic impurities used in Si. However, there are main challenges remaining in fully utilising molecular doping in emerging semiconducting materials such as π-conjugated polymer semiconductors, two-dimensional materials and metal-halide perovskites due to the difficulties in preventing dopant-induced disorder effects while maintaining a high carrier mobility. This talk will introduce concepts that we have developed to minimizing the dopant-induced disorder [1, 2, 3] while mitigating current injection and doping stability issues in electronic devices [4, 5], and finally outline the future challenges remaining in the field to fully uncover the potentials.

Self-Doped Conjugated Polymers and Copolymers - Feasibility and Advantages in Devices JulianHungenberg, AdrianHochgesang, FlorianMeichsner and MukundanThelakkat; University of Bayreuth, Germany

Mixed ionic-electronic conductors are widely studied for accumulation mode (undoped systems) or depletion mode (doped systems) devices. PEDOT:PSS has been established as the working horse for depletion mode organic electrochemical transistors (OECTs) as it consists of the conjugated polymer $PEDOT^+$ which is intrinsically doped and stabilized by PSS^- counterions. It is neither soluble in water nor organic solvents, wherefore thin films are processed from aqueous dispersion. This results in a nonuniform film morphology consisting of doped PEDOT-rich domains surrounded by an insulating PSS matrix. This particular structure leads to several drawbacks such as long-term instability. Furthermore, its complex structure hampers the ability for chemical modification.

In contrast to PEDOT:PSS, most conjugated polymers are intrinsic (pristine or undoped) semiconductors and hence show very low electrical conductivities. Therefore, doping is necessary to increase the charge carrier density and thus the electrical conductivity. Upon molecular doping, active redox species are added to the OSC which can donate (n-type) or accept electrons (p-type) generating free charge carriers. For p-type doping, this means a transfer of electrons from the highest occupied molecular orbital (HOMO) of the OSC to the lowest unoccupied molecular orbital (LUMO) of the dopant. Issues here are the requirement of deep-lying dopant LUMO, thus stability against air/water, and the need for high amounts of dopants for charge carrier formation which ultimately disturbs the film morphology.

To address these challenges, our group took high efforts in the field of molecular doping of conjugated polymers. The first concept published takes advantage of HOMO-HOMO doping by mixing two donor materials (OSC-1 and OSC-2). OSC-2 is a chemically oxidized small molecule semiconductor namely Spiro-OMETAD$(TFSI)_2$ which is capable to oxidize the OSC PDPP[T_2]-EDOT (OSC-1). Thereby, the doping takes place by an electron transfer from the $HOMO_{OSC\text{-}1}$ to the partly occupied $HOMO_{OSC\text{-}2}$.[1] A second work extends this concept through the use of multielectron acceptor salts. For this, oxidized triphenylamines were linked to form multielectron acceptor dopants, which can accept up to four electrons per dopant. This strategy allows for significantly reducing the number of dopant molecules compared to common single electron acceptor dopants.[2]

Here, we present a novel synthetic strategy of a conjugated polyelectrolyte (CPE) based on a polythiophene-derivative toward a stable self-doped system which can be solution-processed from water as well as organic solvents. Our new CPE is intrinsically doped after synthesis, which is promoted by the stabilization of free charge carriers by its ionic side chains. We present self-doping as an elegant way to avoid the use of molecular dopants fully, while still maintaining high and stable conductivity. This was investigated by time-resolved spectroelectrochemistry in aqueous electrolytes, UV-vis spectroscopy in thin films in the dry state as well as conductivity measurements. We were furthermore able to employ our self-doped CPE as a mixed conductor and showed its application in a depletion mode OECT device with high transconductance and currents. By copolymerization with a comonomer, which is not self-dopable, we were able to tune the self-dopability and therefore to switch the transistor's mode of operation towards a well-performing accumulation mode device with a low threshold voltage.[3] These findings could help to study the self-doping processes and to develop new CPEs with low threshold voltages towards innovative device applications.

Challenges in Doping of Organics: Small Molecules vs. Polymers KarlLeo; IAPP, Germany

Controlling the charge carrier densities is a key feature of any semiconductor electronic device. In inorganic semiconductors, general understanding of doping has been achieved early on and research has concentrated on finding dopants in large-gap systems like nitrides. In organic materials, doping is now a routine technique for mass-produced OLED displays and organic solar cells. However, it is still far from a microscopic understanding. Furthermore, doping in organic systems where both electronic and ionic transport happen has recently generated much interest. In this talk, I will address these two very different systems: I will discuss recent progress in understanding the doping in small-molecule semiconductors, touching new dopants and high mobility materials, allowing to realize devices like the first organic bipolar transistors.
I will compare to recent work on the doping of organic electrochemical transistors (OECTs). These devices have recently been investigated broadly since they offer switching and sensing functionality in an electrolytic environment compatible with biological systems. The mixed electron-ion transport of the devices has consequences for the doping process, making it significantly different from the electrostatic doping of standard FET devices.

Molecular Doping of Conjugated Polymers for Flexible and Printed Organic Thermoelectric Generators BoseokKang; Sungkyunkwan University, Korea (the Republic of)

Organic thermoelectric generators (OTEGs) have received significant attention as a promising independent energy harvesting solution in the era of the Internet of Things. The OTEG device is attached directly to the surface of heat energy sources and transforms waste heat energy into valuable electricity based on the principle of the Seebeck effect. Several attempts have been made to achieve high-efficiency solution-processed OTEG devices, but there still remains a challenge to improve the thermoelectric figure of merits and the solution processibility for the device fabrication. In particular, doping is essential for controlling the charge carrier concentration in the conjugated organic media and governing charge transport physics, resulting in optimized device performance. In this talk, I will discuss various doping and molecular design strategies for improving the thermoelectric efficiency and solution processibility of conjugated polymers for flexible and printed OTEGs.

Enhancing the Performance of DPP-Based n-Type Thermoelectrics: The Role of Precise Solvent Selection for Mitigating the σ-S Trade-Off SoyeongJang[1], DiegoRosas Villalva[1], GuorongMa[2], AnirudhSharma[1], AndrewBates[2], AbdelH. Amwas[2], XiaodanGu[2] and DeryaBaran[1]; [1]Kaust, Saudi Arabia; [2]The University of Southern Mississippi, United States

The solubility of conjugated polymers (CPs) significantly determines their device performance. Consequently, understanding the relationship between the solubility of n-type host polymer-dopant-solvent systems and their electronic properties is vital within the CPs realm. This study delves into the impact of various halogenated solvents on the solubility and morphological

properties of a novel pyridine-flanked DPP n-type polymer (2PyDPP-2CNTVT) and Tetrabutylammonium fluoride (TBAF) as the dopant system. We utilized Hansen Solubility Parameter (HSP) for the solubility study. We employed Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) and Atomic Force Microscopy (AFM) to probe the doped polymer thin films' molecular structural disorders and surface morphology. Our findings indicate that Dichlorobenzene (DCB) solvent has superior solubility affinity for the polymer backbone and dopant. This affinity fosters improved host-dopant miscibility, excellent dopant accommodation, and enhanced film processability. Consequently, this leads to increased electron mobility (μe) of 2.3 cm2 V-1 s-1 and conductivity (σ) of 2.64 S cm-1 compared to films made with alternative halogenated solvents in this study. Additionally, our multidisciplinary experimental approach reveals an improved doping efficiency resulting from the lowest activation energy in the DCB system. These insights propose the DCB solvent as the optimal choice for achieving high μ_e and electrical conductivity σ in TBAF-doped 2PyDPP-2CNTVT CP film. This work underscores the importance of selecting solvent based on HSP evaluation to maximize the potential of molecular doping into n-typ DPP-based CP, mitigating the trade-off between σ and Seebeck coefficient (S).

Advancements in Molecular Doping of Semiconducting Polymers: Applications in Organic Thermoelectrics ShrayeshPatel; University of Chicago, United States

Molecular doping of semiconducting polymers holds significant promise for organic thermoelectrics, offering tunable electronic properties and ease of processability. In the first part of the talk, we delve into the fundamental structure-property relationships of sequentially doped thiophene-based polymers, shedding light on dopant segregation, microstructure, and their impact on conduction limits and stability. In the second part, we explore the potential of molecular doping in the development of functionally graded materials (FGMs) for organic thermoelectrics. Specifically, we demonstrate precise compositional control in thin film FGMs through sequential vapor doping of polythiophene derivatives with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ). Utilizing techniques such as grazing incidence wide angle X-ray scattering (GIWAXS) and Raman spectroscopy, we spatially resolve dopant compositional profiles within the FGM thin films. Additionally, we quantify the lateral distribution of electronic conductivity and Seebeck coefficient, providing insights into the spatial distribution of transport parameters. Our research advances the understanding of structure-transport properties and contributes to the development of efficient organic thermoelectric materials through sequential doping and functional grading.

Enhancing Thermoelectric Properties and Optimization Through Coulombic Interactions and AI-Driven High-Throughput Experiments KedarHippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Institute of Materials Research and Engineering, Singapore

Our studies propose a novel approach to enhance thermoelectric properties in conducting polymers by controlling coulombic interactions, without regulating morphology. We observe a significant three-fold enhancement in the thermoelectric power factor of OD-PDPP2T-TT compared to PBTTT-C12, attributed to improved counterion screening, verified experimentally by meauring the dielectric constant of the films, and explaining the enhancement through Boltzmann Transport Equations [1]. We establish a correlation between optical absorption signatures and thermoelectric properties, extracting carrier concentration and confirming the importance of charge mobility amidst structural disorder. Furthermore, we demonstrate the benefits of combining high-throughput experiments with machine learning for materials and process optimization, especially by consider optical signatures that directly provide information about doping [2]. Our automated setup enables rapid thin film preparation and characterization, achieving a >10× improvement in learning cycles. By combining regio-regular poly-3-hexylthiophene with carbon nanotubes, we identify optimal compositions achieving high electrical conductivities [3]. This integrated approach offers insights into enhancing thermoelectric properties and accelerates materials optimization in organic thermoelectrics.

Beyond Doping: Self-Induced Anisotropy Breaks the σ-S Coupling Towards High Performance N-Type Conjugated Polymer Thermoelectrics. DiegoRosas Villalva[1], DenissDerewjanko[2], YongcaoZhang[1], YeLiu[1], AndrewBates[3], AnirudhSharma[1], SoyeongJang[1], XiaodanGu[3], MartijnKemerink[2] and DeryaBaran[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Heidelberg University, Germany; [3]The University of Southern Mississippi, United States

In recent years, there has been continuous progress in the development of N-type organic thermoelectrics (OTE) due to the synthesis of new conjugated polymers and dopants. The primary focus of most designs has been to enhance doping efficiency and increase electrical conductivity, resulting in values surpassing 102 S cm^{-1}. Although effective, doping encounters limitations because of the inherent inverse relationship between the properties that determine the figures of merit in thermoelectric materials. To advance the field further, alternative approaches are needed beyond optimizing doping efficiency and the host:dopant ratio. In this study, we propose the concept of self-induced anisotropy as a solution to overcome the inverse coupling between electrical conductivity and Seebeck coefficient in N-type OTEs. Previous research has suggested methods like rubbing and drawing to induce anisotropy in p-type OTEs based on thiophenes. In our work, we exploit the interactions between solvent, host, and dopant to induce a preferential orientation. This orientation increases the in-plane delocalization length, thereby improving electrical conductivity while maintaining the Seebeck coefficient. By adopting this approach, we have achieved promising results in the 2DPP-2CNTVT:N-DMBI system. At room temperature, we obtained a Power Factor of 115 μW m^{-1} K^{-2} and a figure of merit of 0.17, which further increased to 188 μW m^{-1} K^{-2} and 0.36, respectively, at 105 C. To explain the origin of self-induced anisotropy, we utilized Hansen Solubility Parameters and established guidelines for formulating solvent-host-dopant systems that can achieve a similar effect. This discovery opens new possibilities for advancing N-type OTEs.

Elucidating Design Rules Towards Enhanced Solid-State Charge Transport in Oligoether-Functionalized Dioxythiophene-Based Alternating Copolymers AbigailA. Advincula[1,2,3], AmalieAtassi[1], ShawnA. Gregory[1], KarlThorley[4], JamesPonder[2,1,5], GuillaumeFreychet[6], AustinJones[1], GregorySu[7], ShannonYee[1,1] and JohnR. Reynolds[1,1]; [1]Georgia Institute of Technology, United States; [2]Air Force Research Laboratory, United States; [3]ARCTOS Technology Solutions, United States; [4]University of Kentucky, United States; [5]UES, Inc., United States; [6]Brookhaven National Laboratory, United States; [7]Lawrence Berkeley National Laboratory, United States

Understanding solid-state charge transport in chemically doped, electrically-conductive conjugated polymers (CPs) is important to emerging applications which include organic thermoelectrics, transparent electrodes, and bioelectronics. The synthetic tunability of CPs, e.g., backbone or side chain modulation, affords high control over energy levels (i.e., ionization energy/electron affinity), doping processes, and microstructures, factors which influence the electrical conductivity of a given CP system.

This study investigates the solid-state charge transport properties of the oxidized forms of dioxythiophene-based alternating copolymers consisting of oligoether-functionalized 3,4-propylenedioxythiophene (ProDOT) copolymerized with different aryl groups, dimethyl ProDOT (DMP), 3,4-ethylenedioxythiophene (EDOT), and 3,4-phenylenedioxythiophene (PheDOT) respectively, to yield the copolymers P(OE3)-D, P(OE3)-E, and P(OE3)-Ph. At a dopant concentration of 5 mM $FeTos_3$, electrical conductivities for these copolymers vary significantly (ranging between 9 S cm^{-1} and 195 S cm^{-1}) with the EDOT copolymer, P(OE3)-E, achieving the highest electrical conductivity. UV-vis-NIR and X-ray spectroscopies show differences in both susceptibility to oxidative doping and extent of oxidation for the P(OE3) series, with P(OE3)-E being the most doped. Wide angle X-ray scattering measurements indicate that P(OE3)-E generally demonstrates the lowest paracrystallinity values in the series, as well as relatively small π-π stacking distances. The significant (i.e., order of magnitude) increase in electrical conductivity of doped P(OE3)-E films versus doped P(OE3)-D or P(OE3)-Ph films can therefore be attributed to P(OE3)-E exhibiting both the highest carrier ratios in the P(OE3) series as well as good π-π overlap and local ordering (low paracrystallinity values). Furthermore, these trends in extent of doping and paracrystallinity are consistent with the reduced Fermi energy level and transport function prefactor parameters calculated using the semi-localized transport (SLoT) model. Observed differences in carrier ratios at the transport edge (c_t) and reduced Fermi energies [η(c)] suggest a broader electronic band (better overlap and more delocalization) for the EDOT-incorporating P(OE3)-E polymer relative to P(OE3)-D and P(OE3)-Ph. Ultimately, we rationalize improvements in electrical conductivity due to microstructural and doping enhancements caused by EDOT-incorporation, a structure-property relationship worth considering in the future design of highly electrically conductive systems.

4:00 PM EL16.05.07
Ion-Exchange Doping of Semiconducting Single-Walled Carbon Nanotubes AngusHawkey, AdityaDash, ZhiyongZhao, AnnaChamp, MichaelZharnikov, MartijnKemerink and JanaZaumseil; Heidelberg University, Germany

Due to their unique electronic and thermoelectric properties, networks of purely semiconducting single-walled carbon nanotubes (SWNTs) are a promising material for thermoelectric generators, which convert a temperature difference produced by waste heat into an electrical current. Dense films of SWNTs can be deposited from dispersion (e.g., by printing) and are mechanically flexible. They reach high electrical conductivities upon p- or n-doping and retain a high Seebeck coefficient. To introduce the charge carrier densities relevant for thermoelectric applications, chemical doping is typically used. However, the remaining dopant counterions are often unstable and the impact of the counterion on the thermoelectric properties of the SWNTs

is still not fully explored. The recently developed technique of ion-exchange doping provides a means to exchange the dopant counterion with anions or cations from a huge library of commercially available salts and ionic liquids that do not possess the redox potential to reduce or oxidize the SWNTs themselves. In this work, we fabricated thin film networks of polymer-sorted small and large diameter SWNTs (>99% semiconducting) and chemically p-doped them using ion-exchange doping with a range of dopant counterions at low and high doping levels. Optical and electrical measurements reveal the ion-exchange efficiency and the influence of the counterion size on the electrical and thermoelectric properties.

4:15 PM *EL16.05.08

The Influence of Counterion Structure and Doping Level on the Optical, Electronic, and Thermoelectric Properties of π-Conjugated Polymers KyleN. Baustert, AshkanAbtahi, JoelH. Bombile, AhmedAyyash, ChadRisko, AugustineO. Yusuf and KennethR. Graham; University of Kentucky, United States

Many organic electronic devices use chemical or electrochemical doping to introduce charge carriers into π-conjugated polymers (CPs) and change their optical and electronic properties. As these charge carriers are introduced into a CP, counterions are either created (chemical doping) or injected (electrochemical doping) into the CP to balance the charge associated with the polaron on the CP. The structure of these counterions can exert a pronounced influence on the properties of doped CPs. Understanding how dopants and counterions interact with CPs to influence their optical and electronic properties is thus critical to designing new dopants and electrochemically doped CPs. Here, we focus on the influence of counterion size on the optical, electronic, and thermoelectric properties of selected CPs, including P3HT derivatives and PDPP4T. At the small and large ends of the spectrum we use tetrafluoroborate (BF_4^-) and tetrakis[3,5-bis(trifluoromethyl)phenyl]borate ($BArF^-$), respectively, where $BArF^-$ has a molar volume that is eight times larger than BF_4^-. We find that the electrochemical doping behavior and polaron absorbance of *regioregular*-poly(3-hexylthiophene), *rr*-P3HT, differs significantly depending on whether BF_4^- or $BArF^-$ is the counterion. Through comparing *rr*-P3HT to *regiorandom*-P3HT, *rra*-P3HT, we attribute the counterion-dependent properties of *rr*-P3HT partly to the ability of the counterion to penetrate the crystalline regions. The large counterion $BArF^-$ cannot penetrate the crystalline regions and as a result a higher potential is needed to oxidize *rr*-P3HT with $BArF^-$. Counterion distribution is not the only influential parameter, as the low energy polaron absorbance peak (P1) appears at lower energy with $BArF^-$ for both *rr*- and *rra*-P3HT, which density functional theory calculations indicate is due to the larger size of $BArF^-$ relative to BF_4^- and the resulting increased distance between the charged counterion and charged polaron. Through electron paramagnetic resonance (EPR) measurements we show that the smaller counterion BF_4^-, which can penetrate the crystalline regions, results in increased bipolaron formation relative to $BArF^-$ as a counterion in *rr*-P3HT. Additionally, we find that the choice of counterion impacts both the electrical conductivity and Seebeck coefficient reached at a given charge-carrier concentration for P3HT derivatives and PDPP4T. These results highlight the influential interplay between counterion structure, polymer morphology, and resulting optical, electronic, and thermoelectric properties.

Changing the Charge Transport Mechanism in Conjugated Polymers via Post-Processing Side Chain Removal JamesPonder[1,2], ShawnGregory[3], AmalieAtassi[3], AbigailAdvincula[1,4], JoshuaM. Rinehart[3], ShannonYee[3] and JohnR. Reynolds[3]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States; [3]Georgia Institute of Technology, United States; [4]Arctos, United States

As the processability of electroactive conjugated polymers (CPs) is essential to their application in a range of devices, balancing solubility, processability, and film properties has become a key point of research. Solubilization of the conjugated backbone is typically achieved by introduction of relatively long branched hydrocarbon or oligoether side chains, which allows many degrees of conformational freedom. Such side chains, while enabling a wide range of processing conditions, reduce the relative fraction of active material in the film and obstruct π-π intermolecular interactions, leading to increased localization of charge carriers and compromise many of the desirable properties of the material (such as electrical conductivity). To counteract the deleterious effects introduced by side chains, we report that post-processing side chain removal, exemplified here via ester hydrolysis, significantly increases the electrical conductivity of chemically doped CP films with a corresponding decrease in Seebeck coefficient. In a model alkyl ester functionalized 3,4-propylenedioxythiophene (ProDOT) system, we found that the electrical conductivity of oxidatively doped films increased 10-fold upon side chain removal via hydrolysis. A combination of X-ray photoelectron spectroscopy (XPS), profilometry, and grazing incidence wide angle X-ray scattering (GIWAXS) results show that improvement in electrical conductivity and reduced Seebeck values are not due to an increase in carrier ratio (i.e., number of charge carriers per repeat unit ring), but instead results from an increase in charge carrier density (i.e., number of charge carriers per unit volume) due to densification and increased ordering of active polymer backbone material following side chain removal. This increase in charge carrier density leads to a reduction in charge localization, thereby improving charge transport, as contextualized using the newly developed semi-localized transport (SLoT) model. Applying this method to 3,4-ethylenedioxythiophene (EDOT) copolymer and homopolymer structures, synthesized via direct arylation polymerization, significantly higher average electrical conductivities are attained, with values ranging from 450 to ~1200 S/cm, depending on the repeat unit structure, in thick (> 600 nm) films. In an all EDOT-based system, we observe a change in transport mechanism, from a low electrical conductivity and thermally activated (hopping-like) regime to a high electrical conductivity and thermally deactivated (metal-like) regime. Finally, these results are compared to those of matching oligoether functionalized polymers for a direct comparison of the differences in charge transport between these two reported methods of conductivity enhancement.

Maleimide-Substituted Polyacetylene: A New Highly Conductive n-Type Polymer HarrisonM. Bergman and TimothyM. Swager; Massachusetts Institute of Technology, United States

The development of highly conductive organic semiconductors has been a longstanding goal in materials science due to their chemical tunability, solution processability, mechanical flexibility, and other unique properties. Conjugated polymers are some of the most promising materials in this respect and have been widely employed in diverse device architectures such as organic field effect transistors (OFETs), organic light emitting diodes (OLEDs), and organic photovoltaics (OPVs). These applications generally require both n-type and p-type semiconducting materials, but the development of p-type conducting polymers has greatly outstripped that of n-type and ambipolar systems. Specifically, n-type materials generally display lower conductivities and mobilities in their doped states and are less stable due to oxidation under ambient conditions.

This bottleneck is largely synthetic. Stability against oxidation requires decreasing LUMO levels well below -4.0 eV, yet there are relatively few building blocks that are sufficiently electron withdrawing to achieve this. Furthermore, there are limited design strategies for assembling these building blocks into polymers that retain high backbone planarity and electron delocalization, which are both critical to high mobility and conductivity. Thus, the development of new polymer scaffolds is critical to closing the performance gap between n-type and p-type conjugated polymers.

Polyacetylenes (PAs) are attractive as high conductivity polymers, holding the record for highest reported conductivity in an organic semiconductor. However, they are inherently p-type materials. Although the introduction of strongly withdrawing groups to the PA core is straightforward conceptually, there are several practical challenges. Many standard withdrawing groups are too sterically bulky to preserve backbone planarity, and those that remain are generally incompatible with traditional PA syntheses.

We address this issue by developing a new class of PAs consisting of an alternating sequence of maleimide and vinylene units, dubbed maleimide-polyacetylene or mPA. This structure achieves high backbone planarity while still introducing a high density of strongly withdrawing groups, furnishing a highly conductive polymer with a low LUMO of -4.2 eV. The maleimide unit is also a facile synthetic handle, which enables the introduction of diverse functionality without perturbing backbone conformation. These polymers were accessed via a new synthetic approach, where a nonconjugated precursor polymer was synthesized via ring opening metathesis polymerization (ROMP), followed by an efficient elimination to furnish the final polyacetylene. This strategy is scalable and efficient and enables the synthesis of low dispersity polymers with highly controllable molecular weights. Beyond mPA, it should be generalizable to a range of other electron-deficient polyacetylenes, opening the door to a new class of n-type organic semiconductors.

Negative Polaron in an n-Doped Polymer Semiconductor: Energy Levels and Hubbard *U* InteractionsDominiqueLungwitz[1], SyedJoy[2], AhmedE. Mansour[3], AndreasOpitz[3], ChamikaraKarunasena[4], HongLi[4], NaitikA. Panjwani[5], KarttikayMoudgil[6], KanTang[7], JanBehrends[5], StephenBarlow[7,6], SethR. Marder[7,6], Jean-LucBrédas[4], KennethR. Graham[2], NorbertKoch[3,8] and AntoineKahn[1]; [1]Princeton University, United States; [2]University of Kentucky, United States; [3]Humboldt-Universität zu Berlin, Germany; [4]University of Arizona, United States; [5]Freie Universität Berlin, Germany; [6]Georgia Institute of Technology, United States; [7]University of Colorado Boulder, United States; [8]Helmoltz-Zentrum Berlin, Germany

Doping organic semiconductors leads to the formation of polarons, positive in the case of p-doping and negative for n-doping. The released carrier polarizes neighboring molecular sites and induces intra- and inter-molecular relaxation. In the traditional picture, the formation of a negative polaron results in two localized levels within the gap: a half-occupied level below the

LUMO/CBM, and a doubly occupied level above the HOMO/VBM. Conversely, the formation of a positive polaron results in an empty level below the LUMO/CBM and a half-occupied level above the HOMO/VBM. Recent experimental and theoretical studies have challenged this original interpretation.[1-3] In the case of an added electron (hole), the new picture points to a half-occupied (empty) level below the semiconductor LUMO/CBM, split from an unoccupied (half-occupied) level positioned above (below) the LUMO/CBM (HOMO/VBM). The split corresponds to the intra-molecular Coulomb interaction, also known as Hubbard interaction *U*. In this work, we investigate n-doping of the polymer P(NDI2OD-T_2) with the molecular dopants $[RhCp^*Cp]_2$ and $[N\text{-}DMBI]_2$ as well as Cs, using ultra-violet and low-energy inverse photoemission spectroscopy (UPS, LEIPES) aided by EPR measurements and DFT computations.[4] The UPS data show that all three dopants induce the growth of a DOS in the former empty gap of the polymer while LEIPES shows an additional DOS above the polymer CBM. In agreement with the above-mentioned new interpretation, the additional DOS is assigned to the formation of the singly occupied and unoccupied levels, and allows the direct determination of the Hubbard *U*.

10:00 AM *EL16.06.04
The Role of Redox Doping in Organic Electronics and Opto-Electronics SethR. Marder; University of Colorado Boulder, United States

Organic semiconductors and hybrid/organic materials have attracted interest for electronic applications due to their potential for use in low-cost, large-area, flexible electronic devices. Here we will report on recent developments pertaining to n-dopants that could impact the charge injection/collection processes in organic light emitting diodes, organic field effect transistors, and organic photovoltaic and hybrid organic/inorganic perovskite devices. I will highlight the application of n-doping for the development of electron injection layers for organic light emitting diodes (OLEDs), and their use for doping of electron transport materials which result in high conductivities and in some cases good thermoelectric performance. In the case of OLEDs, it will be shown that photoactivation (as illustrated in the cartoon at the right) can lead to stable doping of materials (i.e. the doping induced conductivity remains relative constant over hundreds of hours) beyond the expected thermodynamic limit, which would be predicted based on a assessment of the effective reduction potential of the n-dopant and the reduction potential of the electron transport material. We will also highlight some of the differences between approaches based upon “dimeric” dopants, vs. hydride donor dopants.

10:30 AM EL16.06.05
Deprotonation-Based n-Doping of a New Acceptor-Acceptor Conjugated Polymer AndreasErhardt[1,2], AdrianHochgesang[2], JohnMohanraj[2] and MukundanThelakkat[2]; [1]Monash University, Australia; [2]University of Bayreuth, Germany

Doped organic semiconductors have proven to be viable materials for heat-to-electrical energy conversion (TE: thermoelectrics). For working large-scale thermoelectric generator devices, the synergistic use of p- and n-type components is necessary. However, as common for organic semiconductors, stable, n-doped polymers are sparse. Besides approaches to solve intrinsic stability issues of the doped acceptor towards ubiquitous oxidizing agents (H_2O and O_2), the choice and underlying mechanism of suitable n-dopants is an open field of research.
Our very recent works report the design and synthesis of an acceptor-acceptor low LUMO copolymer (“DPP-TPD”, [1]) in conjunction with bulk n-doping using Cs_2CO_3.[2] We present a novel acceptor-acceptor copolymer synthetic strategy using direct arylation polymerization and demonstrate excellent viability for n-doped systems for TE applications.
In contrast to previous reports about Cs_2CO_3 n-doped systems, we elucidate the mechanism, that our copolymer is doped via a solid-state acid-base interaction between the polymer and the basic carbonate. The resulting increase of the backbone electron density by deprotonation of the thiophene moiety is accompanied by the formation of bicarbonate. The crucial role of the basicity was demonstrated by comparative doping studies of the host polymer with further organic and inorganic carbonates. The general viability of the concept was evaluated with the strong base n-butyl lithium, which, in agreement with our findings, induces outstanding electron conductivity after thermal annealing. Comparable to N-DMBI hydride/electron transfer, Cs_2CO_3 proton abstraction doping shifts the polymer work function towards the LUMO. Thereby, the anionic doped state is resilient against O_2 but is highly susceptible to H_2O. Based on GIWAXS, Cs_2CO_3 is mainly incorporated into the amorphous region of the film with the help of hydrophilic side chains and has a minor impact on the crystallinity. Together, the synergy between Cs_2CO_3 proton abstraction doping and acceptor-acceptor copolymer strategy creates an n-doped system with promising properties for thermal energy conversion, as evidenced by a remarkable maximum power factor of $(5.59 \pm 0.39) \times 10^{-6}$ W m^{-1} K^{-2} in n-type thermoelectric element.
The main implications and novelty of our work are a: the viability of copolymers, following an acceptor-acceptor design principle, and b: the possibility to n-dope suitable copolymers via deprotonation reactions using simple carbonate dopants, opening a vast field of new n-type dopants.

Factors Promoting or Inhibiting Charge Transfer in Doped Organic Semiconductors IngoSalzmann; Concordia University, Canada

To control the conductivity of organic semiconductors (OSCs) and their energy level alignment in heterostructures and at interfaces, OSCs are being electrically doped by introducing guest species into the semiconductor host. Common doping agents added to initiate electron transfer include strong molecular donors/acceptors and Lewis acids. Complementary to direct integer charge transfer between OSC and dopant to form ion pairs (the ultimate goal of doping OSCs), fractional charge transfer can occur forming ground-state charge transfer complexes instead via intermolecular orbital rehybridization of OSC and dopant, which is detrimental to the doping efficiency [1]. For OSCs including oligothiophenes of different chain length p-doped with strong electron acceptors [2, 3], I will discuss the role that (i) thin film structure plays for the respective doping scenario, (ii) that of the dopant strength, and (iii) of OSC conjugation length. These findings suggest exploiting steric hindrance to suppress CPX formation which we recently demonstrated for a non-planar p-dopant of 3D shape [4]. Finally, I will contrast above doping scenarios to those that have been proposed to be at work for the doping of OSCs using Lewis acids as alternative doping agents.

Engineering Carrier-Dopant Interactions to Improve Charge Transport Properties in Highly-Doped Semiconducting Polymers KilwonCho; Pohang University of Science and Technology, Korea (the Republic of)

Doping is a powerful technique that can easily tune the electrical properties of semiconducting polymers and hence, grant flexibility to their applications. Highly-doped semiconducting polymers with high electrical conductivity have found extensive use in thermoelectric materials and bioelectronics. However, the low dielectric constant of semiconducting polymers causes strong Coulomb interactions between carriers and dopants. As a result, carriers cannot be effectively transported through the host polymer network and tend to localize within a few monomer units or π-stacks. These limitations, distinct from those observed in conventionally doped inorganic semiconductors, necessitate novel engineering strategies to not only generate more charge carriers but also reduce unfavorable electrostatic interactions between carriers and dopants in doped semiconducting polymers. This talk will explore straightforward engineering methods to reduce Coulomb interactions between carriers and dopants in highly-doped semiconducting polymers. The corresponding reduction in charge localization and improved transport achieved through these methods will be discussed. Additionally, I will explore the effects of molecular structures that exhibit resilience to the energetic disorder caused by electrostatic carrier-dopant interactions on charge transport properties. Lastly, the talk will introduce the significant thermoelectric performance achieved in our research and discuss the potential of thermoelectric materials based on doped semiconducting polymers for the near future.

1:30 PM *EL16.07.01
Quantifying Polaron Populations in Sequentially Doped Conjugated Polymers AdamJ. Moule[1], TuckerL. Murrey[1], MelissaBerteau-Rainville[2], MeghnaJha[1], IngoSalzmann[3] and MarkMascal[1]; [1]University of California, Davis, United States; [2]Institut National de la Recherche Scientifique, Canada; [3]Concordia University, Canada

Conjugated polymers can be chemically tailored for a variety of electronic device applications. Sequential solution doping with high electron affinity (EA) molecular dopants is the processing technique that has produced molecularly doped polymeric films with the highest conductivity. In spite of numerous studies quantifying the conductivity of molecularly doped polymers as a function of processing conditions, there is no established method to quantify the charge density. The consequence is that the relationship between conductivity, mobility, and charge density is poorly understood, prohibiting meaningful quantitative comparisons between different polymers and dopants. Here we demonstrate a practical method to quantify the polaron density using the material density, molecular volumes, and optical measurements. Importantly, this method enables quantitative comparisons between multiple different polymer and dopant combinations as we demonstrate using P3HT and a series diketopyrrolopyrrole (DPP) co-polymers doped with a series of ultra-high EA cyano- and ester-substituted cyclopropane-1,2,3-triylidene-based dopants. The Langmuir isotherm is used to fit the solution concentration dependence of the film polaron mole fraction, which enables characterization of the sequential doping process using a single equilibrium constant. The saturated polaron mole fraction saturates with respect to the energetic driving force for doping, indicating that simply increasing the EA of the dopant is not an effective strategy for obtaining 100% ionization of the polymer monomers. To ground this thermodynamic model, we simulated the density of states (DOS) using Gaussian energy distributions. This DOS model predicts the experimental saturated doping level for every polymer/dopant pair within uncertainty. This data and model demonstrate conclusively that increasing the polaron density has a larger effect on increasing both conductivity and charge mobility than the polymer chemistry or structure.

2:00 PM *EL16.07.02
Considerations on "Double Doping" and an Enhanced *p*-Dopant ComplexNorbertKoch[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin, Germany

The double ionization of molecular dopants enables the doping efficiency to rise above 100%. This means increased conductivity can be achieved with fewer dopant molecules, resulting in less disruption to the semiconductor film's structure. However, current models of doped organic semiconductors based on Fermi-Dirac statistics with two distributions that represent the host and dopant density of states, fail to explain double dopant ionization, and also the analogous situation of bipolaron formation on a host semiconductor polymer. This shortcoming is addressed by considering the energy level renormalization of the frontier molecular orbital levels upon electron transfer between host and *p*-dopant. Varying the model parameters host-dopant energy level offset, energetic disorder, reorganization energy, and Hubbard *U* sublevel splitting, robust trends in the fractions of doubly-ionized, singly-ionized, and neutral species are found.
The conventionally used *p*-dopants based on tetracyanoquinodimethane (TCNQ) and its derivatives feature limited oxidation strength especially for modern polymer semiconductors with high ionization energy (IE). These small molecular dopants also exhibit pronounced diffusion in polymer hosts. A facile approach is presented to increase the oxidation strength of several TCNQ-derivatives by coordination with four tris(pentafluorophenyl)borane (BCF) molecules, using a single-step solution mixing process, resulting in bulky dopant complexes. Using a series of polymer semiconductors with IE up to 5.9 eV, the efficiency of doping using such complexes is found to be significantly higher compared to using either of the dopants alone. Additionally, the bulkier structure of the complexes is shown to result in a higher stability against dopant drift in thin films under an applied electric field. The simple approach of solution-mixing of readily accessible molecules thus offers access to enhanced molecular *p*-dopants.

Unlocking the Full Potential of Electron Acceptor Molecules for Efficient and Stable Hole Injection into Organic Semiconductors TakuOono, TakuyaOkada, TsubasaSasaki, TakahisaShimizu and HirohikoFukagawa; Japan Broadcasting Corporation, Japan

Improving the hole injection property are of pivotal importance in the future development of organic optoelectronic devices. Electron acceptor molecules with high electron affinity (EA) are widely used in electronic applications, such as hole injection, p-doping and charge generation. Although p-doping and charge generation have generally been discussed in terms of matching the ionization energy (IE) of organic semiconductors with the EA of acceptor molecules, it has been demonstrated that the EA depends on the charged states of acceptor molecules in recent years [1,2].
In this study, we report a strategy to maximize the potential of acceptor molecules for efficient and stable hole injection into organic semiconductors [3]. This strategy has been developed based on the correlation between the HIL-dependent properties of OLEDs and the actual energy levels around the anodes as determined by both low-energy inverse photoemission spectroscopy and ultraviolet photoemission spectroscopy. Efficient and stable hole injection into an organic semiconductor with a relatively high IE of 5.8 eV is possible by stacking acceptor molecules with EAs of 4.3 and 5.0 eV. This superior hole injection property enables direct hole injection even into materials used as the emitting host for pure blue thermally activated delayed fluorescence (TADF) emitters with a large band gap. A pure blue TADF organic light-emitting diode (OLED) that has both a Commission internationale de l'éclairage (CIE) y coordinate of less than 0.10 and a low turn-on voltage of only 2.67 V was realized by employing a device architecture with no energy barrier in the OLED. The findings are expected to have a wide range of organic electronic applications, such as the efficient hole injection into materials with high IE used in perovskite LEDs, organic thin-film transistors, and organic semiconductor laser diodes.

Imaging the Effect of Nanoscale Morphology on Molecular Doping Efficiency in Conducting Polymers Sung-JooKwon[1], RajivGiridharagopal[1], ShinyaChen[1], RamsessQuezada[1], JiajieGuo[1], JustinNeu[2], WeiYou[2] and DavidS. Ginger[1]; [1]University of Washington, United States; [2]University of North Carolina at Chapel Hill, United States

Understanding the mechanisms underpinning doping of conducting polymers (CPs) is critical for improving their performance in next-generation organic electronic devices. Although a number of studies have investigated molecular or electrochemical doping of conducting polymers, most work has focused primarily on understanding doping via device-level operation using macroscopic probes. Conducting polymers (CPs) are inherently nanostructured, with a mixture of crystalline and amorphous domains. Thus, understanding the underlying mechanisms behind doping can benefit from nanoscale real-space imaging. Here, we investigate the molecular and electrochemical doping on two CPs with very different reported doping efficiencies (# charges/ dopant molecules) using functional atomic force microscopy methods. Specifically, we compare the morphology dependence behind the well-known poly(3-hexylthiophene) (P3HT) polymer, with alkyl sidechains, to a more state-of-the-art polymer p($g_3$2T-TT) that has been reported to exhibit substantially higher doping efficiencies. We use scanning Kelvin probe microscopy and conductive AFM to investigate local doping and visualize the morphology-dependence of local dopant/counterion accumulation. We use these methods to provide a link between optical measurements of doping with spectroelectrochemistry and local work function variations for films that have been molecularly and electrochemically doped. These results show that doping efficiency is linked to the polymer's ability to accommodate the dopant in its three-dimensional structure, where P3HT exhibits significant surface aggregation of molecular dopants that limits its ultimate efficiency compared to p($g_3$2T-TT). We validate these results chemically via time-of-flight secondary ion mass spectrometry, providing a comprehensive view of the interplay between the local structure and ion ingress. This work provides guidance for optimizing future combinations of polymeric materials and molecular dopants to maximize conductivity

4:00 PM EL16.07.05
Thermal Stability of Organic Hole Transport Layers StephanieA. Buchholtz, TobiasAntrack, HansKleemann and KarlLeo; Dresden Integrated Center for Applied Physics and Photonic Materials, Germany

The electrical conductivity of amorphous doped organic hole transport layers, as used in organic light-emitting diodes (OLEDs), solar cells, or photodetectors, increases with temperature due to the dominant hopping-like transport mechanism. However, the conductivity irreversibly breaks down at a certain temperature. For example, OLEDs and organic photovoltaics have operating temperatures up to 80°C and 145°C, respectively. In addition, the active layer of an organic solar cell is deposited on the hole transport layer and has to be annealed at temperatures up to 140°C for a higher efficiency. The reasons for this breakdown are unknown, impeding the development of more stable devices. Here, we show a relation between the breakdown of the conductivity and the glass transition of the small molecule host materials and find that the choice of the dopant and the doping concentration significantly affects the thermal stability of the layer. Based on our investigations, we develop different hypotheses about the cause of the breakdown. With our results, we devise strategies to improve the thermal stability of organic hole transport layers.

Counterion Control and the Electronic Structure of Polarons and Bipolarons in Doped Conjugated Polymers BenjaminJ. Schwartz; UCLA, United States

When an electron is removed from a conjugated polymer, such as poly(3-hexylthiophene-2,5-diyl) (P3HT), the remaining hole and associated changein the polymer backbone structure from aromatic to quinoidal are referred to as a polaron. Bipolarons are created by removing the unpaired electron from an already-oxidized polymer segment. In electrochemically-doped P3HT films, polarons and bipolarons are readily observed, but in chemically-doped P3HT films, bipolarons rarely form. We explain this observation by studying the effects of counterion position on the formation of polarons, strongly coupled polarons, and bipolarons using both spectroscopic and X-ray diffraction experiments and time-dependent density functional theory (TD-DFT) calculations. The counterion positions control whether two polarons spin-pair to form a bipolaron or whether they strongly couple without spin-pairing. When two counterions lie close to the same polymer segment, bipolarons can form, with an absorption spectrum that is blueshifted from that of a single polaron. Otherwise, polarons at high concentrations do not spin-pair, but instead J-couple, leading to a redshifted absorption spectrum. The counterion location needed for bipolaron formation is accompanied by a loss of polymer crystallinity, so that bipolarons can form only in disordered regions of conjugated polymer films. Our TD-DFT calculations of polarons and bipolarons predict absorption spectra that match well with experiment, providing strong evidence that TD-DFT is correctly capturing the electronic structure of the doped material. Several groups, however, who looked at the energies of the Kohn-Sham orbitals from (non-time-dependent) DFT calculations, have recently argued that the traditional band picture is incorrect for doped conjugated polymers. Instead, these non-time-dependent DFT calculations suggest that polaron creation causes only one unoccupied state to move into the band gap near the valence band edge while half-filled states in the conduction and valence bands bend downward in energy. To understand the discrepancy, we also performed an analysis using natural transitional orbitals (NTOs) that shows that our TD-DFT calculations indeed reproduce the traditional band picture of polarons and bipolarons. Taken together, our experimental and theoretical results argue that controlling the counterion location and using the properly level of theory is critical to understanding the electronic structure of polarons and bipolarons on doped conjugated polymers.

Electrical Doping Stabilizes Organic Nanoparticle Dispersions for the Eco-Friendly Fabrication of Solar Cells FelixManger, JonasArmleder, PhilippMarlow, KarenFischer, HolgerRoehm, ChristianSprau and AlexanderColsmann; Karlsruhe Institute of Technology, Germany

Nanoparticle dispersions allow the use of eco-friendly processing agents for the solution deposition of organic semiconductor thin-films for photovoltaic and other optoelectronic applications. Omitting surfactants, which are commonly used to stabilize dispersions, is essential to not jeopardize the solar cell performance. In this work, electrical doping is used to charge the organic nanoparticles. The resulting electrostatic repulsion between the nanoparticles stabilizes the dispersion. Different doping concepts are deployed, compared and their effect on the nanoparticle stabilization is explored. Preference is given to volatile dopants which evaporate from the nanoparticulate light-harvesting layer after thin-film deposition. Finally, using electrical doping and the corresponding electrostatic stabilization, novel surfactant-free nanoparticle dispersions from high-performance organic semiconductors are synthesized by nanoprecipitation, giving rise to record solar cell power conversion efficiencies beyond 10%.

Efficient N-Doping in Organic Semiconductors by Novel Approaches and Materials Design AntonioFacchetti; Northwestern University/Flexterra Inc, United States

In this presentation we will report new strategies to efficiently n-doped organic semiconductor films. Thus, starting from initial work investigating molecular n-doping of naphthalenediimide (NDI) and isomeric benzothiadiazole (isoBT) based polymers we explored how variations in polymer backbone composition, regiochemistry, thin-film processing, and doping affect major film morphology and charge transport characteristics in transistor and diode architectures. For instance, we showed that NDI-$(TVT)_x(TET)_y$ [x+y=100%; TVT = thienyl-CH=CH-thienyl; TET = thienyl-CH_2CH_2-thienyl] charge transport in transistor has a unique dependence on the x,y values. Thus, we explored how charge transport is affected in diodes as well as how NDI-$(TVT)_x(TET)_y$ (polymer acceptor) + polymer donor solar cells perform. Finally, we recently discovered new approaches to enhance doping efficiency and conductivity via 1, tuning film morphology by favoring molecule dopant penetration and, 2, using catalysts that promote the semiconductor+dopant reaction. The latter strategy enables excellent doping efficiencies and conductivities for several organic semiconductors.

The Role of Carrier Density and Morphology on Charge Transport AnnaKohler; University of Bayreuth, Germany

Charge carrier mobility is a decisive factor in controlling the efficiency of organic solar cells (OSCs) and field effect transistors (OFETs). This presentation will discuss how the mobility will be influenced by factors including aggregation, local morphology or carrier density. We employ kinetic Monte-Carlo simulation to study the charge transport[1].

Models of Polymeric Mixed Ionic and Electronic Conductors AlessandroTroisi[1], AlessandroLandi[2], ColmA. Burke[1] and HesamMakki[1]; [1]University of Liverpool, United Kingdom; [2]University of Salerno, Italy

In organic polymeric materials with mixed ionic and electronic conduction (OMIEC), the excess charge in doped polymers is very mobile and the dynamics of the polymer chain cannot be accurately described with a model including only fixed point charges. Ions and polymer are comparatively slower and a methodology to capture the correlated motions of excess charge and ions is currently unavailable. Considering a prototypical interface encountered in this type of materials, we constructed a scheme based on the combination of MD and QM/MM to evaluate the classical dynamics of polymer, water and ions, while allowing the excess charge of the polymer chains to rearrange following the external electrostatic potential. We used this methodology to study the timescale for electronic charge rearrangement and the change in static and dynamic disorder as the doping level increase. We also propose a microscopic mechanism for reversible charging of OMIEC materials that can be used for designing new materials and rationalizing the current experimental observations.

MURI: Doping in Organic and Printed Electronics Center (DOPE Center) WeiYou; University of North Carolina at Chapel Hill, United States

Doping of organic semiconductors plays an important and growing role in organic electronics, ranging from organic light emitting diodes and organic solar cells to thermoelectrics and bioelectronics. However, unlike Si, where parts per million dopant concentrations can significantly alter conductivity, doping organic semiconductors with molecular dopants typically requires a much higher concentration. Complex interplay between the microstructure, electronic structure and molecular interactions of the polymer and dopants has prevented systematic understanding. Progress is largely dependent on heuristically guided, slow, trial-and-error experimentation. Furthermore, only *p*-type doping has been widely implemented in organic semiconductors, and *n*-type doping has met with limited success. Thus, developing air-stable *n*-dopants is an important objective for the field of molecular dopants.

Supported by the DoD MURI program, the DOPE Center aims to to transform the field of solution-processed, doped conducting polymers by 1) co-designing optimized *p*- and *n* -doped conducting polymer systems and achieving facile *n*-doping, 2) extending our recent, paradigm-changing discovery of photoredox doping in conjugate polymers, 3) accelerating the pace of data generation by collaborative workflow integration of robotic experimentation and machine learning (ML) and artificial intelligence (AI) approaches, 4) creating fundamental knowledge that informs novel materials synthesis and system optimization.

This talk will introduce the DOPE Center, and progress made up to this point. Importantly, the DOPE Center welcomes collaboration, and hopes to serve as a coalescing point to work with the large community to rapidly advance the field.

11:00 AM *EL16.08.06
Nanomechanics of Materials used in Flexible Electronics DeepakVenkateshvaran and LeszekJ. Spalek; University of Cambridge, United Kingdom

Organic semiconductors are multifunctional soft electronic materials that play an impactful role in the flexible electronics industry. Their use spans printed electronic circuits, large area displays, flexible solar energy harvesters, and implantable bioelectronics. For their competitive optical, electronic, thermoelectric, and spin-based properties, these soft electronic materials attract significant academic engagement, seeding new technologies for the future. [1, 2, 3]

Although macroscopic flexibility on the centimetre to metre scale is a unique selling point for organic semiconductor technology, not much is known about their mechanical properties on the nanoscale. Quantification of these nanomechanical properties, together with an understanding of nanoscale stiffness tunability and homogenisation, holds significant potential for fundamental and applied science. [4, 5]

During the last decade, the development of high precision atomic force microscopes has made it possible to quantify the mechanical properties of organic polymers on the scale of a few polymer chains. Techniques such as higher eigen mode imaging make it possible to visualise molecular ordering on the nanoscale under ambient conditions with ease. These techniques allow one to correlate molecular ordering with the stiffness that such ordering manifests.

In this talk, the science and technology of precision nanoscale measurement of mechanics will be spotlight. The interrelation between molecular organisation and nanomechanical properties in high-performance polymers used for organic electronics will be shown. [6, 7] A quantification of differences in strain within organic nanocrystal polymorphs will also be demonstrated. The measurement techniques demonstrated in this talk are extendable to a wide variety of multifunctional materials with a broad range of elastic properties and have significant use in both academia and industry.

MXene Synthesis – Pros and Cons of Various Methods YuryGogotsi; Drexel University, United States

MXenes (carbides, nitrides, oxycarbides and carbonitrides of early transition metals) are a very large family of 2D materials. They have a chemical formula of $M_{n+1}X_nT_x$, where M is a transition metal (Ti, Mo, Nb, V, Cr, etc.), X is either carbon and/or nitrogen (n=1, 2, 3 or 4), and T_x represents surface terminations (O, OH, halogens, chalcogens). The large variety of structures and compositions, availability of solid solutions on M and X sites, and control of surface terminations offer a plethora of materials to produce and investigate.[1] Combining their plasmonic properties with ease in aqueous processing, high electronic conductivity (over 20,000 S/cm), biocompatibility, and excellent mechanical properties, which exceed other solution-processable 2D materials, MXenes have the characteristics enabling numerous applications. However, the properties of MXenes depend on their synthesis method. Selective etching of Al, Si or Ga is acidic electrolytes is the most common approach. However, the use of molten salts for selective etching has been gaining the momentum, as MXenes with uniform halogen surface terminations can be produced. Hydrothermal and electrochemical selective etching methods have been introduced. Finally, CVD synthesis and topochemical synthesis using graphene/graphite or metal oxide add a new dimension. A critical overview of various synthesis techniques will be provided.

11:00 AM EL17.01.02
Progress in the Direct Synthesis of Two-Dimensional Transition Metal Carbides and Nitrides (MXenes) DiWang[1], ChenkunZhou[1], AlexanderS. Filatov[1], WoojeCho[1], FranciscoLagunas[2], MingzhanWang[1], Young-HwanKim[1], SuriyanarayananVaikuntanathan[1], ChongLiu[1], RobertF. Klie[2] and DmitriV. Talapin[1]; [1]University of Chicago, United States; [2]University of Illinois at Chicago, United States

MXenes are a large family of two-dimensional (2D) transition metal carbides and nitrides with a general formula of $M_{n+1}X_nT_x$ (n = 1-4), where M stands for early transition metal (such as Ti, V, or Nb), X is C or N, and T is surface terminations (for example, -OH, -F, and -Cl). Their structures can be described as n+1 close-packed M layers interleaved with n layers of X atoms, then sandwiched between surface groups. MXenes have been actively studied for their potential applications in energy storage, electromagnetic interference (EMI) shielding, and catalysis. MXenes are typically synthesized from a series of non-van der Waals precursors (MAX phases, where A is typically Al) by selectively extracting A atoms with hydrofluoric acid-containing solutions. This process is relatively time-consuming and generates hazardous waste, both of which may limit the scalability of MXene manufacture.
We demonstrated two direct ways, bypassing the MAX phase intermediates, to prepare one of the most widely used MXenes, Ti_2CCl_2. One is based on the high-temperature reaction of a stoichiometric mixture of precursors. The other uses chemical vapor deposition (CVD), where gaseous reagents flow through a heated substrate to form a thin film of product. We even pushed MXene bottom-up synthesis to a new level by expanding the scope of MXene available through direct synthesis, tuning the morphology of MXene products from stacks to spheres. The direct synthesis routes save time and minimize hazardous waste production. Besides, these new routes offer synthetic modalities not compatible with traditional methods, especially in cases where corresponding MAX phases are not available. Considering the extensive possibility of element combinations, the direct synthesis method could substantially expand the variety of MXene family. These benefits are expected to improve the efficiency of scaling production and expedite converting lab-scale discoveries into industrial-level applications.

11:15 AM EL17.01.03
Synthesis of Three Families of Titanium Carbonitride MXenes TengZhang, ChristopherE. Shuck, KaterynaShevchuk, MarkAnayee and YuryGogotsi; Drexel University, United States

Layered MAX phases and 2D MXenes derived from them are among the most studied materials due to their attractive properties and numerous potential applications. The tunability of their structure and composition allows every property to be modulated over a wide range. Particularly, elemental replacement and forming a solid solution without changing the structure allows fine tuning of material properties. While solid solutions on M (metal) site have received attention, the partial replacement of carbon with nitrogen (carbonitrides) has received little attention. By applying this concept, herein we report the synthesis of three families of titanium carbonitride $Ti_{n+1}Al(C_{1-y}N_y)_n$ MAX phases and $Ti_{n+1}(C_{1-y}N_y)_nT_x$ MXenes with one, two and three C/N layers. This greatly expands the variety of known MAX phases and MXenes to encompass 16 titanium carbonitrides with tunable X-site chemistries and different 2D layer thicknesses, including MXenes in the $Ti_4(C_{1-y}N_y)_3T_x$ system, which have not been previously reported. We further investigated the relationship between the composition, structure, stability, and synthesis conditions of the MXenes and their respective Al-based MAX phases. This range of materials will enable fundamental studies of the N:C ratio effect on optoelectronic, electromagnetic and mechanical properties of MXenes, as well as tuning those properties for specific applications

11:30 AM *EL17.01.04
Synthesis Science Between MAX Phases and MXenes ChristinaS. Birkel[1,2], RoseSnyder[1] and CarinaBüchner[2,1]; [1]Arizona State University, United States; [2]Technische Universität Darmstadt, Germany

The synthesis of MAX phases and their two-dimensional siblings MXenes, especially when pushing beyond Ti-based compounds, is far from trivial. Our group uses diverse preparation techniques to access new versions of these intriguing types of materials, recent examples include Cr_2GaC in the shape of carbonaceous microwires,[1] hollow and full microspheres[2] as well as hitherto unknown carbonitride phases, such as $Cr_2GaC_{1-x}N_x$ and $V_2GaC_{1-x}N_x$.[3] We specialize in non-conventional methods, such as sol-gel chemistry[4–6] and microwave heating[7] to synthesize the MAX phases.
In this talk, I will highlight two of our recent projects: (i) Our work on a unique “514” MAX phase $(Mo_{0.75}V_{0.25})_5AlC_4$, its structural investigation and transition to the respective MXene including its electrocatalytic properties. (ii) The transition from a MAX-like “221” compound Mo_2Ga_2C to the fully exfoliated MXene Mo_2CT_x as well as Mn-doped variants.
All materials are structurally characterized by diffraction and microscopy techniques and a deeper understanding of their chemical composition, formation mechanism and stability is obtained through spectroscopy and thermogravimetric methods.

SESSION EL17.02: MXene Synthesis and Structure II
Session Chairs: Seon Joon Kim and Ruocun (John) Wang
Monday Afternoon, November27, 2023
Hynes, Level 2, Room 208

1:30 PM *EL17.02.01
MXenes: Science, Applications and Hype MichelW. Barsoum; Drexel University, United States

At this juncture there is no doubt that MXenes have captivated the world's interest and with good reason. The number of potential applications is quite numerous and diverse. The use, or addition, of MXenes can boost some properties sometimes to record levels; in other cases it allows for herewith new applications for 2D materials. Their chemical diversity is also a huge attractor. As MXenes - like other new materials - get more popular, they are accompanied by hype. With hype comes responsibility. Hyping, or overpromising, is bad for the field in general and should be curtailed. In this talk I differentiate between work done in the name of science that has little chance of applicability and other work that may lead to applications. The fundamental, and quite difficult problem to solve, with MXenes is that because we are dealing with essentially a few – 2, 3, 4 - of highly reactive transition metals layers interleaved with C or N, it will be very difficult indeed to render them oxidation resistant. It follows that applications where MXenes are placed in *open*, aqueous-based systems will be few and far between. Hyping such applications - while not simultaneously solving the stability conundrum for times commensurate with the time of use in said applications - is irresponsible since they fall under the purview of science. Another example of hype is work on MXene-based supercapacitors. To date, most of supercapacitor work on MXenes makes use of dilute aqueous-based electrolytes. We have shown that when using such electrolytes, such as sulphuric acid, the self-discharge rate is quite high which, in turn, would again greatly limit the scope of applicability of such devices. Other potential pitfalls will be discussed.

2:00 PM EL17.02.02
High-Entropy Laminate Metal Carbide (MAX Phase) and its Two-Dimensional Derivative MXene JieZhou[1], QuanzhengTao[1], JustinasPalisaitis[1], SuaPark[1], MichelW. Barsoum[2], PerO. Persson[1] and JohannaRosen[1]; [1]IFM, Sweden; [2]Drexel University, United States

High-entropy (HE) ceramics, by analogy with HE metallic alloys, are an emerging family of multi-elemental solid solutions. These materials offer a large compositional space, with a corresponding large range of properties. We here report the experimental realization of a 3D HE MAX phase, $Ti_{1.0}V_{0.7}Cr_{0.05}Nb_{1.0}Ta_{1.0}AlC_3$, and corresponding 2D HE MXene in the form of free-standing flakes of average composition $Ti_{1.1}V_{0.7}Cr_xNb_{1.0}Ta_{0.6}C_3T_z$ (T_z = -F, -O, -OH), as produced by selective removing of Al from the HE MAX phase in aqueous hydrofluoric acid (HF). Initial tests on the HE MXene “paper” electrodes show high potential as electrode material in supercapacitors through a volumetric and gravimetric capacitance of 1688 F/cm^3 and 490

F/g, originating from a combination of diffusion- and surface-controlled charge storage processes. The introduction of the HE concept into the field of 2D materials suggests a wealth of future 2D materials and applications. Moreover, we found that the thickness/atomic arrangement of *M*C slabs within the HE MAX phases and MXenes can be tuned by adding the fifth element to the quaternary *M* (Ti-V-Nb-Ta)-Al-C system, which may provide an insight into the future design, synthesis, and application of HE MXenes.

2:15 PM EL17.02.03
M_5X_4: A Family of MXenes MarleyDownes[1], ChristopherE. Shuck[1], RobertLord[1], MarkAnayee[1], MikhailShekhirev[1], Ruocun (John)Wang[1], TetianaHryhorchuk[1], MartinDahlqvist[2], JohannaRosen[2] and YuryGogotsi[1]; [1]Drexel University, United States; [2]Linköping University, Sweden

MXenes are two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides typically synthesized from layered MAX-phase precursors. With over 50 experimentally reported MXenes and a near-infinite number of possible chemistries, MXenes are the fastest-growing family of 2D materials. They offer a wide range of properties, which can be altered by their chemistry (M, X, T_x) and the number of metal layers in the structure, ranging from two in M_2XT_x to five in M_5X_4. Only one $M_5X_4T_x$ MXene, Mo_4VC_4, has been reported. Herein, we report the synthesis and characterization of two new phase-pure M_5AX_4 mixed transition metal MAX-phases, $(TiTa)_5AlC_4$ and $(TiNb)_5AlC_4$, and their successful topochemical transformation into $(TiTa)_5C_4T_x$ and $(TiNb)_5C_4T_x$ MXenes. The resulting MXenes were delaminated into single-layer flakes, analyzed structurally, and characterized for their thermal and optical properties. This establishes a family of M_5AX_4 MAX phases and their corresponding MXenes. These materials were experimentally produced based on guidance from theoretical predictions, opening the door to exciting new applications for MXenes.

2:30 PM *EL17.02.04
Tailoring of Vacancy Concentration and Pore Size in MXenes JohannaRosen; Linkoping University, Sweden

MXenes show great prospects for surface-related applications owing to their large surface area and unique physical and chemical properties. MXenes with vacancies, whether ordered or randomly distributed, have shown a significant property enhancement, particularly in energy storage devices. Generally, randomly ordered vacancies in 2D monolayers have the possibility to conglomerate and form pores of different size. The performance can then be further enhanced, allowing interaction with various inorganic and organic species depending on the pore size. I will present a general experimental approach for tailoring vacancy concentration and pore size in a selection of well-known MXenes, inspired by theoretical calculations. The method is based on alloying of the parent MAX phases, where the concentration of the alloying element is directly correlated to the vacancy concentration (pore size) in the resulting MXene. The synthesized MXenes are shown to have a large surface area, and are further characterized with respect to structure, composition, and selected properties. The formation of pores is shown to significantly enhance the capacitance, and the materials are predicted to have selectivity towards inorganic and organic chemical species which can play an important role in molecular separation and energy related applications.

3:30 PM *EL17.03.01
MXenes for Solid-State Electrochemical Energy Storage MasashiOkubo; Waseda University, Japan

Layered transition-metal carbides/nitrides (MXenes) are an emerging family of electrochemical energy storage materials. When used as an electrode material with a liquid electrolyte, MXenes exhibit Li+ intercalation without large structural changes, which enables fast ion transport as well as dense charge storage in the open interlayer space between MXene nanosheets. It is well known that the Li+ intercalation of MXene electrodes is significantly affected by liquid electrolytes. However, the charge storage using MXene electrodes in inorganic solid electrolytes has rarely been investigated. Especially, the strain-free property of MXene should be beneficial to maintaining solid-solid interface, which enabling long-term cycling of all-solid-state batteries.

In this work, we investigate the charge storage behavior of various MXene electrodes with solid electrolytes. After clarifying the strain-free charge storage mechanism through the MXene–solid electrolyte interface, we exploit it for the stable operation of a strain-free ASSB using MXene as a negative electrode material.

4:00 PM EL17.03.02
Bringing Together Laser Treated MXene and Titania Nanotubes Towards Composite Electrode Material Active under Visible Light KatarzynaSiuzdak[1], DujearicKouao[1], MiroslawSawczak[1], VitStranak[2], PetrSezemsky[3], JanHanus[3], OndrejKylian[3] and KatarzynaGrochowska[1]; [1]The Szewalski Institute of Fluid-Flow Machinery Polish Academy of Sciences, Poland; [2]Univesity of South Bohemia in České Budějovice, Czechia; [3]Charles University, Czechia

For the past 20 years, taking into account as the starting date the discovery of the extraordinary properties of a single layer graphene, finally the materials exhibiting 2D architecture have gained more attention. Among family of chalcogenides and boron nitrides that became so popular, the carbides and nitrides of transition metals became a rising star due to the attractive properties [1]. In MXene flake one can find a layer of transition metal and interlayer of carbon with some termination (O, OH, F or Cl) that are linked also to the metallic part. Most of known MXene synthesis routes involved fluoride-containing compounds, either aqueous or molten salts treatment of the MAX phase. Despite individual sheets are obtained they are still formed in a specific stack of several micrometers providing some problem when the composite with other materials should be achieved.
To overcome this problematic issue we propose laser treatment as an additional step in the fabrication route. The fabrication of $Ti_3C_2T_x$ is performed in a quite typical way including mixing of MAX phase with HF and HCl solution and further delamination supported with NaCl. Microscopic investigation revealed that MXene sheets form agglomerates and additional efforts should be undertaken. Therefore, the MXene powder was frozen using liquid nitrogen and on such frozen material a liquid isopropanol was poured. Then beam of 1064 nm generated by pulsed Nd:YAG laser was irradiating frozen $Ti_3C_2T_x$. The interaction between laser and this material results in its ablation and its capture in a liquid medium. During the process the solution above the frozen material become grayish and such liquid was collected after different periods of time. Both the resonant peak at 120 cm^{-1} and the out-of-plane vibrations at 736 cm^{-1} of $Ti_3C_2T_x$ are clearly visible on the Raman spectrum confirming the preservation of the MXene structure.
Finally, the material was used for the modification of surface provided by titania nanotubes obtained via anodization of Ti plates and Ti sputtered layer. The modification was carried out via treatment with $TiCl_4/Ti_3C_2T_x$ solution followed by thermal annealing. The SEM inspection revealed that the initially smooth and thin walls of titania were uniformly overgrown and more porous but any agglomerates clogging the tubular interior were not detected. Cyclic voltammetry curves recorded for the series of modified titania electrodes indicated enhanced photoresponse under both visible and UV-vis light. In a particular case when the electrode was exposed to visible light, almost 20 times higher photocurrent at 0 V vs. Ag/AgCl/0.1M KCl comparing to bare titania was reached.
Apart from the improved photoresponse, the electrochemical activity of modified titania in the cathodic range was significantly changed, namely the cathodic current was much higher than the one registered for bare titania. For example at -1.0 V, bare titania exhibits nearly 0.1 mA/cm^2 whereas for the modified substrate the recorded current equals 2.6 mA/cm^2. It should be underlined that when the treatment of titania was carried out with $TiCl_4$ solution but without addition of laser treated MXene, such electrochemical response was not achieved. It indicated that the presence of MXene is crucial for greatly improved electrochemical and photoelectrochemical properties of the composite electrode material.
Summarizing we would like to show the unique laser treatment of 2D metal carbide material and its possible usage for formation of the composite with inorganic platform exhibiting promising electrochemical and photoelectrochemical properties being of high importance for development in the research area of water splitting and photoconversion.

4:15 PM EL17.03.03
Investigation of Electrochemical Properties of Carbonitride MXenes with Different Nitrogen Contents Chun-PeiCho[1,2], TengZhang[2], KaterynaShevchuk[2], Ruocun (John)Wang[2] and YuryGogotsi[2]; [1]National Chi Nan University, Taiwan; [2]Drexel University, United States

Carbonitride MXenes with different nitrogen-to-carbon ratios have been fabricated. As the nitrogen content increases, the plasmonic resonance and A_{1g} characteristic peaks in the Raman spectra become weaker, indicating successful nitrogen substitution in the carbon (X) sublattice of MXene. An additional redox pair in the cyclic voltammetry (CV) curves further confirms the

presence of nitrogen species in the carbonitride MXenes. When utilized as the anode material in a supercapacitor with a 3M aqueous sulfuric acid electrolyte, the highest specific capacitance achieved by a carbonitride MXene is approximately 370 Fg^{-1} at a scan rate of 2 mVs^{-1}. The fitting results of XPS spectra demonstrate the reduction in both carbide and nitride signals, and C-Ti-F becomes the dominant surface termination after electrochemical cycling. The carbonitride MXene with the highest nitrogen level exhibits the best rate capability but the worst cyclic stability. It also shows inferior Coulombic efficiency at lower scan rates. In contrast, the Lithium-delaminated Ti_3C_2 material has the best cyclic stability. The results of Electrochemical Impedance Spectroscopy (EIS) align with the CV results for the carbonitride MXenes. It has been demonstrated by Staircase Potentio-Electrochemical Impedance Spectroscopy (SPEIS) that, with a higher nitrogen content, a less negative applied potential is required to achieve smaller impedance and interlayer spacing.

4:30 PM *EL17.03.04
V_2C and Nb_2C MXenes: An Emerging Tunable Platform for Nanophotonics AlexandraBoltasseva[1], JeffreySimon[1], ColtonFruhlin[1], StefanoIppolito[2], DanzhenZhang[2] and YuryGogotsi[2]; [1]Purdue University, United States; [2]Drexel University, United States

MXenes, or transitional metal carbides, carbon nitrides, and nitrides, have recently emerged as a fascinating class of two-dimensional nanomaterials. These materials follow the chemical formula Mn+1XnTx. A prototypical MXene, Ti_3C_2Tx has been studied extensively over the past two decades demonstrating remarkable electrical and optical properties and utilized for linear optical devices such as broadband absorbers, and nonlinear devices like saturable absorbers in lasing cavities. Here, we expand upon our groups' previous work with Ti_3C_2Tx to new members in the MXene family, specifically V_2C and Nb_2C. By employing ellipsometry, we investigate the optical response of V_2C and Nb_2C. Our findings reveal a metallic transition for V_2C at longer wavelengths, while Nb_2C retains its dielectric nature due to the higher carrier concentration in V_2C. This transition from dielectric to metallic behavior is marked by the permittivity ε crossing zero in a region known as epsilon-near-zero (ENZ), which holds significant implications for optical technology. Furthermore, our research demonstrates that the ENZ point can be manipulated by adjusting the film thickness of V_2C, thereby affecting both its linear and nonlinear properties. These findings lay the foundation for future device development utilizing various members of the MXene family, including the creation of layered metamaterials.

SESSION EL17.04: Poster Session I

Etching Mechanism of Aluminum Layers during 2D MXene Synthesis Chi WonAhn; NNFC, Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Understanding the etching mechanisms of MXene and obtaining direct insights into the influence of etchants on structural features and defects are of critical importance for improving MXene properties, optimization of etching protocols, and exploring new MXene compositions. Despite their importance, such studies have been challenging because of the monoatomic thickness of the A-element layers being etched and aggressive etchants that hinder in situ studies. Here, we visualize the etching behavior of the Ti3AlC2 MAX phase in different etchants at the atomic scale using focused ion beam and electron microscopy. We also report on the structural changes in the Ti3AlC2 phase as a function of etching time and etchant type (LiF/HCl, HF, or NH4HF2) to reveal the etching mechanism for the first time.

Controlling the Interlayer Spacing of Two-Dimensional Titanium Carbide (MXene) Membranes for Selective Ion Separations in Water YaguangZhu, AustinJ. Booth, KimberlyVentura-Martinez and KelseyB. Hatzell; Princeton University, United States

MXenes are an emerging class of two-dimensional nanomaterials with promising applications in critical resource recovery, energy storage, and desalination. Specifically, MXene membranes are able to selectively separate cations based on charge and ionic radius[1], with low permeation rates for large and/or multivalent cations but high permeation rates for alkali-metal cations such as Li^+. Fine-tuning of this ion sieving behavior could enable the energy-efficient recovery of lithium and other critical metals from wastewater. More recently, aluminum ions (Al^{3+}) have shown the ability to "lock" the interlayer spacing of MXene membranes[2] via intercalation between MXene nanosheets, preventing other cations from intercalating and preserving the selectivity of these membranes over time. Other ions[3], as well as water molecules[4], can also readily intercalate between MXene layers; furthermore, intercalation can strongly affect water adsorption/desorption[3].

The exchange rates and mechanisms of ions and water within these confined interlayer spaces remain poorly understood, yet understanding these mechanisms is critical to the use of MXenes for advanced ion sieving technologies. To explore these processes, we have examined the changes in MXene membranes' interlayer spacing in response to intercalation (and exchange after pre-intercalation) with a variety of metal cations, including hydrophilic ions such as Mg^{2+} as well as more hydrophobic cations such as Cs^+. We have also investigated the effects of water intercalation on interlayer spacing, especially the ability of hydrophilic cations to introduce additional layers of water between MXene nanosheets. Understanding how to reliably control the interlayer spacing (i.e., pore size) of MXene thin films will improve our ability to design selective ion sieves for metal recovery from water.

Development of Rapid Synthesis Method of MAX Phase Composites by Combination of Induction Heating and Self-Propagating High-Temperature Synthesis DaisukeNishine, RyosukeNumata, RikuSawamura, TaroShimomura, MahitoYamamoto and MitsuruInada; Kansai University, Japan

MXene, a two-dimensional layered material, is expected to be applied in a wide variety of fields. Generally, MXene is prepared by etching MAX phase. Therefore, it is very important for MXene research to develop a low-cost and simple method to synthesize the MAX phase. In most cases, the MAX phase is synthesized by high-temperature heating at around 1500°C under high pressure. Hot-pressing, spark plasma sintering, and other methods are used to satisfy these synthesis conditions, but they are specialized, expensive, and sometimes require several hours to synthesize the MAX phase. Therefore, it is desirable to develop a simple, low-cost and rapid synthesis method.

We have developed an original, low-cost and simple MAX-phase synthesis equipment by combination of the induction heating (IH) and the self-propagating high-temperature synthesis method. The IH method can rapidly heat a sample in a carbon crucible up to about 2000°C. This rapid heating induces local chemical reactions. The heat of the chemical reaction then propagates throughout the sample and then the MAX phase is synthesized. We have tried to synthesize two types of MAX phases using this equipment. One is Ti_3AlC_2 and the other is V_2AlC. XRD measurements and SEM observations showed that both MAX phases were successfully synthesized. It should be noted that this method can synthesize both in vacuum and in inert gas atmosphere. And it took less than a minute from the start of heating to the end of synthesis. These results indicate that this method is one of the candidates for a low-cost, simple, and rapid MAX phase synthesis method that can be applied to various types of MAX phase synthesis.

8:00 PM EL17.04.04
Synthesis of MXenes via Dry Selective Extraction from MAX Phases MarkAnayee, ErvinRems, EiaraFajardo, RobertLord, DavidBugallo and YuryGogotsi; Drexel University, United States

MXenes are a rapidly growing family of two-dimensional (2D) transition metal carbides and nitrides which are promising for various applications, including energy storage and conversion, electronics, and healthcare. Hydrofluoric acid-based etchants are typically used for large-scale and high-throughput synthesis of MXenes. Herein, we present a computational thermodynamic model with experimental validations to explore the feasibility of fluorine-free synthesis of MXenes by dry selective extraction (DSE) from precursor MAX phases using iodine vapors at elevated temperature. A range of MXenes with iodine surface terminations are systematically screened using first-principles calculations to find candidates with high phase stability and low etching energy. We further demonstrate a thermodynamic model based on the CALculation of PHAse Diagrams (CALPHAD) approach, using $Ti_3C_2I_2$ as an example, to assess the Gibbs free energy of the reaction and the state of the byproducts (*e.g.*, gas or solid) as a function of temperature and pressure. Based on the assessment, the optimal etching temperature and vapor

pressure are predicted, and further verified by experiments. This work opens an avenue for scalable, fluorine-free dry synthesis of MXenes with compositions and surface chemistries that are not accessible using wet chemical etching.

8:00 PM EL17.04.05
Microwave-Assisted Hydrothermal Synthesis of MXene-Derived Bilayered Vanadium Oxides for Aqueous Zinc Ion Battery Shang-TungChiang and MajidBeidaghi; Auburn University, United States

V_2O_5 shows great promise as a cathode material in zinc-ion batteries (ZIBs) due to its impressive theoretical capacity of 589 mAh/g, which is based on a two-electron transfer mechanism. However, its limited conductivity poses a significant challenge to its widespread application. In this study, we propose a universal approach to produce high-rate cathodes by creating heterostructures through a single-step process of ion intercalation and phase transition of MXene-derived hydrated vanadates. In our experiment, we introduced Zinc ions (using $ZnCl_2$) into the V_2C MXene precursor to increase the spacing between layers, and then applied hydrothermal treatment using a microwave. This significantly reduced the synthesis time from several hours to 15 minutes while maintaining the excellent conductivity of MXene and the high theoretical capacity of V_2O_5. The resulting material, denoted as Zn-V_2C-V_2O_5, exhibits a high specific capacity of 352 mAh/g at 0.1 A/g and demonstrates remarkable cycling stability. These findings position Zn-V_2C-V_2O_5 as a promising candidate for cathode materials in Zinc-ion batteries, offering a new approach for enhancing zinc ion storage in vanadium-based materials.

8:00 PM EL17.04.06
Reaction Barrier and Desorption Energy Co-Determined CO2 Electroreduction Selectivity on Mo2C-Based Catalysts by Modulating Terminations Species and Defects CaihongLiang, ZhonghanZhang, ZhengLiu, ShuzhouLi and Yeng MingLam; Nanyang Technological University, Singapore

Using electrocatalysts to convert CO_2 to useful products via CO_2 reduction reaction (CO_2RR) is one of the solutions to greenhouse gases problems. Recently, MXenes have been recognised as potential CO_2RR electrocatalysts for its efficiency and tunability. However, comprehensive understanding on the relationship between CO_2RR performance and terminations of MXenes still remains open. For the sake of rational design for effective catalysts, Mo_2CT_x, a widely applied type of MXenes, is used as the model to systematically investigate the effect for CO_2RR from terminations via density functional theory (DFT) calculations. In this study, it is verified that different terminations over Mo_2CT_x exhibit different CO_2RR performances. This work puts forward that the selectivity is co-determined by desorption energy and reaction barrier of each product. Slabs completely covered with -O- or -F are tended to produce HCOOH, while slab with full -OH coverage are inclined to generate CO. Furthermore, results from a reconstructed slab based on one published experimental work with mixture terminations of 5.5% F, 5.5% Vacancy, 33.5% O, and 55.5% OH shows good consistency for the major products (selectivity towards C_1 products as HCOOH >> CO >> CH_4 >> CH_3OH). Additionally, this study predicts CO_2RR performance of Mo_2CO_2 with 0%, 5.6%, 11.1%, and 100% oxygen vacancy (Ov). The models with 5.6% or 100% Ov are beneficial to generate more valuable final products - methanol or methane, respectively, while the model with medium Ov (11.1%) tend to produce CO. This work provides useful insight and guidance to future research that utilizing terminations of MXene to design CO_2RR electrocatalysts, especially for Mo_2CT_x systems.

8:00 PM EL17.04.07
Broad-Wavelength Light-Driven Hybrid MXene/Molecular Crystal Actuators Actuated inside Tissue-Like Phantoms Dong WookKim[1], YukiHagiwara[2], HidekoKoshima[2] and MetinSitti[1]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Waseda University, Japan

Significant progress has been made in the research of molecular crystals that can undergo light-driven actuation. This progress has been achieved through the development of different molecules and the identification of driving mechanisms. However, the crystals that have been developed so far have primarily been driven by ultraviolet (UV) or blue light, and the use of red or near-infrared (NIR) light for actuation has not been explored. In this study, we have successfully created molecular crystals that can be actuated by light across a broad range of wavelengths, including UV, visible, and NIR light, using the photothermal effect. To achieve this, we incorporated titanium carbide ($Ti_3C_2T_x$) MXene nanosheets into salicylideneaniline crystals. Unlike the original thin molecular crystals, which only exhibited slow bending under UV light due to photoisomerization, the addition of the MXene layer enabled rapid actuation of the molecular crystals at various thicknesses and wavelengths. The hybridization of MXene with molecular crystals not only provides strong biocompatibility but also allows for the bending of the hybrid crystals within agar phantoms that mimic biological tissue. Furthermore, we demonstrated that this MXene hybridization approach can be extended to other common molecular crystals, including different derivatives of salicylideneaniline and anisole.

8:00 PM EL17.04.09
Probing the Thermoelectric and Thermodynamic Properties of Hexagonal M3AC2 MAX-Phase by First-Principles Calculations NaziaNasr; Northwestern Polytechnical University China, China

The thermodynamic and thermoelectric properties of hexagonal M3AC2 (M = Ti, V; A Al, Si) within MAX-phases have been investigated by first-principles calculations. The considered properties of M3AC2 compounds at 0 GPa were in reasonable agreement with available experimental and other theoretical data. The investigation probed into the thermodynamic attributes of M3AC2 (M = Ti, V; A= Al, Si) MAX-phases across diverse temperature and pressure conditions, elucidating the impact of these factors on heat capacity, bulk modulus, thermal expansion coefficient, Debye temperature, enthalpy, entropy, and Gibbs free energy. Notably, the bulk modulus and Debye temperature exhibited inverse trends with increasing temperature and direct trends with rising pressure. The impact of pressure and temperature on heat capacity (Cv and Cp) were found to be operated in opposing manners, devoted by the elevated atomic thermal velocity. The impact of the Seebeck coefficient and electrical conductivity also becomes evident at higher temperatures. At 200 K, the power factor (PF) sequence among M3AC2 (M = Ti, V; A= Al, Si) compounds is Ti3SiC2 > Ti3AlC2 > V3AlC2.

8:00 PM EL17.04.10
Enhancing The Ion Intercalation of MXene in Molecular Crowding Electrolytes ChaofanChen, Albertde Kogel and XuehangWang; TU Delft, Netherlands

The charge storage mechanism and performance of the MXenes electrode are highly dependent on the electrode and electrolyte composition. For example, $Ti_3C_2T_x$ has shown rapid pseudocapacitive (de)intercalation of protons and transformation between the oxygen surface groups (=O) and hydroxyl (-OH) groups in acidic aqueous electrolytes.[1] As a result, $Ti_3C_2T_x$ exhibit an ultrahigh volumetric capacitance of 1500 F cm^{-3} in H_2SO_4 electrolyte.[2] In less corrosive neutral aqueous electrolytes, the cation intercalation is accompanied by negligible charge transfer, leading to ultrafast charge storage.[3] Consequently, a moderate capacitance with superior cycling stability is reported in neutral electrolytes compared to acidic electrolytes. Compared to dilute aqueous electrolyte, which has a limited electrochemical stability window (ESW), the water-in-salt (WIS) electrolyte possesses a large ESW owing to the depressed activity of free water. Besides, the unique solvation structure of WIS electrolyte induces novel solvation-free Li^+ intercalation and increases capacitance.[4] As a result, WIS electrolyte helps overcome the drawback of the low energy density of MXene in neutral aqueous electrolytes. We further explored the electrochemical behavior of 2D Ti_3C_2 MXene in safe, low-cost, and environmentally benign polyethylene glycol (PEG)-based molecular crowding electrolytes (MCE). The addition of PEG-based molecular crowding agents can also widen the potential window of the MXene electrode up to 1.6 V due to the suppressed hydrogen evolution reaction. Additionally, a pair of redox peaks at -0.25 V/-0.05 V vs. Ag (cathodic/anodic) emerged in cyclic voltammetry after adding the PEG, yielding an additional 25% capacitance. We used in-situ XRD to reveal the charge storage mechanism in MCE electrolytes. Interestingly, we observed the co-insertion of the molecular crowding agent PEG-400 during the Li^+ intercalation process. As a result, $Ti_3C_2T_x$ electrodes presented a large interlayer space change of 4.7 Å during a complete charge/discharge process.

MXene Functionalized Kevlar Yarn via Automated Dip Coating LingyiBi[1], WilliamPerry[1], RobertLord[1], Ruocun (John)Wang[1], TetianaHryhorchuk[1], AlexInman[1], OleksiyGogotsi[2], VitaliyBalitskiy[2], VeronikaZahorodna[2], IvanBaginskiy[2], StepanVorotilo[1], GenevieveDion[1] and YuryGogotsi[1]; [1]Drexel University, United States; [2]Materials Research Center, Ukraine

The rise of the Internet of Things (IoT) has spurred extensive research on integrating conductive materials into textiles to turn them into sensors, antennas, energy storage devices, and heaters. MXenes, owing to their high electrical conductivity and solution processability, offer an efficient way to add conductivity and electronic functions to textiles through simple dip coating. However, manual development of MXene-coated textiles restricts their quality, quantity, and variety. Here, we developed a versatile automatic yarn dip coater tailored for producing continuously high-quality MXene-coated yarns and conducted the most comprehensive MXene-yarn dip coating study to date. Compared to manual methods, the automatic coater provides lower resistance, superior uniformity, faster speed, and reduced MXene consumption. It also enables rapid coating parameter optimization, resulting in a thin Ti3C2Tx coating uniform over a 1 km length on a braided Kevlar yarn while preserving its excellent mechanical properties (over 800 MPa) and adding Joule heating and damage sensing to composites reinforced by the yarns. By dip-coating five different yarns of varying materials, diameters, structures, and chemistries, we gained new insights into MXene-yarn interactions. Thus, the automatic dip coating presents

ample opportunities for scalable integration of MXenes into a wide range of yarns for diverse functions and applications.

SESSION EL17.05: MXenes Electrochemistry and and Electrochemical Applications

8:00 AM *EL17.05.01
MXenes and Two-Dimensional Transition Metal Carbo-Chalcogenides as Electrocatalysts for Hydrogen Evolution Reaction ElhamLoni[1], AhmadMajed[1], KunLiang[2], AnikaTabassum[3] and MichaelNaguib[1]; [1]Tulane University, United States; [2]Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China; [3]University of the District of Columbia, United States

MXenes are a group of two-dimensional (2D) materials composed of transition metal carbide, nitrides, and carbonitrides denoted as $M_{n+1}X_nT_x$; M is an early transition metal, X is carbon/nitrogen, and T_x stands for surface terminations. These materials are created by selectively etching thin metal layers from layered ceramics. MXenes have shown great promise in various electrochemical energy storage and conversion applications. For instance, Ti_3CNT_x MXene demonstrated an onset overpotential of 53 mV and an overpotential of 148 mV at 10 mA/cm^2 when used as an electrocatalyst for the hydrogen evolution reaction (HER). Another class of 2D materials called transition metal carbo-chalcogenides (TMCCs) combines characteristics of MXenes and transition metal dichalcogenides on an atomic scale. They are synthesized via solid-state synthesis at ambient pressure, followed by intercalation and delamination in water without the use of surfactants. The conductive carbide core and catalytically active chalcogenides surface of TMCCs make them appealing as electrocatalysts. In this study, we will present the large-scale synthesis and characterization of various TMCCs (e.g., Ta_2Se_2C, Ta_2S_2C, Nb_2S_2C, and their solid solutions: $(Ta_yNb_{1-y})_2S_2C$; y = 0.25, 0.5, and 0.75). Additionally, we will discuss the electrochemical performance of MXenes and TMCCs as electrocatalysts for the HER.

8:30 AM EL17.05.02
Tuning the Structure of MXene-Based Composites for Electrochemical Carbon Dioxide Reduction GuangxinSun[1,2], ChunnianHe[3] and AndrewB. Wong[1,1]; [1]National University of Singapore, Singapore; [2]The Joint School of NUS-TJU, China; [3]Tianjin University, China

The electrochemical CO_2 reduction reaction (CO_2RR) is a promising way to valorize CO_2 and realize net-zero CO_2 emissions. For CO_2RR, MXene is a good candidate that can adsorb CO_2. However, one of the critical challenges for CO_2RR is the control of selectivity. In our case, titanium carbide-based MXene materials were usually found to have high competing hydrogen evolution reaction (HER) performance, where HER is a competing reaction to CO_2RR. Therefore, to improve selectivity to CO_2RR products, we tuned the electronic structure of MXene to suppress HER and enhance the CO_2RR performance via a cations-alloying method. Through systematic investigations, we found that the MXene electronic structure can be tuned, which accompanies microstructure evolution, which is dependent on the reduction potentials of introduced cations. Additions of cations with lower reduction potentials, e.g., Na^+, Co^{2+}, Ni^{2+}, did not change performance significantly, while Cu^{2+} and Ag^+ have significant effects, which was confirmed by systematic characterizations.

Taking the *in-situ* reduced Ag nanoparticle decorated MXene as a model system, we demonstrate that these materials showed a significant improvement in CO_2RR performance. The ratio of CO to H_2 in the product can be tuned in the range of 1:3 to 1:1 by changing the added amount of Ag^+. The result can be attributed to the change in electronic structure. With a moderate addition of cations and moderate redox reaction between MXene and cations, the electronic structure can be tuned while the MXene microstructure is maintained. Therefore, with the well-kept MXene structure, the electrons can be transferred from MXene to Ag nanoparticles, and the HER performance is suppressed. With much more cation addition, the MXene structure was degraded, which resulted in nearly 100% HER.

8:45 AM EL17.05.03
Rational Selection of Transition Metals in M_4C_3 MXenes to Control the Electrocatalytic Hydrogen Evolution Reaction AnupmaThakur, NithinChandran B S, BrianWyatt and BabakAnasori; Indiana University-Purdue University Indianapolis, United States

2D MXenes have shown great promise as active materials in electrocatalytic hydrogen evolution reaction (HER). In this work, we present the selection of transition metal elements (V, Nb, Ta) in three $M_4C_3T_x$ MXenes ($V_4C_3T_x$, $Nb_4C_3T_x$, $Ta_4C_3T_x$) to control their electrocatalytic performance for HER using an experimental approach. We synthesized $V_4C_3T_x$, $Nb_4C_3T_x$, $Ta_4C_3T_x$ MXenes from their parent MAX phases via a selective etching route using hydrofluoric acid, followed by an organic intercalant (tetramethylammonium hydroxide)-assisted delamination. Further, we used an ion exchange process to modify the MXenes' surface chemistry and interlayer spacing by replacing (TMA^+) with Li^+ cations. By comparing the electrocatalytic HER performance of the resulting $V_4C_3T_x$, $Nb_4C_3T_x$, $Ta_4C_3T_x$ MXenes, we demonstrate the role of exposed transition metals (V, Nb, Ta) on the basal plane. Notably, $V_4C_3T_x$ MXenes exhibit the lowest HER overpotential of ~ 248 mV at 10 mA/cm^2 under acidic conditions (0.5 M H_2SO_4), surpassing $Nb_4C_3T_x$ (~ 317 mV at 10 mA/cm^2) and $Ta_4C_3T_x$ MXenes (~ 426 mV at 10 mA/cm^2). This improved performance can be attributed to the catalytically active vanadium basal planes in $V_4C_3T_x$. Our findings provide insight into the design of efficient and cost-effective catalysts through the rational selection of transition metals in MXenes for application as HER catalysts and tailoring electrocatalytic properties of 2D materials for sustainable energy applications.

9:00 AM EL17.05.04
Elucidating the Interactions Between Different Transition Metal Cations and $Ti_3C_2T_x$ MXene Through Intercalation Method for Electrochemical Applications ShianlinWee, DarioGomez Vazquez and MariaLukatskaya; ETH Zurich, Switzerland

MXenes, are a family of two-dimensional (2D) transition metal carbides, nitrides and/ or carbonitrides.[1] The intercalation of different metal cations and organic molecules into MXenes for tuning MXenes' electronic and electrochemical properties have been widely reported.[2][3][4] However, transition metals (TMs) which have distinct electrochemical behaviors[5][6] have not been explored in the literature of MXenes' intercalation. Therefore, we herein compared the intercalation effects of different TM cations including (Ni^{2+}, Co^{2+}, Zn^{2+}, Mn^{2+}) on $Ti_3C_2T_x$, for offering a general insight on the influences of multi-valent, redox-active TMs on MXenes. In particular, the changes on the physiochemical and electrochemical properties of MXenes were investigated using different in-situ and ex-situ methods, for a better understanding on the interfacial interactions between TM cations and MXenes in the confined environment of MXenes' multilayer structures. Additionally, we studied the TM-intercalated MXenes in hydrogen evolution reaction to further explore the their electrocatalytic performances. This work serves as a foundation for the fine-tuning of MXenes' properties by utilizing a variety of TM cations intercalation for different electrochemical systems.

9:15 AM EL17.05.05
Electrochemical Charge Storage Process of $Ti_3C_2T_x$ in Neutral Aqueous Electrolyte ChaofanChen[1], GlennQuek[2], Albertde Kogel[1], RuipengLi[3], XuehangWang[1] and Guillermo CarlosBazan[2]; [1]Department of Radiation Science and Technology, Delft University of Technology, Netherlands; [2]Departments of Chemistry and Chemical & Biomolecular Engineering, National University of Singapore, Singapore; [3]Brookhaven National Laboratory, United States

MXenes, a group of two-dimensional transition carbides/nitrides, have demonstrated remarkable performance as pseudocapacitive electrodes, owing to their unique transition metal oxide-like surface, large interlayer spacing and high electrical conductivity[1]. The charge storage behavior of MXene electrodes are strongly dependent on the interaction between MXene surface chemistry and the electrolyte solution[2]. In acidic electrolyte, the (de)intercalation of hydrated H^+ (from) into $Ti_3C_2T_x$ interlayer leads to a reversible conversion between =O and -OH surface groups, which is accompanied by the Ti valence change[3]. Consequently, $Ti_3C_2T_x$ displays a pseudocapacitive behavior with a mirrored redox peaks emerged in the CV curve. In contrast, $Ti_3C_2T_x$ electrodes typically exhibit EDL-like behavior in neutral aqueous electrolytes, with a rectangular CV and a sloping GCD curve within a narrow (ca. 1.2 V) potential window, resulting in a relatively lower capacitance (80 -120 F g^{-1})[4]. Recently, it has been found that the charge storage mechanism of MXene electrodes in different electrolytes can be elucidated through in-

situ UV-Vis spectroscopy[5].
Engineering the MXene electrode and optimizing the electrolyte composition have the potential to further enhance the pseudocapacitive performance of MXene. An extended potential window of 1.6 V can be obtained by employing water-in-salt electrolyte (WIS). Using WIS electrolyte also induces a novel intercalation process that fully solvated Li^+ ions intercalate into MXene layer at positive potential[6]. Partially oxidizing $Ti_3C_2T_x$ in the WIS electrolyte can further enhance the pseudocapacitance in the neutral aqueous electrolyte by activating a new surface redox reaction at <−0.2 V. This is due to the higher valence of Ti (+2.86) in the partially oxidized $Ti_3C_2T_x$, which is more prone to be reduced than the Ti (+2.43) in the pristine MXene[7].
In our recent research, we try to improve the electrochemical performance of $Ti_3C_2T_x$ by employing PEG-based Molecular crowding electrolyte (MCE) and designing MXene-based heterostructure. By introducing PEG as the molecular crowding agent into dilute LiTFSI electrolyte, a 25% increase in capacitance (100.8 F g^{-1}) is obtained in MCE. The capacitance increase is possibly due to additional intercalation process of fully-solvated Li^+, accompanied by the co-insertion of the PEG molecules. Furthermore, We construct a Ti_3C_2@Naphthalenediimide (NDI) heterostructure, in which a n-type conjugated polyelectrolyte is incorporated with $Ti_3C_2T_x$ MXene through a facial self-assemble process. Contributing from both the faradaic reaction from NDI and the pseudocapacitance from MXene, a high specific capacitance of 126.1 F g^{-1} is obtained in 1 M NH_4Cl electrolyte, which is 1.5 times higher than that of pristine $Ti_3C_2T_x$. Benefiting from the unique structure, Ti_3C_2@NDI also showed a superior rate performance of 102.8 F g^{-1} at 10 A g^{-1} (81% capacitance retention of 0.1 A g^{-1}) and a great cycling stability of 89% capacitance retention upon 10 000 cycles for NH_4^+ storage.

9:30 AM *EL17.05.06
Tuning the Electrochemical Response of MXenes Through Cation Intercalation MariaLukatskaya; ETH Zurich, Switzerland

As electronic technology advances, there is an increasing demand for safe and compact energy storage devices with long-lasting performance. Pseudocapacitors offer a promising solution by providing short charging times, ranging from several seconds to minutes, and energy densities comparable to batteries. Pseudocapacitors belong to the subclass of supercapacitors, where capacitance is mediated through fast redox reactions. They have the potential to store at least an order of magnitude more energy compared to typical electrical double-layer capacitors. Common examples of pseudocapacitor materials include transition metal oxides (e.g., RuO_2, MnO_2) and conducting polymers (e.g., polyaniline). However, these materials often suffer from high cost and/or low cycling stability. Consequently, there is an ongoing search for new pseudocapacitive materials, which represents a crucial research direction.

In this talk, I will delve into how the key performance metrics of pseudocapacitors – capacitance and charging rates – can be pushed to the limits in the materials that combine good electrical and ionic conductivities (ensuring fast charge transfer and hence charging rates) with high density of redox-active and ionically accessible sites (enabling high capacitance and charging rates). In particular, the electrochemistry of 2D transition metal carbides (MXenes), with an emphasis on the mechanism of charge storage and factors affecting the overall capacitive response in these materials will be discussed. Moreover, I will discuss the role of cation intercalation in layered MXenes to tune their electrochemical response.

MXene Chemistry and Applications VadymMochalin; Missouri University of Science and Technology, United States

A large family of two-dimensional transition metal carbides and nitrides (MXenes) raises interest for many applications due to their high electrical conductivity, mechanical properties [1], potentially tunable electronic structure [2], nonlinear optical properties [3], and the ability to be manufactured in the thin film state [4]. However, their chemistry that is key to development of these applications, still remains poorly understood [5,6]. In this presentation we will discuss recent progress in understanding fundamental MXene chemistry and harnessing it for suppressing unwanted reactions and prolonging stability of these materials.

For example, suppressing oxidation and hydrolysis at high pH was demonstrated as an effective way to prolong shelf-life and stability of MXene aqueous colloids [7]. Use of polyphosphate also has been shown to improve chemical stability of MXene aqueous colloids [8].
Other selected examples illustrating connections between understanding MXene chemistry and development of their applications will also be considered.

Atomistic Insights into the Degradation Mechanism of $Ti_3C_2T_x$ValentinaNesterova and KonstantinKlyukin; Auburn Univeristy, United States

Understanding the degradation mechanism at the molecular level is increasingly needed for a variety of clean energy applications, including membranes, batteries, and catalysts. MXenes, a family of 2D transition metal carbides and nitrides, demonstrate outstanding electrochemical performances and intriguing mechanical properties. However, the stability of MXenes remains a concern because of their fast degradation in water solution or air under ambient conditions. The mechanisms responsible for the oxidative degradation of MXenes remain elusive. In this work, we use ab initio molecular dynamics (AIMD) and density functional theory (DFT) simulations to resolve the atomistic mechanism of oxidative degradation of titanium carbide layers in the presence of water molecules and elucidate the role of surface chemistry on its stability. To reveal factors controlling the degradation rate, we correlate activation barriers of oxidation processes to chemical and physical traits of MXene surfaces.

11:15 AM EL17.06.03
Effect of Synthesis Conditions on the Morphology, Stability and Electrochemical Properties of Nb_2CT_x MXenes YeonjinBaek and MajidBeidaghi; Auburn University, United States

MXenes have gained significant attention in recent years for their unique properties and potential applications. Among several compositions of MXenes synthesized so far, Niobium carbide (Nb_2CT_x) MXene has shown promise for use in batteries, supercapacitors, photocatalysts, and fuel cells. However, despite many studies on the properties of this material, the effect of the synthesis process on the morphology, stability, and electrochemical properties of single-layer Nb_2CT_x MXenes, has not been extensively studied before. In this study, we have explored various etching and delamination processes for Nb_2CT_x and propose an improved synthesis process. Etching of the Nb_2AlC MAX phase was performed in two different etchants and followed

by delamination with TBAOH or TMAOH. Our results show that the synthesis yield is highly dependent on the composition of the etchant. Also, the size and quality of the produced MXene can be tuned by adjusting the etching and delamination conditions. To evaluate the electrochemical properties of Nb_2CT_x synthesized using different methods, free-standing films of the MXene were fabricated and tested as supercapacitor electrodes. These studies also showed the dependence of the electrochemical properties and stability of produced MXenes on the synthesis condition.

11:30 AM *EL17.06.04
Hybrid Organic-Inorganic MXenes ChenkunZhou, DiWang, Young-HwanKim and DmitriV. Talapin; University of Chicago, United States

Two-dimensional (2D) transition-metal carbides and nitrides (MXenes) show impressive performance in applications, such as supercapacitors, batteries, electromagnetic interference shielding, or electrocatalysis. These materials combine the electronic and mechanical properties of 2D inorganic crystals with chemically modifiable surfaces, and surface-engineered MXenes represent an ideal platform for fundamental and applied studies of interfaces in 2D functional materials.
The comprehensive understanding of MXene surfaces is required for prescriptive engineering of their physical and chemical properties. We discuss general strategies to install and remove surface groups by performing substitution, reductive elimination and oxidative addition reactions. Successful synthesis of MXenes with oxo-, imido-, thio-, seleno-, or telluro- terminations, as well as bare MXenes (no surface termination), and hybrid organic-inorganic MXenes are demonstrated. The description of MXene surface structure requires a mix of concepts from the fields of coordination chemistry, self-assembled monolayers and surface science. MXene surface groups control biaxial lattice strain, phonon frequencies, electrochemical performance, the strength of electron-phonon coupling, making MXene surfaces not spectators but active contributors to conductivity, superconductivity, and catalytic activity.

SESSION EL17.07: MXenes Applications

Tuesday Afternoon, November28, 2023
Hynes, Level 2, Room 208

1:30 PM *EL17.07.01
Bioelectronics and Beyond: MXenes for Sensing, Treating and Restoring Human Health FlaviaVitale; University of Pennsylvania, United States

MXenes have sparked a rapidly growing interest for applications in biomedical research and medicine. Alongside with the remarkable combination of properties and scalable processability, the growing selection of tunable MXene species, and the increasing recognition of their broad biocompatibility are paving the way for the integration of MXenes in high-performance sensing and therapeutic platforms.
In this talk I will first highlight the most recent developments of MXene-based biomedical technologies, particularly in the areas of sensing, therapeutics, and regenerative medicine. Then, I will present our most recent work on $Ti_3C_2T_x$ MXene-based wearable and implantable bioelectronics for recording and stimulating brain and muscle activity. Due the combination of high conductivity and low electrochemical impedance, these human-scale MXene bioelectronics can establish highly conformable interfaces with the body without the need for any conductive adhesives and gels that are typically required with conventional metal-based electrodes. Furthermore, the low density and low magnetic susceptibility mismatch between $Ti_3C_2T_x$ and biological tissues enable artifact-free clinical imaging with magnetic resonance (MRI) and computed tomography (CT), which is precluded when using metals such as Pt. Finally, we recently demonstrated that $Ti_3C_2T_x$ films and devices can be effectively sterilized with clinical thermal and chemical sterilization processes, without any degradation of their properties and structure. To illustrate the potential of $Ti_3C_2T_x$ MXene bioelectronics, I will review examples of application in cognitive neuroscience research, clinical neurological monitoring, and neuromuscular rehabilitation. In conclusion of the talk, I will discuss the opportunities and challenges for clinical translation and commercialization of MXene-based medical technologies.

2:00 PM EL17.07.02
3D Microporous $Ti_3C_2T_X$ MXene for Electrochemical Sensing of Antibiotics in Tissue Engineered Scaffolds AnandP. Tiwari, KatieHixon and William J.Scheideler; Dartmouth College, United States

3D continuous mesoscale architectures of nanomaterials provide opportunities to enhance performance and integration of electrochemical biosensors through control over the distribution of active sites and facilitation of ion transport. We present 3D printed microporous electrochemical biosensors integrating biocompatible 2D $Ti_3C_2T_X$ MXenes to monitor antibiotic drug release in tissue engineering scaffolds. The 3D microporous $Ti_3C_2T_X$ MXene is synthesized by a simple deposition of MXene ink on a microscale 3D-printed polymer scaffold coated in conductive ZnO:Al. Due to the microporous hybrid structure of $Ti_3C_2T_X$ MXene, direct electron transfer is facilitated and the 3D biosensors displayed efficient detection of common antibiotics such as gentamicin and vancomycin. The engineered 3D pore structure exposes more electrochemically active surfaces of MXene, resulting in remarkable sensitivity for detecting gentamicin concentrations from 10 nM to 1 mM and vancomycin concentrations from 100 nM to 1 mM, which are 1000 times more sensitive than planar 2D films of MXene. Additionally, this study characterized the suitability of these implantable sensors for bone tissue regeneration applications. Osteoblast-like (MG-63) cells are seeded on the microporous 3D MXene architectures for 3, 5, and 7 days. An increased concentration of cells is noted over the 7 days along both the edges and pores where MXene had been deposited, demonstrating biocompatibility and clinical translation potential. Based on these results, this combination of 3D scaffolds with biocompatible 2D $Ti_3C_2T_X$ MXene materials can provide a platform for mediator-free biosensing, enabling new applications for *in vivo* monitoring of drug elution.

2:15 PM EL17.07.03
MXene-Based Stimuli-Responsive Transdermal Patches for Wound Healing FatemeFayyazbakhsh, LevSuliandziga, VadymMochalin, Yue-WernHuang and MingC. Leu; Missouri University of Science and Technology, United States

MXenes, a recent large family of 2D materials, are now intensely researched for various biomedical applications including drug delivery and release via intercalaion/deintercalation mechansisms. Through a unique combination of high hydrophilicity with excellent electrical conductivity and strong photothermal response, MXenes offer unique capabilities to trigger and regulate drug release, while being compatible with hydrogels that are widely used in wound healing. In this talk, we will present our results on MXene-hydrogel stimuli-responsive transdermal patches for alleviating inflmatory response during wound healing. Hydrogel-based transdermal patches (HTPs) can serve as effective drug carriers for localized delivery of various therapeutic agents, while leveraging their inherent healing properties as wound dressings. The incorporation of anti-inflammatory and antibacterial agents empowers the therapeutic activity of HTPs to alleviate pain and combat bacterial infection. However, their application is limited by low stability, inadequate therapeutic effect, and systemic side effects caused by excessive drug release. To address these limitations, we developed novel stimuli-responsive HTPs capable of on-demand drug release. For this development we incorporated a titanium carbide MXene into gelatin-alginate hydrogel mixture. After loading with ibuprofen (IBU), the obtained bioinks were 3D printed and characterized. The drug release was measured after applying electric current to the samples. In addition, we assessed the biocompatibility, cell migration, and *in vitro* wound healing functionality of MXene-HTPs using a scratch test with human dermal fibroblasts, and measured the level of inflammatory markers. We will discuss our results in terms of correlations between the drug release and external stimuli (e.g., applied current), as well as immunomodulatory activity of MXene, which are the two important factors improving the progression of wound care products. Overall, these findings position MXene incorporating hydrogels as promissing candidates for alleviating inflammatory response and enabling other external-stimuli responsive functionality in the field of smart wound care.

2:30 PM EL17.07.04
Sustained Superlubricity in Mo_2TiC_2 MXenes Facilitated by Tribocatalytic Reaction at The Sliding Interfaces Sai VarunSunkara[1], BrianWyatt[2], YuziLiu[1], SubramanianSankaranarayanan[1], BabakAnasori[2], AndreasRosenkranz[3] and AnirudhaSumant[1]; [1]Argonne National Laboratory, United States; [2]Purdue University, United States; [3]University of Chile, Chile

The materials community has witnessed remarkable progress over recent decades in exploring various attractive properties of MXenes due to their excellent, physical, chemical, and mechanical properties. These properties encompass its outstanding physical, chemical, and mechanical attributes, all of which have demonstrated exceptional potential across diverse application domains, ranging from energy storage, and electromagnetic shielding, to advancements in biological and medical technology. Recent interest in exploring their tribological properties is rooted in their layered structure and ability to shear easily coupled with their robust mechanical properties. While numerous studies have been published showcasing MXenes' promise as an additive under lubricated conditions or as a solid lubricant in dry environments, the critical factor of long-term stability as a reliable lubricant in either scenario has remained unproven, thereby constraining its full application potential within the lubrication industry.
In this current work, we study an ordered double transition metal MXene (Mo_2TiC_2) and demonstrate its exceptional tribological performance in dry nitrogen atmosphere using macro-scale pin-on-disc tribo-testing. We demonstrate sustained superlubricity, with a friction coefficient as low as 0.005, persisting over the extensive course of linear sliding, spanning an astonishing distance of 86 kilometers, with no signs of failure and minimal wear rates. We will elucidate the intricate mechanisms governing wear and friction, which underpin such extraordinary

tribological performance. Additionally, we explain the pivotal role played by tribo-catalytic reactions at the sliding interface, which yield a stable, lubricious tribolayer. This milestone achievement represents a game-changer across a spectrum of tribological applications and marks a significant leap forward in the development of innovative solid lubricants based on MXene.

Work performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, was supported by the U.S. DOE, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

2:45 PM EL17.07.05
Effect of 2D MXenes on The Densification and Stability of Boron Carbide-Ti_3C_2 Composites NithinChandran B S[1,2,3], KartikNemani[2,1], AnupmaThakur[2,1] and BabakAnasori[1,2]; [1]Purdue University, United States; [2]IUPUI, United States; [3]Indian Institute of Technology Madras, India

MXenes are explored as additive materials for structural and high-temperature applications due to high temperature stability and two-dimensional(2D) layered morphology. Boron carbide (B_4C) holds significance as a structural ceramic due to its superior hardness (up to 43 GPa) along with low density (2.52 g cm^{-3}), and high melting point (2763 °C). However, poor sinterability of B_4C is attributed to the presence of strong covalent bonds between boron and carbon, the presence of nanoscale B_2O_3 on the surface, and low self-diffusion coefficients. Incorporating 2D MXenes in the B_4C matrices can improve the fracture toughness. MXenes' layered morphology combined with colloidal stability due to their high negative zeta potential (-35 to -50 mV) allows additive-free self-assembly on ceramic grains, leading to their uniform distribution in the sintered ceramic composite. In this work, we demonstrate the preparation of green bodies of B_4C with nanometer-thin $Ti_3C_2T_x$ MXene flakes via electrostatic self-assembly. The prepared green bodies of MXene-wrapped B_4C, up to 10 wt.% MXene, are sintered by pressure-assisted spark plasma sintering. We also discuss the effect of MXene flake concentration on the improvement of B_4C sinterability and mechanical properties. Our study present the first use of MXene in B_4C manufacturing and MXenes effects on the densification and stability of boron carbide sintered ceramics and offers insights into the potential of MXenes as sintering additives in ceramic systems.

Applications of 2D Metal Carbides in Catalysis YueWu; Iowa State University, United States

Many novel applications have been discovered for 2D metal carbides (MXenes), among which catalysis is a unique one. Due to their different crystal structures, MXenes behave differently from conventional bulk carbides. In this presentation, we will discuss the metal-support interactions observed in different MXene systems and how they alternate the catalytic reactions, including alkane dehydrogenation, methane coupling, and electrochemical reactions, from both experimental studies and theoretical modelings. These newly-discovered metal-support interactions could enable MXenes as exciting platforms for reactions important to petrochemical industry and low-carbon energy development.

4:00 PM EL17.08.02
Environmentally Stable Organo-MXene Gas Sensors Based on Surface Chemical Functionalization Seon JoonKim; Korea Institute of Science and Technology, Korea (the Republic of)

The demand for low-power chemical sensing has been increasing due to the emergence of flexible, portable, and wearable devices. To achieve this, two-dimensional (2D) nanomaterials have drawn attention due to their high surface area, and high tunability, and room-temperature operation. Among them, MXenes especially show outstanding performance due to their simultaneous existence of high electrical conductivity and high-density surface functional groups. However, issues such as limited environmental stability need to be addressed for further utilization. Here, we introduce ligand-grafting surface chemical functionalization methods to develop organo-MXene gas sensors that have enhanced environmental stability over pristine MXene gas sensors. Based on the good dispersibility of organo-MXenes in organic solvents, a self-assembly method was designed and employed to fabricate nanometer-scale thin film gas sensors. Gas responses were greatly enhanced compared to that of pristine MXene where the modification of surface tail groups allowed tunable selectivity toward various VOC gases. Furthermore, organo-MXene gas sensors showed good stability in ambient environments for extended periods of time.

4:15 PM EL17.08.03
Three-Dimensional MoS_2/MXene Heterostructure Aerogel for Chemical Gas Sensors with Superior Sensitivity and Stability HaminShin[1], SeulgiKim[2], JaewoongLee[1], JihanKim[1], DongjuLee[2] and Il-DooKim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Chungbuk National University, Korea (the Republic of)

The concept of integrating diverse functional 2D materials into a heterostructure provides unparalleled platforms for exploring novel physics not accessible in a single 2D material. Here, physical mixing two 2D materials, MXene and MoS_2, followed by freeze drying is utilized to successfully fabricate a 3D MoS_2/MXene van der Waals heterostructure aerogel. The low temperature synthetic approach effectively suppresses significant oxidation of the $Ti_3C_2T_x$ MXene, and results in a hierarchical, and freestanding 3D heterostructure composed of high-quality MoS_2 and MXene nanosheets. Functionalization of MXene with MoS_2 catalytic layer substantially improves sensitivity and long-term stability toward detection of NO_2 gas, and computational studies are coupled with experimental results to elucidate that the mechanism behind enhancements in the gas sensing properties is effective inhibition of HNO_2 formation on MXene surface, due to the presence of MoS_2. Overall, this study has a great potential for expansion of applicability to other classes of two-dimensional materials as a general synthesis method, thus laying a foundation to be applied in future fields of catalysis and electronics.

4:30 PM EL17.08.04
MOF-MXene Heterostructure for Promising Detection of Asthma Through H_2S Biomarkers SakshiKapoor[1], HilalAhmad[2] and J. P.Singh[1]; [1]Indian Institute of Technology Delhi, India; [2]Jamia Millia Islamia, India

Chronic wheezing and dyspnea episodes, which differ in intensity and frequency from person to person, are hallmarks of asthma. Asthma is thought to have a biomarker called H_2S. Here, a 5 ppb detection limit ultrasensitive chemiresistive H_2S gas sensor based on a MOF-MXene heterostructure has been created. This sensor reveals, pathologically, that the concentration of H_2S in one's exhaled breath steadily rises when asthma is treated. This sensor may be used to monitor the severity of asthma since it can precisely detect this minute concentration fluctuation of H_2S. This sensor may be combined with circuits to create a low-cost, clever, and portable H_2S detecting device. This device can be easily accessed by asthmatic patients and can make asthma severity monitoring simple, especially for young people and the elderly. Nitric oxide (NO), obtained as a biomarker of asthma and utilised in clinical diagnosis, is one effective example. H_2S is also thought to be a biomarker for halitosis, chronic obstructive pulmonary disease, and asthma. A more thorough explanation of the asthma phenotypes may be provided by further research into this substance, which may also result in advancements in the diagnosis and management of this condition. Although H_2S may be found in serum, sputum, and exhaled breath, there is still no consistent standard procedure for analysis. According to reports, the amounts of exhaled H_2S are influenced by airway inflammatory processes. A high-performance H_2S gas sensor is characterized and modelled by fusing the distinctive properties of various materials.

4:45 PM EL17.08.05
Mxene-Based Engineering for Photoelectrochemical Detection by Combining Nanozyme and Oxygen Reduction AkhileshB. Ganganboina; National Institute of Materials Sciences, Japan

Efficient photoelectrochemical (PEC) detection requires a deep understanding of the processes involved in generating, separating, and reacting photoinduced carriers at interfaces. However, slow interfacial reactions and the need for appropriate photoactive layers pose significant challenges to constructing advanced PEC platforms. In this study, platinum single-atom catalysts (Pt SACs) were integrated onto CuO_2 and two dimensional Mxene as a proof of concept, amplifying PEC signals by boosting oxygen reduction reactions. As a newly emerging class of 2D materials, $Ti_3C_2T_x$ MXene was used as fantastic support to uniformly anchor Cu_2O nanoparticles due to its electronegative surface. Pt SACs were also shown to exhibit efficient peroxidase-like activity, depressing PEC signals through Pt SACs-mediated enzymatic precipitation reactions. By utilizing the oxygen reduction and peroxidase-like activity of Pt SACs, a robust PEC

sensing platform was successfully constructed for the sensitive detection of SARS-CoV-2. This research provides valuable insights into the use of SACs for sensitive PEC analysis.

8:00 PM EL17.09.01
The Adsorption Ability of Urea on Single 3d Metal Doped MXene ($Ti_3C_2T_x$) via DFT Calculations and Experiments CaihongLiang, ZhihaoYen, TeddySalim and Yeng MingLam; Nanyang Technological University, Singapore

Dialysis is a process used to remove excess urea toxins from the body through adsorption or conversion. Urea adsorption by emergent 2D materials such as MXenes is one probable approach. However, MXenes synthesized by the safer and easier MILD method (MILD $Ti_3C_2T_x$) has lower affinity to urea, which can be improved by surface modifications. Density Functional Theory (DFT) studies indicate that oxygen-terminated $Ti_3C_2O_2$, which is the dominant species on MILD $Ti_3C_2T_x$, have a much better urea adsorption ability when introduced with Cu, Co, and Ni dopants and the corresponding adsorption energy (E_{ads}) are −2.16 eV, −1.91 eV and −1.78 eV respectively. These adsorption energies are much more favourable than the undoped one (E_{ads} = −0.52 eV). Experimentally, the adsorption studies found that low concentration of Cu, Co, Ni on $Ti_3C_2T_x$ showed a removal efficiency of 21.9 %, 6.0 % and 0.2 %, respectively, much better than 0 % removal efficiency of unfunctionalized $Ti_3C_2T_x$. Both DFT calculations and experiment showed that various metal functionalized MXenes has similar trend for urea adsorption, highlighting the feasibility of using computational approach to predict urea adsorption and further opening a new promising direction for the urea adsorption.

8:00 PM EL17.09.02
Langmuir-Like Adsorption Behavior of Amine Ligand for Surface Chemistry of MXene WoojaeJeong, HwansooShin and Tae HeeHan; Hanyang University, Korea (the Republic of)

Surface chemistry is important to compresence the stability of oxidation and dispersion of MXene in different organic media, thereby expanding its potential applications. Amine ligands is a potential candidate to modify the surface of MXene nanosheets due to strong interaction between Amine functionalities and MXene surface. Among those, Oleylamine (OAm) is a promising ligand due to its amine functionalities and commercial availability. The OAm is grafting onto MXene by covalent bonds through nucleophilic reactions and hydrogen bonding at room temperature. Furthermore, the OAm develop monolayer on MXene surface behavior by Langmuir-like adsorption. It is finely confirmed by that the slope decreases as the OAm concentration (C_l) increases in coverage vs C_l. The monolayer formation occurs in two distinct steps: a lying-down phase followed by an ordered monolayer. The OAm grafted MXene nanosheets (OAm-MX) represent highly stable dispersion in various organic solvents including non-polar solvents, as well as excellent oxidation stability. This be attributed to the hydrophobic properties and steric stabilization induced by the long alkyl chain of OAm on the MXene surface. Moreover, the OAm-MX nanosheets was facially assembled by solution process on the various substrate, demonstrating enhanced coating performance. Therefore, this study provides key comprehension of the adsorption behavior and interaction between amine ligands and MXene nanosheets for the surface chemistry of MXene.

8:00 PM EL17.09.03
High Performance Waste-Based Triboelectric Nanogenerators with Sulfur-Rich Polymer and MXene SungsuKim[1,1], WoongbiCho[1,1], HyeonhooLee[1,1], MinbaekLee[2], Tae HeeHan[1] and Jeong JaeWie[1,1,1]; [1]Hanyang University, Korea (the Republic of); [2]Inha University, Korea (the Republic of)

Recently, we reported utilization of inverse-vulcanized sulfur-rich polymer (SRP) prepared by surplus annually generated 7 million tons during petroleum refining processes, as tribo-negative materials for a triboelectric nanogenerator (TENG). Since the TENG generates power by charge separation on friction surfaces, utilization of fluorine with the highest electronegativity induced excellent electron-withdrawing ability is widely used in the TENG. Previous studies employed F2 gas or fluorine-rich polymers to enhance SRP tribo-negative characteristics. However, F2 is toxic, and the TENG with fluorine-rich polymers requires higher output current to stably operate electronic devices. Herein, we introduce MXene as a filler for the reinforcement of SRP tribo-negative characteristics. MXene is a metallic 2D nanomaterial with a high electronic conductivity and specific surface area. Hence, the inclusion of minute amount of MXene can significantly improve the electric properties of composites. In a same area 12.5 cm2-sized, incorporating 0.4 wt% MXene into the SRP composite in the TENG without using toxic gas had shown output voltage and current 2-fold and 3-fold higher compared to the neat SRP. We believe that the SRP/MXene composites will contribute to the advancement of waste-based and self-powered devices in the form of the TENG.

8:00 PM EL17.09.04
Revolutionizing Greenhouse Gas Monitoring with Layered MXenes: Room-Temperature Chemoresistors NiravkumarJ. Joshi, SachinT. Navale and AlbertRomano-Rodriguez; University of Barcelona, Spain

Greenhouse gas (GHG) emissions, particularly carbon dioxide, methane, and nitrous oxide, are the primary cause of global warming and climate change. To effectively monitor the actual impact of emission of these gases, specialized gas measurement systems that are specifically adapted are necessary. Currently, National surveillance agencies rely on highly sensitive, selective, complex, bulky, and expensive systems to monitor the environment. These systems serve as reference units and are only installed in a few specific, mostly fixed, key locations. However, in order to achieve a more comprehensive monitoring approach and develop climate change models, it is essential to have a distributed network of sensing system. This can be achieved through the deployment and connection of numerous gas sensing systems enabled by the Internet of Things (IoT). These devices need to be sensitive, selective, and energy-efficient, although they may have lower accuracy and precision compared to the reference instruments. Existing commercial sensors do not meet all the necessary requirements, highlighting the need for new and enhanced functional nanomaterials and sensors.
The objective of this research is to demonstrate the current state of development regarding advanced miniaturized gas sensing devices for monitoring GHG emissions. For this, we have developed a chemiresistive sensor platform that utilizes a layered structure of 2D MXenes, serving as an advanced sensing platform for detecting GHGs. The layered MXenes were synthesized using a chemical etching method involving a strong HF etchant, resulting in the formation of multilayered Ti3C2TX (MXene) sheets. These MXene sheets were then integrated onto a chip with interdigitated electrodes to form a microsensor. In this way, a low-cost gas-sensitive sensor for methane (CH4) was developed, which exhibited superior selectivity in front of other gases.
Throughout this research, a comprehensive investigation of the synthesis and of greenhouse gas detection application of these 2D MXenes has been conducted. This study is expected to pave the way for the utilization of a broad range of MXenes as highly sensitive sensors for greenhouse gases.

SESSION EL17.10: MXenes Structures and Properties I

Hynes, Level 2, Room 208

8:00 AM *EL17.10.01
Tailoring MXene Crystal Defects & Surface Terminations for Electronic and Energy Applications Chong MinKoo; Sungkyunkwan University, Korea (the Republic of)

Surface chemistry and defect engineering play a crucial role in determining not only the physicochemical, electrochemical, and optoelectronic properties, but also environment stability and processability of 2D MXene nanomaterials. MXenes, transition metal carbides/carbonitrides/nitrides, are a very large family of 2D materials with the general formula $M_{n+1}X_nT_x$, where M, X, T_x, and n represent transition metal(s), carbon or nitrogen, surface terminal groups such as –OH, -O and -F, and integers ranging from 1 to 4, respectively. MXenes have been attracted in many electronic, electrochemical, and optoelectronic applications, due to their high electronic conductivity, and solution processability. However, achieving high quality MXenes with precise stoichiometry remains a challenge due to difficulties in controlling the oxygen substitution in both the precursors and final MXene products. Furthermore, the presence of complex oxidation states, surface terminal groups, and interactions with the environment pose obstacles to post-surface functionalization of MXenes. As a result, the establishment of robust surface chemistry and defect engineering protocols for MXenes is still in progress, impeding practical applications. This presentation will briefly demonstrate recent our progress in controlling the surface

chemistry and crystal defects of MXenes.

8:30 AM EL17.10.02
The Effect of Carbon Compounds on MXene Surfaces YusukeOgawa, SeijiKawasaki, YasuakiOkada and TakeshiTorita; Murata Manufacturing Co. Ltd.,, Japan

MXene can be used in a wide range of material applications because of its diverse material properties, derived from its various compositions and surface termination groups. Surface terminations, such as –F, –O, –OH, are introduced by the etching process, and many works related to surface terminations have already been published. One publication has already explored how surface terminations affect the resulting material properties, as well as how to control surface termination groups.[1]
However, in reality, MXene also captures carbon compounds spontaneously by electrostatic interaction. Therefore, we should also take these factors into account. XPS is a useful method for evaluating surface properties. Generally, we use Ar sputtering to remove contaminants on the sample surface, but sputtering also affects the inherent surface condition. In such case, gas cluster ion beam (GCIB) provides an alternative way to clean the sample surface, while causing less damage.[2] Accordingly, herein we present on GCIB treatment of MXene samples, and outline property differences before and after carbon compounds are removed from the MXene surface.

Enhancing Heating Efficiency and Protection of MXene Through Graphene Skin DongjunKang and Tae HeeHan; Hanyang University, Korea (the Republic of)

$Ti_3C_2T_x$ MXene has outstanding characteristics of high electrical conductivity and facile processability in benign water solvents, and has been highlighted as a versatile Joule heating material with low-voltage operation with stable heating performance. However, MXene can be easily oxidized in warm and damp environments due to its plentiful hydrophilic functional groups on sheets. In addition, the high convective heat loss from the MXene surface limits their heating efficiency. Therefore, we tailored a multifunctional graphene skin (with a thickness of ~370 nm) for MXene, to protect the venerable surface properties of MXene. Both MXene and graphene layers have tortuous pathways with similar layered structures; however, the water impermeability of graphene was ~70 times higher than that of bare MXene due to narrow d-spacing and the hydrophobic nature of graphene skin. In addition, we found that the heat loss regulation effect of graphene skin increased the heating efficiency, indicating that the graphene skin is promising for developing adaptive heating materials. Our research has inspired a new hybrid skin strategy that exploits the full potential of materials for developing functional coatings for various applications.

9:00 AM EL17.10.04
Hybrid MXene-Polydopamine Nanocomposites for Targeted and Effective Photothermal Therapy IgorIatsunskyi[1], DanielAguilar-Ferrer[1], MaksymPogorielov[2,3], OleksiyGogotsi[4] and EmersonCoy[1]; [1]Adam Mickiewicz University, Poland; [2]University of Latvia, Latvia; [3]Sumy State University, Ukraine; [4]Materials Research Center, Ukraine

Hybrid MXene-Polydopamine (PDA) nanocomposites have emerged as a promising targeted and effective photothermal therapy (PTT) platform. PTT utilizes light-absorbing materials to convert light energy into heat, resulting in localized hyperthermia that selectively damages cancer cells. However, challenges such as limited photothermal conversion efficiency, inadequate tumor targeting, and potential side effects hinder the clinical translation of PTT.
MXenes, a class of two-dimensional transition metal carbides/nitrides, possess exceptional optical absorption properties in the near-infrared (NIR) region, where biological tissues exhibit maximum transparency. The combination of MXenes with PDA offers synergistic advantages for enhanced PTT. MXenes serve as efficient photothermal agents, while PDA provides a versatile coating that promotes biocompatibility and allows surface functionalization for targeted therapy.
The hybrid MXene-PDA nanocomposites exhibit excellent photothermal conversion efficiency due to the strong light absorption of MXenes and efficient heat transfer facilitated by the PDA coating. The nanocomposites can be easily functionalized by targeting ligands or biomolecules, enabling selective accumulation and internalization in cancer cells. Moreover, the MXene-PDA nanocomposites can be further engineered to release therapeutic agents, such as chemotherapy drugs, in response to the photothermal effect, achieving combined photothermal-chemotherapy treatment.
This research highlights experimental results in developing MXene-PDA nanocomposites for targeted and effective PTT. The synthesis methods employed to fabricate the nanocomposites, including surface modification and functionalization, are discussed, along with their photothermal conversion efficiency and biocompatibility. We explored the effect of PDA layer thickness over MXene flakes on PTT. Antibodies for various types of cancers were used as targeting ligands. We demonstrated that the hybrid MXene-PDA nanocomposites are promising to advance PTT as a cancer treatment modality. Their unique properties, such as high photothermal conversion efficiency and surface functionalization capabilities, make them attractive candidates for targeted therapy.

Electrochemically Modulated Interaction of MXenes with Microwaves DanzhenZhang, MeikangHan, ChristopherE. Shuck, BernardMcBride, TengZhang, Ruocun (John)Wang, KatherynaShevchuk and YuryGogotsi; Drexel University, United States

Controlling the reflection and absorption of incident electromagnetic waves at gigahertz frequencies in thin films is important for protecting electronics and humans. The ability to dynamically depress electromagnetic wave jamming is significant for enabling communication while protecting electronics. However, conventional electromagnetic interference (EMI) shielding materials don't offer this capability. MXenes, as a large family of two-dimensional transition metal carbides and nitrides, have shown a broad range of EMI shielding performance as well as different energy storage mechanisms from electric-double-layer capacitance to pseudocapacitive behavior. Herein, we report a method for active control of electromagnetic wave interactions with various MXene films, including $Ti_3C_2T_x$, Ti_2CT_x, V_2CT_x, $V_4C_3T_x$ and $Nb_4C_3T_x$, leading to EMI shields with unprecedented bidirectional modulation of shielding capability. The reversible tunability of EMI shielding effectiveness was achieved by electrochemically driven ion insertion/desertion and charge transfer in MXene layers with different electrolytes, accompanied by expansion and shrinkage of layer spacing, as well as a change in the oxidation state of the transition metal. An EMI shielding 'switch' was demonstrated through the electrochemical oxidation of MXene films. Our results offer opportunities to develop smart EMI protection with active modulation, which is different from conventional 'static' shielding and can adapt to demanding environments.

9:30 AM *EL17.10.06
Enhancing MXene's Heating Functionality Through Surface Modification Tae HeeHan; Hanyang University, Korea (the Republic of)

MXenes are a class of two-dimensional materials with potential applications in fields such as thermal management and high-temperature materials. In this talk, I focus on two key aspects: the thermal evolution of Ti3C2Tx MXene during annealing and the grafting behavior of amine ligands for MXene surface modification. (1) The thermal decomposition behavior of MXene is explored using X-ray photoelectron spectroscopy (XPS) and two-dimensional correlation spectroscopy (2D-COS), providing insights into its structural changes, providing practical information for thermal applications of MXene. (2) Surface modification strategies are employed to enhance MXene's stability and dispersibility. Oleylamine (OAm) is grafted onto MXene nanosheets, resulting in improved oxidation and dispersion stability. The modified MXene exhibits excellent solution processability and coating performance. Additionally, the potential of OAm-MX as a heating element is investigated, leading to the development of a scalable electrothermal heating membrane with high efficiency. These advancements broaden the applications of MXene in thermal management and water desalination.

Plasmonic Properties of 2D MXenes SarahB. King[1], JosephSpellberg[1], JanekRieger[1], CalvinRaab[1], FranciscoLagunas[2], RobertF. Klie[2], DiWang[1], DmitriV. Talapin[1] and JordanA.

Hachtel[3]; [1]University of Chicago, United States; [2]University of Illinois at Chicago, United States; [3]Oak Ridge National Laboratory, United States

Despite their tremendous potential as plasmonic materials because of their 2D metallic properties, very little is known about the fundamental plasmonic resonances of MXenes. This is primarily due to irregularity in plasmonic responses from mixed surface terminations and varying material shape and thickness. In this talk I will discuss experimental methods we are using in my group to probe the nanoscale plasmonic response of MXenes, both traditional mixed-terminated $Ti_3C_2T_x$ as well as singly terminated Mxenes synthesized by both CVD and molten salt synthesis, Ti_2CCl_2 and $Ti_3C_2Cl_2$. Leveraging the time-resolution and spatial-resolution of time-resolved photoemission electron microscopy we are investigating the evolution of plasmonic fields in MXenes in space and time. Using the (MAC)-STEM/EELS facility at ORNL we can directly image energy-resolved plasmonic resonances of MXenes, where we find that surface oxidation substantially decreases the plasmonic response of $Ti_3C_2Cl_2$. Together our experiments highlight the variation in nanoscale plasmonic properties of MXenes and opportunities for control.

11:00 AM *EL17.11.02
Ultrafast Photoexcitations in 2D MXenes LyubovV. Titova; Worcester Polytechnic Institute, United States

MXenes are 2D transition metal carbides and nitrides with electronic properties that can be tuned by their chemistry and structure. Metallic-like conductivity, flexibility, high optical damage threshold and ease of processing owing to their hydrophilicity, make MXenes candidates for a host of electronic and optical applications. We use ultrafast optical and THz spectroscopic techniques to investigate the nature and behavior of photoexcitations in MXenes of different chemistries. We show that electronic and optical properties of MXenes can be engineered by choices of the transition metals and their order as well as by controlling the intercalants in the interlayer gaps [1,2]. Furthermore, we demonstrate that MXenes with high free carrier density show promise as polarizers and tunable electromagnetic interference shields in the THz range [3,4].

11:30 AM EL17.11.03
Stability of Pseudocapacitive Energy Storage in $Ti_3C_2T_x$ MXene over Wide Temperature Range RuocunWang, MarkAnayee, TengZhang, YuanZhang, MikhailShekhirev, KaterynaShevchuk and YuryGogotsi; Drexel University, United States

Pseudocapacitors have the potential to achieve high energy and high power density simultaneously, a holy grail for electrochemical energy storage. However, one obstacle facing pseudocapacitors is their shorter lifetime compared to commercial supercapacitors using the double-layer charge storage mechanism. In MXene-based pseudocapacitors, this concern is pronounced particularly at high temperatures due to the limited stability of the active material in contact with aqueous solutions, which can lead to oxidation and hydrolysis. This work shows that $Ti_3C_2T_x$ MXene thin-film electrodes in 5 M H_2SO_4 possess excellent rate capabilities from -50 °C to 100 °C but also a sufficient lifetime at 70 °C using a float test holding at -0.9 V vs. Hg/Hg_2SO_4 reference electrode. Post-mortem characterization using X-ray photoelectron spectroscopy, Raman spectroscopy, and scanning electron microscopy with energy-dispersive X-ray spectroscopy showed no signs of oxidation in the bulk of the film. This work suggests sufficient electrochemical stability of $Ti_3C_2T_x$ MXene as a negative electrode in protic aqueous electrolytes across a wide temperature range, making it promising for pseudocapacitor energy storage.

SESSION EL17.12: MXenes Structures and Properties II

1:45 PM *EL17.12.01
High-Temperature Stability and Phase Transformation of 2D $Ti_3C_2T_x$ and $Mo_2TiC_2T_x$ MXenes BrianWyatt[1], KartikNemani[1], MatthewBoebinger[2], RaymondR. Unocic[2] and BabakAnasori[1]; [1]Purdue University, United States; [2]Oak Ridge National Laboratory, United States

2D MXenes have a wide array of impressive properties due to their inherent transition metal carbide cores with abundant surface functionalities. While MXenes can be rapidly oxidized in air at high temperatures, they can be transformed into ultra-high temperature carbides when annealed under an inert atmosphere or vacuum. By annealing stacks of 2D MXene flakes, we can fabricate refractory carbides with controlled morphologies and crystal orientations. In this talk, we present our current understanding of the phase transformation of different MXenes, including $Ti_3C_2T_x$ and $Mo_2TiC_2T_x$, by annealing them in the 600 °C to 2000 °C range under argon. We used a combination of ex-situ and in-situ characterization techniques and identified the effect of defects, such as vacancies and cation decorations, on phase stability and transformation of MXenes to refractory carbides. Our results suggest that MXenes can be used as nanosized building blocks for ultra-high temperature coatings or ceramic composite additives.

2:15 PM EL17.12.02
Prediction of Stable Titanium Carbonitride Alloy MXenes using a Cluster Expansion Approach KrishnamohanThekkepat[1,2,3] and Seung-CheolLee[1,2,3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]KIST School, Korea University of Science and Technology, Korea (the Republic of); [3]Indo-Korea Science and Technology Center, India

MXenes are the largest and rapidly growing class of 2D materials with a general chemical formula $M_{N+1}X_NT_x$-where N=1,2 or 3 represents the number of layers; M is a transition metal; X is either Carbon or Nitrogen; and T represents surface terminations. Over the last decade since they were first synthesized, several different MXenes have reported with different transition metals, thickness and surface terminations. They exhibit a versatile and distinct set of properties ranging from high strength and stiffness, high electrical conductivity, redox active surface sites. These properties make them stand out among other 2D materials and make them promising candidates in energy storage, wireless communications, electrocatalysis and gas sensing applications.[1] Moreover, these properties can be tuned by forming alloys of transition metal elements at the M site or by changing the surface terminations as demonstrated in various experimental and theoretical reports.[2,3,4] However, very little attention has been given to carbonitride alloys, although they have shown outstanding promise, especially in wireless communications.[5] MXenes are synthesized from precursor MAX phases. They are layered hexagonal ternary ceramics formed by stacking MXenes, with a layer of A group metals (usually Al) in between. MXenes are separated from MAX phases by selectively etching out the A layers. Hence stability of MAX phases is very important for the synthesis of MXenes.

In this work, we carried out a comprehensive study of the phase stability of 3 types of titanium carbonitride MXenes $Ti_2(C,N)$, $Ti_3(C,N)_2$ and $Ti_4(C,N)_3$ and their corresponding Al based MAX phase precursors $Ti_2Al(C,N)$,$Ti_3Al(C,N)_2$ and $Ti_4Al(C,N)_3$. We train cluster expansion Hamiltonians for each of the pseudo-binary alloys using state-of-the-art machine learning algorithms implemented in the LACOS package developed in-house. These Hamiltonians are then used to search for low energy stable structures from among thousands of possible carbon/nitrogen ordered configurations. Temperature and composition dependent ordering behaviour and phase stability is also assessed using Monte Carlo simulations sampled with the cluster expansion Hamiltonians. We theoretically predict 3 new types of stable ordered titanium carbonitride MAX phases, $Ti_2Al(C_{1-x}N_x)$, $Ti_3Al(C_{1-x}N_x)_2$ and $Ti_4Al(C_{1-x}N_x)_3$ which have not been reported previously. Additionally, we predict new MXenes with different layer thicknesses and nitrogen compositions that are synthesizable from these MAX phases. We also find stable MAX phases consisting of 2 different MXene layers with different atomic arrangements and nitrogen compositions. To aid experimental efforts to synthesize and characterize these new MXenes, we checked the effect of surface terminations on their stability and carried out lattice dynamics calculations to identify Raman active vibration modes. This is the first comprehensive study of Titanium carbonitride MXene alloys and their synthesizability. Identifying a new family of alloys of varying X-site composition would open up new opportunities to further fine tune properties for promising applications.

Electroactive Soft Actuators Based on MXene-MOF Nanoarchitectures IlkwonOh; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Electro-ionic soft actuators, capable of continuous deformations replacing non-compliant rigid mechanical components, attract increasing interest in the field of next-generation metaverse interfaces and soft robotics. Here, we report a novel MXene ($Ti_3C_2T_x$) electrode anchoring manganese-based 1,3,5-benzenetricarboxylate metal-organic framework (MnBTC) for ultrastable electro-ionic artificial muscles. By a facile supramolecular self-assembly, the $Ti_3C_2T_x$-MnBTC hybrid nanoarchitecture forms coordinate bond, hydrogen bond, and hydrophilic interaction with the conducting polymer of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), resulting in a mechanically flexible and electro-ionically active electrode. The superior electrical and electrochemical performances of the electrode stem from the synergistic effects between intrinsically hierarchical nanoarchitecture of MnBTC and rapid electron transport behavior of Mxene, leading to fast diffusion and accommodation of ions in the ion-exchangeable membrane. The developed artificial muscle based on $Ti_3C_2T_x$-MnBTC is found to exhibit high bending displacement (12.5 mm) and ultrafast response time (0.77 s) under a low driving voltage (0.5V), along with wide frequency response (0.1 to 10 Hz) and exceptional stability (98% retention at 43,200 s) without any distortion of actuation performance. Furthermore, the designed electro-active artificial muscle was successfully used to demonstrate mimicry of eye motions including eyelid blinking and eyeball movement in a doll.

4:00 PM EL17.13.02
Salt-Assisted Assembly of $Ti_3C_2T_x$ Nanosheets on Arbitrary Polymers LiangZhao[1], LingyiBi[2], JiayueHu[3], GuanhuiGao[4], DanzhenZhang[2], YunLi[1], AidanFlynn[1], Ruocun (John)Wang[2], LingLiu[3], YuryGogotsi[2] and BoLi[1]; [1]Hybrid Nano-Architectures and Advanced Manufacturing Laboratory, United States; [2]A.J. Drexel Nanomaterials Institute, Drexel University, United States; [3]Temple University, United States; [4]Shared Equipment Authority, Rice University, United States

MXenes are promising materials for next-generation flexible electronics and wearable systems due to their excellent conductivity, low infrared emissivity, and high mechanical properties. However, in a solution-based assembly process, hydrophilic MXenes are not compatible with many polymers, especially some high-performance polymers with inert and/or hydrophobic surfaces, such as Kevlar. Unlike many harsh surface treatment methods that induce dangling bonds on the polymer surface, we proposed a universal solution-processed salt-assisted assembly (SAA) strategy that enables ultra-thin and uniform $Ti_3C_2T_x$ MXene coatings with high conductivity on diverse polymers without their modification. The salt added to the MXene aqueous solution neutralizes the charge, coagulates the colloid, and deposits MXene aggregates, leading to the ultrafast assembly of MXene from the solution on arbitrary polymer substrates. A library of salts has been demonstrated to be effective. Importantly, our method enables $Ti_3C_2T_x$ assembly on high-performance thermally stable polymers such as Kevlar fabric. This SAA strategy may significantly broaden the applications of MXene coatings.

4:15 PM EL17.13.03
Metal Ion-Driven Gelation in MXenes for Multiproperty and Multifunctional Hydrogels and Aerogels StefanoIppolito and YuryGogotsi; Drexel University - Drexel Nanomaterials Institute, United States

To date, MXenes include over fifty different structures and compositions, with more than a hundred compositions predicted computationally (more than a thousand if surface terminations are also taken into account), being the largest known family of 2D materials. Owing to their extremely versatile structural and chemical composition, as well as surface chemistry, MXenes are one-of-a-kind materials in many research fields, embodying a true revolution in materials science. They introduce a large number of 2D building blocks in materials science, providing an exciting and wide-ranging portfolio of physicochemical properties and promoting the production of several MXenes-based hybrid systems for numerous applications.
Here, we will discuss the production of all-MXene hydrogels and aerogels, where the gelation process is induced by metal ions. Taking advantage of the coordination chemistry between -OH groups on the surface of MXene flakes (resulting from the wet chemical etching steps) and metal ions, the gelation (in aqueous environment) is very fast (< 5 min) and the physicochemical properties of the resulting hybrid systems are strongly related to the nature of the MXene/metal ion dyad. Rheological measurements show a strong relationship between the metal ion and the loss tangent *tanδ* (equal to the ratio between loss Modulus and storage Modulus, namely viscous modulus and elastic modulus) of the related hydrogel, where the main parameter seems to be represented by the charge density of the selected ion. Such a dependence is also observed in the surface area of corresponding aerogels (prepared from hydrogel by means of freeze-drying), where metal ions with higher charge density return lower surface area, glimpsing the chance to tune the latter parameter based on the envisaged final applications. In this regard, pore shape and aerogel structure are strongly affected by the chemical nature of the metal ions too, as a result of the different coordination geometry. Considering the extremely high versatility of such all-MXene hydrogels and aerogels (in terms of chemical and structural composition, as well as physicochemical properties), many different applications are being tested. For instance, the different and tunable electrostatic behavior of MXene aerogels could result crucial to produce gas and/or particle capture and sensing systems, whose regeneration *via* Joule heating might be possible because of their high electrical conductivity and versatile thermal properties. Also, the metal ions trapped within the MXene porous structure can be converted to metal clusters by simple thermal annealing (performed at 300°C, under Ar/H_2), allowing the formation of ferromagnetic particles for electromagnetic sensing and other related applications. Moreover, due to their tunable porosity, mechanical properties, and composition, MXene aerogels are being tested for acoustic insulation/damping and sensing as well. Finally, thanks to the abovementioned gelation process, MXene hydrogels and aerogels can be shaped in many forms, including fibers that might be use for bioelectronics and sensing. Finally, this versatile approach can be employed for several metal ions and MXene structures, leading to the production of hybrid systems with tunable properties according to envisaged applications.

4:30 PM EL17.13.04
Developing Vitrimer-MXene Laminated Sheets for Stimuli-Responsive Coatings and Improved Composite Functionality AbigailA. Advincula[1,2], JustinBrackenridge[3,1], PhilipBarnett[4], ChristopherMuratore[3], MadelineBuxton[5], VladimirTsukruk[5], YuryGogotsi[6] and DhritiNepal[1]; [1]Air Force Research Laboratory, United States; [2]ARCTOS, United States; [3]University of Dayton, United States; [4]University of Tennessee Knoxville, United States; [5]Georgia Institute of Technology, United States; [6]Drexel University, United States

Organic-inorganic hybrid structures found in nature, e.g., nacre (“mother-of-pearl”), are often remarkably tough and exhibit multi-functional properties due to highly ordered arrangements of organic and inorganic components in such structures at the nanometer-to-micron length scale. Inspired by these hierarchical biological structures, this work details our efforts to fabricate a hybrid composite of ordered, alternating layers of organic vitrimer polymer and inorganic MXenes. Vitrimers, as a new class of polymers, ideally exhibit thermoset-like behavior at lower temperatures and thermoplastic-like reformability at higher temperatures due to their permanent yet dynamic polymer networks. MXenes, as a class of inorganic two-dimensional (2D) transition metal carbides and nitrides, exhibit excellent metallic conductivity, good transparency in the visible wavelength range, and high photon-to-phonon conversion efficiency.

In this work, we demonstrate the fabrication of highly ordered, ultra-thin (nearly single to a few layers) MXene films onto thin, free-standing sheets of vitrimer, yielding electrically conductive, highly transmissive vitrimer-MXene sheets for self-healing coatings and multi-functional composites. Large area (20 x 20 cm), thin (<65 µm) free-standing vitrimer sheets are first obtained utilizing industrially-relevant compression molding techniques. Thermomechanical testing (TGA, DSC, DMA, TMA, micro-indentation) indicates excellent spot-to-spot consistency in the fabricated sheets. Subsequently, a thin film of MXene is deposited onto the vitrimer sheet surface using an advanced deposition technique that leverages Rayleigh-Benard convection and the Marangoni effect. Surface morphology and mechanical properties of the vitrimer-MXene sheets are investigated at different length scales using micro-indentation testing and quantitative nanomechanical (QNM) analysis. UV-vis measurements and electrical conductivity measurements additionally indicate reasonably good transparency (>75 %T in the visible spectrum) and electrical conductivity values (~100 S/cm) for the vitrimer-MXene layers. Self-healing mechanisms of the vitrimer-MXene sheets in response to light are demonstrated, leveraging the high photon-to-phonon conversion efficiency of MXene. Finally, compression molding of multiple individual MXene-coated vitrimer layers together yields a hybrid composite with alternating ordered layers of vitrimer and MXene. DMA and tensile testing are subsequently used to evaluate modulus, creep resistance, and toughness. This work presents a novel approach to accessing composites with ordered layers of vitrimer and MXene, techniques useful towards further enhancing vitrimer functionality towards structurally robust electronic applications.

4:45 PM EL17.13.05
$Ti_3C_2T_x$ MXene for Enhancing Hydrogel Adhesion and Structural Integrity Elham (Ellie)Jafarigol and NaderTaheri-Qazvini; University of South Carolina, United States

Self-adhesive hydrogels are lauded for their tunability and ability to stick to a range of surfaces without needing extra adhesives, making them highly promising for tissue engineering and regenerative medicine. However, their relatively weak adhesion limits their application in load-bearing uses. This study aims to address this limitation by integrating $Ti_3C_2T_x$ MXene, a two-dimensional nanomaterial recognized for its exceptional mechanical properties and conductivity, to improve hydrogel flexibility and adhesion. We utilized a simple synthesis process to create MXene-based hydrogels at different concentrations. The results revealed substantial enhancements in the mechanical strength and interfacial toughness as the MXene concentration increased. Impressively, the molecular interactions of MXene within the hydrogel network resulted in high stretchability, reaching up to 1600% of their initial value. The inclusion of MXene also shifted the bond fracture mechanism from adhesion failure to cohesion failure. This shift confirmed the increased structural integrity and crosslinking density. With excellent extrudability and shape fidelity, these MXene-based hydrogels are ideally suited for 3D printing applications. Overall, introducing MXene into hydrogels is a promising strategy for improving their robustness and self-adhesiveness, while maintaining their injectability. This advancement holds significant advantages for biofabrication and biomedical engineering.
KEYWORDS: MXene, hydrogels, adhesion, cohesion failure, injectability, flexibility

SESSION EL17.14: MXenes Structures and Properties IV

8:00 AM *EL17.14.01
MXetronics: Integrated Electronics using MXenes HusamN. Alshareef[1], XiangmingXu[1], TianchaoGuo[1], MrinalK. Hota[1] and HalaA. Al-Jawhari[2]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]King Abdulaziz University, Saudi Arabia

This talk will focus on MXenes and their development for integrated electronic device applications. MXenes can be considered as 2D metal contacts with tunable conductivity and tunable work function which makes them in principle suitable for a variety of electronic devices. To realize electronic devices, we have been developing deposition processes, transfer techniques, interface engineering, surface functionalization, photolithographic and e-beam patterning, wet and plasma etching of MXenes. In this talk, I will discuss the various aspects of device fabrication methods to integrate MXenes in several types of electronic devices. The benefits and challenges of using MXenes in each device type will be discussed, with particular focus on the role of interface. Example devices that will be discussed include using MXenes as electrical contacts in thin-film electronics, quantum dot electronics, CMOS devices, GaN high electron mobility transistors (HEMT), memristors, and solar cells. We show that the device performance strongly depends on the quality of the interface between MXene and the semiconductor material, whose control is critical for achieving good device performance. We have also integrated MXene films as active materials for photodevices, photothermal devices, and sensors.

8:30 AM EL17.14.02
Structural Strategies of MXene-Based Materials for Thermoconductive Electromagnetic Interference Shielding Materials with Excellent Mechanical Flexibility CanhM. Vu; University of Chicago, United States

MXenes, which are a type of 2D transition metal carbides and nitrides, have shown great potential as electromagnetic interference (EMI) shielding materials owing to their properties of electrical conductivity, low density, and flexibility. However, the weak interfacial interaction and the low thermal conductivity of MXenes resulted in poor mechanical flexibility and heat-dissipating capability. In this study, we developed structural strategies of MXenes-based carbon nanomaterials to fabricate MXenes films with enhanced mechanical strength, electromagnetic interference (EMI) shielding, and thermal conductivity properties. Compared to MXene films, the resulting hybrid MXenes films exhibited significantly improved mechanical strength of over 270 MPa, a toughness of 5 MJ m^{-3}, EMI shielding effectiveness of 70 dB, and an ultrahigh in-plane thermal conductivity of 110 W m^{-1} K^{-1}. This study presents a promising methodology for the development of high-performance materials that exhibit mechanical flexibility, electrical conductivity, electromagnetic interference shielding, and thermal conductivity properties.

Development of Polymeric/MXene Composites Towards 3D Printable Electronics AlejandraSalas Chavez[1], IgnazioRoppolo[1], MatteoCocuzza[1], HannaPazniak[2], JesusGonzalez-Julian[3], StefanoBianco[1], JuliaAmici[1] and ThierryOuisse[2]; [1]Politecnico di Torino, Italy; [2]Institut Polytechnique de Grenoble, France; [3]RWTH Aachen University, Germany

[Accepted Manuscript]
3D printing is an emerging technology for many applications, including electronics. On the other hand, to gather the applications' requirements with the possibility to produce complex 3-dimensional structures, the development of novel 3D printable materials is necessary. In this context, we studied the synthesis of 3D printable photocurable resins embedding $Ti_3C_2T_z$-MXenes, a class of 2D layered materials with outstanding electrical and electronic properties.

Starting from the pioneering works of Y. Gogotsi and M.W. Barsoum, MXenes envisage promising performances in different fields like energy storage[1], electromagnetic shielding[2], photodetectors[3], sensors[4] and electrocatalysis[5]. Nevertheless, their translation to devices nowadays is mainly limited to 2D configuration or conventional production processes.

Herein the motivation for this work stands for the development of stable polymeric inks suitable for Digital Light Processing (DLP) 3D printing technology using $Ti_3C_2T_z$-MXenes as functional fillers. Those were successfully synthesized using Ti_3AlC_2 as a MAX phase precursor etched by a strong acid (hydrofluoric acid- HF) and using tetrabutylammonium hydroxide (TBAOH) as an intercalator, providing a few layered flakes presentation. Then, employed to fabricate complex 3D composite structures with high printing fidelity. To enhance the material's electrical conductivity, annealing treatments have been performed, followed by a complete characterization of the so obtained. The results show that objects with improved electrical conductivity have been successfully obtained. To this end, this achievement would open new perspectives towards developing complex 3-dimensional electronic applications.

MXene and Their Surface Functionalization for the Development of Functional MXene Organic Inks Tae YunKo; Korea Institute of Science and Technology, Korea (the Republic of)

Due to their unique metallic conductivity, transparency, and outstanding solution processability in water, MXenes have been attracted to many potential applications such as EMI shielding, energy storage, and electronic applications. However, oxidation instability of aqueous MXene dispersions and poor dispersion stability in organic solvents prevent the utility of MXenes in potential applications. Surface functionalization of MXene is critical for controlling the dispersion system, surface chemistry, processing, physicochemical properties, and applications. Herein, we designed and conceptualized various organic ligands that can improve oxidation stability and organic dispersibility of the functionalized MXene. The recently developed surface functionalization methods demonstrate a range of processes for synthesizing MXene organic inks into composites with different polymer and metal nanoparticles without chemical oxidation issues. Moreover, utilizing these functional inks as highly efficient electrodes, it is also possible to achieve fine patterning and direct writing on hydrophilic or hydrophobic substrates with excellent conductivity.

Controlling Aerosol-Jet Printed Mxene Flakes Morphology for Neural and Energy Storage Applications JavierGutierrez Gonzalez[1,2,3], DahnanSpurling[1], TaraMcGuire[2], KeLi[1], IanWoods[2,3], AdrianG. Dervan[2], ValeriaNicolosi[1,3] and FergalO'Brien[2,3]; [1]Trinity College, Ireland; [2]Tissue Engineering Research Group, Royal College of Surgeons in Ireland (RCSI),

Ireland; [3]Advanced Materials Bio-Engineering Research Centre (AMBER, RCSI and TCD), Ireland

MXenes are a class of 2D layered materials consisting of carbides and nitrides of transition metals which has found application in a wide range of fields due to their excellent electrical conductivity, charge storage, and biocompatibility. Mainly used as aligned flakes, under certain processing conditions these 2D flakes can also fold in crumpled 3D structures. Despite being occasionally associated with faulty deposition, crumpled MXenes hold untapped potential, harboring intriguing properties that remain largely unexplored. Thus, the main goal of this study was to investigate the uncharted role that crumpled MXenes can play in both neural and energy storage applications.
In this work, the production of crumpled and aligned MXene ($Ti_3C_2T_x$) flake morphologies was systematically studied by using high-resolution Aerosol Jet 3D printing, while assessing their novel physical properties, such as roughness, conductivity, and optical properties. Furthermore, cell line -derived and primary neurons were plated on either morphology to examine the ability of both forms to support neuronal growth and development. In addition, to assess the potential utility of crumpled MXenes for energy storage applications, crumpled MXene flakes were used as a conductive spacer between aligned MXene layers for developing an all-MXene supercapacitor.
By modifying several 3D printing parameters, MXene flakes could both align and crumple at specific mass and sheath flow regimes, depending on the nozzle size, speed, and solvent mixture, while flake morphology was rapidly monitored using the in-built camera.
To assess biocompatibility, mouse neurons were seeded on printed crumpled and aligned MXene films, revealing distinct behavior depending on the flake morphology: crumpled MXene facilitated higher cell adhesion (as indicated by DNA count and immunostained cells), whereas neurons grown on aligned MXene films possessed longer neurite outgrowth. Further analysis using mouse primary neurons, resulted in healthy neuronal growth on both types of MXene for 8 days, while crumpled surfaces elicited decreased expression of GFAP, as observed in image analysis, suggesting reduced astrocytic reactivity.[1]
MXene supercapacitors were aerosol jet printed with the first layer being a highly conductive aligned MXene current collector, followed by alternating layers of crumpled and aligned MXene, resembling a *lasagne* structure. This hierarchical architecture effectively prevented excessive restacking of the flakes by smartly combining both morphologies, preserving a nanoporous network and achieving up to 65 (F/g) gravimetric capacitance, 193 (F/cm^3) volumetric capacitance and 88 (mF/cm^2) areal capacitance.
Taken together, these results demonstrate that crumpled and aligned MXenes can be easily 3D printed with Aerosol Jet printing; both MXene morphologies exhibited unique characteristics when supporting neuronal growth, and also powered energy-dense *lasagne* structured supercapacitors. This study highlights the need for precise management of MXene deposition and customized flake design, encouraging material scientists to intensify the study of crumpled MXenes and other 2D materials, and their application in multiple fields including biomedicine, electronics and energy storage.

9:30 AM EL17.14.06
Understanding Light-Matter Interactions of MXene Family of 2D Materials HyunhoKim[1,2], DanzhenZhang[1,2], TengZhang[1,2] and YuryGogotsi[1,2]; [1]A.J. Drexel Nanomaterials Institute, United States; [2]Drexel University, United States

The MXene family, two-dimensional transition metal carbides, nitrides, and carbonitrides, have been the subject of extensive research activities for the past decade. Recent developments in the molten-salt route have enabled the engineering of MXenes' surface termination groups. For example, molten-salt rouet synthesized $Ti_3C_2Cl_2$ is found to have a vis-NIR absorption band centered at ~880 nm, which is red-shifted from 770~800 nm for the acid route prepared $Ti_3C_2T_x$ with O, OH, and F terminations. The origin of this vis-NIR absorption band is yet to be understood, and the red-shift is difficult to explain by carrier density with the surface plasmon concept. Instead, we adapt an interband transition mechanism with consideration of light polarization to explain both UV and vis-NIR absorption bands of MXenes. The light-matter interactions of MXenes will be analyzed by using in-situ UV-vis spectroscopy under electrochemical modulation and Raman spectroscopy, and correlated with the literature on nonlinear optics, ultrafast terahertz spectroscopy, and pump-probe transient absorption. The important relationships between photons, electrons, and phonons in MXene, which are important for numerous applications of those materials, will be discussed.

Application of Two-Dimensional Metal Carbides (MXenes) for the Removal of Emerging Contaminants from Water KhaledMahmoud; Hamad Bin Khalifa University, Qatar

Characteristic properties of two-dimensional (2D) transition metal carbides and nitrides (MXenes), such as high conductivity, hydrophilicity, and catalytic activity have led to a growing research interest in their use in environmental remediation and water treatment applications. The ability to process MXenes into flexible films with negative surface charge and hydrophilicity adds a possibility to control ion flux and biofouling by applying a small potential to the membrane. MXene shows a much higher antibacterial efficiency toward both Gram-negative and Gram-positive bacteria as compared with other 2D nanomaterials. Consequently, MXene membranes demonstrated outstanding water flux, and selective rejection of salts and organic molecules, which makes them ideal UF/NF membrane materials. Moreover, MXene has been successfully used for the efficient adsorption and removal of heavy metals such as Hg, and Cu. This talk summarizes the recent advances in the applications of MXenes as adsorbents, desalination membranes, electrodes for electrochemical deionization, and catalytic or antibacterial agents for water purification and other environmental remediation processes. The overview also features discussions on the computational attempts, biocompatibility, and environmental impact in the exploration of MXenes for water applications, highlighting the challenges and opportunities of these advanced 2D materials. The biocompatibility and cytotoxicity assessment of MXene and its impact on the environment will be highlighted.

The Effect of Lateral Size and Surface Functional Groups on Membrane Performance of the Ti_3C_2Tx MXenes KiandokhtPakravan and MajidBeidaghi; Auburn University, United States

The applications of MXenes in membrane-based separation technologies have been rapidly expanding in recent years due to their hydrophilicity, exceptional flexibility, superior thermal stability, high electrical conductivity, and large surface area. In this presentation, we demonstrate significant enhancement in the performance of MXenes ($Ti_3C_2T_x$) membranes through understanding the effects of lateral sizes and surface chemistry of MXenes on the permeability and separation properties of the fabricated membranes. Single-layer $Ti_3C_2T_x$ nanosheets with different lateral sizes were obtained by applying high-power sonication with varying times to MXene dispersion. The resulting MXene dispersions were used to fabricate membranes for studying the effect of lateral size on the membrane performance. Also, to investigate the effect of surface chemistry on membrane performance, $Ti_3C_2T_x$ was synthesized by two different methods. The first method was the conventional MXene synthesis based on the MILD etching method, where delamination and etching were performed in a single step using a mixture of LiF and HCl as the etchant. The second method used a mixed acid etchant (HF/HCl) followed by delamination with LiCl. The existence of HF in the mixed acid method results in a higher concentration of -F functional groups, which can decrease the hydrophilicity of MXene membranes. Our initial permeability measurements indicate that membranes fabricated using MXenes with smaller lateral sizes have higher permeability compared with MXenes membranes with larger flakes. Also, the permeability of the MXene membrane varies across different methods.

11:00 AM EL17.15.03
Highly Efficient Electrochemical Performance of MXene-Based Nanocomposites for Capacitive Deionization of Metals and Cations Ruey-AnDoong, Nai-YingWang and Thi Kim AnhNguyen; National Tsing Hua University, Taiwan

Mxenes, a promising 2D materials derived from MAX phases, have been potentially applied to energy storage devices and pollution purification systems including ion-sieving membranes and ion removal. MXene has also established its prospective as electrodes for capacitive deionization (CDI) application for water purification and reuse due to the similar principle of charge storage in supercapacitors that uses the faradaic ion intercalation phenomenon. Electrode materials for asymmetric capacitive deionization, by combining carbonaceous materials with metal oxides, have emerged as a potential electrode material for CDI applications, which enable high ion removal capacity in comparison with devices containing only carbon materials. In this study, MXene based nanocomposites including MoS_2@MXene and Prussian blue analogues (PBA)@MXene have been fabricated to serve as the electrode materials for symmetric and asymmetric CDI applications. Results show that all the developed nanocomposites have a high surface area, suitable pore texture, and low electrical conductivity to accelerate the electron and

ion transfer rate. The specific electrosorption capacities (SECs) of the MXene-based nanocomposites are in the range of 39.5 – 43.8 mg/g with a charge efficiency of > 82%. Additionally, the as-developed MXene nanosheet has an excellent selective adsorption capacity toward heavy metal and ammonium ions removal. The Ti_3C_2 Mxene can selectively electroadsorb NH_4^+ with the SEC of 40 mg/g. When combining the vanadium aluminum carbide (V_2AlC-OH_x) with activated biochar (AB), the asymmetric AB||V_2AlC-OH_x device exhibits a superior deionization performance for Cr(VI) removal. These results clearly demonstrate the superiority of the as-developed MXene nanocomposites and can pave a gateway for combining MXene materials with novel metal oxides for highly efficient deionization of salty water as well as toxic metal and inorganic ions in water and wastewater treatment.

11:15 AM EL17.15.04
Synergistic Effect of Combining UIO-66 Nanoparticles and Mxene Nanosheets in Pebax Mixed Matrix Membranes for CO_2 Separation EyasuG. Ajebe; National Taiwan University of Science and Technology, Taiwan

Membrane gas separation has received much attention due to its low cost, high efficiency, and environmental benefits. Mixed matrix membranes (MMMs) can significantly improve the performance of gas separation membranes, but poor filler-matrix interactions and the aggregation of highly loaded fillers in mixed matrix membranes limit the benefit of overcoming the trade-off limitation. Therefore, how to regulate the state of fillers in the membrane becomes a key factor in the development of MMMs. In this work, Mxene ($Ti_3C_2T_x$) nanosheets and UIO-66 nanoparticles were prepared and used as combined fillers with Pepax-1657 matrix to synthesize MMMs for CO_2 capture. As-prepared MMMs were used to capture CO_2; the large porosity of UiO-66 served as a highway to enhance CO_2 permeability, and Mxene nanosheets were used as selective channels to achieve high selectivity via the terminal polar surface groups of Mxene. The combination of UIO-66 and Mxene not only enhanced selectivity but also increased solubility and diffusivity via the CO_2 adsorbing carboxylate group of UIO-66 and the tortuous pathway provided by Mxene nanosheets. As a result, adding MXene and UiO-66 in Pebax can help MMMs break through the trade-off limit. Pebax-based MMMs incorporated with 10-wt% MXene /UIO-66 provide CO_2 permeability of 214 barrers and CO_2/N_2 selectivity of 102. The as-prepared MMMs showed enhanced CO_2 permeability and CO_2/N_2 selectivity, compared to pristine Pebax membrane. The CO_2 capture performance of Mxene/UiO-66/Pebax membrane has been successfully exceeded the upper limit of Robeson (2008) which indicates that MXene/UiO-66/Pebax MMMs has great potential for CO_2 capture. This work provides a roadmap to fabricate high performance MMMs for CO_2 capture.

Deciphering the Dominant Activity Origin of a Single-Atom Catalyst Anchored on a MXene Membrane for Recalcitrant Deterioration Mohammed AskkarDeen F; Indian Institute of Technology Guwahati, India

Water is an elixir of life, but only about 0.5% of freshwater is available in an accessible form, resulting in enormous demand for the freshwater supply. A substantial increase in the need for wastewater treatment to meet its demand arises.Though many wastewater treatment technologies exist, advanced oxidation processes (AOPs), particularly sulfate radicals-based AOPs, offer a complete deterioration of recalcitrant. These sulfate radicals are highly oxidizing species that can be activated by the single-atom catalysts (SACs) in the presence of persulfate (SO2-5). The utmost efficiency of SACs can be attained by tracking down their superior activity origin. This elusive knot can be untied by computational modelling to determine the superior activity origin of SACs. Computational modelling using first principle calculations unveils the specific catalytic site at which the SACs activity can be enriched for the maximum radicals' generation. This method results in one of the most active catalysts for PS conversion in recalcitrant deterioration. Transition-metal carbides (MXenes) incorporated with the membrane are active support that can result in unique properties combining inherent polymer characteristics and inorganic materials, offering a potential platform for efficient catalytic processes
for sustainable wastewater treatment. In this work Ti_3C_2 MXenes mixed matrix membrane will be used to support SACs to overcome the synthesis challenge and pave the way for an efficient catalytic process. This study will use computational modelling and simulations to determine the specific type of transition metal atom, i.e. SACs and its electronic configuration that results in superior activity for generating highly oxidizing reactive species. Moreover, it will be followed by the synthesis of TCM3 and anchoring of SACs on the TCM3 for maximum recalcitrant deterioration.

***Operando* Synchrotron Radiation X-Ray Diffraction Study on Phase Evolution of Nb2GaC MAX during Molten Salt Etching**ChangdaWang; University of Science and Technology of China, China

Lewis acidic molten salt method is a promising synthesis strategy to achieve MXenes with controllable surface terminations from numerous MAX materials. However, the molten salt etching strategy is not totally controllable and most experimental parameters are usually set empirically due to the unclear reaction process. Understanding the phase evolution chemistry and time-dependency during etching and post-processing is highly desirable, but still a key challenge due to the lack of operando characterizations and the complexity of the reaction process. Herein, we introduce an operando synchrotron radiation X-ray diffraction (SRXRD) technique to unveil the phase evolution process of Nb_2GaC MAX under molten-salts ambient. Several critical steps are demonstrated, including ultra-fast evolution from Nb_2GaC to Nb_2CuC, quick extraction of Cu atoms to form Nb_2CT_x MXene, and interlayer expansion caused by Cl grafting. Accordingly, we propose a controllable synthesis of Nb_2CT_x through precise temperature-controlling and time-adjusting. Afterward, the phase structure of Nb_2CT_x is also successfully tailored from hexagonal to amorphous by the time-dependent subsequent persulfate oxidation. The amorphous Nb_2CT_x with well-patterned morphology and numerous chloride terminations exhibits highly improved specific capacity, rate, and long cycling capability in lithium-ion batteries (LIBs). In conclusion, the operando SRXRD with online devices is promising for the dynamic study of the Lewis acid molten salt etching process such as phase evolution, lattice change, and etching time scale, which could not be provided by ex-situ methods.

MXene Label-Free Detection and Immune-Based Applications LuciaG. Delogu[1,2], LauraFusco[1,3,4], AriannaGazzi[1], ChristopherE. Shuck[3], MarcoOrecchioni[5], Sènan MickaelD'Almeida[6], DarawanRinchai[4], EimanAhmed[4], LeeatKeren[7], DavideBedognetti[4] and YuryGogotsi[3]; [1]Unviersity of Padua, Italy; [2]New York University Abu Dhabi, United Arab Emirates; [3]A.J. Drexel Nanomaterials Institute, United States; [4]Sidra Medicine, Qatar; [5]La Jolla Institute for Allergy and Immunology, United States; [6]Flow Cytometry Core Facility, School of Life Sciences Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland; [7]Department of Molecular Cell Biology, Weizmann Institute of Science, Israel

Two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides (MXenes) are rapidly growing as nanoplatforms in biomedicine.[1-3] Considering the central importance of the immune response for any clinical translation of nanomaterials, we explored the potential biomedical applications of MXenes and their immune impact exploiting our expertise on the biological effects of 2D materials.[1-4]
To satisfy a critical unmet need to detect 2D materials at the single-cell level while measuring multiple cell and tissue features, we proposed the "Label-free sINgle-cell tracKing of 2D matErials by mass cytometry and MIBI-TOF Design" (LINKED) strategy, enabling nanomaterial detection while surveying a high degree of information from single samples.[5] This strategy is based on single-cell mass cytometry (CyTOF) and ion-beam imaging by time-of-flight (MIBI-TOF). MXenes ensured mass detection within the cytometry range while avoiding overlap with more than 70 available tags. We demonstrated their detection in 15 human immune cell populations. We used mass cytometry to capture MXene biocompatibility and cytokine production after their uptake. *In vivo* biodistribution experiments using a mixture of MXenes in mice confirmed the versatility of our strategy and revealed MXene accumulation in the main organs.
In addition, envisaging future MXene-based biomedical nanotools and drug nanoformulations we further explored MXene immune modulation and antiviral activity taking SARS-CoV-2 as a model.[6,7] We analyzed four SARS-CoV-2 genotypes. When viral inhibition was tested *in vitro*, Ti_3C_2, was able to reduce infection in SARS-CoV-2/clade GR-infected Vero E6 cells. Among the other MXenes tested, $Mo_2Ti_2C_3$ also showed antiviral properties. Proteomic and functional annotation analysis revealed that MXene-treatment exerts specific inhibitory mechanisms. The immune impact of MXenes was evaluated on human primary immune cells by flow cytometry and CyTOF on 17 distinct cell subpopulations. Moreover, 40 secreted cytokines were analyzed by Luminex technology. MXene immune profiling revealed i) the excellent bio and immune compatibility of the material, as well as the ability of MXene ii) to inhibit monocytes and iii) to reduce the release of pro-inflammatory cytokines, suggesting an anti-inflammatory effect elicited by MXene.
Finally, we considered that although vanadium-based metallodrugs have been recently explored for their effective anti-inflammatory activity, they frequently cause undesired side effects. Therefore, we hypothesized that vanadium immune properties could be extended to MXene compounds.[8] Therefore, we synthesized V_4C_3, evaluating its biocompatibility and immunomodulatory effects. By combining multiple experimental approaches, we investigated the effects on hemolysis, apoptosis, necrosis, activation, and cytokine production. We demonstrated the ability to inhibit T cell-dendritic cell interactions, evaluating the modulation of CD40-CD40 ligand interaction, two key co-stimulatory molecules for immune activation. We confirmed the biocompatibility at the single-cell level on 17 human immune cell subpopulations by single-cell mass cytometry. Finally, we explored the molecular mechanism underlying V_4C_3 immune modulation, demonstrating a MXene-mediated downregulation of antigen presentation-associated genes. Our findings set the basis for further V_4C_3 investigation as a negative

modulator of the immune response in inflammatory and autoimmune diseases.
Taken together, our results provide a compendium of knowledge on the biocompatibility of MXenes for the safe development of multi-functioning nanosystems in biomedicine.

Achieving of High Power MXene Electrode through Laser-Driven treatment AsmitaDutta; Ariel University, Israel

MXenes-based compounds, particularly Ti3C2Tx T_x were studied intensively as electrodes for supercapacitors due to their layered structure and high conductivity, enabling facile ions diffusion and charge transfer. However, tight restacking of the 2D layers limits their practical, accessible surface area, thereby impeding their capacity and rate capability performance. To mitigate this phenomenon, we present in this study a processing method based on laser beam irradiation on Ti3C2Tx film. The laser induces chemical and morphological changes in the 2D material, optimizing the stacking arrangement of the MXene layers, resulting in considerably improved electrochemical of the treated MXenes. In concentrated neutral aqueous electrolytes (7 M LiCl), the laser treatments increase the electric double layer (EDL) capacitance by 126%, from 96 F/g to 121.23 F/g at a scan rate of 5 mV/s. In acidic aqueous electrolytes (3 M H_2SO_4), capacitance enhanced by 132%, from 214 F/g to 284 F/g. Furthermore, the laser-modified MXene electrodes demonstrate excellent rate capabilities of 84% retention at extreme rates of 0.5 V compared to only 33% of the original Ti3C2Tx electrodes. Finally, we discuss the chemical and physical changes induced by the laser treatments and their influence on the electrochemical behavior of the lasered MXene.

The Influence of Hydration on the Mixed Charge Conduction of Conjugated Polymer Films SahikaInal; King Abdullah University of Science and Technology, Saudi Arabia

Organic mixed (ionic and electronic) charge conductors and electrochemical phenomena at the solid-liquid interface have garnered significant attention for applications in bioelectronics, electrochromics, energy storage/generation, neuromorphic computing, and thermoelectrics. These devices operate in electrolytes that render ions mobile in the film, making the coupling between electronic and ionic charges crucial. An example of such a device is the organic electrochemical transistor (OECT), a high-gain transducer commonly used to monitor bioelectronic signals. In this talk, I will show that the ions entering the semiconducting polymer channel are hydrated, and the water they bring inside the channel significantly affects OECT performance, which can be traced back to changes in the overall structural order. I will show the generality of this phenomenon with p and n-type materials. I will demonstrate how the amount of water the film takes governs its dielectric constant and the polaronic species formation. I will introduce one synthetic method and one postprocessing approach that can limit the water uptake of the film during device operation. These approaches enhance the mixed conductivity of polymers while preventing material degradation with oxygen, leading to OECTs with longer shelf life and operational stability.

11:00 AM EL18.01.02
Are Existing OECT Models Broad Enough? The Role of the Counter Ion and Ionic Contact Blocking SapirBittons and NirTessler; Technion-Israel Institute of Technology, Israel

OECTs have many advantages making them a promising technology for the future of electronics and bio-electronics. They have high transconductance which leads to a high sensitivity [1], and low operating voltage [2]. They can be fabricated on flexible substrates, [3] are scalable, and cost-effective for mass production. [4] The above attributes make them suitable for various applications, including healthcare (biosensors, drug delivery devices), robotics (sensors and actuators), and flexible electronics (e-skins, displays). However, they have limitations and challenges, such as stability and reversibility issues, manufacturing complexity, and the need for further optimization in certain applications. [5]
In our study, we simulated an OECT with PEDOT: PSS as the semiconductor layer. At the ON state, no cations are present in the bulk, resulting in a hole current within the PEDOT: PSS bulk. Conversely, at the OFF state, cations penetrate the bulk, depleting it and causing a significant drop in current. The above is well-known and detailed modeling has already revealed the importance of the ions' distribution with the semiconducting layer. [6,7]
Here we expand on previous studies using the industry-standard device simulator Sentaurus by Synopsys. Using the ion ("hydrogen") diffusion module allows for self-consistent simulation of the ionic electronic conduction as well as the contact phenomena. The first new observation to report is that, like in some memory technologies, ion accumulation close to the contact interface blocks the contact injection. In fact, this contact blocking plays an important role in obtaining low enough off currents.
Next, since the counterions (anions) are explicitly incorporated into the model, we report their influence on the OECT's conductance. We will present hole, cation, and anion distributions in

the electrolyte and semiconductor for ON and OFF states under three scenarios: (1) Anions can move freely in the electrolyte but are blocked by the semiconductor, (2) Anions can move freely in the electrolyte and penetrate the semiconductor, and (3) Anions are static in the electrolyte (as in solid electrolytes). We identify the scenario resulting in the highest transconductance and demonstrate the potential role of the electrolyte's counter ions (anions) in achieving best-performing OECTs.
We will discuss how our new findings suggest that the models used abundantly to describe OECT's performance may not be general enough. [8]

Ion-Associated Charge Transport in Conjugated/Non-Conjugated Polymer Layers for Wet and Dry Electronic Devices TakeoSuga; Waseda University, Japan

Electro-active organic polymers (*i.e.* p-conjugated polymer conductors/semi-conductors) have attracted increasing interest for organic electronics applications, such as solar cells, field-effect transistors, and batteries, because of their facile integration to soft/flexible device configurations, and environmentally benign/sustainable feedstock compared with rare metals, etc. Non-conjugated, redox-active polymers such as radical polymers have also attracted research attention to their utilization as an electrode-active material for rechargeable batteries and a charge-transport layer for electronic devices. Any of these applications, the role of associated ion transport is indispensable for efficient charge injection, transport, and storage. Here we take three examples: a) stable charge-storage in radical/conducting polymers, b) modulated charge-transport in the radical-containing resistive memory, and c) efficient charge collection through polymer semiconductors in the perovskite solar cells, and discuss each role of ions for charge-transport in electro-active polymers.

Elucidating Oxygen Reduction Mechanisms on Organic Mixed Ionic-Electronic Conducting Polymers AnaDe La Fuente Duran[1], Allen Yu-LunLiang[1], IlariaDenti[1], EmilyPenn[1], AdamMarks[1], William C.Chueh[1], AlbertoSalleo[1], AlexanderGiovannitti[2] and J. TylerMefford[1]; [1]Stanford University, United States; [2]Chalmers University of Technology, Sweden

Atmospheric oxygen is an attractive oxidant for the generation of electricity from chemical fuels and for the electrochemical production of hydrogen peroxide. Although not universal, it is generally assumed that an electrocatalyst is needed to reduce oxygen. Recently, a variety of organic mixed ionic-electronic conducting polymers (OMIECs) have been reported to exhibit catalytic behavior for both the 4-electron/4-proton and the 2-electron/2-proton oxygen reduction reaction (ORR).

This work sets out to identify the operative oxygen reduction mechanism of OMIECs through a multi-faceted experimental and theoretical approach. We primarily focus our efforts on p(NDI-T2 P75)—a random copolymer comprised of naphthalene diimide (NDI) and bithiophene (T2) units with 75% polar sidechains—and then expand the understanding built on this system to a range of other OMIECs. Using rotating ring disk electrochemistry, we find that the OMIECs investigated exhibit a high selectivity towards the 2-electron ORR product. Using *operando* UV-Vis and Raman spectroscopy measurements, we identify changes in OMIEC performance when in the presence of O_2. To gain further insights about the catalytic reaction path, we construct and test a microkinetic model. Through this model, we show that the performance of our tested OMIECs can be rationalized through an EC'D reaction mechanism. Our results suggest that these materials do not operate as electrocatalysts for the initial reduction of oxygen to superoxide but do function as catalysts for the disproportionation of superoxide.

Asymmetric Side-Chain Engineering of Thiophene-Based Polymers for Organic Electrochemical Transistor Applications PreetiYadav and ChristineLuscombe; Okinawa Institute of Science and Technology Graduate University, Japan

Conjugated polymers with mixed ion-conducting properties have recently gained considerable attention due to their potential applications in various emerging technologies spanning from bioelectronics to energy harvesting and storage. The soft and biocompatible nature of conjugated polymers coupled with their mixed conduction properties has been leveraged to develop many organic bioelectronic devices including organic electrochemical transistors (OECTs), neural probes, organic electronic ion pumps, and conducting polymer actuators. Among these, an OECT device comprising of a redox-active organic semiconductor layer interfacing a source, a drain electrode, and an electrolyte solution is capable of directly transducing small ionic fluxes into electrical signals making it ideal for sensing biomolecules. To achieve a high-performing OECT device, carrier mobility, and ion transport should be balanced in such a way that maximum transconductance is achieved, highlighting the crucial role played by crystallinity and morphology in mixed conduction. Therefore, it is important to establish an in-depth understanding of the chemical structure of the semiconducting polymer, charge transport, and morphology for designing high-performance OECT materials. In this work, we have synthesized polythiophene derivatives and explore how the polymer morphologies will affect carrier mobility and ion transport. The fundamental design idea is to obtain a highly planarized polymer structure by enhancing the side-chain organization through the incorporation of asymmetric side chains. Specifically, we investigate the effect of the enhanced side-chain organization on film morphologies, carrier mobility, and ion transport. Thiophene monomer is synthesized using Stille coupling and subsequently polymerized using Kumada catalyst transfer polymerization. The obtained polymer is characterized using NMR, MALDI, DSC, TGA, UV-vis absorption spectroscopy, and cyclic voltammetry. The morphologies and microstructure of the polymer films are examined using AFM and GIWAX followed by OECT device fabrication and characterization.

***Operando* Studies of Organic Mixed Ionic-Electronic Conductors: Structure, Composition and More…**JonathanRivnay; Northwestern University, United States

Organic mixed ionic-electronic conductors (OMIECs) have gained considerable interest in bioelectronics, power electronics, circuits and neuromorphic computing. These organic, often polymer-based semiconductors rely on a combination of ionic transport, electronic transport, and high volumetric charge storage capacity. Despite recent progress and a rapidly expanding library of new materials, a full understanding of fundamental processes of OMIECs remains largely unexplored. Critically, useful studies require us to probe these systems in device-relevant conditions, fully considering the effects of ions and solvent on microstructure and transport. To this end, we report on recent efforts towards structure/composition-property relations in high performance organic mixed conductors using ex-situ, in-situ, and operando scattering and spectroscopic techniques. We use a combination of GIWAXS, GISAXS, XPCS, E-QCMd, UV-Vis, XRF, as well as device measurements to explore kinetics, composition, and structural evolution during electrochemical operation. Importantly, these findings provide insights into materials design for enhancing device performance and stability.

2:15 PM EL18.02.03
Probing Polarons in Mixed Conductors via the Photoinduced Stark Effect ChristopherGrieco, Abdul RashidUmar and AustinDorris; Auburn University, United States

Conjugated polymers are promising candidates for high performance bioelectronics due in part to their ability to conduct ions and charge carriers simultaneously. However, the fundamentals of mixed ion and charge transport, including their complex dependence on polymer structural dynamics occurring *in operando*, remain unclear due to limited characterization methods. Using ultrafast transient absorption spectroscopy, we demonstrate a new approach to probing the nature and local environment of polarons in a mixed conducting, electrochromic polymer, 3,4-propylenedioxythiophene-*co*-3,4-ethylenedioxythiophene (ProDOT-*co*-EDOT).[1] Selectively photoexciting hole polarons via the P1 and P2 polaronic transitions causes spatial separation of the hole from its counterion during thermalization. The resulting electric field, which induces a Stark shift of the bandgap transition of nearby polymer chains, creates signals in the transient spectrum that reflect the electronic structure and environment of the charge carrier. As a first step, we show how this optical spectroscopy method, which effectively senses polarons in both

amorphous and crystalline domains, can be implemented in spectroelectrochemical measurements to elucidate mixed conduction mechanisms.

2:30 PM EL18.02.04
Swelling of Side Chain Free Polymers upon Electrochemical Cycling LucasFlagg[1], LeeRichter[1], JiajieGuo[2], DavidS. Ginger[2] and JianguoMei[3]; [1]NIST, United States; [2]University of Wasington, United States; [3]Purdue University, United States

Organic mixed ionic-electronic conductors (OMIECs) are an exciting class of new materials with a range of potential applications including biosensors, electrochromics, and neuromorphic computing. For many of these applications the performance of n-type materials trails p-type materials by at least an order of magnitude. Recently, a pair of side-chain less polymers have been demonstrated as promising n-type OMIECS. These materials challenge the existing understanding of this class of materials, where polar (often ethylene glycol) side chains enable electrolyte and ion ingress, which subsequently enables volumetric doping. Here, we seek to understand the swelling during electrolyte contact and during redox cycling of these side chain less materials using *in-situ* GIWAXS. These measurements reveal drastic differences in how the two polymers swell in response to applied bias. In water-based electrolytes, BBL shows a redox induced swelling upon first passage, and remains swollen during subsequent doping cycles. In contrast, PBDF does not show any lattice expansion when in contact with water regardless of doping state. However, in propylene carbonate electrolyte PBDF shows a reversable melting during dedoping to the point where all diffraction peaks disappear. Upon electrochemical redoping, the crystallinity returns to its original level. Additionally, in the partially doped state the lattice spacing depends strongly on the exact doping state. We investigate this melting/recrystallization and swelling phenomena in relation to conductivity of the system. Overall, this work provides insights into the role of swelling in side-chain less OMEIC materials which can inform design rules moving forward.

3:15 PM *EL18.03.01
Electronic and Ionic Conduction in Radical-Containing Small Molecules and Polymers BryanW. Boudouris; Purdue University, United States

Optoelectronically active small molecules and polymers have made critical inroads in many solid-state electronic devices (e.g., organic field-effect transistors), and excitingly, organic molecules capable of providing mixed electronic and ionic conduction offer unique opportunities in many application areas including bioelectronic devices. Here, we describe electronic and ionic conduction in both low molecular weight and polymeric materials containing stable open-shell sites. While the chemical nature of the two classes of materials differs, the key premise is that controlling the spatial distance between the radical groups is critical for electronic transport and that the redox behavior of open-shell species allows for facile ion transport if it is controlled appropriately.

First, we demonstrate how control of the local structure in radical-containing small molecules and polymers impacts charge transport in these materials. In one example, we implement radical polymers, which are macromolecular materials that have flexible polymeric backbones and pendant groups that bear stable open-shell moieties. In contrast to almost all other optoelectronically-active polymers, radical polymers lack backbone conjugation and are completely amorphous in the solid state. Despite this shift in macromolecular design archetype, we demonstrate that the solid-state electrical conductivity of a designer radical polymer exceeds 20 S m-1, and this places this nonconjugated polymer conductor in the same regime as many grades of common commercially-available, chemically-doped conjugated conducting polymers. Thus, this work presents an alternate design paradigm for next-generation organic electronic materials. In a second example, small molecules that bear stable radical groups and form macroscopic single crystals are evaluated. Specifically, we quantified the electrical conductivity in two organic radical single crystals and demonstrated that a subtle change in atomic connectivity drastically alters the macroscopic electronic properties of the materials. One radical-based crystal had an electrical conductivity of ~3 S m-1, which is the highest value for nonconjugated radical conductors over a 1 μm-scale reported to date. However, the other radical crystal has a 1,000-fold lower conductivity despite their extremely similar molecular structures. The temperature-dependent conductivity follows the variable range hopping mechanism for both radical crystals, and the difference in effective charge mobility is the reason for the conductivity difference. These results present a clear picture of the design rules and charge transport mechanism for radical-based materials.

Next, we describe how a blend of a common conjugated polymer, poly(3-hexylthiophene) (P3HT), and a radical polymer (i.e., a macromolecule with a nonconjugated backbone and with stable open-shell sites on its pendant groups), poly(4-glycidyloxy-2,2,6,6-tetramethylpiperidine-1-oxyl) PTEO, allows for the creation of high-performance organic electrochemical transistors (OECTs) through a unique mixed conduction mechanism. Second, we will discuss how this type of archetype can be translated to biomedical device applications through a practical demonstration of a stretchable and flexible polymer-based biosensor. This bioelectronic device is inkjet-printed atop a commercial soft contact lens in a high-throughput manner, and our electroretinogram (ERG) sensor shows performance that is superior to current clinical gold standards in human subjects. In this way, we couple the materials science mixed organic electronic conductors to translational performance to demonstrate clear patient impact.

3:45 PM EL18.03.02
Generalised Framework for Controlling and Understanding Ion Dynamics with Passivated Lead Halide Perovskites TomiBaikie[1], PhilipCalado[2], KrzysztofGalkowski[1], SamuelD. Stranks[1] and Piers R. B.Barnes[2]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Metal halide perovskite solar cells have gained widespread attention due to their high efficiency and high defect tolerance. The absorbing perovskite layer is as a mixed electron-ion conductor that supports high rates of ion and charge transport at room temperature, but the migration of mobile defects can lead to degradation pathways. We combine experimental observations and drift-diffusion modelling to demonstrate a new framework to interpret surface photovoltage (SPV) measurements in perovskite systems and mixed electronic ionic conductors more generally. We conclude that the SPV in mixed electronic ionic conductors can be understood in terms of the change in electric potential at the surface associated with changes in the net charge within the semiconductor system. We show that by modifying the interfaces of perovskite bilayers, we may control defect migration behaviour throughout the perovskite bulk. Our new framework for SPV has broad implications for developing strategies to improve the stability of perovskite devices by controlling defect accumulation at interfaces. More generally, in mixed electronic conductors our framework provides new insights into the behaviour of mobile defects and their interaction with photoinduced charges, which are foundational to physical mechanisms in memristivity, logic, impedance, sensors and energy storage.

4:00 PM EL18.03.03
Ion-and Charge Transport in Dense Films of Semiconducting Single-Walled Carbon Nanotubes DanielHeimfarth, MerveBalci Leinen, XuqiangXu and JanaZaumseil; Heidelberg University, Germany

Dispersions of purely semiconducting single-walled carbon nanotubes (SWCNTs) can be sorted and purified by polymer-wrapping and subsequently printed into thin or thick SWCNT films that are suitable for various electronic devices. Here, we demonstrate that these porous composites of conjugated polymer and semiconducting nanotubes enable mixed ionic and electronic transport with high charge carrier mobilities in electrochemical transistors with different electrolytes. The ionic transport and hence also the effective volumetric capacitance of the nanotube network can be increased substantially by changing from a hydrophobic polyfluorene copolymer with alkyl sidechains to one with tetraethylene glycol sidechains, thus reaching over 200 $Fcm^{-1}V^{-1}s^{-1}$ as the product of carrier mobility and volumetric capacitance (*ACS Appl. Mater. Interfaces* 2022, *14*, 8209). We find that the maximum transconductance for hole transport in SWCNT networks also depends on the size of the electrolyte anions, suggesting a direct impact on the delocalization of charge carriers along the nanotubes. Furthermore, we monitor the ion movement and thus charge carrier concentration within a nanotube network by spatially resolved in-situ Raman- and photoluminescence spectroscopy and explore the role of the network morphology and density for both charge and ion transport. Finally, we demonstrate the direct sensing of cupric ions and indirectly of glyphosate in water-gated transistors with polyfluorene copolymer-wrapped nanotubes (*Nanoscale* 2022, *14*, 13542).

Controlling Mixed Ionic-Electronic Conducting Polymer Properties with Amphiphilic Chemical Design Strategies NicholasD. Siemons; Imperial College London, United Kingdom

Semiconducting polymers bearing hydrophilic glycol side chains can transport aqueous electrolytes through their bulk, allowing for the simultaneous movement of electronic and ionic charges during electrochemical doping (therefore called organic mixed ionic-electronic conductors, or OMIECs). Their mixed charge transport properties, chemical tuneability and easy synthetic scalability make them attractive materials for bioelectronic devices such as transistors [1] and charge storage devices [2]. While hydrophobic alkylated polythiophenes have demonstrated favourable charge transport properties [3] and the ability to operate stably in devices such as field-effect transistors, upon glycolation (making them into OMIECs) some of these favourable properties are deteriorated. For example, heavily glycolated polythiophenes have shown to excessively swell when electrochemically doped in the presence of an aqueous electrolyte [4], damaging their operational stability and charge transport properties. We explore how amphiphilic chemical design strategies can be leveraged to design OMIECs that retain their operational stability and high charge transport properties. We explore two strategies – 1) the random copolymerisation of alkylated and glycolated repeat units together and 2) using homopolymers with both alkyl and glycol moieties on their side chains. In the first case we find that a small level of alkylation leads to a large increase in the electrochemical cycling stability of the OMIEC, while leaving the electrochemical doping characteristics broadly unchanged. When using homopolymers with mixed alkyl/glycol side chains, we show how the size of the alkyl group on the side chain can control the polymer backbone conformation, impacting its electronic transport properties. Through a joint experimental/theoretical approach we identify the underlying microstructural mechanism behind both the inhibited swelling in alkyl/glycol copolymers and the effect on the backbone morphology in amphiphilic homopolymers. We identify the driving forces causing them to adopt their particular microstructure and draw parallels between the formation if micelles and vesicles in surfactants. Identifying these mechanisms and their driving forces in OMIEC systems will aid in the design of future polymers which optimise the transport of both ionic and electronic charges, while having high operational stability and charge transport properties.

Enhanced Thermoelectric Performance of PEDOT:PSS-Based Composites by Constructing Sequential Energy-Filtering Interfaces and Energy Barriers SiqiLiu[1] and ChaobinHe[1,2]; [1]National University of Singapore, Singapore; [2]Institute of Materials Research and Engineering, Singapore

Among all reported organic thermoeletric materials, poly(3,4-ethylenedioxythiophene):poly(styrenensulfonate) (PEDOT:PSS) has drawn extensive attention owing to its high electrical conductivity. However, the Seebeck coefficient of PEDOT:PSS needs to be enhanced without sacrificing electrical conductivity. As one approach, modulating the energy filtering effect at the component interfaces can enhance the Seebeck coefficient with only a slight reduction in electrical conductivity. In this presentation, I will report an effective strategy to significantly enhance the thermoelectrical properties of PEDOT:PSS by integrating core-shell PEDOT/polypyrrole (PPy) nanowires to form multiple sequential interfaces and enabling more effective energy filtering process in between. By tailoring the energy barriers among PEDOT/PPy/PEDOT:PSS interfaces, the Seebeck coefficient of the PEDOT:PSS composites was increased by ~46% with only a slight decrease in electrical conductivity. As a result, a significant improvement of over 85% in power factor was achieved compared with pristine PEDOT:PSS.

8:00 PM EL18.04.02
Textile-Embeddable Fibriform Organic Electrochemical Diodes with Rectifying, Complimentary Logic and Transient Voltage Suppression Function for Wearable E-Textile Circuits Kwang-HunChoi[1,2], Soo KinKim[1,2], Ho WonJang[2,2], ChangsoonChoi[1], HyunsuJu[1] and Jung AhLim[1,3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Korea University of Science and Technology of Korea, Korea (the Republic of)

Electronic textile (E-textile) are considered ideal wearable platforms for human-machine interaction due to their flexibility and flexible, comfortable-wearing textile properties. For realization of a multi-functional, fully integrated E-textile circuit system, fibriform electronic devices become a key component that can merge a multifunctionality of integrated circuits and a textile nature. Here, we propose a fibriform electrochemical diode (fOED) as a building block for E-textile circuits. The fOED is fabricated by twisting metal/polymer semiconductor/ion gel coaxial microfibers and microfiber electrodes. The fOED exhibits a prominent asymmetrical current flow similar to that of the diode, with a rectification ratio of over 10^2. From the fundamental studies on the electrochemical interaction between polymer semiconductors and ions, we reveal that the faradaic current by electrochemical reaction originates an abrupt current increase under a forward bias. Then, the threshold voltages of devices are determined by the redox potential of the polymer semiconductor. The fOED exhibit great bending and washing robustness, and was embeddable on the textile platform by its one-dimensional architecture (diameter < 300 μm). It also could be expanded to integrated circuit systems by simply merging the electrode threads, the full-wave rectifiers and logic gates (AND/OR) could be easily accomplished on textiles. Furthermore, it was also confirmed that fOED could be utilized as a protection diode, a fOED integrated electrocardiogram monitoring system could be protected from circuit damage by instant transient voltages. Our approach offers a new form factor for electrochemical diodes and we believe that this work will contribute to the development of next-generation wearable E-textile circuit systems.

8:00 PM EL18.04.03
Aerosol Jet Printed Organic Electrochemical Transistors using n-Type Naphthalene Dimide-Based Small-Molecule Organic Mixed Ionic-Electronic Conductor SeongdaeKang[1], PaulLavryshyn[1], JiaxinFan[2] and ManishaGupta[1]; [1]University of Alberta, Canada; [2]Polytechnique Montréal, Canada

Organic semiconductors are capable of transporting both the ionic and electronic charges representing a new class of material: organic mixed ionic-electronic conductor (OMIECs). OMIECs have been used for a variety of organic electronics, including organic electrochemical transistors (OECTs) and energy conversion/storage devices. Most reported OMIECs are hole-transporting p-type polymeric material, such as PEDOT:PSS and polythiophene derivatives. In contrast, electron-transporting n-type OMIECs are less reported and often have poorer performance and stability, despite their need in fabricating complementary circuits or biosensors that require electron transfer. Compared to polymeric OMIECs, small-molecule mixed conductors offer significant potential thanks to their mono-dispersity and synthesis simplicity.[1)]
We recently reported the first naphthalene-diimide-based n-type small-molecule organic mixed ionic-electronic conductors and their utilization as a channel material in accumulation mode organic electrochemical transistors. The glycolated naphthalene diimide n-type OMIEC, gNDI-Br_2, was characterized for its electrochemical behaviour and used to fabricate an OECT via a simple drop-casting technique. The gNDI-Br_2 OECT operated as an n-type accumulation mode and showed a maximum transconductance ($g_{m,\ max}$) of 814 ± 124.2 μS and a mobility capacitance product (μC^*) of 0.23 ± 0.04 F $cm^{-1}V^{-1}s^{-1}$.[2)]
The transconductance of the OECT is affected by its intrinsic material figure-of-merit (μC^*) and channel geometry.[3)] Drop-casted gNDI-Br_2 devices pose a challenge for practical applications due to their unpredictable channel geometry and hence their repeatability. To resolve this issue, we fabricated gNDI-Br_2 OECTs using an aerosol-jet 3D printing technique with the Optomec Aerosol Jet 5X 3D printer. This method creates the sub-micron size aerosols using ultrasonic atomization which are deposited onto the substrate via a nozzle.[4)] Owing to the AJ5X 3D printing system, we were able to manipulate the OECT channel geometry and fabricate repeatable OECT devices.
Additionally, for the aerosol jet printing, the gNDI-Br_2 solution with low evaporation rate was required while transitioning to an aerosol. By using low-volatile solvent for the solution and aerosol-jet 3D printing, the gNDI-Br_2 molecules were evenly distributed onto the substrate, resulting in higher crystallinity as compared to the drop-casted OECTs. This resulted in an improved performance of the gNDI-Br_2 OECT ($g_{m,\ max}$ = 1.12 mS, μC^* = 0.75 F $cm^{-1}V^{-1}s^{-1}$). Moreover, we achieved a fully printed n-type OECT by printing other component, including metal electrodes onto flexible polymer substrates. Using this gNDI-Br_2 OECT, we were able to fabricate aerosol-jet printed complementary logic circuit with a PEDOT:PSS p-type counterpart.

Ionic Liquid Driven Enhancements in the Electromagnetic Interference Shielding Capabilities of Carbon-Based Polymer Composites PaulAl Malak[1,2], CedricVancaeyzeele[1], Pierre-HenriAubert[1], FrédericVidal[1], Giao T.M.Nguyen[1], PaoloBondavalli[2] and CédricPlesse[1]; [1]CY Cergy-Paris Université, France; [2]Thales Research & Technology, France

Electromagnetic interference (EMI) has emerged as a crucial problem in the modern world because of the rapid proliferation of electronic and telecommunication systems, which emit electromagnetic radiation that may perturb the performance of electronic devices on one hand, and could be harmful to the human body on the other [1]. As a result, considerable endeavors have been devoted to the development of efficient materials for EMI shielding/absorption. Polymers and polymeric composites with a wide array of fillers, especially carbon-based fillers have been widely used as promising candidates in the development of commercially viable EMI shielding materials. Lately, extensive research efforts have been put forward, towards effective dispersion of the fillers throughout the matrix. Ionic liquids have emerged as a promising dispersing agent for CNTs through non-covalent functionalization by interacting with the CNTs surface through π-π, cation-π or even Van der walls interaction [2]. They have been also used as fillers in metamaterial structures, where they actively engage in attenuating the electromagnetic wave thanks to their polarity [3]. Accordingly, it would be really interesting to develop a shield where we can take advantage of the already proven excellent EMI shielding capabilities of carbon based composites and in exploring the capabilities of ionic liquids in a more active manner in a polymer matrix.
Here, we demonstrate the use of carbon-based nanomaterials (MWCNT, Graphene derivatives) incorporated in ionogels as effective EMI shields. These ionogels combine the unique properties of ionic liquids and their ability to attenuate the electromagnetic wave through dipole reorientation and translational motion (movement of the ions). The structural support is provided by the gel matrix, which also aids in matching the impedance of the shield with the surrounding environment, while the presence of carbon-based nanomaterials not only facilitated the formation of conductive pathways but also introduced interfacial polarization and dipole polarization between them and the ionic liquid-gel matrix. The ionogels exhibited remarkable performances across a wide frequency range, where the presence of the ionic liquid led to an enhanced absorption of the electromagnetic wave, with over 97% attenuation, of which over 55% is by absorption. Morphological characterizations revealed the homogeneous envelopment of the CNTs by the ionic liquid enhancing the interfacial polarization. The electrical conductivity measurements confirmed the conductive behavior of the carbon-based nanomaterial incorporated ionogels, which is essential for effective EMI shielding.

8:00 PM EL18.04.05
Elucidating the Role of Side-Chain Polarity of Conjugated Polyelectrolytes by Doping Through Organic Electrochemical Transistor Sung HyunLee[1], ChangwhaJung[1], HyunhoJeong[1], ChaeyeonPark[2], SoonyongLee[2], Han YoungWoo[2] and HyunjungLee[1]; [1]Kookmin University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Conjugated polyelectrolytes (CPEs) exhibit a novel structure composed of electron or hole conducting π-conjugated backbone and ion conducting pendant ionic functionalities. Anionic narrow-band-gap CPE named poly[2,6-(4,4-bis-potassium butanylsulfonate-4H-cyclopenta-[2,1-b;3,4-b0]-dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBTSO3K, or CPE-K) is well known for self-doped property which is fabricated as a channel material for organic electrochemical transistor (OECT).
In this work, electronic and ionic transport is studied by OECT system. Different types of polarity of side chain attached to the same backbone that contains an alternating D-A units of cyclopentadithiophene (CPDT) and benzothiadiazole (BT) were synthesized. The affect of different polarity was examined as a channel material by using gel-type ionic liquid electrolyte (1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide or $[EMIM]^+[TFSI]^-$) which allows wider range of gate voltage and constant measurement conditions etc. All three channel materials each showed ON and OFF state both in accumulation and depletion mode only by changing the polarity of gate and drain voltage. Ion transport mechanism was compared through OECT system by measuring transfer/output curve, μC^* value and response time etc. Our work allows for maximizing doping effect through ion penetration and utilize as a dual mode switching system.

8:00 PM EL18.04.06
Study on the Impact of Ions Uptake on the Thermoelectric Performance in Organic Electrochemical Transistors HyunhoJeong[1], ChangwhaJung[1], Sung HyunLee[1], ChaeyeonPark[2], SoonyongLee[2], Han YoungWoo[2] and HyunjungLee[1]; [1]Kookmin university, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

The aim of our research is to explore the effects of penetrated ions in the polymer matrix by electrochemical doping on the thermoelectric performance in organic electrochemical transistors (OECTs). Controlling the Seebeck coefficient and electrical conductivity values of organic thermoelectric (TE) materials has been widely studied. However, earlier works were primarily conducted based on the chemical doping method. In terms of controlling the TE performance, the electrochemical doping method has the advantage of finely tuning doping levels by changing the applied gate voltage (V_g). Anions or cations from ionic liquid penetrate the polymer matrix depending on the sign of applied gate voltage and modulating the conductivity. This method provides an easy way to study the TE performance of organic TE materials.

Generally, the focus is on the doped organic TE materials by penetration of mobile ions, and penetrated ions induced Seebeck coefficient is seldom considered. The temperature gradient causes not only the potential difference created by the polymer film but also the potential difference due to ions in the ionic liquid moving by the Soret effect. Thus, it is essential to clarify the contribution of ions to TE performance for further application.

Here, we demonstrate the influence of the uptake of mobile ions in an electrolyte (1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide, ($[EMIM]^+[TFSI]^-$)) on TE performance using different polarity side chain polymers. We characterize the time-dependency of the potential difference between the cold side electrode and the hot side electrode based on the OECT system to investigate the ionic and electronic induced Seebeck coefficient separately.

Molecular Design for Tunable Ionic Thermopower with High Stretchability MinjuPark; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Wearable and stretchable electronics have attracted tremendous attention due to their wide applications in various areas. However, the lack of efficient, light-weighted and environmental friendly power sources has been the bottleneck that hinders the wide applications of wearable technologies. One of the attractive solutions is the thermoelectric generators (TEGs), which can directly convert waste heat from human body or environment into electricity. Though great development has been achieved with conventional TEGs, present inorganic thermoelectric materials still suffer from rigid properties and low Seebeck coefficient (several hundred uV/K scale), which requires an integration of hundreds of elements. To overcome these challenges, ionic thermoelectric materials utilizing ionic transport open up new possibilities for the recuperation of waste heat due to their enormous Seebeck coefficient, which can operate supercapacitors by energy harvesting.
Herein, we introduce intrinsically stretchable acrylamide based polymers (PAM) as the ion conductive materials comprising graphene derivatives, which possess high stretchability and excellent thermoelectric performance. Interestingly, ionic conductivity and thermopower could be tunable according to the molecular structure of graphene-based additives. Chemical structure of graphene-based additives was successfully modified by covalent functionalization with phenylsulfonic acid (SGO) and amine species (NGO), resulting in strong positive and negative charged graphene nanosheets, respectively. Induced charge could significantly affect to Coulombic interaction between ion and polymer, or ion and solvent, rendering in large difference in ion concentration under temperature gradient. As a result, the proposed materials exhibit excellent and tunable Seebeck coefficient (up to 39.7 mV/K) as well as remarkable stretchability. The ionic thermoelectric performance was sustained during multiple stretch-release cycles (50% strain, 1000 cycles), which demonstrates high durability under severe deformation. Furthermore, we fabricate ionic thermoelectric supercapacitors (ITESC) with ionogels, demonstrating the heat-to-electricity conversion was successfully established. These findings show a promising strategy to obtain multifunctional ionic thermoelectric materials by engineering the molecular structures, and demonstrate the great potential of ionogels for harvesting low-grade heat in human-comfortable humidity environments.

Pyrene Dianhydride Condensation Ladder Polymer: Synthesis and Film Characterization. KatherineJohnston, EmmaMikita and JuliaA. Schneider; Fordham University, United States

Organic materials that display mixed-conductance–the ability to conduct both ions and electrons–are actively sought after for their possible use in organic electrochemical transistors and sodium-ion batteries, among many other applications. Of only a few n-type polymers reported to display mixed-conductance, poly(benzobisimidazobenzophenathrolinedione) (**BBL**) is the most promising to date. Its conjugated ladder structure makes it very environmentally stable and its ability to maintain a planar backbone when swelling in ionic media has led to high capacitance and electron mobility. The success of **BBL** in terms of its mixed-conductance has renewed interest in the study and development of n-type ladder polymers. We will present the synthesis of a new mixed-conducting material, a pyrene-based ladder polymer, poly(benzimidazobenzo(d,e,f)phenanthrenedione) ladder (**BPyL**), formed from the polycondensation reaction between our pyrene dianhydride monomer unit and 1,2,4,5-tetraaminobenzene tetrahydrochloride (**TAB.4HCl**). The larger aromatic core of **BPyL** vs. **BBL** influences the packing of the

polymer, and therefore, how well the polymer can form films and perform in electronic devices. We will study and present how **BPyL** and **BBL** differ in regard to their film making abilities using spectro-electrochemical analysis, UV-Vis, and TEM. The capacitance of **BPyL** will also be measured and reported.
Through our synthesis of the pyrene dianhydride monomer, two isomers are produced. We will present the synthesis and characterization of each isomer in its diimide forms. The pyrene diimide units themselves and their spectral and electrochemical properties are useful to study for future incorporation into conjugated polymers. Pyrene is impactful as a core for these molecules due to its unique fluorescence property: excimer formation. Excimer formation causes a shift in fluorescence when the molecule is close to a neighboring molecule and can be a useful way to visualize the molecule's ability to stack or congregate. Determining the monomers' ability to form excimers can help with determining their ability to pack when in the polymer form. The synthesis of both pyrene diimide isomers will be presented with their fluorescence spectrum, which demonstrate excimer formation at higher concentrations.

8:00 PM EL18.04.09
Nanoscale Perspective on Charge Carrier Transport in Sepia Melanin ShahidKhaleel, AnthonyCamus, JoaquinIsasmendi and ClaraSantato; Polytechnique Montreal, Canada

Sepia melanin, a naturally occurring pigment found in the ink sac of cuttlefish, has garnered significant interest for its intriguing electrical properties and potential as an organic semiconductor material. Sepia melanin exhibits properties of disordered organic semiconductors which display charge transport behavior attributable to a combination of band-like and hopping transport mechanisms[1]. The electrical conduction in Sepia melanin is influenced by its complex hierarchical structure, which consists of melanin nanoparticles self-assembled into granules. These nanoparticles result from variety of arrangements of pi-pi stacked molecules[2].
Understanding charge carrier transport in organic materials at the nanoscale is key for the advancement of emerging optoelectronic technologies. In this study, we investigate the charge transport properties of Sepia melanin at the nanoscale. The unique properties of Sepia melanin, including its moisture dependent electrical response[3] and broadband optical absorption[4], make it a promising material for applications in organic electronics, energy harvesting, and bioelectronics. By understanding the charge transport phenomena at the nanoscale, we aim to unlock the full potential of Sepia melanin for these technological applications.
We focus our investigations on an inter-digitated planar geometry of patterns (inter-electrodes distance ~200-700 nm) as we try to catch signals from individual granules of Sepia melanin. Patterns are fabricated by Electron Beam Lithography.
Preliminary findings from our ongoing study reveal the influence of structural disorder on charge carrier transport in Sepia melanin, such as charge carrier localization and trapping effects, which offer opportunities for tailored charge transport characteristics in devices.
Work is in progress to study the Electrochemical Impedance Spectroscopy (EIS) response in different atmospheres to confirm the nature of the charge carriers. Temperature dependent electrical characterization are helping us to shed light on aspects pertaining to hopping transport (e.g. to calculate the activation energy).
The insights gained from this research have the potential to advance the field of organic electronics and open up new avenues for the development of bioinspired electronic devices and sensors.

Enhancing Adhesion of PEDOT Coatings on Metal Electrodes: A Promising Approach SaraEbrahimi, FabioCicoira and SadafKhoomortezaei; Polytechnique Montreal, Canada

The use of electrodes as biomedical devices in healthcare is undergoing innovative advancements, employing novel techniques that bridge the gap between biological systems and electronics. Nonetheless, traditional metallic electrodes encounter a substantial hurdle in the form of impedance, impeding the smooth transmission of electrical signals within living tissues. To tackle this challenge, recent breakthroughs suggest the utilization of poly(3,4-ethylene dioxythiophene) (PEDOT), an organic conducting polymer, as a solution to overcome the impedance obstacle [1]. PEDOT exhibits favourable qualities that make it an excellent candidate for bioelectronic devices. These desirable characteristics include its ability to maintain low impedance, high conductivity, excellent electrochemical stability, and biocompatibility, rendering it an optimal material for such applications [2]. When left uncoated, copper electrodes are susceptible to rapid oxidation, which challenges their direct compatibility with a PEDOT coating. To address this limitation, we propose applying nickel-phosphorus and gold/nickel-phosphorus layers onto the copper electrodes (Au/Ni-P/Cu). This coating approach helps overcome the oxidation issue and enhances the compatibility between the electrodes and the PEDOT material [3]. Afterward, the process involves depositing PEDOT onto the surface of the electrodes. The primary goal is to develop cutting-edge biomedical electrodes that exhibit enhanced conductivity, minimized impedance, and improved mechanical adhesion to the underlying metal substrate. However, it has been observed that PEDOT does not adhere adequately to the metal substrates [4]. In this work the main strategy employed for enhancing adhesion is etching the substrate.
The Ni-P/Cu electrodes were prepared through electroless plating, and applied gold and PEDOT layers onto the Cu electrodes. The deposition of PEDOT onto the electrodes was achieved using galvanostatic chronopotentiometry (CP) electropolymerization, gradually transforming the electrodes into a dark blue colour. The chronoamperometric method yielded PEDOT films that were uniform and consistent across the electrodes. To analyze and characterize the PEDOT coatings on both Ni-P/Cu and Au/Ni-P/Cu electrodes, several techniques were employed, including electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV) in a phosphate-buffered saline solution (PBS), X-ray photoelectron spectroscopy (XPS), and scanning electron microscopy (SEM). The adhesion of the coatings to the substrate was evaluated through sonication and a tape test, demonstrating their robustness and strong adherence. Furthermore, the electrochemical and mechanical stability of the PEDOT material, doped with LiClO4, on the metal electrodes was successfully demonstrated by optimizing the conditions of the electro-polymerization process and pre-treatments of the substrates.

8:00 PM EL18.04.11
Advanced in *Operando* Atomic Force Microscopy Studies of the Gating Mechanisms at Metal Oxide Ion-Gated TransistorsLuanP. Camargo[1,2], LarielC. Neres[1,3], MartinS. Barbosa[4], RaminKarimi[1], JoseR. Herrera[1] and ClaraSantato[1]; [1]Polytechnique Montreal, Canada; [2]State University of Londrina, Brazil; [3]State University of São Paulo (UNESP), Brazil; [4]Federal University of Goias, Brazil

Characterization of interfaces by advanced techniques *in operando*, including Atomic Force Microscopy (AFM), are gaining significance in the scientific investigation of electrochemical devices since they permit to follow materials' dynamics, which in turn are linked to device performance.
Ion-Gated Transistors (IGTs) enable the modulation of electronic conductivity in a semiconducting channel upon the application of an electrical bias between the channel material and the gate electrode, through an ionic medium. Metal oxides such as WO_3 and TiO_2 as channel materials interfaced with ionic liquids, such as 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIM][TFSI]), shows great promise for low-power, large-area electronics but also, at the fundamental level, the study insulator-to-metal transitions. The presence of Li^+ ions in the ionic liquid can enhance the versatility of IGTs in terms of the degree of doping and time response [1,2].
The doping mechanisms establishing the effectiveness of the ion gating mechanism are not well understood. Gaining insight into the structure of the electric double layer (EDL) forming at the channel ionic medium interface is expected to advance such understanding.
We report on a nanoscale study at interfaces between WO_3 and TiO_2 films and ionic liquids, possibly including Li ions, by AFM, force-distance profiling. The aim of the study is to shed light on phenomena and processes such as ion layering, ion packing density and shrinking, and ion reorientations. Scanning probe studies have been paralleled by computational efforts (Molecular Dynamics, MD). AFM force-distance profiling in conjunction with simulation methods, allows the characterization and understanding of the structure of the EDL and its evolution with the applied bias, thus permitting optimizing device performance.

8:00 PM EL18.04.12
Investigating Doping/Dedoping Processes in Electropolymerized Organic Mixed Ionic-Electronic Conductors MeijingWang[1,2], JanineMauzeroll[2] and FabioCicoira[1]; [1]Polytechnique

Montréal, Canada; [2]McGill University, Canada

Organic electrochemical transistors (OECTs) based on organic mixed ionic-electronic conductors (OMIECs), which possess both electronic and ionic transport capabilities, have shown promising application potentials in bioelectronics. [1] OECTs utilize the reversible doping/dedoping properties of active OMIEC channel materials by applying a gate voltage across the electrolyte to modulate the channel conductance. [2] Although there has been extensive research to understand the working principle which involves mixed ionic and electronic transport, the study on the fundamental understanding of ionic transport and injection/ejection is still limited. For example, in one of the model OMIECs, poly(3,4-ethylenedioxythiophene) (PEDOT) doped with organic polyanions poly(styrenesulfonate) (PSS), the dedoping mechanism is believed to be mainly due to the insertion of cations from the electrolyte to the PEDOT:PSS film. However, when small anion-based dopants, such as ClO_4^- and BF_4^-, are used in the PEDOT system, the anions may be released from the material to the electrolyte. [2] The doping/dedoping mechanisms are therefore becoming more complicated. To better understand these doping/dedoping processes, we utilized an *in situ* film fabrication method, electropolymerization, to prepare PEDOT-based films with various dopants, such as PSS^-, ClO^- and BF_4^-. This approach allows the material properties to be readily adjusted by controlling the dopant type, dopant concentration, and other electropolymerization parameters [3]. The polymer films were deposited on the source and drain electrodes and grow gradually to cover the gap in between. The effects of dopant type, concentration, and deposition time on the performance of OECTs were systematically studied. Next, the electrochemical quartz crystal microbalance (EQCM), which can monitor the mass exchange between the film and electrolyte, was incorporated to explore the doping/dedoping behavior. Our work contributes to a deeper understanding of the ionic charge transport in small anion-doped OMIECs and the working mechanism of corresponding OECTs.

8:00 PM EL18.04.13
Dynamic Surface Phases Controlling Asymmetry of High-Rate Lithiation and Delithiation in Phase-Separating Electrodes BonhoKoo[1], JinkyuChung[1], JuwonKim[1], MartinZ. Bazant[2] and JongwooLim[1]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

Lithium-ion batteries (LIBs) are a cornerstone of modern energy storage systems due to their ability to store and release electrical energy as chemical energy. However, at high cycling rates, the conversion becomes irreversible, resulting in higher overpotential and decreased capacity. This is particularly pronounced during lithiation compared to delithiation and is a major challenge for electrodes undergoing phase transitions. Despite attempts to understand the root cause of this asymmetry, the impact of these electrochemical conditions on the dynamics and pathways of lithium ion insertion and extraction remains unclear.
In this study, we used *operando* X-ray microscopy to observe the surface and bulk Li compositions in [100]-oriented Li_xFePO_4 sub-micron particles over a wide range of currents, 0.07C-7C. We clearly visualised anisotropic and rate-dependent phase-transformation pathways, revealed how surface and bulk phase separation strongly depend on the direction and magnitude of the current, and thereby reconciled contradictions among existing models. The dynamical asymmetry between fast lithiation and delithiation is attributed to autoinhibitory (negative self-feedback on reaction rate) Li-rich and autocatalytic (positive self-feedback) Li-poor domains, respectively. These domains are stabilised in proximity to the active crystal surface, which is the origin of asymmetry in the overpotential and rate capability between fast lithiation and delithiation.
New insights on how dynamic phase transition controls the lithium ion transport kinetics can be applied to a variety of electrode materials undergoing phase transitions, such as $Li_{4/3}Ti_{5/3}O_4$ and $LiCoO_2$, Ni-rich $LiNiMnCoO_2$, $LiNiO_2$ etc., paving the way for improved performance and stability in future LIBs. Moreover, our study may also have applications in lithionic memristors that can store information by modulating the electronic conductivity of Li surface phases (*e.g.,* in LTO and LCO), which have to be visualised at the nanoscale.

The Role of Alky Spacers and Functionality in Polar Carboxylated Functionalized Polythiophene for High-Performance Organic Electrochemical Transistors ZeyuanSun[1] and BrianKhau[2]; [1]Lehigh University, United States; [2]The University of Chicago, United States

Side chain engineering of polar hydrophilic substituents on the mixed conductor backbones has been proved as a successful strategy in developing robust bioelectronic devices, including organic electrochemical transistors (OECTs). However, prevailing design principles rely heavily on the ethylene glycol moiety, limiting the ability to tailor chemistry to serve the vast application space for OECTs. In this work, we report a family of carboxylic acid functionalized polythiophenes, poly [3-(4-carboxyalkyl) thiophene-2,5-diyl], processing with a varying carboxyalkyl chain lengths (propyl, butyl, and pentyl) as a novel hybrid alkyl-polar side chain moiety. With the aid of a fully aqueous processing strategy, this family of material provides an opportunity for a comprehensive evaluation of both the length effect of alkyl spacer and the impact of carboxylic acid functionality on the electrochemical characteristics in aqueous environment. Our results show that longer alkyl spacers in carboxylic acid functionalized side chain yield disadvantages for achieving higher volumetric capacitance (C*), however, significantly reducing detrimental swelling, with P3C(Pe)T exhibiting a thickness change upon passive swelling of only +1.9%. By integrating these high-performance mixed conductors into planar OECT architectures, it has been found that polymer bearing with butyl spacer exhibits the highest performance (= 128.6 5.5), which render them as one of the best performing conjugated polyelectrolytes. By integrating these high-performance mixed conductors into both interdigitated and planar OECT architectures, material dependent properties were evaluated, including device performance and stability as well as geometry dependent effects. Furthermore, *in-situ* Raman spectroscopy and spectroelectrochemistry studies are also conducted which provide meaningful insights into structural reorganization and optical progression upon electrochemical doping/de-doping, yielding a molecular level understanding toward ionic-electronic coupling and device operation upon varying side chain length. Overall, through these extensive and methodical investigations, we were able to uncover distinct properties associated with the increased alkyl length in these carboxylated polythiophenes. Our study highlights that even minor alterations and structural variation in the side chain can have a significant impact on electrochemical, optical, microstructural, and electrical properties of a polymeric mixed conductor.

8:00 PM EL18.04.15
High-throughput microfluidic-assisted machine learning to investigate vertical phase separation of small molecule:polymer blend Jun HeeWoo and StevePark; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Solution-based thin-film processing has been deemed as a promising technology that enables the fabrication of various devices such as field-effect transistors (FETs), solar cells, and sensors in a cost-efficient, facile, and scalable manner. One key feature of solution-based processing is the tunability of the ink formulation, through which the thin-film coating process and device performance can be controlled. Also, blending solutions containing different solutes has been shown to significantly improve the performance of the resulting devices compared to that of their unmixed counterparts. When small molecule organic semiconductor is mixed with insulating polymer, bilayer structure can be formed by the induction of vertical phase separation during drying process, which yields drastically improved charge transport properties, and hence the transistor performance. Despite the advantage of having controllability of ink formation, there also exists the critical challenge of finding the ideal ink composition that yields optimum device performance amongst numerous possible compositions. To generate a thin-film large enough to conduct device testing, several to hundreds of microliters of solution is required. However, since precisely controlling the ink formulation at this volume is difficult, several milliliters of solution is typically prepared. Therefore, ink formula optimization is inevitably a highly time-consuming and resource-intensive process. Added on top of this issue is the fact that the coating process parameters (e.g., substrate temperature, coating speed) also changes the thin-film properties and therefore the device performance, resulting in orders of magnitude increase in the number of possible combinations of experimental parameters (e.g., different combinations of ink composition, substrate temperature, coating speed) that need to be tested. The sheer number of combinations renders it impractical to test all combinations. Hence, researchers typically resort to iterative experiments based on intuition and heuristic approach, which limits or prolongs the optimization process and results in poor understanding of process-performance correlations. Resolving this challenge involves addressing two important questions. Firstly, how can thin-films of varying combinations of experimental parameters (i.e., various experimental conditions, where condition refers to a set of specific values of parameters under which thin-film was formed) be made in a time-efficient and resource-efficient manner so that data can be collected rapidly and economically? Secondly, how can the correlation between experimental parameters and device performance be systematically analyzed without reliance on human intuition? In this work, microfluidic screening-embedded thin-film processing technique is developed, through which thin-films of varying ratios of small molecule semiconductor:polymer blend were simultaneously generated and screened in a time- and resource-efficient manner. The vertical phase separation of C8-BTBT and PS blend solution was demonstrated, and was shown to have relatively high transistor performance, owing to the high intrinsic mobility of C8-BTBT and high viscosity of PS-added solution. Moreover, utilizing the thin-films of varying combinations of experimental parameters, machine learning models were trained to predict the transistor performance. Gaussian Process Regression (GPR) algorithms tuned by Bayesian optimization showed the best predictive accuracy amongst the trained models, which enables narrowing down of the combinations of experimental parameters and investigation of the degree of vertical phase separation under the predicted parameter space. Our technique can serve as a guideline for elucidating the underlying complex parameter-property-performance correlations in solution-based thin-film processing, thereby accelerating the optimization of various thin-film devices in the future.

Vertical-Structure Improves The Strain Limit of OMIEC-Transistors ShileiDai, ZhongruiWang and ShimingZhang; The University of Hong Kong, Hong Kong

Organic mixed ionic-electronic conductors (OMIECs), also known as organic mixed conductors, such as PEDOT:PSS, are becoming increasingly important materials in various applications. One typical application is the development of organic electrochemical transistors (OECTs), which enable high sensitivity at low power consumption. PEDOT:PSS OECTs find significant applications in diverse fields, including brain-machine interfaces and ubiquitous wearable biosensing.

To enhance the robustness for skin-integrated applications, stretchable OECTs (sOECTs) have been developed [1]. However, most sOECTs require OMIECs films to possess good mechanical properties, which limit their use in this emerging area.

In this study, we introduce the design of vertical sOECTs [2]. The unique vertically sandwiched structure between the source, OMIEC channel, and drain electrodes enables significantly higher stretchability, surpassing the strain limit of OMIECs. sOECTs developed with this design can be stretched in arbitrary directions, making them suitable for a wide range of skin-interfaced bioelectronic applications.

Dual Gate Electrochemical and Transistors and Inverters based on WO3 for Improved Transconductance and Dynamic Response LuisPereira[1,2]; [1]FCT NOVA, Portugal; [2]AlmaScience, Portugal

Electrolyte-gated transistors (EGTs) and electrochemical transistors (ECTs) have received special attention over the last decade due to their advantages, deriving from using electrolytes as gate dielectrics. These include low operating voltages, printability and solution processability, low contact resistances, and the possibility of fabricating new device architectures. High driving currents due to electric double layer (EDL) capacitance (C DL) in EDL transistors (EDLTs) or 3D-channel formation in ECTs, complement the list and open routes for their application in biosensors, electrochemical logic gates, wearable electronics, or low-power consumption and flexible devices..
This work shows a novel architecture of ECTs based on the electrochromic material WO3. Introducing a fourth electrode behind the channel (Back-electrode -BE) stabilized drain current, as electrons can be channeled into the active layer for electrochemical reactions. Additionally, control over the ion movement in the channel and the electrolyte and, consequently over the occurring redox reactions is possible. As a consequence thereof, it was found that Von can be controllable through the applied voltage at the BE (VBE) and that VOn can be shifted from any negative VG up to 0 V and possibly beyond. The devices can be ‘programmed’ to work in normally-off (enhancement) or normally-on (depletion) mode. On-Off ratios of 10^5 and transconductances of 0.35 mS were achieved. Dynamic characterization with an asymmetric square (VG between -6 and 4 V) wave potential demonstrated On-Off ratios of 4 orders of magnitude for frequencies up to 1 Hz. Data suggests that the cut-off frequency lies way beyond that value. It was demonstrated that with precise control over VOn, electrochemical logic inverters with two identical devices are feasible, presenting very high and controllable gains. The possibility of keeping load and driver transistors respectively at normally-on and normally-off makes transistor sizing redundant. Further, with this transistor architecture, problems like small logic swings or small noise margins, usually related to enhancement-load inverters, can be counteracted.

8:00 PM EL18.04.18
Unraveling The Critical Hydration Effect on Size-Dependent and Ion-Specific Ion Pairing Inside Sub-1nm Graphene Nanoslits FanFeng, ZheLiu and DanLi; The University of Melbourne, Australia

The intriguing phenomena of ion pairing and salt aggregation inside two-dimensional nanoslits have recently been reported in experiments and numerical simulations, leading to the anomalous gate-voltage modulated ion transport and memoresistive properties. An in-depth grasp of the intricate mechanisms governing this ion pairing effect is imperative for engineering advanced materials with specific functionalities and heightened performance. Nevertheless, despite extensive investigations into the dielectric properties of confined water and its confining medium, a unified understanding of how ion-pairing effects are governed by the interplay of hydration effect and nanoconfinement has remained elusive.
This study delves into the ion pairing effect within sub-1nm graphene nanoslits and offers a novel insight into the mechanisms driven by hydration effects. Conducting atomic-level molecular dynamics (MD) simulations of alkali ion electrolytes within multilayered graphene membranes, we unveil a nuanced dependence on slit size and ion-specific behaviors influencing the ion pairing phenomenon, which are confirmed in our experiments. Furthermore, we conclude that the complicated dehydration and renormalization processes primarily determine the propensity for nanoconfined ion-pairing effects, by displaying a comprehensive analysis of the structural and energetic characteristics of water molecules within the hydration shells. We validate this mechanism by elucidating both slit-size and ion-specific effects: as the slit size decreases from 1nm to 7 Å, the structure of the hydration shell becomes increasingly ordered, resulting in a corresponding reduction in entropic free energy; on the other hand, the ion-specific effect is driven by distinct enthalpic changes associated with the formation of larger ion clusters, rather than the mere presence of individual ion pairs.

Ultrafast Dynamics of n-Type Organic Mixed Ionic-Electronic Conductors for Photoelectrochemical Transistor Applications ChristopherE. Petoukhoff[1], VictorDruet[1], LatifahAlmullah[1], NisreenAlshehri[1], CatherineDe Castro[1], SophieGriggs[2], MaryamAlsufyani[2], IainMcCulloch[2], SahikaInal[1] and FredericLaquai[1]; [1]King Abdullah University of Science & Technology (KAUST), Saudi Arabia; [2]University of Oxford, United Kingdom

Conjugated polymer-based organic mixed ionic-electronic conductors (OMIECs) have been widely employed as the active materials in the channel of organic electrochemical transistor (OECT) devices, which are ideal for electronic devices in aqueous media. Due to their ease of chemical functionalization, tunable softness, and flexibility, polymer OMIECs are uniquely suited for biological applications, where OECT devices are expected to play a major role. Although the photosensitivity of conjugated polymers has been widely studied and applied for solar cells, photodetectors, and photocatalysts, the light-sensitivity of polymer OMIECs has been largely underexplored in OECT devices. While there have been several reports on light-sensitivity of organic photoelectrochemical transistors (OPECTs) employing OMIECs, these have largely relied on incorporation of additional light-sensitive inorganic materials at the gate terminal. Very recently, we have demonstrated that a single *n*-type OMIEC can serve as the photoactive material in OPECT devices, without additional materials in the gate terminal [1]. We then demonstrated for a variety of different *n*-type OMIEC polymers that the intrinsic photosensitivity of the polymer is critically important for achieving large open circuit potentials, which must be balanced against the transconductance for the best performance of OPECT devices [2].

In this breaking news contribution, we discuss the origin of the photosensitivity of five different OMIECs. We combine doping-induced absorption (DIA), femtosecond transient absorption (TA), time-resolved photoluminescence (TRPL), and time-resolved THz (TRTS) spectroscopies to investigate the excited state dynamics. We compare the photoexcited species in dry, intrinsic OMIEC films and demonstrate that the instantaneous formation of intramolecular charge transfer (ICT) excitons is largely responsible for facilitating charge dissociation at interfaces, such as either at the ITO or electrolyte interface. We demonstrate that the exciton lifetime plays a critical role in determining the open-circuit potential of photoelectrochemical cells. However, the responsivity of OPECT devices is balanced by the dark transconductance, which is orders of magnitude larger for self-doped polymers, having conductivities on the order of 190 ohms-per-cm. Finally, we show that the exciton-to-charge conversion process is faster when the OMIEC is immersed in electrolytic solutions, which we attribute to the increased dielectric constant of the medium.

Navigating The Complex Hole-Transport Material Additive Cocktail: Doping Methodologies for Small-Molecule HTMs BenjaminVella, MadeleineMcRoberts, GraemeCooke and PabloDocampo; University of Glasgow, United Kingdom

Most organic molecular hole transporters used in perovskite solar cells require effective doping to reach conductivity values necessary to achieve maximum device efficiencies. This is typically achieved by incorporating a cocktail of additives including tert-butylpyridine, ionic salts (LiTFSI, $Zn(TFSI)_2$) and metal complexes (FK209) which results in the partial oxidation of the semiconducting material, introducing additional free holes within the HTL and thus providing effective hole transport. However, a detailed study of the relationship between doping level and the quantity of free holes within the matrix has not been carried out. Indiscriminately adding the same additive cocktail to different HTM systems can lead to sub-optimal doping and an excess of reactive substances within the film that can catalyse degradation mechanisms. In this study, we investigate a range of HTMs possessing amide or imine linker groups. Our research highlights that oxidation and doping are not synonymous, and while oxidation generally leads to doping, this is not always the case. In addition, we reveal the intricate relationship between the different additives and the doping mechanism as a function of the chemical structures used. We conclude that a ‘one size fits all’ approach to HTM doping can lead to the misdiagnosis of effectively oxidised molecules, and therefore propose spectroscopic techniques to monitor the efficacy of doping, promoting rational HTM design and expediting the characterisation of new

HTMs.

Regioregularity Effects on Mixed Conduction in a Glycolated Polythiophene DilaraMeli[1], EllaKelly[2], JoshuaTropp[1,3], RuihengWu[1] and JonathanRivnay[1,1]; [1]Northwestern University, United States; [2]Kalamazoo College, United States; [3]Texas Tech University, United States

Organic mixed ionic/electronic conductors (OMIECs) are a versatile class of materials that have found use in a wide variety of applications, from bioelectronics to neuromorphic computing. Much effort has been devoted in recent years to improve OMIEC performance, primarily focusing on systematic side chain and backbone engineering. Usually, novel OMIECs are characterized in organic electrochemical transistor (OECT) test beds from which the figure of merit, μC^* (mobility × volumetric capacitance), is extracted. μC^* is an attractive metric for comparison, as it scales with device dimensions. However, care must be taken to emphasize that μC^* is not only dependent on synthetic chemistry, but also processing conditions and operating electrolyte environments.

Most prominent high-performing OMIECs synthesized to date are only available at the lab scale, leading to large batch-to-batch variability. Such issues of replicability further hinder systematic structure-property studies. To this extent, we herein study a commercially available glycolated polythiophene OMIEC, P3MEEET. Previous work on this polymer has revealed strong dependence of μC^* on operating electrolyte environment, an effect found to also be molecular weight dependent. It was shown that doping occurred with cation expulsion in KTFSI electrolytes, but via traditional anion uptake in NaCl electrolyte. This had dramatic impacts on charge percolation, which ultimately resulted in large observed differences in mixed conductivity.

To further probe the interplay between microstructure and electrolyte choice, we study regiorandom (RRa) and regioregular (RR) P3MEEET operated in two model electrolytes, aqueous KCl and KTFSI. Surprisingly, we observe little difference in μC^* for as-cast microstructures between the RRa and RR polymers. GIWAXS of as-cast RRa films reveals strong lamellar diffraction and DSC shows distinct side-chain melting. RRa P3MEEET is found to preferentially order edge-on, while the RR polymer shows more distinct face-on scattering. We further conduct electrochemical quartz crystal microbalance (EQCM) measurements to probe doping kinetics in both polymers.

Studies of post-processing treatments on other RR glycolated polythiophenes, in particular annealing, have previously been shown to dramatically affect swelling and thus mixed conduction. Here, we find strong dependence of μC^* on structural changes when operated in KCl electrolytes, whereas in KTFSI electrolytes μC^* appears relatively unchanged given the same post-processing conditions. In particular, annealed RRa polymers in KCl show improved performance, whereas RR polymers exhibit a decrease in μC^*. For the RRa polymer, this enhancement is primarily driven by an increase in C* due to annealing, which is in contrast to the RR polymer which experiences a decrease in C^*.

In summary, we find that post-processing tunes mixed conductivity differently given differences in polymer regioregularity. However, these effects are also dependent on electrolyte environments, further emphasizing that μC^* must be treated as a system figure of merit.

Controlling Volume and Mechanical Properties of Polythiophenes via Electrochemical Doping EleniStavrinidou; Linkoping University, Sweden

The properties of organic mixed ionic-electronic conductors such as conductivity, volume and even mechanical properties can be tuned via electrochemical doping. These dynamic processes rely on exchange of ions with the surrounding electrolyte combined with injection or extraction of electronic carriers through the addressing electrode. Polythiophenes with glycol side chains are single component OMIECs where the glycolated chains facilitate the ion transport. We demonstrated that a polythiophene with tri-ethylene glycol side chains reversibly expands by 300% upon electrochemical addressing, relative to its previous contracted state, while the first irreversible actuation can achieve values of 10000%, outperforming any other conjugated polymers. Here I will present our findings on how the molecular structure impacts the volume change based on a study with series a of polythiophenes that differ in the length and/or in the distribution of the ethylene glycol side chains. Furthermore, I will discuss the effect of the electrolyte and molecular design not only on the volume change but also on the mechanical properties of the polymer. Molecular Dynamics also provide insight on the mechanisms involved at the nanoscale correlating the volume changes with ion and water molecule intercalation to the polymer matrix as well as conformational changes of the polymer chains. Finally, I will preset our results on applying these materials for dynamic microfiltration and drug delivery.

Magnetic Resonance Studies of Highly Doped Polymeric Semiconductors TarigMustafa, Dionisius Hardjo LukitoTjhe, IanJacobs, XinglongRen, YaoFu, ClareP. Grey and HenningSirringhaus; University of Cambridge, United Kingdom

Doped organic semiconductors have proved attractive for future device applications such as thermoelectrics, bioelectronics and spintronics. At low doping levels, coulombic trapping of intercalated counter ions is believed to limit charge transport while at high doping levels conductivity is limited by disorder in the material.[1] However, a more detailed understanding of the couplings between the charge/spin carrying polarons of these materials and their environment remains sought after. Work has been done to understand such interactions in undoped materials by means of field induced Electron Spin Resonance (ESR) and has yielded valuable insight into the intimate couplings between charge, spin and structural dynamics.[2] Here, we extend that work to the study of systems systematically doped in-situ by means of an electrochemical transistor architecture and investigate the effects of interactions between polarons and with the counterions as function of temperature and varying doping levels. We complement the ESR measurements with Nuclear Magnetic Resonance (NMR) characterisation which has been shown to be a powerful technique for characterising ion dynamics in polymeric semiconductors.[3] We therefore use NMR to understand ionic motion and interactions in these systems and explore how they could impact the electronic properties of the material.

Mixed Electron-Ion-Solvent Transfer in Conjugated Polymers Monitored using Quartz Crystal Microbalance with Dissipation Monitoring RatulThakur and JodieLutkenhaus; Texas A&M University, United States

Conjugated polymers have promising applications in electronics and energy storage due to the polymer's tunable conductivity and redox activity. For example, the conductivity of poly(3-hexylthiophene) (P3HT) is heavily dependent upon the doping level and the dopant type. This feature becomes especially important when considering P3HT or similar conjugated polymers for devices that require switching between electronic states (conductive vs insulating). In this study, the mechanism of mixed ion-electron transfer studied using electrochemical quartz crystal microbalance with dissipation monitoring (EQCM-D) is discussed for P3HT and poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS). During cyclic voltammetry and galvanostatic charge-discharge experiments, the mass change of the polymer film is monitored in real time. Distinct mass transfer regions are quantified as a function of doping level and potential, which are then correlated to changes with *in situ* conductance and spectroelectrochemical response. To identify the time scale at which the doping reaction transitions from kinetic to diffusion control, electrochemical impedance spectroscopy is coupled with EQCM-D. Combinging these insights with an electron and mass balance on the process, the number of solvent molcules per ion are estimated. This work gives valuable insight into the nature of mixed ion-electron transfer, including its time scale, as it relates to the electronic properties of conjugated polymers.

9:45 AM EL18.05.04
Ion Trapping and Induced Ordering of Regiorandom Poly(3-hexylthiophene) upon Repeated Electrochemical Doping SethJackson, RandKingsford, GarrettCollins and ConnorG. Bischak; University of Utah, United States

Conjugated polymer organic mixed ionic electronic conductors (OMIECs) are promising materials for bioelectronics and other organic electronic devices. How these materials behave with repeated electrochemical doping matters for the stability and longevity of these devices. In this work, we employ a combination of grazing incidence wide-angle X-ray scattering (GIWAXS), UV-vis spectroelectrochemistry, and nanoscale imaging of the ions with photoinduced force microscopy (PiFM) to monitor film morphology changes in regiorandom poly(3-hexylthiophene) (RRa P3HT) when exposing the polymer film to various aqueous electrolytes upon repeated electrochemical doping. When using potassium bis(trifluoromethansulfonyl)imide (KTFSI) as our electrolyte, we see increased ion trapping and an increase in crystalline order in RRa P3HT, as well as the crystallization of $TFSI^-$ ions, upon repeated electrochemical doping. Upon thermal annealing at 120 °C after continuous doping of RRa P3HT with $TFSI^-$, we see a significant increase in lamellar stacking intensity compared to the film without thermal annealing. When comparing less chaotropic ions to $TFSI^-$, we see these ions do not order RRa P3HT to the same extent as $TFSI^-$. Overall, this study shows that both ion trapping and structural reorganizations occur in disordered conjugated polymers upon repeated electrochemical cycling.

Improvement of the Electrical, Mechanical and Adhesive Properties of PEDOT:PSS JianyongOuyang; National University of Singapore, Singapore

Poly(3,4-ethylenedioxythiophene):Polystyrene sulfonate (PEDOT:PSS) is a popular mixed ion-electron conductor, and it can have important application many areas. However, its electrical. mechanical and adhesive properties must be greatly improved for the practical application in some areas. Here, I will present some of our methods to signifiantly improve the electrical, mechanical and adhesive properties. We also demonstrate their application in wearable/flexible electronics.

11:00 AM EL18.06.02
Tailored Design of Mixed Ionic-Electronic Conductors for both P-Type and N-Type OECTS MukundanThelakkat[1,2], AdrianHochgesang[1], AndreasErhardt[1], GertKrauss[1], FlorianMeichsner[1] and PhilipSchmode[1]; [1]University of Bayreuth, Germany; [2]Bavarian Polymer Institute, Germany

Mixed ionic electronic conductors (MIECs) were designed by various strategies of polymer architecture. For all materials, Cyclic voltammetry (CV), spectroelectrochemistry (SEC), ultraviolet photoelectron spectroscopy (UPS), Ultraviolet-Visible (UV-Vis) absorption spectroscopy, and organic field effect transistor (OFET) characterization were carried out and these properties demonstrate the suitability for OECT (organic electrochemical transistor) devices.
For p-type OECTs, conjugated polyelectrolytes and their copolymers based on polythiophene family was first designed and studied [1-2]. The concept was extended to hydrophilic polythiophenes carrying different oligoethylene glycol (OEG) substituents [3]. The advantage of the latter class is that no crosslinking is necessary to prevent the thin films from delamination. The concept of OEG substitution and the required degree of OEG substitution was further applied in the class of poly(diketopyrrolopyrrole) copolymers using different comonomers [4]. For this, four Polydiketopyrrolopyrroles (PDPPs) with increasing ethylene glycol (EG) content and varying nature of comonomer were synthesized. The studies of these hydrophilic PDPPs in NaCl electrolyte-gated OECTs reveal that a high amount of OEG on the DPP moiety is essential for MIEC. The PDPP containing 52 wt.% EG exhibits a high volumetric capacitance of 338 Fcm^{-3} (at 0.8 V), a high hole mobility in aqueous medium (0.13 $cm^2V^{-1}s^{-1}$) and a μC* product of 45 $Fcm^{-1}V^{-1}s^{-1}$. OECTs using this polymer retained 97 % of its initial drain-current after 1200 cycles (90 min of continuous operation). In cell-growth medium, the OECT-performance was fully maintained as in NaCl electrolyte. In vitro cytotoxicity and cell viability assays reveal the excellent cell compatibility of these novel systems, showing no toxicity after 24 h of culture. Due to the excellent OECT performance with a considerable cycling stability for 1200 cycles and an outstanding cell compatibility, these PDPPs render themselves viable for in vitro and in vivo bioelectronics.
For the n-type OECTs, two different classical acceptor motifs diketopyrrolopyrrole (DPP) and thienopyrrolodione (TPD) are copolymerized to yield the acceptor-acceptor polymer, Poly(DPP-TPD) [5]. The fundamental design idea is to maximize the electron affinity, thus increasing the ambient stability of the reduced state against oxygen and water while ensuring high ion compatibility through the incorporation of hydrophilic oligoethylene glycol N-substituents. Additionally, a highly planarized polymer structure is anticipated, due to the extended non-covalent interactions (conformational locking) between the carbonyl oxygen and the thiophene protons. The acceptor-acceptor system poly(DPP-TPD) for n-type devices exhibit high electron affinity (EA), and good electron mobility ($\mu_{e(OFET)}$), in addition to the electrochemical reduction of polymer films in aq. electrolyte. In n-type OECTs, poly(DPP-TPD) demonstrates a moderate threshold voltage of Vth = 0.58 V, and an outstanding μC* value of 7.62 F cm^{-1} V^{-1} s^{-1}. Cycling studies consisting of pulsed on- and off-switching of the device at gate voltages between Vg = 0.6 - 0.8 V in the saturation regime reveal high stability for more than 2700 cycles with rapid switching kinetics.

11:15 AM EL18.06.03
Mechanically Adaptive Mixed Ionic-Electronic Conductors Based on a Polar Polythiophene Reinforced with Cellulose Nanofibrils YoungseokKim[1], MarizaMone[1,2], SozanDarabi[1,2], SepidehZokaei[1], LovisaKarlsson[1], MariavittoriaCraighero[1], SimoneFabiano[3,4], ReneeKroon[3,4] and ChristianMüller[1,2]; [1]Chalmers University of Technology, Sweden; [2]Wallenberg Wood Science Center, Chalmers University of Technology, Sweden; [3]Linköping University, Sweden; [4]Wallenberg Wood Science Center, Linköping University, Sweden

Conjugated polymers with oligoether side chains are considered as one of the promising active materials for organic electrochemical devices due to their ability to facilitate mixed ionic-electronic conduction in the electrolyte. However, they tend to have a low glass transition temperature and, consequently, a low elastic modulus, which prevent their use if mechanical robust materials are required. Carboxymethylated cellulose nanofibrils (CNF) are found to be a suitable reinforcing agent for a soft polythiophene with tetraethylene glycol side chains. Dry nanocomposites feature a Young's modulus of more than 400 MPa, which reversibly decreases to 10 MPa or less upon passive swelling through water uptake. The presence of CNF results in a slight decrease in electronic mobility but enhances the ionic mobility and volumetric capacitance, with the latter increasing from 164 to 197 F cm^{-3} upon the addition of 20 vol% CNF. Overall, organic electrochemical transistors (OECTs) feature a higher switching speed and a transconductance that is independent of the CNF content up to at least 20 vol% CNF. Hence, CNF reinforced conjugated polymers with oligoether side chains facilitate the design of mechanically adaptive mixed ionic-electronic conductors for wearable electronics and bioelectronics.

11:30 AM EL18.06.04
Engineering Response Time and Synaptic Behavior of Organic Ion-Gated Transistors Through Structural Modifications RaminKarimi[1], ZhaojingGao[1], Afzal-AhmedDar[1], LarielC. Neres[1,2], PatrickDang[1] and ClaraSantato[1]; [1]Polytechnique Montreal, Canada; [2]State University of São Paulo (UNESP), Brazil

The von Neumann architecture was designed for processing tasks serially. The amount of data produced in the present *intelligent* era renders this architecture unable to keep up. As a result, new solutions, such as neuromorphic parallel computing, are being developed to increase data storage and processing speed. There are concerns, however, about the sizes of the chips composed of synaptic transistors and their parallel computing capacity.
In this work, we present the effect of poly (3-hexylthiophene) (P3HT) film thickness on the synaptic behavior and response time of ion-gated transistors (IGTs) based thereon. The P3HT films' thickness varies from 50 to 300 nm. The drain-source current, I_{ds}, and charge carrier mobility increase with thickness, likely due to an increased degree of crystallinity in the films with the thickness. The presence of crystalline domains is expected to increase the de-doping time (time to remove the anions from the p-type P3HT channel). In turn, this increases the transistor response time and permits to achieve transition from short-term plasticity (STP) to long-term plasticity (LTP). Further, increasing the thickness of the channel increases the plasticity and

paired-pulse facilitation (PPF) index.
The molecular weight (MW) is another parameter that we consider to control synaptic functions and response time. The XRD patterns of films obtained from three different MW, low (ca. 24 kDa), intermediate (ca. 42 kDa), and high (ca. 91 kDa), show that the degree of crystallinity decreases with increasing MW. This is expected to strongly affect ion permeability, and therefore the advancement of doping and redistribution time of anions.
In conclusion, we propose a methodology to control the response time and synaptic functions of IGTs with changing P3HT MW at constant film thickness or varying the thickness of channel fixing MW.<quillbot-extension-portal></quillbot-extension-portal>

11:45 AM EL18.06.05
Surface Functionalization for High-Performance and Water-Stable PEDOT:PSS Thin Films for Bioelectronics PeterO. Osazuwa, AbigailNolin, Chun-YuanLo, XuFeng, CharlesDhong and LaureV. Kayser; University of Delaware, United States

Organic mixed ionic-electronic conductors such as poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) have attracted attention as materials for the fabrication of organic electrochemical transistors (OECTs) for bioelectronics. The PEDOT:PSS dispersions are typically blended with (3-glycidyloxypropyl)trimethoxysilane (GOPS) before spin-coating to ensure strong adhesion of the films to device substrates and maintain their long-term stability in aqueous solutions. However, blending with GOPS changes the morphology of PEDOT:PSS films, affecting their electrical properties and significantly reducing the performance of OECTs. Here, we functionalized the surface of the substrates with GOPS to introduce a silane monolayer with epoxy groups before spin-coating PEDOT:PSS. The resulting films were compared to those obtained by blending and showed similar long-term stability in aqueous solutions under passive conditions and electrochemical cycling. However, the surface functionalization approach led to increased electronic conductivity (2650 ± 467 S cm^{-1}), higher transconductance (24 ± 4 mS μm^{-1}), and [μC^*] value (376 ± 74 F cm^{-1} V^{-1} s^{-1}) in OECT devices, and larger volumetric capacitance (109 ± 5 F cm^{-3}). Detailed characterization using time of flight secondary ion mass spectrometry (TOF-SIMS), atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS) confirmed that the silane crosslinker was not present in the bulk of the film which allowed an increased phase separation between PEDOT and PSS, and the formation of enlarged PEDOT-rich domains. We expect that this study will strengthen the case for the functionalization of substrates with GOPS instead of the conventional blending approach for the development of stable films in water and high-performance organic mixed ionic-electronic conductors for biological interfaces.

Operando Experiments and Continuum Modeling of Mechanical Breathing and Multiphysics Coupling in Organic Mixed Ionic-Electronic Conductors KejieZhao; Purdue University, United States

Organic mixed ionic-electronic conductors (OMIECs) are the core functioning component in electrochemical devices such as organic electrochemical transistors (OECTs) and bioelectronics owning to their unique capability of mixed conduction. In electrochromic polymers, the cyclic redox reaction is associated with a mechanical breathing strain, which deforms the OMIECs and degrades the device reliability. We measure the breathing strain, the evolution of the mechanical properties of electrochromic thin films, and mechanical damage using customized environmental nanoindentation. Further, we formulate a continuum theory following the thermodynamics framework to describe the concurrent transport of charge carriers, mechanical swelling, and phase separation in the OMIEC. The free energy consists of contributions from the deformation of the polymer chains, the mixing of the polymer with salts and solvents, the electrostatic field, and the two-phase interfaces. We implement the theory into a finite element model and study the mechanics and electrochemistry of the OMIEC channel in an electrolyte-gated OECT. The computational model replicates the electrochemical performance of an OECT which agrees well with the experiments. Overall, this work provides a basic understanding of electrochemical and mechanical behaviors of organic mixed conductors.

1:45 PM EL18.07.02
Modelling the Performance of a Novel Mixed Ionic-Electronic Conductor Based on $SmCoO_3$NoraH. de Leeuw; University of Leeds, United Kingdom

One of the main challenges facing solid oxide fuel cell (SOFC) technology is the need to develop materials capable of functioning at intermediate temperatures (500-800°C), thereby reducing the costs associated with SOFCs. Here, a novel SOFC cathode material is presented, predicted through a holistic approach of a combination of complementary computational techniques to optimise the material properties. This approach is transferrable to any material optimisation problem and allows the effect of A/B-site doping to be understood, on the scale of the individual property, but also the device as a whole. The electronic, magnetic, and physical properties as well as the thermal behaviour of $Sm_{0.75}A_{0.25}Co_{1-x}Mn_xO_{2.88}$ (A = Ca, Sr; x = 0.125, 0.25) is systematically described, showing important trends and correlations that are directly coupled to its potential practical application in sustainable energy generation. The magnetic and electronic structures of these materials were directly coupled to the electronic conductivity, a finding that is applicable to other perovskite systems and to the wider energy materials community. Furthermore, evaluating the ionic conductivities of $Sm_{0.75}A_{0.25}Co_{1-x}Mn_xO_{2.88}$ (A = Ca, Sr; x = 0.125, 0.25), a distinct improvement is identified in comparison to both $SmCoO_3$ and the traditional cathode material strontium-doped lanthanum manganate. By coupling the electronic and ionic conductivity properties to the thermal expansion coefficients, we have shown that this material is compatible with traditional SOFC electrolytes. Combining all these insights from density functional theory calculations and molecular dynamics simulations strongly suggests that $Sm_{0.75}A_{0.25}Mn_{0.25}Co_{0.75}O_{2.88}$ possesses the necessary properties that are desirable in an efficient intermediate temperature SOFC cathode material.

2:00 PM EL18.07.03
Proton and Small Polaron Association and Migration in $H_xV_2O_5$, $H_xTa_2O_5$, H_xMoO_3, H_xWO_3PjotrsZguns and BilgeYildiz; Massachusetts Institute of Technology, United States

Neuromorphic computing based on electrochemical random access memory (ECRAM) enables low-energy computing and nanosecond timescale operation [1–3]. The nanosecond switching relies on fast proton and small polaron diffusion in the working channel materials, transition metal oxides. Here we investigate the fundamental limit of mixed proton–polaron diffusion in $H_xV_2O_5$, $H_xTa_2O_5$, H_xMoO_3, and H_xWO_3 by means of first-principles calculations. We apply the DFT+*U* method to describe the electronic structure and polaron localization in the host oxide lattice. By investigating various spatial arrangements of these defects, we identify the ground state configuration of the proton–polaron. We probe microscopic factors that control carrier mobility, *viz*. the migration barriers and proton–polaron association energy (*i.e.*, the energy required to break the pair). Our results indicate that the polaron migration barrier is comparable to the association energy (in V_2O_5, on the order of 0.1 eV–0.2 eV), highlighting that the attraction between polarons and protons plays an important role in diffusion. Altogether, these computations will help us to identify the most suitable oxide for nanosecond switching of ECRAM devices.

Influence of Chemical Structure on Properties of Mixed Conducting Conjugated Polymer Electrodes JennyNelson[1], NicholasD. Siemons[1], HangYu[1], IonaAnderson[1], SachetanTuladhar[1] and AlexanderGiovannitti[2]; [1]Imperial College London, United Kingdom; [2]Chalmers University, Sweden

Organic mixed electronic and ionic conductors based on conjugated polymers with polar side chains are attractive candidates for electrodes in electrochemical devices. Their electrochemical and redox properties can be tuned through choice of polymer backbone and side chain [1, 2] while the processible nature of the polymer materials facilitates both manufacture and recycling. When applied as electrodes in electrochemical energy storage devices, conjugated polymer electrodes show excellent charging and discharging rates, high coulometric efficiency and compatibility with simple aqueous electrolytes. However, their specific capacity and their operational stability need to be improved [3]. In this work, we use electrochemical measurements and modelling to investigate the relationship between polymer chemical structure and the redox properties, charging behaviour and cycling stability of the polymer electrodes. We focus on the

effect of side chains, since small changes in side-chain composition or structure can significantly influence the electrode properties. We use molecular dynamics simulations for series of polymers, to investigate how the side chain polarity influences polymer packing [4]; how the composition of mixed polar and non-polar side chains influences film swelling and stability; how backbone and side-chain structure influence electronic transport properties; and how polymer-ion interactions depend on the ion type. Finally, we consider design strategies for enhancing specific capacity. The findings can help to develop chemical designs for improved conjugated polymer electrodes for aqueous environments.

3:15 PM EL18.08.01
In-Plane Orientation of Organic Mixed Ionic-Electronic Conductors to Enhance Charge Transport Properties IsabelleHolzer[1], DemetraTsokkou[1], ShubhradipGuchait[2], BadrJismy[2], MartinBrinkmann[2], NicolasLeclerc[2] and NatalieBanerji[1]; [1]University of Bern, Switzerland; [2]CNRS University of Strasbourg, France

Organic mixed ionic-electronic conductors (OMIECs) are perfectly suited to interface biology and electronic devices as they enable both ionic and electronic transport; feature mechanical flexibility; can be successfully fabricated in versatile processing conditions; and are synthetically tunable.[1] While most recent progress in bioelectronics has been focused on device fabrication and comparing performance of different materials, there is still a lack of a more in-depth understanding of the fundamental processes occurring in functioning OMIECs.[2] The charge transport is happening mainly on the π-conjugated backbone of the organic semiconductor, while ions penetrate the bulk material. In PBTTT, a polymer with high charge-carrier mobility, ion uptake in the polymer matrix can be facilitated by incorporating alkyl side chains with an ether group, further improving the performance.[3,4] Therefore, in this study we use high temperature rubbing to orient PBTTT-^{8}O films helping to unravel the fundamental processes of both the charge and ion transport. For comparison the same experiments were carried out with an OMIECs model material P3HT, which was already characterized by multiple different research groups.[5]
Combining electrochemical and chemical doping with spectroscopic techniques and chronoamperometry the oxidation behavior of the OMIECs was investigated. Foremost, with *in-situ* terahertz (THz) spectroscopy we can detect the scattering frequencies of charge carriers in semiconductors, this allows us to get the intrinsic nanoscale conductivity and short-range mobility of the studied OMIECs, which is not affected by any grain boundaries or electrodes. The analysis of the complex THz conductivity unveils the mobility and density of charges altogether. We were able to get conductivities of more than 1000 Scm^{-1} for P3HT and PBTTT-^{8}O for electrochemical doping. Furthermore, with chemical doping conductivities of more than 2000 Scm^{-1} were obtained and band like transport behavior was observed for PBTTT-^{8}O, showing the large effect of high in plane orientation of OMIECs.

Blend-Based Organic Electrochemical Transistors GittiL. Frey; Technion - Israel Institute of Technology, Israel

Organic electrochemical transistors (OECTs) are building block devices for applications in a variety of fields including bioelectronics, energy storage, mechanical actuators, sensors etc. OECTs utilize organic mixed ionic-electronic conductors (OMIECs) and rely on the injection/extraction of ions from an electrolyte into an OMIEC material to modulate its bulk conductivity. Recently, we introduced a new strategy for the design of OECTs where the bulk includes a blend of two OMIECs endowing the device with multifunctionality. For example, we demonstrated that judicious selection of p- and n-type OMIECs and optimization of the blend ratio can lead to a fully balanced ambipolar OECT where both ions and cations are modulated in a single device. A variety of characterization methods including optical and impedance spectroscopy, x-ray diffraction, and device measurements were used to gain insights on the structure-property relationships in the system. The blend strategy was further extended to offer multifunctional performance by blending components that operate in different conditions such as solvents, temperature, and ions. To study multifunctionality in OECTs we used a series of judicially synthesized non-fullerene small molecules and blended each with a commercial n-type mixed conducting polymer. We investigated the effects of blend composition, electrolyte and ion type, and thermal treatments on the electrochemical performance using spectro-electrochemistry, cyclic voltammetry, electrochemical quartz crystal microbalance, and OECTs. The blends were also characterized using X-ray scattering and electron microscopy to reveal film morphology. We find that the small differences in the structure of the small molecules have significant effects on both the morphology and the electrochemical performance of the blends. For example, ion selectivity and reversibility can be modulated by the type and composition of the blend. A better understanding of these systems will allow us to design a new generation of materials and device structures for multifunctional bioelectronic applications.

4:00 PM EL18.08.03
Influence on the Performance of Organic Electrochemical Transistors of PEDOT:PSS Blends with Polyethylene Oxide of Different Molecular Weight Chun-YuanLo[1], LucasFlagg[2] and LaureV. Kayser[1]; [1]University of Delaware, United States; [2]National Institute of Standards and Technology, United States

The addition of polyethylene oxide (PEO) to organic mixed ionic-electronic conductors, such as PEDOT:PSS, is commonly done to increase biocompatibility, hydrophilicity, or stretchability. In particular, when blended with PEDOT:PSS, PEO has been shown to change the microstructure of the thin films. In this study, we were interested in the effect of PEO on mixed ionic-electronic transport properties, particularly when the films are immersed in aqueous solutions such as for organic electrochemical transistors (OECTs). PEO is water soluble and therefore could easily leached out of the films when immersed in water or an aqueous electrolyte. We studied PEO of two different molecular weights (MW), 400 Da (low MW) and 20,000 Da (high MW), in PEDOT:PSS:PEO blends at 5 wt% PEO in solution, and crosslinked with GOPS. We monitored the composition of the spin-coated films by X-ray photoelectron spectroscopy (XPS) over a period of 4 hours of immersion in water. We found that most, if not all low MW PEO is removed from the films after 2 hours of immersion, while for high MW PEO, nearly 50% was still present in the films with a stable concentration after 1-2 h. In both cases, we noted the removal of excess PSS in the films, which is common for PEDOT:PSS immersed in water. The removal of PEO and PSS following water immersion was also confirmed by a significant reduction in film thickness, as measured by profilometry and atomic force microscopy. We then performed transconductance measurements on OECT devices to extract the mobility-capacitance product, [μC*], of our PEDOT:PSS formulations. In all cases, without PEO, or with low or high MW PEO, the transconductance increased significantly after immersion in water, consistent with the removal of insulating material. What was more surprising, however, was a much higher [μC*] when low MW PEO was used as an additive and then removed by soaking in water. The [μC*] values obtained, which have yet to be validated externally, are higher than those obtained when doping with ethylene glycol and close to that of previously reported crystalline PEDOT:PSS obtained by sulfuric acid treatment. We are still exploring the exact reasons for this increase, but it seems to stem from both an increase in the charge mobility and volumetric capacitance (up to 129±22 F cm^{-3}). GIWAXS measurements did not indicate a change in film crystallinity, but spectroelectrochemistry revealed a higher charge density which is consistent again with the removal of PSS and PEO from the films. This study provides an avenue towards improving the performance of PEDOT:PSS electrodes without using sulfuric acid. We also hope to encourage others to study the fate of polymeric additives and small molecules in devices operating under aqueous conditions.

4:15 PM EL18.08.04
Phase Separation in Mixed Ionic and Electronic Conductors for Information Storage YiyangLi; University of Michigan, United States

Mixed ionic and electronic conductors (MIECs) enable vast changes in chemical composition induced by electrochemical currents and voltages. This electrochemically-induced change in chemical composition enables a substantial chemical capacitance, which can be harnessed for energy storage and emerging microelectronic devices. This change in composition can yield phase transformations and spinodal decomposition in MIEC materials due to materials thermodynamics. In this presentation, we show how this phase separation in metal oxide MIECs enables

the coexistence of multiple physical states that are identical in energy. By switching between these physical states, we can provide a thermodynamically nonvolatile form of information storage. We demonstrate this phenomenon in two types of memory cells: resistive memory and electrochemical memory. We anticipate that phase separation can be broadly generalized to other forms of MIECs.

SESSION EL18.09: New Materials and Characterization Tools for Mixed Ionic-Electronic Conductors

1:30 PM EL18.09.01
Understanding the Disparity Between Doping and Dedoping Kinetics in Organic Electrochemical Transistors with Operando Optical Microscopy JiajieGuo[1], ShinyaChen[1], RajivGiridharagopal[1], ConnorG. Bischak[1,2], JonathanW. Onorato[1], KangrongYan[3], ZiqiuShen[3], Chang-ZhiLi[3], ChristineLuscombe[4,1] and DavidS. Ginger[1]; [1]University of Washington, United States; [2]The University of Utah, United States; [3]Zhejiang University, China; [4]Okinawa Institute of Science and Technology, Japan

Organic electrochemical transistors (OECTs) operate via electrochemical doping, where an applied gate potential in an aqueous electrolyte modulates the channel conductivity through counterion injection into and explusion from the semiconducting polymer. This doping process, and the resulting current in OECT devices, is far from instantaneous and exhibits significant disparity between doping and dedoping kinetics. Existing models of device operation cannot explain the experimental observations that turn-off times are generally much faster than turn-on times in accumulation mode OECTs, yet this difference in kinetics has significant practical implications for devices where designing for optimal switching times is critical. We address this shortcoming through operando optical microscopy, where we directly image the local doping level of the transistor channel (in real time) in combination with device measurements to present a comprehensive view of the physical process. We use these microscopy data to show that device turn-on occurs in two stages, while turn-off occurs in one stage. We attribute the faster turn-off to a combination of engineering as well as physical and chemical factors including channel geometry, differences in doping and dedoping kinetics, and carrier density-dependent mobility. We further show that ion transport is limiting the device operation speed in our model devices. Our study provides insights into the asymmetric kinetics in OECTs and gives practical guidelines for rationally engineering faster OECTs.

Application Guided Design of Conjugated Polymers Towards Next-Generation Iono-Electronic Devices AristideGumyusenge; Massachusetts Institute of Technology, United States

Conjugated polymers, particularly organic mixed ionic-electronic conductors (OMIECs), continue to shine as promising conductors for applications requiring coupled conduction, particularly in bioelectronics. However, only a few mixed conductors are implemented in functional devices to date and a one-material-fits-all bottleneck continues to hamper rapid advancements. The challenge lies in the lack of a cross-disciplinary design approach for high-performance materials. Establishing the needed balance between the two antagonistic modes of transport (ion permeability and electronic charge transport) to yield high performance devices has not only become an exciting field of fundamental research, but also a conduit towards advanced electronics. My research group at MIT (the laboratory of organic materials for smart electronics, OMSE Lab) employs polymer modularity to design novel iono-electronic semiconductors. We employ an application-guided approach and create tailored structures for integrating into devices. In this talk, I will share our ongoing efforts in designing new semiconductors with varying degrees of ion-responsiveness and the scope of applications enabled by their molecular tuning. We utilize copolymerization as a facile route to yield a library of mixed conductors enabling a variety of applications ranging from rapidly switching electrochemical transistors to high-fidelity artificial synapses. We have shown that by systematically tethering polar side groups onto known excellent electron conductors, we can probe the contribution from both ionic and electronic conduction to the resulting device performance and determine suitable applications. We have also studied a hybridization strategy between different polymer components to yield extrinsic properties especially environmental robustness. This hybridization strategy has also shown effective for widening the scope of target analytes toward which our mixed conductors can respond, thus enabling new electronic designs.

2:15 PM EL18.09.03
***In-Situ* Characterization of Ordering/Disordering in Electrochemically Doped Oligo-Ether Sidechain Modified Polythiophenes**LeeRichter[1], LucasFlagg[1], MaximilianMoser[2], IainMcCulloch[2], JonathanW. Onorato[3] and ChristineLuscombe[4]; [1]National Institute of Standards and Technology, United States; [2]University of Oxford, United Kingdom; [3]University of Washington, United States; [4]Okinawa Institute of Science and Technology, Japan

Organic mixed ionic and electronic conductors (OMIECs) are a novel material class, emerging as potential enablers for devices as diverse as actuators, biosensors and neuromorphic computing. In an OMIEC, volumetric doping (gating) of the active material is achieved through ingress of electrolyte ions, under potential control. This opens unique transduction modalities due to the mixed (ionic and electronic) modes of conduction. However, the complex changes in film structure: swelling by both electrolyte and counter ion coupled with electrochemical doping, requires in-situ and in-operando measurements to develop quantitative process-structure-function relationships. Side-chain modification, typically by the introduction of oligoethylene glycol (oEG) units, of traditional semiconducting polymers, has emerged as a powerful paradigm for OMIEC material design. We have applied in-situ grazing incidence X-ray diffraction (GIXD) to the study of 3 oEG modified polythiophenes, p3MEEMT[1], p(g3T2) and p(g1t2-g5t2).[2] All are regio-regular, but differ in terms of the length of the oEG side chain (2 units for P3MEEMT, 3 units for p(g3T2), and up to 5 units for p(g1T2-g5T2)) and in repeat unit symmetry. While the optoelectronic properties of these polymers are similar, consistent with the common backbone, the swelling behavior of the polymers were notably distinct. With moderate thermal annealing, all polymers exhibit semicrystalline behavior, typical of polythiophenes, with an edge-on habit of pi-stacked lamella. When characterized in-situ we find a remarkable disordering of the p(g3T2) in the neutral, dedoped state. Effectively no diffraction can be observed. However, a degree of order comparable to that observed ex-situ (dry) is obtained upon doping. This severe doping induced ordering is similar to that observed in doped regio-random P3HT[3] and is consistent with the enhanced pi-pi interaction (evidenced by a decrease in the interchain separation) typically observed for doped polythiophenes. This electrolyte induced “melting” is also present in the asymmetric sidechain p(g1T2-g5T2) but is absent in the shorter side chain polymer. While significant effort has been placed on characterization of swelling in OMIECs, the observation of nominal melting of semicrystalline material has not been extensively discussed and may limit the oEG content. In general, order within the polymer is considered important to electronic transport [4] thus the doping induced ordering may be essential to the final device performance.

2:30 PMBREAK

3:30 PM *EL18.09.04
Tailoring Organic Semiconductors for Mixed Ionic and Electronic Transport ChristianNielsen; Queen Mary University, United Kingdom

The emerging research field of organic bioelectronics has developed rapidly over the last few years and elegant examples of biomedically important applications including for example in-vivo drug delivery and neural interfacing have been demonstrated.

The organic electrochemical transistor (OECT), capable of transducing small ionic fluxes into electronic signals in an aqueous environment, is an ideal device to utilise in bioelectronic applications. Initially, nearly all OECTs were fabricated with commercially available PEDOT:PSS, heavily limiting the variability in performance. We have previously shown that tailor-made semiconducting polymers are fully capable of matching the performance of PEDOT:PSS and over the last few years the library of mixed ionic-electronic conductors for OECT applications have expanded significantly. To capitalise on this development and the versatility of the organic chemistry toolbox, further materials development is needed. In my talk I will discuss our recent work in this area covering examples of both molecular and polymeric semiconducting materials and their performance in organic electrochemical transistors.

4:00 PM EL18.09.05
Nanoscale Mapping of Ions, Polarons and Bipolarons in Organic Mixed Conductors SethJackson, GarrettCollins and ConnorG. Bischak; The University of Utah, United States

Organic mixed ionic-electronic conductors have emerged as promising materials for biosensors, bioelectronics, neuromorphic computing, and electrochromics. These technologies all operate based on electrochemical doping of organic mixed ionic-electronic conductors, which are most commonly conjugated polymers. The locations of ions, polarons, bipolarons directly impact how electronic charge carriers move through the OMIEC matrix. Using photoinduced force microscopy (PiFM) with visible, near-infrared, and infrared wavelengths, we generate maps of ion,

polaron, and bipolaron densities with ~10 nm spatial resolution. In poly(3-hexylthiophene), we demonstrate using a combination of UV-vis spectroelectrochemistry, grazing incidence wide angle X-ray scattering (GIWAXS), nanoscale stiffness mapping, and PiFM, that ions and polarons reside preferentially in crystalline regions. We extend these initial studies to other OMIEC polymers with oligo(ethylene glycol) side chains to visualize the arrangement of ions, polarons, and bipolarons in the polymer matrix.

4:15 PM *EL18.09.06
Effect of Backbone Linearity on Mixed-Conductance in New Pyrene Dianhydride-Based Conjugated Ladder Polymers JuliaA. Schneider, KatherineJohnston, EmmaMikita and EmilJaffal; Fordham University, United States

We report the synthesis of a new organic n-type ladder conjugated polymer, poly(benzimidazobenzo(d,e,f)phenanthrenedione) (**BPyL**), for applications utilizing mixed ionic-electronic semiconductors. This pyrene-based ladder polymer is an exciting core-expansion of the high performing naphthalene-based polymer, poly(benzimidazobenzophenanthroline) **BBL,** but unlike **BBL**, it allows for structural variety in the conjugated backbone.
Electronic charge transport and ion diffusion in organic conjugated polymers are both dependent on interchain interactions, yet maximizing these processes equally is a significant challenge toward achieving mixed conductance. The crystalline assemblies necessary for charge transport can often limit ion diffusion and hinder the capacitance of the material. While studies have shown that amorphous films perform better due to uniform swelling by the electrolyte, the insertion of conjugation-break spacers or hydrophilic side chains leads to decreased charge transport. With **BPyL**, we present a new approach for controlling polymer crystallinity by tuning backbone linearity using “linear” and “bent” isomeric monomers. We have synthesized two isomers of pyrene dianhydride for the polycondensation with 1,2,4,5-tetraaminobenzene tetrahydrochloride (TAB.4HCl) into conjugated ladder polymers. By tuning the ratio of pyrene comonomers we can impact film-formation ability and performance.
We will present comparisons of **BBL** and **BPyL** (linear and bent) via spectro-electrochemical analysis, TEM imaging, electrochemical characterization, and organic electrochemical transistor (OECT) devices.

4:45 PM EL18.09.07
Revealing The Microstructure of Hydrated Conjugated Polymers using Cryogenic Electron Microscopy MasoudGhasemi and EnriqueGomez; The Pennsylvania State University, United States

Organic mixed ionic-electronic conducting (OMIEC) polymers have attracted a tremendous amount of attention due to their easy tunability and potential for various applications, such as neuromorphic computing and biosensing. Among different OMIECs, poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) is the most widely used polymeric system due to its commercial availability and ease of processibility as an aqueous dispersion. PEDOT is a p-type conjugated polymer with poor solubility in both polar and nonpolar solvents, hence it is usually processed along with PSS which also serves as a dopant to induce positively charged electronic carriers in PEDOT. It has been shown that both the electronic and mechanical properties of PEDOT:PSS can be modulated through post-processing or the application of different additives. Despite its wide range of applications the underlying mechanisms behind the improvement in the mechanical properties of PEDOT:PSS in the presence of additives remains poorly understood. In this work, we use cryogenic electron microscopy (Cryo-EM) to investigate micro- and nano-structure of PEDOT:PSS in different hydrated and swollen states. Our results suggest that in a hydrated state PSS rich regions of the PEDOT:PSS swell while the PEDOT-rich phases maintain an interconnected network which highlights the importance of a charge percolation pathway as well as the amorphous phase connectivity to achieve high mobility and stretchable OMIECs. Our findings may pave the way to a deeper understanding of OMIECs and their structure-function relationships.

Monolithic Integration of Single-Crystalline 2D Standalone Circuitry Enabled by Ultra Low Temperature Growth JeehwanKim; Massachusetts Institute of Technology, United States

It is necessary to find a strategy obtain single-crystalline TMDs on a Si wafer without transfer for seamless integration of TMDs for CMOS technologies. However, so far, epitaxial methods has been an only way to obtain single-crystalline TMDs which requires a single-crystalline hexagonal substrate and transfer them onto the Si wafer. Here my team at MIT has succeeded to directly grow single-crystalline MoS2 and WSe2 on a HfO2-coated Si wafer without needing to have an epitaxial seeding. We geometrically confine the growth of the first set of nuclei by defining selective growth trenches before the second set of nuclei is introduced. By utilizing the edge of trenches as a heterogeneous nucleation site, we were able to grow TMDs as low as at 380 oC which will enable monolithic integration of logic devices on various circuitry. Also, such low temperature direct non-epitaxial singe-crystalline growth methods lay foundations to finally obtain vertically stacked complementary FETs by monolithic integration of MoS2 nMOS on top of WSe2 pMOS.

11:00 AM EL19.01.02
Area-Selective Atomic Layer Deposition on a 2D Monolayer Lateral Superlattice JeongwonPark[1], Seung JaeKwak[2], Won BoLee[2], YongJooKim[3] and KibumKang[1]; [1]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]Seoul National University (SNU), Korea (the Republic of); [3]Kookmin University, Korea (the Republic of)

Recently, area-selective atomic-layer-deposition (AS-ALD), which allows the direct deposition of target materials on the desired area using a deposition barrier, has emerged as an advanced patterning process. In conventional AS-ALD (CAS-ALD), various barriers, including self-assembled monolayers, surface terminations, and inherent selectivity in metal-insulator combinations, have been deployed. Nevertheless, these barriers have not yielded satisfactory results when confronting highly reactive ALD precursors or when handling diverse materials in AS-ALD. Furthermore, CAS-ALD, which selectively deposits materials in predefined regions through top-down patterning, has not successfully reduced pattern sizes beyond the resolution of

optical lithography.
In this research, we report a novel superlattice-based AS-ALD (SAS-ALD) using a 2D lateral superlattice as a patterning template. The lateral superlattice is grown by coherent lateral epitaxy of monolayer MoS_2 and $MoSe_2$ with chemical vapor deposition (CVD) process. Due to the unique feature of lateral growth in 2D materials, the superlattice is composed of linear patterns of MoS_2 and $MoSe_2$. Interestingly, we have discovered that when various materials (Al_2O_3, HfO_2, Ru, Te, Sb_2Se_3, and TiN) are deposited via ALD on the MoS_2-$MoSe_2$ lateral superlattice, they selectively deposit only on the $MoSe_2$ regions, resulting in linear patterns of target materials.
Since the width of linear pattern is determined by the duration time of gaseous CVD precursors, a scaling down is significantly easier compared to conventional pattering methods. As a result, we patterned target materials on the lateral superlattice template with a sub-10 nm half pitch size. Furthermore, unlike CAS-ALD, which controls the chemisorption of ALD precursors, SAS-ALD has a completely new mechanism that utilizes physisorption differences and diffusions. Through molecular dynamics (MD) simulations and density functional theory (DFT) calculations, we confirmed that the adsorption energy of ALD precursor on 2D transition dichalcogenides (TMDs) is influenced by local strain and curvature of TMDs. Importantly, we observed that the most stable adsorption of the precursors occurs on the compressed $MoSe_2$ valley region, which has compressive strain and concave surfaces. The computational results were further supported by experimental evidence showing initial nucleation of ALD materials on the compressed $MoSe_2$ valley region. Based on the physisorption differences and diffusion of ALD precursors, SAS-ALD has been able to selectively deposit various materials such as Al_2O_3, HfO_2, Ru, Te, Sb_2Se_3, and TiN. Additionally, we successfully achieved Al_2O_3 AS-ALD using a trimethyl aluminum, the highly reactive precursor, and this was possible even at a few nanometer scales.
SAS-ALD, based on a novel mechanism, allows for patterning of target materials in a linear shape using a 2D lateral superlattice template. From a patterning perspective, the width is controlled by the duration time of CVD precursor, making scaling down very easy. In addition, in terms of AS-ALD, we were able to effectively fabricate various materials in very narrow patterns. This technology is expected to have even greater potential when combined with guide patterns created through photolithography for precise positioning. Additionally, since SAS-ALD utilized 2D TMDs as pattern templates, we anticipate that various 2D/3D hybrid structures can be created.

11:15 AM EL19.01.03
Reconfigurable Mixed-Kernel Heterojunction Transistors for Personalized Support Vector Machine Classification JustinQian[1], XiaodongYan[1], JiahuiMa[2], AoyangZhang[2], StephanieLiu[1], MatthewBland[1], KevinLiu[1], XuechunWang[2], VinodK. Sangwan[1], HanWang[2] and MarkC. Hersam[1]; [1]Northwestern University, United States; [2]University of Southern California, United States

The continual increase in the volume of data generated by sensors, robots, and mobile devices poses a challenge for cloud computing centers in terms of power costs, efficiency, accessibility, and scalability. In particular, artificial intelligence (AI) based classification has shown tremendous potential in a variety of applications such as signal processing and image recognition but often has huge data and energy costs due to the underlying von Neumann architecture of complementary metal-oxide-semiconductor (CMOS) chips. In contrast, the use of edge computing to locally analyze and process data has the potential to alleviate the burden on large data centers, while also improving latency, security, and privacy. Because edge computing resources are often limited, edge-based hardware needs to be more power-efficient than conventional graphics processing units (GPUs), application-specific integrated circuits (ASICs), or field programmable gate arrays (FPGAs).
This presentation will discuss edge computing at the device level using a highly reconfigurable mixed-dimensional dual-gated MoS_2/carbon nanotube (CNT) van der Waals heterojunction device achieved in a self-aligned manner. By tailoring the degree of electric-field screening through control over CNT density and overlapping heterojunction area, the heterojunction device is shown to generate tunable Gaussian, sigmoid, and mixed Gaussian/sigmoid functions. These heterojunction-generated functions are then used as kernels for support vector machine (SVM) based arrhythmia detection from electrocardiogram (ECG) signals. For a single device, mixed kernels were found to outperform purely Gaussian and purely sigmoid kernels. Bayesian optimization was further used to determine the optimal Gaussian/sigmoid hyperparameters and mixing ratio for a full mixed-kernel library that was generated from the integration of two devices, resulting in exceptionally high classification accuracies. Compared to existing literature on Gaussian transistors and CMOS circuits, our mixed-kernel heterojunction (MKH) transistors show unprecedented tunability in a compact four-terminal geometry with close to two orders of magnitude fewer circuit elements. In this manner, CNT-MoS_2 MKHs have the potential to be widely applicable to SVM classification in diverse wearable and edge applications.<!--![endif]---->

11:30 AM *EL19.01.04
Hexagonal and Amorphous Boron Nitride Thin Films Hyeon SukShin; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Hexagonal boron nitride (hBN) is a promising two-dimensional (2D) material owing to its unique optical properties in the deep-UV region, mechanical robustness, thermal stability, and chemical inertness. hBN thin films have gained significant attention for various applications, including nanoelectronics, photonics, single photon emission, anti-corrosion, and membranes. Thus, wafer-scale growth of hBN films is crucial to enable their industrial-scale applications. In this regard, chemical vapor deposition (CVD) is a promising method for scalable high-quality films. To date, considerable efforts have been made to develop continuous hBN thin films with high crystallinity, from those with large grains to single-crystal ones, and to realize thickness control of hBN films by CVD. However, the growth of wafer-scale high crystalline hBN films with precise thickness control has not been reported yet. The hBN growth is significantly affected by substrate, in particular the type of metals, because the intrinsic solubilities of boron and nitrogen depend on the type of metal. In this talk, state-of-the-art strategies adopted for growing wafer-scale, highly crystalline hBN are summarized, followed by the proposed mechanisms of hBN growth on catalytic substrates [1]. Furthermore, various applications of the hBN thin films are demonstrated, including a dielectric layer, an encapsulation layer, a wrapping layer of gold nanoparticles for surface enhanced Raman scattering, a proton-exchange membrane, a template for growth of other 2D materials or nanomaterials, and a platform of fabricating in-plane heterostructures. In addition, amorphous BN (aBN) as a counterpart of crystalline hBN is introduced [2]. Detailed structural characterisation indicates that a-BN is sp^2-hybridised, with no measurable crystallinity, and mechanically robust, with excellent diffusion-barrier characteristics. The aBN thin film shows ultra-low dielectric constant (< 2.5), indicating great potential for its applications in Cu interconnects of integrated circuits.

Ultraclean Layer Transfer and Atomic Reconstruction in Twisted TMD Lattices RomanGorbachev; University of Manchester, United Kingdom

Layer-by-layer assembly of van der Waals (vdW) heterostructures underpins new discoveries in solid state physics, material science and chemistry. Despite successes, all current assembly techniques use polymeric supports which limit their cleanliness, ultimate electronic performance, and potential for optoelectronic applications. In the first part of the talk, I will introduce a polymer-free platform for heterostructure assembly using re-usable flexible silicon nitride membranes. This approach enables production of heterostructures with interfaces free from interlayer contamination and correspondingly excellent (opto)electronic behaviour. In addition, eliminating polymeric supports allows new possibilities for vdW heterostructure fabrication: assembly at temperatures up to 600°C, and in different environments including ultra-high vacuum (UHV) and liquid submersion. We demonstrate UHV heterostructure assembly for the first time and show the reliable creation of moiré superlattices with over x10 improvement in homogeneity.
In the second part of the talk, I will review our recent progress on twisted bilayer TMDs bilayers in the reconstruction regime. I will discuss their atomic structure observed in STEM, which is strikingly different for aligned (R) and anti-aligned (H) TMD monolayer orientations. This difference gives rise to correspondingly different optoelectronic properties, with ferroelectric domains arising in the former case and piezoelectric charge texturing in the latter. I will report our recent investigation of sliding ferroelectricity, and its switching behaviour observed in double gated structures using the electron channelling contrast SEM.

2:00 PM *EL19.02.02
More Magic with Atomic Crystals JiwoongPark; University of Chicago, United States

Atomically thin crystals, that are grown, combined, and integrated in large scale, can enable novel properties previously unimaginable. Such "magical" properties can span functional dimensions that go beyond widely-explored electronic phenomena, resulting in extreme thermal, photonic, and mechanical properties. In this talk, I will discuss latest examples with such magical properties realized with atomic crystals. First, we demonstrated three atom thick photonic waveguides, named delta-waveguide, that can generate light plane waves that propagate freely along the waveguide plane but confined along the out-of-plane direction. This enables integrated two-dimensional photonics and seamless mode matching with free-beam optics. Second, we demonstrated the fabrication and measurements of wafer-scale atomic crystal membranes on water that behave like a freestanding mechanical film. We discover that these

membranes are not flat; instead they self-wrinkle with the wrinkle morphologies following a universal scaling law, as shown by continuum mechanics theory. This enables a tuning of their mechnical moduli over multiple orders of magnitude.

Exploring the Inter-Layer Interactions of 2D Materials with Sub-Angstrom Resolution Modulated Nanoindentation RyanKhan, DanielVizoso, FrankDelrio and RemiDingreville; Sandia National Laboratories, United States

As the field of 2D materials continues to grow, more intriguing and complex structures will be discovered, increasing the demand for techniques to properly characterize the local nanoscale mechanical properties of any and all varieties of materials. While traditional nanoindentation can measure the in-plane modulus of suspended films over holes, the technique fails to accurately determine the out-of-plane modulus, requiring such large indentation depths that substrate effects cannot be distinguished. We employ modulated nanoindentation with Angstrom resolution (MoNI/ÅI), a novel technique that enables non-destructive measurements of the out-of-plane elasticity of ultra-thin materials with sub-angstrom level indentation depths. With such high resolution, even atomically thin materials can be examined in their most practical state on any underlying substrate, without erroneous contributions from the substrate. MoNI/ÅI has been previously used to explore local pressure induced phase transformations only possible in few layer 2D materials. In our work we explored the multi-layer stiffness dependence of deposited graphene and uncovered a peak transverse stiffness in bilayer graphene that was previously unknown. We complemented these findings with MD simulations and other characterization techniques to further elucidate this phenomenon providing a deeper insight of the inter-layer forces and interactions in graphene and other 2D materials.

Electronic and Electrochemical Properties of Moiré Superlattices DanielK. Bediako; University of California, Berkeley, United States

The formation of moiré superlattices alters the electronic band structure in a manner that is systematically dependent on the interlayer twist angle, but spontaneous strain relaxation has considerable impact on the resulting physics. This talk will focus on the use of four-dimensional scanning transmission electron microscopy measurements to map lattice relaxation in bilayer and trilayer moiré superlattices and how these structural perturbations impact both the correlated electron physics of the materials as well as their interfacial electrochemical behavior measured by scanning electrochemical cell microscopy.

Introduction to the MonArk NSF Quantum Foundry HughChurchill; University of Arkansas, United States

The MonArk Quantum Foundry is an NSF program jointly led by Montana State University and the University of Arkansas with a mission to accelerate two-dimensional materials research for quantum technologies. The rapid prototyping and characterization capabilities of the foundry will be used to serve a broad range of collaborators and users interested in the development of 2D materials and devices for quantum technologies. In this talk I will provide an introduction to the goals and capabilities of MonArk, which are centered on robotic and AI-assisted creation, identification, and fabrication of 2D quantum materials and devices. I will provide a status report on the development of these capabilities and an outlook for the collaborator and user program that will begin in 2024.

4:15 PM *EL19.16.07
Upconversion Electroluminescence in Plasmonic Van der Waals Tunnel Diodes GokiEda; National University of Singapore, Singapore

Plasmonic tunnel junctions comprising van der Waals semiconductor are an attractive platform where the interplay between inelastically tunneling electrons, surface plasmons, and excitons is expected to give rise to novel light emission phenomena. Here, we report observation of peculiar upconversion electroluminescene in van der Waals tunnel diodes comprising a monolayer transition metal dichalcogenide (TMD) in the electron tunneling pathway. The device exhibits bimodal electroluminescence with a broad low energy band and a narrow high energy band. Interestingly, the high energy emission, which is attributed to the TMD ground exciton, is found to turn on at applied biases significantly lower than the threshold defined by its emission energy, whereas the low energy emission, which arises from plasmonic emission, strictly obeys the quantum cut-off. We examine several possible model and show that momentum-indirect excitation of high energy carriers enabled by inelastic electron tunneling is a key component enabling the apparent energy gain.

Ultra-Low Gas Permeability of Irreversibly-Bonded Two-Dimensional Polyaramid (2DPA-1) Films CodyRitt, QuienMichelle, YuwenZeng, Yu-MingTu and MichaelS. Strano; Massachusetts Institute of Technology, United States

Polymers that extend covalently in two dimensions (2D) have attracted recent attention as a means of combining the mechanical strength and in-plane energy conduction of conventional 2D materials with the low densities, synthetic processability, and organic composition of polymeric materials. Our recent synthesis of irreversibly-bonded, solution-phase 2D polyaramid (2DPA-1)—exhibiting exceptional mechanical strength and chemical stability—presents a new material class for thin films. Here, we report spin-coated 2DPA-1 films, between 4 to 65 nm in thickness, with gas permeability on the order of 10^{-4} Barrer. Gas permeation measurements are enabled by atomic force microscopy (AFM) of inflated bulges over microwells. We find the gas barrier properties of 2DPA-1 thin films, which are commensurate with liquid crystal polymers, are largely immutable over the span of two years. The resistance of 2DPA-1 to degradation contrasts its hygroscopic 1D polyaramid counterparts. Further, the inflation of 4-nm-thick bulges suspended across microwells indicates the absence of defects such as pinholes that commonly plague graphene-based thin films. Despite the intrinsic porosity of a single 2DPA-1 platelet, the ultralow permeability, negligible BET surface area, and orientation-dependent fluorescence of its films suggests 2DPA-1 platelets align anisotropically in a tightly packed and staggered order. Overall, our work elucidates the potential of 2DPA-1 as a next-generation gas barrier material and warrants its further exploration for selective gas separations.

8:00 PM EL19.03.02
Scalable Solution Synthesis and Photocatalytic Activity of Layered ZnO and MoS_2 Heterostructures MariaSushko, LiliLiu, LiborKovarik, JunLiu and XinZhang; Pacific Northwest National Laboratory, United States

Numerous inorganic materials have been identified as potential candidates for high-performance photocatalysts. However, their solar-to-energy conversion efficiencies still fail to meet commercial requirements. The main hurdle is the rapid recombination of photoexcited electrons and holes in single-phase materials. A viable predicted approach to suppress charge recombination is coupling two materials to form a two-dimensional (2D) heterostructure that physically separates photoinduced electrons and holes in different layers. In this work, the heterostructure-based paradigm was tested and a scalable solution synthesis of epitaxial ZnO-MoS_2 heterostructure was developed. A 2D ZnO-MoS_2 heterostructure was synthesized under hydrothermal conditions by stabilizing intermediate Zn-hydroxide states on a functionalized MoS_2 surface. Detailed characterization showed the formation of multilayer heterostructure with MoS_2 flakes intercalated between large size ZnO plates. The performance of this heterostructure was evaluated using photocatalytic degradation of rhodamine B. A degradation efficiency of 70‰ was measured within 90 minutes of visible light irradiation, almost doubling the efficiency of the corresponding single-phase materials or their physical mixtures.

8:00 PM EL19.03.03
Synthesis, Exfoliation and Characterization of 2D Materials Nasimul AlamSyed, ArkaGhosh, NityanandaSahoo and UddeshyaShukla; National Institute of Technology Rourkela, India

Abstract
Two-dimensional (2D) materials, also known as single-layer materials, consisting of a single or few atomic layers in which the in-plane interaction is much stronger than the interaction between the planes stacked over each other have excellent mechanical, electrical, optical and thermal properties. Since the discovery of graphene in 2004, 2D materials have attracted enormous attention due to their unique properties. 2D materials have a wide range of application in areas like flexible electronics, semiconductors, energy storage, nanoelectromechanical

systems (NEMS), water purification, gas sensing and several others. In a 2D material, the atomic layers stacked over each other, are held together by weak van der Waals forces. By breaking the van der Waals forces between the adjacent layers, the 2D materials can be exfoliated. Understanding the exfoliation mechanism can provide useful information to optimize and improve the parameters of the exfoliation technique in order to obtain high quality as well as higher yield of 2D materials. The properties of 2D materials are highly dependent on the number of layers it is made up of. Ultrasonication, shear exfoliation, micromechanical cleavage, ball milling, mechanical processes, hydrothermal processes, electrochemical processes, laser-assisted and microwave-assisted methods and chemical vapour deposition (CVD) are some of the most commonly used techniques to separate layers of 2D materials and exfoliate them. The choice of the technique depends on the exfoliation yield and quality of the exfoliated 2D materials. It is essential to know how the parameters of these techniques affect both the yield and quality of the exfoliated materials. This paper presents the results of the exfoliation of materials like graphene, hexagonal boron nitride (hBN) and molybdenum disulphide (MoS2) by mechanical methods like high energy ball milling, by chemical routes through the synthesis of graphite intercalation compound (GIC), ultrasonication technique and centrifugation will be discussed in detail. The various conditions under which these processes were carried out will be discussed. Here, the effectiveness of these techniques in exfoliating different types of 2D materials has been analyzed and the exfoliated 2D materials have been characterized by several analytical techniques to determine the number of atomic layers stacked together in the exfoliated 2D materials. Apart from this, the functional groups that were attached to the surfaces of the 2D materials and their thermal stability were also determined. Using various characterization techniques like x-ray diffraction (XRD), scanning electron microscopy (SEM), high resolution transmission electron microscopy (HRTEM), Raman spectroscopy, atomic force microscopy (AFM) and ultraviolet-visible (UV-vis) spectroscopy and photoluminescence (PL) it is possible to determine the number of layers stacked over each other in a 2D material. Other characterization techniques like Fourier transform infrared spectroscopy (FTIR) and differential scanning calorimetry and thermogravimetric analysis (DSC/TGA) can determine the functional groups attached to their surfaces and the thermal stability of the 2D material. The results show that the exfoliation techniques used here were highly successful in exfoliating the 2D materials. The synthesis of graphene from bulk natural flake graphite (NFG) by the formation of a graphite intercalation compound will also be discussed. The synthesis of graphene oxide (GO) by modified Hummers' method and its thermal reduction to obtain reduced graphene oxide (rGO) will also be discussed in detail.

8:00 PM EL19.03.04
Electrochemically Exfoliated BCN-Cu Nanosheet Electrocatalysts for Efficient Green Hydrogen Evolution: Tuning the Intermolecular Electron Transfer NagehK. Allam; American University in Cairo, Egypt

The search for materials with superior electrocatalytic performance has attracted attention during the past few years aiming to identify a convenient material that works at a low overpotential with long-term stability. Herein, we introduce an innovative technique to fabricate two-dimensional BCN heterostructure nanosheets with various Cu:BCN weight ratios. The fabricated composites showed unique electrocatalytic properties for hydrogen evolution reaction (HER). The morphology and structure of the electrocatalysts were characterized using field emission scanning electron microscopy, Raman, Fourier transform infrared spectroscopy, and X-ray photoelectron spectroscopy techniques. Remarkably, this study reveals the effect of electrochemical chronopotentiometry on facilitating electrochemical exfoliation and hence enhancing the catalytic activity of the fabricated nanosheets. This effect was further confirmed via density functional theory (DFT) calculations, unveiling the effect of the formed oxide layer on the charge transfer process. The overpotential of the 0.125 Cu-BCN composite at a current density of -10 mA/cm^2 vs RHE is 50% lower than that of pristine BCN. These findings were also affirmed by the DFT calculations, which showed that incorporating copper on BCN has significantly reduced the G_{H*} value of the HER and subsequently accelerates the kinetics of the reaction and the overall catalytic activity of the material.

8:00 PM EL19.03.05
Predicting Mechanical Properties of Nanocomposites Embedded with Carbon-Based Low Dimensional Materials AbigailL. Eaton, MarcoFielder and ArunK. Nair; University of Arkansas, United States

Carbon-based low dimensional materials, such as 1D carbyne and 2D cyclo[18]carbon (C18), offer a broad range of material properties that may be beneficial for the development of metal-matrix nanocomposites. However, the interface properties of these carbon-based materials with metal matrix could affect the nanocomposite mechanical properties. Thus, it is important to study the interface properties and perform mechanical testing of the nanocomposites embedded with carbon-based low dimensional materials to determine the most efficient material combinations to improve the mechanical properties.
Using molecular dynamics and density functional theory methods, we develop and study the interface properties of carbon-based materials embedded in Cu metal matrix. We focus on the use of 1D carbyne, 2D C18, and 2D C18-carbyne hybrids due to their low dimensionality and range of strength and elasticity. We then conduct uniaxial tensile testing of the nanocomposites to determine if the nanomaterials improve their mechanical properties when compared to single crystal Cu. From the mechanical property prediction and interface analysis, it is possible to determine the nanocomposite that would be most compatible for future development and applications.

8:00 PM EL19.03.06
Synthesis of Atomically Thin Yellow Pearl: An Impetus for Non-Linear Optical Effects Assisted Light Scattering Applications NabarunMandal, VidyaKochat and ChandraS. Tiwary; Indian Institute of Technology Kharagpur, India

Synthesis of 2D materials from natural resources, and having unique functionalities have created enormous research interest among material scientists. Naturally occurring organic gemstones such as pearl are found to have a van der Waal's heterostructure with alternating layers of aragonite and complex organic compound conchiolin. In modern laser generation setups, simple optical mirrors on either side of an optical gain medium are being replaced by Bragg's mirrors since such heterostructures increase reflectivity significantly. Hence, 2D pearl, owing to its Bragg's mirror like structure, can replace conventional passive scatterers such as 2D-hBN, 2D-TiO2 and graphene in generation of amplified spontaneous emission (ASE) and random lasing (RL) applications. Such 2D materials can be used as impetus for light scattering to generate continuous wave (CW) pumped random laser (RL) emission even at room temperature. In this work, defects-free 2D yellow pearl (2D-YP) has been synthesized from bulk south sea pearl using liquid-phase exfoliation (LPE) technique. Thereafter, 2D-YP has been employed as passive scatterer to achieve CW pumped RL emission from a conventional gain molecule. Compared to other semiconductor (TiO2) and 2D (Graphene and h-BN) passive scatterers, ~25 times improvement in gain volume is observed for the disordered system consisting of 2D-YP, and is due to the formation of a large refractive index gradient via thermal nonlinear optical (NLO) interaction. Hence, incoherent RL (ic-RL) emission ~591 nm is reported at a lowest threshold input pump power and a linewidth of 65 mW and 3 nm, respectively. Additionally, a clear transition from ic-RL to mode tunable coherent RL (c-RL) emission is also demonstrated by altering the pump configuration. Therefore, the newly designed van der Waals heterostructure, i.e., 2D-YP with intrinsic photon trapping capability may pave an avenue towards developing exciting optoelectronic devices.

8:00 PM EL19.03.07
Synthesis of Layered Conducting Polymer Electrode for Superior Ultracapacitor Performance DuyPham; Kennesaw State University, United States

Ultracapacitors (UCs) are electrochemical energy storage (EES) devices that provide fast charge-discharge capabilities and large storage capacity. UCs are comprised of two electrodes that house an electrolyte solution with a porous separator. Electrochemical double layer capacitors (EDLC) that are comprised of carbon-based materials such as activated carbons have an electrostatic charge storage mechanism, also known as non-Faradic charge transfer. The other well-known UCs are psuedocapacitors that are comprised of conducting polymers or metal oxides and have a redox charge storage mechanism, known as Faradic charge transfer. Currently, pseudocapacitors are thoroughly researched, however, the role of conducting polymer structure and property as a function of the deposition method currently remains limited. In this work, conducting polymer electrodes, polypyrrole (PPy) are synthesized using electrochemical depositions with controlled cycles and their performance is investigated. The UCs will be tested using cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS), and galvanostatic charge/discharge (GCD) to understand the role between deposition cycles and electrochemical performance. Material characterization such as XRD and FT-IR with surface morphology such as SEM are analyzed to give more insights into this charge kinetics between these variations of cycles.

8:00 PM EL19.03.08
Graphene Based Nanofibrous Scaffold for Embedding Bacteriorhodopsin for Bioengineered Memory Application PhilipByrne, EvanMcCarthy and IsaacMacwan; Fairfield University, United States

The photoactive protein, Bacteriorhodopsin (bR), is being implemented into optical memory applications, most notably for its photochemical and thermal stability. Due to this photochemical stability, bR can remain in one of two stable photostates, bR (ground state) and Q (elevated state), which are used to designate binary bits '0' and '1'. The challenge with this phenomenon is that the Q photo state has a low quantum yield, meaning that bR will not absorb enough photons to undergo photoisomerization. To increase the quantum yield of the photocycle, a molecular dynamics simulation involving graphene monolayer and crystal structure of the bR protein was performed to study the adsorption and preservation of the photostates of bR, where it was found that graphene has a potential to increase the quantum yield. However, a major challenge is to have a porous surface with even distribution of graphene nanoparticles to employ it as a scaffold to anchor the bR protein. The porosity of the surface would help anchor the protein onto the surface and the distribution of graphene nanoparticles would ensure proper chemical interactions. Such a porous surface is achieved through electrospinning where nanofibrous scaffold of poly vinyl alcohol (PVA) with graphene nanoparticles is utilized to immobilize the bR protein. Four different scaffolds on aluminum and Indium Titanium Oxide (ITO) surfaces are fabricated with and without graphene having PVA as a common matrix with optimized electrospinning parameters including flow rate, nozzle collector distance, voltage between nozzle and collector, viscosity of the polymer solution and type and configuration of the collector. It is found that the synthesized nanofibers have average diameters of ~200nm with graphene monolayers embedded within the nanofibrous scaffolds. The resulting scaffolds are characterized using scanning electron microscopy (SEM), profilometry and electrochemical impedance spectroscopy (EIS) to quantify its physical and electrical properties and are compared to the control PVA-bR

scaffolds without graphene. The distribution of the purple membrane discs containing bR embedded within the nanofibers is also quantified based on the fiber diameter, porosity and collector surface. The synthesized scaffolds are also tested using lasers with wavelengths ranging from 380nm to 640nm to drive the bR molecules to the branched photostates to demonstrate their use as a bioengineered memory device.

8:00 PM EL19.03.09
Faradaic and Non-Faradaic Charge Transfer Mechanism for Energy Storage Systems BenMcKinney, SonnettKowalski, AshishAphale and DuyPham; Kennesaw State University, United States

Faradaic and non-Faradaic charge transfer mechanisms play an essential role in energy storage and conversion processes. The faradaic charge transfer mechanism involves electrochemical reactions that result in the exchange of electrons between the electrode and the electrolyte. Whereas the non-faradaic charge transfer mechanism involves charge storage without significant chemical reactions at the electrode-electrolyte interface. In this work we report a hybrid nanocomposite material operating on both Faradaic and non-Faradaic mechanisms simultaneously. The hybrid electrodes containing conducting polymer and graphene oxide were synthesized using electropolymerization process and the effects of graphene oxide (GO) on polypyrrole were studied. Details of electrode synthesis, electrochemical testing, and fabrication of device as a button cell will be discussed. Polypyrrole and graphene oxide (PPy/GO) films were tested using electrochemical methods such as cyclic voltammetry (CV), Electrochemical Impedance Spectroscopy (EIS), and Galvanostatic Charge Discharge (GCD) to assess electrode performance. The results generated from such tests will provide insights into the ohmic, non-ohmic, and Warburg resistances along with specific capacities and charge discharge behavior of the electrodes. These insights will be discussed and compared with electrodes with different levels of graphene oxide.

8:00 PM EL19.03.10
Solar Assisted Expansion of Graphite Flakes for an Effective Exfoliation of Graphene Sheets ShanavasShajahan[1,1], RamiA. Elkaffas[1] and YarjanAbdul Samad[1,1,2]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]University of Cambridge, United Kingdom

Synthesis of scalable monolayer or few-layered graphene sheets is challenging due to the complex production processes [1-3]. Liquid phase exfoliation is considered as one of the most feasible techniques to produce industrially scalable [1] defect-free graphene sheets [4,5]. In ultrasonic exfoliation techniques, long exposure (up to 48 hours) [6] of graphene sheets to the ultrasonic waves considerably decreases its lateral size [7], which limits the mechanical and electrical properties of produced graphene [8]. In this study, we successfully achieved the preparation of graphene sheets with high (4-5 mm) lateral sizes by pre-expanding the graphite through solar-assisted expansion process [9]. The graphite flakes with a lateral size of about 600 µm are intercalated with the perchloric acid ($HClO_4$) at 120 °C for 30 min to prepare stage II intercalated graphite (S_2IG). In the S_2IG, $HClO_4$ is intercalated in between every two layer of graphene sheets, which can be confirmed through Raman analysis [10]. The S_2IG is expanded by focusing sunlight on its surface using a simple magnification lens (diameter = 75 mm, focal length = 10 cm). The solar expansion process (SEP) resulted in the formation of expanded graphite with an expansion ratio of about 1:240 (graphite: solar expanded graphite) and lateral size of solar expanded graphite is about 400 µm, which is similar to the intercalated graphite flakes. The solar expanded graphite is exfoliated through probe sonication (500-watt, 20 kHz) for 20 min to obtain few-layer graphene sheets [11]. Raman analysis confirms the formation of defect-free solar expanded graphite as well as few-layer graphene sheets. The obtained results clearly show that the lateral size of graphene sheets can be enhanced by pre-expanding the graphite sheets through solar irradiation before the probe sonication process.

First-Principles Study of Electronic Structure and Nonlinear Optical Responses of Novel Two-Dimensional Materials and Moiré Superlattices AlexStrasser and XiaofengQian; Texas A&M University, United States

Janus two-dimensional (2D) materials and moiré superlattices exhibit rich physical properties and novel fundamental effects. In addition, the recent discovery and synthesis of MA_2Z_4 2D materials prompt further exploration of a new family of van der Waals materials, as well as their Janus counterparts. We investigate and compare the electronic structure and nonlinear optical responses in transition metal dichalcogenides (TMDCs) and Janus TMDCs, MA_2Z_4 and Janus $MABZ_4$ (M = Mo, W; A, B = Si, Ge; Z = N, P), as well as twisted multilayer graphene systems. Using first-principles density functional theory, we show that the Janus structuring of TMDCs and $MABZ_4$ leads to out-of-plane nonlinear responses in both second harmonic generation and shift current, enabling applications for nonlinear electronics and optoelectronics. Furthermore, phosphorous-based MA_2Z_4 2D crystals exhibit enhanced nonlinear response in both low- and mid-frequency of second harmonic generation and shift current, comparable to and beyond that of 2D transition metal dichalcogenide MX_2 materials. These phosphorous materials present strong Rashba spin splitting as evidenced in spin texture. Finally, a Wannier tight-binding model of twisted multilayer graphene is used to calculate nonlinear optical response, including k-point resolved shift vector. The data reveal intense shift current in twisted bilayer graphene on hexagonal boron nitride. In summary, our theoretical results suggest that 2D Janus materials and twisted moiré superlattices offer significant opportunities for the design and manipulation of optoelectronic responses and devices.

8:00 PM EL19.04.02
Long-Lived Charge Separation in Large-Area, Single Crystal MoS_2 Monolayers Interfaced with Non-Fullerene Acceptor Y6 ChristopherE. Petoukhoff, ZhengYang, ShahidulAlam, NisreenAlshehri, JoseP. Jurado Carlin, CatherineDe Castro, VincentTung and FredericLaquai; King Abdullah University of Science & Technology (KAUST), Saudi Arabia

Semiconductor heterojunctions based on 2D transition metal dichalcogenides (TMDs) have displayed record thickness-normalized current densities and absorption coefficients, particularly when interfaced with organic semiconductors [1]. As such, 2D TMDs have been employed as both charge transport layers in organic [2] and perovskite photovoltaics [3], as well as the active layer in mixed dimensional organic-2D heterojunctions [4]. MoS_2 and WS_2 have been demonstrated as alternative hole transport layers in high-efficiency organic photovoltaics (OPVs), leading to devices having greater than 17% power conversion efficiencies [5,6]. However, these works have focused on either mechanically-exfoliated, single-crystal TMDs or liquid-phase exfoliated films, which either limit the size or the homogeneity of the resulting devices. There have not yet been works incorporating large-area, single crystal TMD monolayers as hole transport layer materials for OPVs.

In recent years, the advancement of OPV efficiencies has largely been driven by the development of non-fullerene acceptor materials, such as the molecule BTP-4F (i.e., Y6). This molecule has sub-units of electron donating (D) and accepting (A) groups, in the form of A-DA'D-A structure, which give rise to large exciton delocalization with excitons having charge-transfer-like character. In fact, there has been growing evidence that neat Y6, unlike most neat organic semiconducting materials, can generate charge-separated states even without a donor/acceptor interface typical for OPVs.

In this work, we investigate the charge generation, transfer, and separation processes that occur when neat Y6 is interfaced with large-area, single crystal MoS_2 monolayers. We explore these processes using femtosecond transient absorption (TA) and time-resolved photoluminescence (TRPL) spectroscopies. Our results demonstrate that MoS_2/Y6 interfaces lead to long-lived charges in both the MoS_2 and Y6 layers. We will compare the impact of MoS_2 on charge separation in neat Y6 compared to a typical donor:acceptor blend, PM6:Y6. These results demonstrate the viability of using MoS_2 as an effective hole transport layer in high-efficiency solar cells, particularly for single component OSCs fabricated from Y6-type materials.

Monolayer 2D Material-Polymer Nanohybrid Crystals MingyuanSun[1], DongZhou[1], AkashSingh[2], LuAn[1], Jan MichaelY. Carrillo[3], JongK. Keum[3,3], MiguelFuentes-Cabrera[3], RaymondR. Unocic[3], KunlunHong[3], IliaIvanov[3], ChristopherM. Rouleau[3], FengGang[1], KaiXiao[3], JihuaChen[3], YumengLi[2] and BoLi[1]; [1]Villanova University, United States; [2]University of Illinois at Urbana Champaign, United States; [3]Oak Ridge National Laboratory, United States

Ultrathin and mechanically robust structures and devices with nanoscale dimension resolution are critical for miniaturized nanoelectromechanical systems (NEMS) and integrated circuited (IC). It is extremely challenging to achieve such structures from hybrid inorganic-organic systems because the lack of controllability of depositing/assembly organic structures. The attainment of precise fabrication control and comprehension of atomic-level interactions stands as the principal objectives of this research. Here, we propose the utilization of monolayer two-dimensional (2D) materials, such as graphene and MoSe2, synthesized through chemical vapor deposition (CVD), as 2D atomic templates to induce the epitaxial assembly of orthorhombic polyethylene (PE) crystals. By meticulously regulating the assembly temperature and time, the growth of PE lamellar crystals can be modulated, ranging from a few nanometers to hundreds of nanometers with an accuracy of sub-nanometer resolution. Adding PE will not only increase the mechanical robustness of 2D materials in fabricating the suspended structures, but also create a dielectric layer with controlled thickness to realize ultrathin device fabrication. The incorporation of polymer nanocrystals, monolayer graphene, and MoSe2 yields a pioneering category of hybrid nanostructures, wherein the crystalline architectures of both constituents are highly controlled, thereby potentially reshaping the paradigm for manufacturing superior materials and devices with precisely engineered structures and properties.

2D Materials Junction-Templated Photoelectrochemistry RadhaRaman[1,2,3], Ya-PingHsieh[2] and MarioHofmann[3]; [1]National Central University, Taiwan; [2]Academia Sinica, Taiwan; [3]National Taiwan University, Taiwan

In recent years, the development of lateral junctions between 2D materials has enabled a new class of nanostructures with precise transitions in electronic structure. In this study, we have utilized the unique carrier transport properties of lateral junctions to conduct electrochemistry with unprecedented spatial resolution and dynamic controllability. By electrostatically confining electrons within the junction, we were able to localize electrochemical reactions with nanometer precision in their lateral position. We have also developed a scalable process for the formation of graphene pn-junction networks that is compatible with various materials and techniques, including dielectrophoretic deposition. The high spatial selectivity of the deposition process allowed us to create complex 1D fractal-shaped nanostructures with ultrahigh Raman enhancement.
Furthermore, we have extended our study to utilize MoS2 junctions to photo-deposit gold nanoparticles. The incorporation of MoS2 lateral junctions facilitated the deposition of gold nanoparticles with high spatial resolution. The resulting nanostructure morphology can be used for various applications including surface-enhanced Raman spectroscopy and nanoelectronics. These results offer exciting possibilities for the assembly of a new type of neural network based on axon-like guided growth of interconnected neurons. Such a network could have significant applications in the development of evolvable, brain-like future electronics. The potential of this technology highlights the importance of continued research in the field of photoelectrochemically deposited nanostructures on 2D material lateral junctions.

Exploring Two-Dimensional Indium Oxide for Memristive Switching: Fabrication, Characterization and Potential Applications Kuan-HungChen[1], Chang HsunHuang[1], Chen-YuanWeng[2], Chen-ChihHsiang[1], Yi-HsiangYen[1] and Yi-ChiaChou[1]; [1]Nation Taiwan University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

Since its groundbreaking discovery in 2004, graphene has captivated the scientific community[1], igniting an unprecedented interest in the exploration of two-dimensional materials (2DMs). These materials have garnered immense attention due to their exceptional properties resulting from their reduced dimensions, charge carrier confinement, and dangling-bond-free surface. Their distinctive van der Waals nature holds tremendous potential for applications in the scaling era of semiconductor[2], propelling researchers into a realm of innovation. In particular, liquid indium and its alloys have emerged as highly promising candidates in the realm of printed electronics, owing to their low melting point, high stability and remarkable conductivity. A novel top-down technique called liquid metal printing (LMP) has ushered in a new era for the production of 2D metal-oxide films, operating at lower temperatures and simplifying the fabrication process compared to traditional deposition methods. By skillfully tailoring the temperature and oxidation time during LMP, researchers can fashion films of varying thicknesses while preserving their 2D attributes. The striking electrical behavior observed in liquid indium-based metals, stemming from their oxide interfaces, has paved the way for exciting prospects in electronic device design. Among these devices, memristors stand out, offering an array of advantages including rapid operation speed, low power consumption, and the ability to retain multiple memory states.
This study embarks on an exploration of the untapped potential of two-dimensional indium oxide (InO_x) as a medium for memristive switching, a territory that has thus far remained relatively unexplored. We successfully extracted InO_x from liquid indium and adeptly transferred it onto a SiO_2/Si substrate utilizing the LMP technique. The resultant InO_x showcased a considerable area coverage along with an ultra-thin atomic thickness, emphasizing its remarkable properties. A thorough analysis validated the presence of high-quality, structurally stable InO_x. To expand the horizons of this investigation, the fabrication process encompassed the creation of InO_x memory device, revealing distinct memristive characteristics. Delving further into the intricacies of the relationship between defect and fabrication temperature, we uncovered a direct correlation between oxygen vacancies and temperature, thereby influencing the memristive behavior of InO_x. To elucidate the switching mechanism, an elaborate model was constructed, unraveling the indispensable role played by preferential oxygen segregation along the grain boundaries. Besides, the memristor exhibited outstanding performance in terms of low power consumption and retention, holding its on/off ratio over multiple operating cycles with remarkable stability. Furthermore, the InO_x memristor showcased the ability to assume multi-level states under specific conditions, highlighting its potential for diverse applications. An intriguing revelation emerged from this study: the behavior of oxygen vacancies within the InO_x memristor exhibited a resemblance to the behaviors observed in ion migration within bionic neurons. This striking similarity opens up new vistas for the application of InO_x devices in constructing artificial neural network. This discovery holds immense significance as it enhances our understanding of the precise characteristics of oxygen defects and our ability to control the oxygen vacancies in atomically thin oxide films. Moreover, it carries substantial implications for the field of memory technology.

8:00 PM EL19.04.06

Spontaneous Enthalpy-Uphill Exciton Dissociation at Organic/2D Heterostructures FatimahH. Rudayni[1,2], KushalRijal[1], NenoFuller[1] and Wai-LunChan[1]; [1]The University of Kansas, United States; [2]Jazan University, Saudi Arabia

Bound interlayer excitons (IXs) at type-II transition-metal dichalcogenide (TMD) heterostructures are usually stable against thermal dissociation because of their large binding energy. In this work, we show that by combining TMD with organic molecules, IXs can dissociate spontaneously into free carriers despite it is an enthalpy-uphill process. Time-resolved photoemission spectroscopy is used to probe the exciton dynamics at the fluorinated zine phthalocyanine (F_8ZnPc)/monolayer-WS_2 heterostructure. It is found that bound IXs can gain an energy of 240 meV in 50 ps without any external driving force. We attribute this anormal enthalpy-uphill process to the entropy-driven IX dissociation. The face-on orientation of F_8ZnPc molecules on TMD allows the electron within the IX to delocalize along a direction perpendicular to the interface. This geometry reduces the density of bound IXs and enhances the entropic driving force. This kind of organic/2D heterostructures is advantageous to applications that require the generation of free carriers from bound excitons.

8:00 PM EL19.04.07

The Electrical, Optical, Structural and Chemical Properties of Molybdenum Ditelluride Film (MoTe2) using Ion-Beam Assist Magnetron Sputtering for the Device Application of Phototransistor Hyeong GiPark[1] and Jae-HyunLee[2]; [1]Ajou Kiuri Research Center, Korea (the Republic of); [2]Ajou University, Korea (the Republic of)

In this study, we investigate transition metal dichalcogenide materials as active layers for heterojunction phototransistors and optimize their physical properties through numerical simulation programs. Numerical analysis was performed using the AFORS-HET 1D program, and we optimized the parameters of $MoTe_2$, WS_2, and other materials for the active layer along with Si, SiC, and GaAs substrates to improve the external and internal quantum efficiency. We deposited the $MoTe_2$ by ion-beam assisted magnetron sputtering. Tuning of the Fermi level in $MoTe_2$ leads to phototransistors with excellent electrical, structural, chemical and optical properties. Specifically, we investigated the different parameters such as power, pressure, temperature and gas atmosphere by sputtering process. Subsequently, we illuminated n-type $MoTe_2$ sample with ion-beam source under Ar, oxygen (O_2) and nitrogen (N_2) gas environment and then transversed the carrier type into p-$MoTe_2$. However, unveil of the doping mechanism effect on various thicknesses using ion-beam is still challenging. In addition, we investigated the photoresponse of MoTe after illumination of ion beam. After that, the phenomenon of carrier modulations and photoresponse paves the way for wide applications of $MoTe_2$ in optoelectronic devices.

8:00 PM EL19.04.08

Two-Dimensional Transition Metal Dichalcogenide Nanosheets for Therapeutic Drug Monitoring of Human Blood Samples TaeG. Lee[1], SunhoJoh[1], Hee-KyungNa[1], Jin GyeongSon[1], JaekakYoo[1,2], A YoungLee[1], Cheol-HeeAhn[3], Da-JeongJi[3], Jung-subWi[4], Mun SeokJeong[5] and Sang-GukLee[3]; [1]KRISS, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Younsei University College of Medicine, Korea (the Republic of); [4]Hanbat National University, Korea (the Republic of); [5]Hanyang University, Korea (the Republic of)

Two-dimensionally layered transition metal dichalcogenides (TMDs) have been widely used in various biomedical applications such as biosensing and cancer therapy due to their characteristics including UV absorbance, photoinduced thermal effect, tunable bandgap and photoluminescence.[1] However, their applications in therapeutic drug monitoring, which is essential for individualizing drug dosage regimens, is rarely reported. In this regard, we exemplarily present a facile platform for rapid quantitative determination of therapeutic drugs and biomarkers that can satisfy clinical diagnostic demands. Two-dimensionally layered TMDs including tungsten disulfide (WS_2), tungsten ditelluride (WTe2) and molybdenum ditelluride ($MoTe_2$) were fabricated by chemical exfoliation and incorporated as matrices for laser desorption/ionization mass spectrometry (LDI-MS) to promote the ionization efficiency of the analytes. The WS_2 nanosheet allowed for a sensitive detection of commonly prescribed immunosuppressive drugs including cyclosporine A and tacrolimus in the blood of organ transplant patients by LDI-MS, up to nanomolar concentration with a good linear response within the therapeutic concentration range.[2] Quantification of antiepileptic drugs in human blood was achieved using WTe_2 and $MoTe_2$ nanosheets, while they also facilitated the concentration determination of vitamin D3, which is a well-known biomarker for osteoporosis, Parkinson's disease, and cancers.[3] The validity of our method was further verified by performing statistical agreement assessment to compare our results with those of conventional analytical techniques such as liquid chromatography tandem mass spectrometry. The contribution of the physicochemical properties of TMDs to the ionization efficiency was studied by performing density function theory (DFT) calculations. The results of DFT calculations indicated that the WTe_2 and $MoTe_2$ tend to assist the ionization of small molecules more efficiently by yielding greater proton affinities for the anti-epileptic drugs, suggesting that the metallic nature of telluride is one of the contributing factors. It is anticipated that our LDI-MS based method would expand the applicability of TMDs in diagnostic medicine, while it can also provide the evidences to elucidate their roles in ionization properties under laser irradiation.

Trace Detection of Ciprofloxacin in Milk by Label-Free Raman Enhancement using Two-Dimensional Magnesiochromite AnyeshaChakraborty, ChandraS. Tiwary and BasudevLahiri; Indian Institute of Technology, Kharagpur, India

Exploring the noteworthy features of the non-Van der Waals two-dimensional (2D) metal oxide, 2D-Magnesiochromite (2D-$MgCr_2O_4$), we have developed a simple, flexible, and scalable optical sensing method. The presence of antibiotics in food products is no doubt a concerning issue these days, increasing the risk of the formation of antibiotic-resistant bacteria, which can lead to severe infections and allergies in the human body that can be challenging to cure. Ciprofloxacin (CFX, $C_{17}H_{18}FN_3O_3$) is a second-generation fluoroquinolone that is highly effective in treating several bacterial infections affecting the urinary tract, respiratory tract, skin, and gastrointestinal tract. Its broad-spectrum activity has made it a popular choice for treating a wide range of organisms, including humans, livestock, and aquaculture. Due to incomplete metabolism within the body, the drug's residue is expelled through urine and faeces, resulting in significant environmental pollution. Besides, due to drug overdoses in cattle, traces of the drug can often be found in the milk produced by them. To eliminate the antibiotic from the milk supply chain, early detection of the drug is necessary. To meet the demand, 2D-$MgCr_2O_4$ has been used for its biocompatibility, high thermal stability, abundance of surface defects, high density of surface oxygen ions which act as active binding sites, and ease of availability. We used a real-time label-free Raman enhancement mechanism for antibiotic detection, along with a Raman spectral mapping method for clear chemical fingerprint imaging for rapid identification. Here, we have used UV-Visible spectroscopy, Raman spectroscopy, and Raman imaging to analyse the 2D material's detection potential in water initially and finally in milk. The sensor has over a month-long shelf life, even when stored in typical atmospheric conditions, and the acquired detection limits are 260 ng/ml by UV-Visible spectroscopy and 120 ng/ml by Raman spectroscopy in milk. Such methods can be extended to the detection of other toxic ingredients in near future.

8:00 PM EL19.04.10

Evolution of Bandgap in WS_2 from Monolayer to Multilayer XuHe, JinpengTian, SaienXie and AntoineKahn; Princeton University, United States

Transition metal dichalcogenides (TMDs) are 2D van der Waals materials with a chemical formula MX_2, where M represents a transition metal such as tungsten (W) or molybdenum (Mo) and X represents a chalcogen atom such as sulfur (S) or selenium (Se). TMDs are layered compounds and can be stacked from mono- to multi-layer films. Unlike graphene, which has a zero gap, TMDs are more versatile in their applications in electronics due to their sizable electronic gaps, tunable with composition and thicknesses. Many theoretical works have been done to study and predict the electronic structures of these materials. It is now a consensus that TMD electronic gaps decrease as the number of layers increases. However, no experimental study has been completed to show how the electronic gap evolves from monolayer to multilayer structures.

In this work, we explore the evolution of optoelectronic properties such as energy level positions, electronic gap (E_G), and exciton binding energy (E_B) using ultraviolet and inverse photoelectron spectroscopies (UPS / IPES), complemented with Raman spectroscopy and photoluminescence (PL) measurements. High-quality large-scale monolayer and multilayer continuous films of WS_2 are grown by chemical vapor deposition on p-Si (with a native SiO_2 layer). Raman spectroscopy and PL help differentiate between mono- and multi-layer films. UPS and IPES are used to measure occupied and unoccupied states and determine valence band maximum (VBM), conduction band minimum (CBM), Fermi level position, and associated ionization energy, electron affinity, and E_G. We find that the valence (conduction) states shift toward (away from) the vacuum level from mono- to multi-layer films, decreasing the electronic gap from 2.29 eV to 1.61 eV. The optical gap (E_{OPT}) measured by PL for the monolayer film is 1.96 eV. Finally, by subtracting E_{OPT} from E_G, we determine E_B for the monolayer film to be ~0.33 eV. Further studies are being conducted on other TMDs, including WSe_2, to confirm our findings. These experimental studies will shed light on understanding TMDs bandgap evolution, making predictions on bandgap and energy levels possible for new TMD materials. This will help better decide on TMDs for appropriate band alignments in devices such as LEDs and solar cells where suitable energy levels are of essential importance.

High Drift Velocity in Multilayer Indium Selenide at High Electric Fields YongwookSeok[1,2], HanbyeolJang[2], YiTaekChoi[2], HeungsoonIm[2], KenjiWatanabe[3], TakashiTaniguchi[3], JunghyoNah[4] and KayoungLee[1]; [1]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]Gwangju Institute of Science and Technology (GIST), Korea (the Republic of); [3]National Institute for Materials Science, Japan; [4]Chungnam National University, Korea (the Republic of)

Creating a high-frequency electron system demands a high saturation velocity (υ_{sat}). Herein, we report high-field transport properties of multilayer van der Waals indium selenide (InSe). The InSe is on a hexagonal boron nitride substrate and encapsulated by a thin, non-continuous indium layer, resulting in an impressive electron mobility that approaches 3000 cm^2/Vs at room temperature. Along with the high mobility, the temperature dependence characteristics of the insulating state reveals the presence of minimal disorder and impurities in our InSe. By utilizing four-terminal pulsed measurements, the drain current (I_{DS}) at high drain bias (V_{DS}) was accessed, reaching up to 3.8 mA at 8 V. I_{DS} vs V_{DS} was measured at different carrier densities and temperatures, which are converted into electron drift velocity (υ_d) vs electric field (F). υ_d vs F data allow us to extract υ_{sat} values, which are as high as 1.8×10^7 cm/s at room temperature, superior to those of other gapped 2D semiconductors. Finally, we suggest an optical phonon emission model modified for parabolic dispersion to explain the current saturation, and determine the optical phonon energy of InSe as 22.9 meV, which is close to the theoretically expected value of monolayer InSe.

8:00 PM EL19.05.01
Applications of Ambipolar Molybdenum Disulfide with Van der Waals Contacts JungiSong[1], SuyeonLee[1], YongwookSeok[1], YeonghyeonKo[1], HanbyeolJang[2] and KayoungLee[1]; [1]KAIST, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials are promising to replace silicon because they do not exhibit performance degradation when scaled down to the nanoscale. However, their high contact resistance and Fermi-level pinning hinder the modulation of a single 2D semiconductor into n-type and p-type, and restrict their potential applications. To overcome those limitations, ambipolar transistors, which can dynamically switch the type of majority carriers, have been proposed. However, a few semiconductors with small bandgaps, such as graphene, black phosphorus, and tungsten diselenide, have shown ambipolar properties. Achieving ambipolar characteristics in 2D materials with a relatively large bandgap remains challenging. Here, we show ambipolar molybdenum disulfide (MoS_2) transistors by employing van der Waals contacts. MoS_2 shows great potential for the future semiconductor industry, thanks to its sufficient bandgap (1.2–1.9 eV), decent mobility, stability, and mature large-area growth technology. Our devices achieve outstanding ambipolar current characteristics, with both PMOS and NMOS On/Off current ratios > 10^6 and two-point hole mobility > 23 $cm^2/V*s$. By utilizing the ambipolar current characteristics, we have designed a new multifunctional electronics that is reconfigurable between an ambipolar transistor, an n-type transistor, a rectifier (rectification ratio of ~10^6), a reversible negative breakdown diode (On current of ~0.1 mA), and a photodetector. The talk will be concluded with a brief discussion regarding our demonstration of a complementary inverter based on ambipolar MoS_2 homojunction.

8:00 PM EL19.05.02
Modification of Mono-layer MoS_2 Through Post-Deposition Treatment and Oxidation for Enhanced Optoelectronic Properties JonathanRommelfangen[1], Marco A.Gonzalez-Angulo[2], DevendraPareek[2], LeventGütay[2], Phillip J.Dale[1] and AlexRedinger[1]; [1]University of Luxembourg, Luxembourg; [2]Carl von Ossietzky University of Oldenburg, Germany

Atomic layer deposition is a great tool for growing large-scale high-quality mono-layer (ML) MoS_2 and with a dedicated high temperature post-deposition treatment the amount of sulfur vacancies can be controlled. Sulfur-containing atmospheres, such as H_2S, lead to MoS_2 with low number of sulfur vacancies and increased stability against oxidation in air, whereas post-annealing treatments in N_2 increase the number of vacancies and the material is more prone to oxidation. Post-deposition annealing treatments thereby offer a great possibility to tune the properties of the 2D layer.

Here we show that the sulfur vacancy-rich ML MoS_2 films oxidize already at room temperature, which strongly affects the photoluminescence yield, the MoS_2-Al_2O_3 substrate interaction and the structural integrity of the films. We used X-ray photoelectron spectroscopy to monitor the formation of MoO_3 and possibly $MoS_{2-x}O_x$ after exposure to air and to quantify the number of sulfur defects in the films. Atomic force microscopy (AFM) measurements allow us to pinpoint the exact regions of oxidation and to develop a dedicated low temperature heating procedure to remove the oxidized species, leading to MoO_3-free MoS_2 films. Interestingly, AFM and Kelvin probe force microscopy show that the MoS_2-Al_2O_3 substrate coupling is changed, which also affects the ML MoS_2 work function significantly (variations by approximately 300 meV). In addition, the reduction in MoS_2-substrate coupling leads to a 10-fold increase in the PL intensity, and the ratio between trions and neutral excitons is changed.

Our work highlights the importance of oxidized sulfur vacancies and provides useful methods to measure and manipulate the number of vacancies on MoS_2. Furthermore, the changes in the MoS_2-substrate interaction via sulfur vacancies and oxidation offer a new pathway to tune the optoelectronic properties of the 2D films.

8:00 PM EL19.05.03
Band Alignment Tunability of 2-Layer MoS_2/SiO_2 Interface with The Use of Inorganic Salts in Liquid-CVD Sulfurization AlessioLamperti[1], Pinaka PaniTummala[1,2,3], AlessandroCataldo[1], SaraGhomi[1,4], ChristianMartella[1], ValeriAfanas'ev[2] and AlessandroMolle[1]; [1]IMM-CNR Agrate Brianza, Italy; [2]KU Leuven, Belgium; [3]Università Cattolica del Sacro Cuore, Italy; [4]Politecnico di Milano, Italy

Among two-dimensional (2D) transition metal dichalcogenides (TMDs), molybdenum disulfide (MoS_2), in the semiconducting 2H phase, is one of the most extensively studied, because of its stability, versatility, and applicability in several fields, such as electrochemistry, optoelectronics, and microelectronics [1, 2]. To achieve sustainable exploitation of 2D-MoS_2, a scalable synthesis over large macroscopic areas is required. In this respect, chemical vapor deposition (CVD) is a versatile and cost-effective method to address the deposition of high-quality few-to-single layers MoS_2 with controlled thickness, uniformity and defectivity up to the wafer scale and with satisfactory carrier mobility [3]. Having 2D-MoS_2 based microelectronic devices as target, the electron band alignment at MoS_2/SiO_2 interface is a key-parameter dictating the electrostatic properties of the stacks such as built-in voltages, transistor thresholds, as well as the tunneling barrier heights. Therefore, the electrostatic control of the MoS_2/SiO_2 interface, entailing the energy barrier height at the junction and the emergence of interface dipoles, is essential to overcome parasitic or undesired short-channel effects in ultra-scaled field-effect transistors (FETs) based on MoS_2 [1], or to fabricate compliant stacks in ultra-steep sub-threshold slope tunneling FET [4].
Despite previous attempts proved that the use of inorganic salts, such as NaCl, is effective in promoting selective extended 2D-MoS_2 growth [5], no attention has been put on the electrical properties at the MoS_2/SiO_2 interface. Here, we performed internal photoemission (IPE) spectroscopy, a method successfully applied to 2D layered materials interfacing [6], on large-area (cm^2) bi-layers MoS_2 directly grown on SiO_2/Si substrates via liquid precursor CVD (L-CVD) sulfurization, where the ammonium heptamolybdate (AHM) Mo precursor, is provided via solution deposition with inorganic salts (NaCl, NaOH, KCl, KI) spun over the substrate, to assess any possible effect of these inorganic molecules on the MoS_2/SiO_2 interface properties, in particular to determine the energy band alignment of MoS_2 with SiO_2. We measured IPE thresholds from 3.9 to 4.2 eV, depending on the type of inorganic salt in solution, which in any case disagrees with the 3.6 eV value obtained in CVD grown MoS_2 from MoO_3 and S powders with the assistance of organic perylene-3,4,9,10-tetracarboxylic acid tetra-potassium salt (PTAS) [7]. To in-depth elucidate the origin of such discrepancy, we performed structural, morphological, and chemical analysis (SEM, AFM, Raman, XPS). For the case of NaOH, we revealed the presence of Na and OH residuals. Our findings are consistent with the emergence of Si-OH dipoles at the interface that individually dependent with each surface treatment in use, thus explaining the observed 0.6 eV energy widening in the IPE threshold.

Our study evidence the impact of the junction characteristics, and thus the need to consider them, on the real electrical behavior of devices integrating 2D materials, with critical implications on proposed models and reported values so far. We also report a relatively easy route to tune the band alignment at 2D-MoS_2/SiO_2 interface, a fundamental property to consider in the perspective of direct integration of 2D materials in the process flow for microelectronic devices.

This study was supported by the Government of Italy through Ministero dell'Università e della Ricerca (MUR) under the PRIN projects "aSTAR", n. 2017RKWTMY and "PHOTO" n. 2020RPEPNH.

Galvanic Displacement Across Single-Layer Graphene for The Fabrication of Metal Nanostructures IsabelleCunitz and RohitKarnik; Massachusetts Institute of Technology, United States

This work aims to advance the scientific and engineering understanding of galvanic displacement reactions as buffered by a monolayer of graphene, specifically by investigating palladium deposition on graphene on a copper foil substrate via galvanic displacement between the copper and palladium (II) ions in solution. To understand palladium nanoparticle deposition and determine how this process can be controlled, electrochemical thermodynamics and classical nucleation theory are first synthesized into a thermodynamic model of the system. Next, scanning electron microscopy is used to characterize palladium deposition on the graphene/copper surface after galvanic displacement. Copper etch pits are observed to form during the reaction, maintaining contact between the deposition solution and the copper and thereby ensuring that the reaction is not self-limiting under the conditions studied. Palladium is observed to preferentially deposit along atomic steps in the copper foil, at graphene defects where the copper is exposed to the deposition solution, and at etch pits. The effects of varying palladium concentration and graphene/copper surface treatments are characterized, and these results are synthesized to propose a mechanism of palladium deposition via galvanic displacement through graphene. Finally, galvanic displacement is investigated in a novel engineering application, as a method of sealing graphene defects for the synthesis of centimeter-scale nanoporous atomically thin membranes. Palladium nanoparticles deposited on the graphene surface are observed to largely survive graphene transfer to a support membrane substrate, as well as mounting and use in

aqueous diffusion cell experiments. However, diffusion experiments show that graphene treated via galvanic displacement has higher leakage than untreated graphene, indicating that under the reaction conditions studied here, galvanic displacement has a net effect of graphene defect enhancement rather than defect sealing. This work contributes new insights regarding galvanic displacement as a method of modifying monolayer graphene, as well as exploring this method in the novel application of membrane separations. With further development, this simple, quick, and inexpensive technique for the fabrication of 2D material/nanoparticle composites may have a myriad of applications relevant to sustainability and beyond.

Substrate Effects on Spin Defects in Two-Dimensional Hexagonal Boron Nitride Chi-CheWu and ElizabethM. Lee; University of California, Irvine, United States

Two-dimensional (2D) hexagonal boron nitride (hBN) is a single atom thick wide band gap semiconductor with high thermal conductivity and chemical stability. Negatively charged boron vacancies (V_B^-) in hBN have recently emerged as a promising platform for quantum sensing and quantum information science applications, owing to their long spin coherence times even at room temperature. Here, we investigate electronic structure properties of V_B^- in 2D hBN on top of solid-state substrates using density functional theory calculations and *ab initio* molecular dynamics simulations. By using substrates ranging from metals (e.g., copper) to insulators (e.g., silica), we discuss how the substrates and their surface chemistry can greatly impact the electronic and mechanical stability of V_B^-. Our results suggest ways to control the spin defect properties for 2D materials using substrate engineering and surface modification.

Synthesis of V-Doped WTe_2 Nanolayers and Single Crystals VeraM. Gospodinova[1], DimitreDimitrov[1,2], PeterRafailov[2], NikolaMalinowski[1], J.F.Sierra[3] and SergioValenzuela[3]; [1]IOMT-BAS, Bulgaria; [2]ISSP, Bulgaria; [3]Catalan Institute of Nanoscience and Nanotechnology (ICN2), Spain

The discovery of 2D topological insulator in monolayer 1T'-WTe_2 indicates great potential for novel electronic, spintronic, and quantum metrology. Theoretically, the interaction between the topological states and the magnetic ordered states of Td-WTe_2 enables the modulation of Weyl semimetal states by an external magnetic field and potentially the creation of a quantum anomalous Hall phase [1-3]. However, currently, ferromagnetism in layered 1T'-WTe_2 is still not observed. We are attempting to synthesize nanolayers/ flakes of 1T'-WTe_2 with vanadium doping in order to induce magnetism. V-doped WTe_2 nanolayers/ flakes were synthesized in an atmospheric pressure CVD (APCVD) quartz tube reactor with three independent thermal zones. LP (liquid precursors) method based on ammonium metatungstate hydrate (AMT) and ammonium metavanadate (AMV) or vanadium(IV) oxide sulfate ($VOSO_4$) with addition of PTAS was used for the synthesis. The obtained nanolayers/clusters/flakes were studied by optical microscopy and Raman spectroscopy.
In addition, we are reporting growth of V -doped WTe2 single crystals by using flux (high-temperature solution) method. Particularly the self- flux method was used for crystal growth, and tellurium was used as a solvent (flux). The grown crystals were studied by XRD, XPS and Raman spectroscopy and the typical for WTe2 X-ray diffraction patterns and Raman modes were observed. Vanadium incorporation (1.8 at. %) in the crystal structure was detected by XPS measurements. The estimated overall elemental composition in at. % confirms the presence of vanadium.

Photogeneration at a Dirac/Charge-Compensated Semimetal Heterojunction based on Graphene and WTe_2FarimaFarahmand, AoShi and NathanielGabor; University of California, Riverside, United States

The unique photocurrent characteristics of pure semimetal heterojunctions composed of atomically thin materials remains a new frontier in optoelectronics. A novel pairing of a Dirac semimetal and a charge-compensated semimetal provides an opportunity to investigate photogeneration when photo-thermoelectric, photovoltaic, and other important photogeneration effects coexist. We employ near-infrared scanning photocurrent microscopy to investigate the dynamics of photoexcited electrons that control the electrical and optical conductivities at the interface to clarify the heterojunction band alignment between WTe_2 and graphene, which have charge compensated electron-hole bands and a Dirac point, respectively. Our findings highlight the important role that the photo-thermoelectric effect plays in the photocurrent distribution, alongside other phenomena such as the photovoltaic effect that have been seen earlier in p-n junctions. Our measurements not only define the essential photocurrent and band alignment characteristics of this combined Dirac-Weyl system but also provide valuable insights for the design and enhancement of highly sensitive infrared sensors based on van der Waals heterostructures. These discoveries pave the way for exciting advancements in the field of quantum optoelectronics.

Atomic Reconstruction of Large-Lattice-Mismatched Transition Metal Dichalcogenides Heterobilayers into Strained-Commensurate Structures SeongchulHong[1], Ji-HwanBaek[1], YunyeongChang[1], Hong M.Nguyen[2], ChangheonKim[1], YeonjoonJung[1], HyoengseokLee[1], KenjiWatanabe[3], TakashiTaniguchi[3], JangyupSon[4], HyeonsikCheong[2], MiyoungKim[1] and Gwan-HyoungLee[1]; [1]Seoul National University, Korea (the Republic of); [2]Sogang University, Korea (the Republic of); [3]National Institute for Materials Science, Japan; [4]Korea Institute of Science and Technology, Korea (the Republic of)

Moiré superlattices between vertically stacked van der Waals (vdW) layers with twist angle or lattice mismatch generate periodic moiré potentials, which induce renormalization of electronic band structures and corresponding modulation of electrical and optical properties of moiré crystals. In addition, lots of attentions have been paid for spontaneous atomic reconstruction of small-mismatched vdW layers into periodic commensurate domains separated by incommensurate boundaries because of unprecedented physical properties of these unique vdW layers. Unlike small-mismatched vdW layers, the spontaneous reconstruction has not been observed in large-mismatched vdW layers owing to their large formation energy of commensurate structures. Here, we report thermally induced atomic reconstruction of a large-mismatched $MoS_2/MoSe_2$ heterobilayer (lattice mismatch = 3.88%) into a strained-commensurate (SC) heterostructure that has angle- and lattice-matched commensurate domains separated by saddle point (SP) structures through hBN-encapsulation annealing. We verified that the SP structure has large dilatational and shear strains of 4% and the SC structure exhibited splitting of the intralayer excitons owing to the inhomogeneous strain distribution. Our work verifies that even hetero-bilayers with large lattice mismatches can transform into lattice-aligned heterostructures regardless of twist angle and expands our understanding for electrical and optical properties of vdW heterostructures with new stacking sequences.

A High-κ Wide-Gap Layered Dielectric for Two-Dimensional Van der Waals Heterostructures AljoschaSöll[1], EdoardoLopriore[2,3], AsmundOttesen[2,3], JanLuxa[1], GabrielePasquale[2,3], JiriSturala[1], FrantišekHájek[4], VítězslavJarý[4], DavidSedmidubský[1], KseniiaMosina[1], AndrasKis[2,3] and ZdenekSofer[1]; [1]University of Chemistry and Technology, Czechia; [2]Institute of Electrical and Microengineering, Switzerland; [3]Institute of Materials Science and Engineering, Switzerland; [4]Institute of Physics of the Czech Academy of Sciences, v.v.i., Czechia

Van der Waals heterostructures of two-dimensional materials have opened up new frontiers in condensed matter physics, unlocking unexplored possibilities in electronic and photonic device applications. However, the investigation of wide-gap high-κ layered dielectrics for devices based on van der Waals structures has been relatively limited. In this work, we demonstrate an easily reproducible synthesis method for the rare earth oxyhalide LaOBr, and we exfoliate it as a 2D layered material with a measured static dielectric constant of $\varepsilon_{0,\perp} \approx 9$ and a wide bandgap of 5.3 eV. Furthermore, our research demonstrates that LaOBr can be used as a high-κ dielectric in van der Waals field-effect transistors with high performance and low interface defect concentrations. Additionally, it proves to be an attractive choice for electrical gating in excitonic devices based on 2D materials. Our work demonstrates the versatile realization and functionality of 2D systems with wide-gap and high-κ van der Waals dielectric environments.

8:00 PM EL19.06.04
Synthesis and Characterization of (3D/2D) α-Fe_2O_3/Graphene Heterostructure for Application as a Toxic Gas Sensor AriadneC. Catto[1], LuisF. da Silva[1], EduardLlobet[2] and ElsonLongo[1]; [1]Federal University of Sao Carlos, Brazil; [2]Universitat Rovira i Virgili, Spain

Metal semiconducting oxides (MOXs) have been widely employed in gas sensors due to their potential features, such as high sensitivity, selectivity, rapid gas detection, and stability. N-type

MOXs (e.g. SnO_2, WO_3, ZnO, and α-Fe_2O_3) have been successfully applied as sensing elements in gas sensor devices for the detection of a variety of toxic gases, such as NO_2, NH_3, O_3, and H_2S. Among the n-type MOXs, hematite (α-Fe_2O_3) nanostructures have gained attention due to their high oxygen ion mobility at the material surface, excellent chemical and thermal stability under ambient atmosphere, and low cost. Despite its advantages, few studies have investigated the sensing activity of hematite. Therefore, efforts have been paid to improving the sensing performance of α-Fe_2O_3 by using distinct strategies, such as combination with other components including noble metals, semiconductors, and carbon-based materials. Among these, graphene has received considerable attention due to its unique two-dimensional (2D) structure, high electron conductivity and mobility, and high surface area. Also, various MOxs may be combined with GO and/or rGO resulting in a self-assembled heterostructure with unique properties for the most diverse applications. Regarding gas sensing applications, hydrophobic graphene-based materials have been cited as an effective way to be employed in gas sensor devices leading to high sensitivity and selectivity even in high humidity conditions. Motivated by these considerations, we report here a versatile approach towards the production of advanced materials based on (3D/2D) α-Fe_2O_3/graphene sheets heterostructure to be applied as a resistive NO_2 gas sensor. The effect of different amounts of addition ratios of graphene on the sensing performance has been studied. The α-Fe_2O_3/Gr heterostructures were obtained by hydrothermal method and the crystalline phase, morphological, and surface properties were studied by XRD, FESEM, TEM and XPS techniques. Additionally, we successfully combined experimental and DFT calculations to understand the role played by the heterointerface and the chemical environment along the exposed surfaces α-Fe_2O_3/Graphene sheets in the sensing properties towards NO_2 gas. The gas sensing experiments show that the α-Fe_2O_3/graphene heterostructure gas sensor has better sensing performance for NO_2 than the pristine graphene, such as high response, excellent selectivity, and low detection limit. The effects of temperature and moisture on the NO_2 sensitivity of α-Fe_2O_3/graphene heterostructures were also investigated. The optimal operating temperature for the highest gas response is around 150 °C, and the formation of α-Fe_2O_3/graphene heterostructure improved the NO_2 sensitivity against moisture. Furthermore, the selectivity was also evaluated by exposing the heterostructures to different gases such as O_3, NH_3, and CO. These findings show that (3D/2D) α-Fe_2O_3/Graphene sheets heterostructures have a remarkable potential for practical applications as NO_2 gas sensor in environmental monitoring devices.

8:00 PM EL19.06.05
High-Performance Self-Powered UV Photodetector Based on NGQD/Graphene Schottky Diode Muhammad ShehzadSultan[1], WojciechJadwisienczak[2], Alejandra P FloresRivera[1], BradWeiner[1] and GerardoMorell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]Ohio University, United States

Nitrogen doped graphene quantum dots (GQDs) have been widely used for various optoelectronic devices as a photoactive material due to their high absorption coefficient and tunable bandgap. However, the low mobility of NGQD films results in poor charge collection and device performance. By combining NGQDs with graphene into hybrid NGQD/Graphene photodetectors, photocarriers from NGQDs are transferred to graphene, improving charge collection and transport, and drastically increasing the photoresponsivity. In this study, we report the preparation of a NGQD/Graphene heterostructure in order to investigate the effect of NGQD on the photoactive response of graphene. Using UV–vis absorption and photoluminescence (PL) spectra, the optical properties of NGQD/Graphene heterostructure were measured. Moreover, to investigate their electronic and charge transfer properties, we fabricated the photodetectors with pristine graphene quantum dots and NGQD/Graphene heterostructure to analyze and compare their photoactive electrical properties. Under illumination, NGQD/Graphene PD showed an increase in both current and carrier mobility as compared to NGQD PD. The increased current and carrier mobility of NGQD/Graphene PD is due to the presence of a large number of photoexcited charge carriers. This is explained by NGQDs' n-type doping effect on graphene, which reduces the accumulation of holes in the active p-channel near the insulating layer and causes charge to be transferred from the NGQDs to the graphene. As a result, we discovered a charge transfer effect in the NGQD/Graphene heterostructure, which could be used in optoelectronic devices.

SESSION EL19.07: 2D Semiconductors—Quantum Emitters and Dopants
Session Chairs: Kibum Kang and Andrew Mannix

8:30 AM EL19.07.01
Macroscopic Transition Metal Dichalcogenides Monolayers with Uniformly High Optical Quality QiuyangLi, AdamAlfrey, JiaqiHu, NathanialLydick, EunicePaik, BinLiu, HaipingSun, YangLu, RuoyuWang, StephenR. Forrest and HuiDeng; University of Michigan, United States

The unique optical properties of transition metal dichalcogenide (TMD) monolayers have attracted significant attention for both photonics applications and fundamental studies of low-dimensional systems. TMD monolayers of high optical quality, however, have been limited to micron-sized flakes produced by low-throughput and labor-intensive processes, whereas large-area films are often affected by surface defects and large inhomogeneity. Here we report a rapid and reliable method to synthesize macroscopic-scale TMD monolayers of uniform, high optical quality. Using 1-dodecanol encapsulation combined with gold-tape-assisted exfoliation, we obtain monolayers with lateral size >1 mm, exhibiting exciton energy, linewidth, and quantum yield uniform over the whole area and close to those of high-quality micron-sized flakes. We tentatively associate the role of the two molecular encapsulating layers as isolating the TMD from the substrate and passivating the chalcogen vacancies, respectively. We demonstrate the utility of our encapsulated monolayers by scalable integration with an array of photonic crystal cavities, creating polariton arrays with enhanced light-matter coupling strength. This work provides a pathway to achieving high-quality two-dimensional materials over large areas, enabling research and technology development beyond individual micron-sized devices.

8:45 AM EL19.07.02
Unraveling the Role of Dopant Clustering in Magnetic Impurity Doped Monolayers of Transition Metal Dichalcogenides RehanYounas, GuanyuZhou and ChristopherL. Hinkle; University of Notre Dame, United States

Efforts to achieve above room temperature ferromagnetism in monolayers of transition metal dichalcogenides (TMDs) through substitutional doping with magnetic impurities are actively being pursued for energy-efficient logic and memory devices. However, the current limitations stem from phase separation and multi-layered growth at heavy doping levels, restricting the doping in monolayers to levels well below the threshold established by density functional theory (DFT) for above room temperature Curie temperature. On the other hand, room temperature magnetism has been frequently observed at significantly lower doping levels (0.1-1%), but this magnetism arises from a combination of substitutional dopants, point defects, contaminants, interstitials, or edge states. As a result, the origin of purely substitutional doping-induced ferromagnetism remains a subject of debate.
Towards this end, this study employs molecular beam epitaxy to achieve up to 30% substitutional doping of vanadium (V) and iron (Fe) in a monolayer of tungsten diselenide, surpassing the doping requirements (>15%) indicated by DFT for room temperature ferromagnetism. Magnetometry measurements, however, reveal the absence of ferromagnetism down to a temperature of 4 K in these phase-pure films, with only the phase-separated films exhibiting any room temperature ferromagnetic behavior at Fe doping levels exceeding 30%. Structural characterization utilizing plan-view transmission electron microscopy reveals significant dopant clustering, even at modest doping levels (~5%), which serves as the primary factor responsible for the absence of ferromagnetism in phase-pure films. Remarkably, these observations align with DFT calculations, which predict a low formation energy for dopant clustering, leading to a weakened exchange interaction that subsequently suppresses ferromagnetism. The insights gained from this exploratory study offer a promising pathway to attain high doping densities in monolayer TMDs while emphasizing the influence of dopant clustering on the magnetic properties of the films.

Structure-Property Relations of Quantum Emitters in 2D Materials Su YingQuek; National University of Singapore, Singapore

Quantum emitters in the form of point defects in 2D materials are of interest as scalable single photon sources for photonics-based quantum technologies. It is important to know the optical signatures of intrinsic defects, but also critical to be able to controllably synthesize quantum emitters with desirable and known optical properties. In this work, we use state-of-the-art first principles calculations to elucidate the structure-property relations of quantum emitters in the wide-band-gap hexagonal boron nitride (hBN) layer, as well as in transition metal dichalcogenide (TMD) monolayers. Defects in hBN can be controllably created by carbon implantation and electron or ion bombardment. We present the photophysical properties of defects derived from boron vacancies and carbon impurities [1], as well as preliminary results on other point defects created by the electron or ion bombardment process. Comparisons are made with recent experiments. In the second part of the talk, we discuss the optical properties of unintended oxygen-related defects and intentional substitutional defects in TMDs. We find that chalcogen vacancies in WSe_2 are readily passivated by oxygen, and oxygen interstitials are a possible source of single photons in WSe_2 [2]. For both Re [3] and Nb dopants in WS_2, we present theoretical and experimental evidence of optical defect-to-bulk state transitions that partially preserve the valley polarization. We will also touch on preliminary results on THz quantum emitters in TMDs.

Magnetic Fluctuations in V-Doped WSe_2Dinh LocDuong[1,2], Lan-AnhT. Nguyen[3], JinbaoJiang[4], Tuan DungNguyen[3], PhilipKim[5], Min-kyuJoo[6] and Young HeeLee[3]; [1]Department of Physics, Montana State University, United States; [2]Montana State University, United States; [3]Center for Integrated Nanostructure Physics, Institute for Basic Science, Korea (the Republic of); [4]National University of Defense Technology, China; [5]Harvard University, United States; [6]Sookmyung Women's University, Korea (the Republic of)

Vanadium-doped tungsten dichalcogenide (V-doped WSe_2) reveals ferromagnetic order at room temperature, which can be controlled by a gate bias. In this presentation, we report electrically tunable magnetic fluctuations associated with RTNs in V-doped WSe_2 at a low doping concentration using vertical tunneling graphene/V-WSe_2/graphene devices. We identify bistable magnetic states from discrete Gaussian peaks of the RTN histogram, which were further confirmed by $1/f^2$ features in the noise power spectrum. Three fluctuation categories in the resistance change were detected: small changes from the intralayer coupling between magnetic domains at high temperatures, anomalous large resistance changes over a wide range of temperatures, and persistent large resistance changes originating from magnetic interlayer coupling at low temperatures. We demonstrate the switching of the bistable state and further modulate the cut-off frequency of RTNs with bias. The observed electrical switching of a tunable bistable state in magnetic 2D materials can be utilized for low-power spintronics.

9:45 AM EL19.07.05
Elucidating Ferromagnetic Properties of Fe-Doped MoS_2, WSe_2 and WS_2 at Various Temperatures MengqiFang[1], Hee SukChung[2], Jae HyuckJang[2], ChunliTang[3], WencanJin[3] and Eui-HyeokYang[1]; [1]Stevens Institute of Technology, United States; [2]Korea Basic Science Institute, Korea (the Republic of); [3]Auburn University, United States

Transition metal-doped transition metal dichalcogenides (TMDs) have attracted significant attention due to their potential for spintronic and magneto-optical applications [1, 2]. By introducing transition metal dopants, such as vanadium [3], rhenium [4], and iron [5, 6], into TMDs, it is possible to create new electronic and magnetic properties, leading to the emergence of diluted magnetic semiconductors (DMS). These DMS materials combine the advantages of semiconductors with ferromagnetic behavior, enabling the development of spintronic devices for efficient information storage and processing [7, 8].

In this study, we present the synthesis and characterization of Fe:MoS_2, Fe:WSe_2, and Fe:WS_2 to elucidate their magnetic properties. The Fe-doped TMD materials were synthesized using contact-growth, of which detailed synthesis methods are reported elsewhere [5, 9]. To determine the ferromagnetic properties of synthesized materials, various techniques were employed: The structural and morphological characterizations were carried out using techniques such as optical, atomic force microscopy (AFM), and scanning transmission electron microscopy (STEM), confirming their successful synthesis and the presence of desired structural features. Furthermore, vibrating sample magnetometry (VSM) measurements were performed to determine the macroscopic magnetic properties, including coercivity and saturation magnetization. These measurements indicate that Fe:WSe_2 displays a more pronounced ferromagnetic signal than that from Fe:MoS_2. Further investigation is needed to gain deeper insights into the underlying mechanisms responsible for these observations.

This research may pave the way for developing novel TMD materials with tailored magnetic properties for low-power spintronics applications and quantum information science.

Controlling Quasiparticle Excitations in 2D Solids Through Atomically Precise Heterostructures AlexanderWeber-Bargioni; Lawrence Berkeley National Laboratory, United States

In this presentation, we investigate how atomically defined heterostructures, such as 2D stacks, 1D boundaries within a 2D material, and 0D vacancies and substitutes in 2D materials, localize new protected states that host quasiparticle excitations. Quasiparticles are emergent excitations in condensed matter systems that behave like particles, but are not elementary particles like electrons or protons. In 2D solids, a wide variety of quasiparticle excitations can be experimentally accessed, including localized electrons, excitons, superconducting states, and polaritons, as well as more exotic systems like Tomonaga Luttinger liquid. Each specific quasiparticle excitation is a result of a specific crystalline symmetry. By inducing atomically defined 0D, 1D, and 2D heterostructures, it is possible to localize, protect, and create novel quasiparticle excitations.
We demonstrate how to engineer heterostructures into 2D Transition Metal Dichalcogenides and visualize the resulting electronic structure using Scanning Tunneling Microscopy. We discuss the resulting quasiparticle excitations that we directly capture using Scanning Tunneling Microscopy, as well as Time Resolved optical Spectroscopy. We show how 0D heterostructures or defects in 2D MoSe2 and 2D WS2 carry intrinsic point defects that substantially modify electronic properties. For instance, individual S vacancies create two-level systems within the band gap with extremely high spin-orbit coupling, and can mediate single photon emission via optical or electric stimulation. We also demonstrate how C-H for S or Se substitutes in 2D WS2 and 2D WSe2 form locally charged hydrogen-like states. Upon deprotonation, the localized carbon radical hosts a deep in-gap state with a net spin and electron-phonon coupling that is similar to NV color centers in diamond, but with atomistic control. Furthermore, individual Chalcogen Vacancies can be decorated with a variety of different adatoms, creating new types of 0D heterostructures, such as Co-S substitutes that could become relevant for Quantum Information Science.
In 1D heterostructures, such as Mirror Twin Boundaries in MoSe2 or WS2, we discovered atomically thin metallic conductors that undergo a quantum phase transition at low temperature to form a Tomonaga Luttinger Liquid (TTL). TTLs are correlated electron systems, where electrons couple to form a bosonic system, and that can foster partial electron and spin transport.
As a 2D heterostructure, we explore WS2/WSE2 stacks, where we study the formation and recombination channels of interlayer excitons formed in WS2/WSE2 stacks, which may relate to the recently reported formation of excitonic Bose-Einstein condensates. Another fascinating area of research is coupling quasiparticles to form new quasiparticles. By stacking 2D WSe on linear plasmonic cavities, we were able to couple excitons to plasmons, creating plexcitons. We use techniques such as photo low-temperature Scanning Tunneling Microscopy, near-field optical microscopy, and low-temperature time-resolved optical spectroscopy to investigate the properties and behavior of these quasiparticle excitations.

Moiré Minibands, Interlayer Coupling and Hybridization in vdW Stacks from Optical Spectroscopies UrsulaWurstbauer; University of Münster, Germany

Two-dimensional (2D) materials exhibit unique properties due to their atomically thin structure and weak van der Waals (vdW) coupling between layers. This vdW nature allows for the precise engineering of 2D quantum systems through stacking, twisting, and inducing defects. External stimuli, such as electric or magnetic fields and charge doping, enable in-situ control of these systems.
In this study, we employ advanced optical spectroscopy methods to characterize interlayer coupling, interfacial quality, interlayer hybridization, and miniband formation in twisted vdW homo- and heterobilayers prepared from semiconducting transition metal dichalcogenides (TMDCs) such as $MoSe_2$ an WSe_2. Photoluminescence and spectroscopic imaging ellipsometry (SIE) provide insights into the hybridization of band-edge and higher-lying interband transitions [1,2]. Non-resonant Raman spectroscopy is used to study the phonon fingerprint, which is sensitive to interlayer coupling, strain, and doping [3-4].
Resonant Raman spectroscopy (RRS) is found to be highly sensitive to exciton-phonon coupling [5,6], and electronic Raman known as resonant inelastic light scattering (RILS) allows spectroscopy of Moiré mini-bands by probing collective electronic inter-miniband excitations [7]. Our research aims to deepen our understanding of the interplay between interlayer coupling,

hybridization, and mini-band formation in 2D materials. These findings have implications for the design and development of novel quantum devices and applications.

Overcoming Industrial Challenges in Implementing 2D Materials in CMOS ByunKyung-Eun, MinsuSeol, JunyoungKwon, AlumJung and Min SeokYoo; Samsung Advanced Institute of Technology, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have received great attention for their potential role as the channel material in electronic devices. Although 2D materials have demonstrated exceptional promise in academic research, significant industrial challenges must be confronted to integrate them into next-generation Complementary Metal-Oxide-Semiconductor (CMOS) technologies. In this talk, we highlight the significant challenges that the industry faces in implementing 2D materials into current semiconductor devices. These include issues related to material synthesis with high-throughput, fast and nondestructive characterization, proper integration processes for TMDs. We'll present the ongoing research about growth, characterization and integration. We demonstrate high-throughput production of 8-inch wafer-scale MoS_2 and WS_2. Utilizing our TMD, we have successfully achieved the TMD FETs on an 8-inch wafer scale through a conventional CMOS process, demonstrating consistent electrical performance with a high yield of over 99%. Through our research on TMD FET structures, we have achieved remarkable advancements in device performance. We're also accelerating the Lab to Fab transition by using artificial intelligence (AI), which proves beneficial in predicting material behaviors and optimizing processing parameters. The talk will provide insights into the extensive efforts companies are making to navigate these challenges.

Unconventional vdW Heterostructures Assembled from Bespoke 2D Atomic and Molecular Lattices ThomasJ. Kempa, ReynoldsDziobek-Garrett, OnaAmbrozaite, YifeiZhu and DaraWeiss; Johns Hopkins University, United States

Quantum materials have the potential to revolutionize sensing, analytical instrumentation, information processing, and energy conversion. Unconventional vdW superlattices assembled from precisely tailored 2D atomic and molecular lattices encode heterointerfaces which can provide an unprecedented control over charge, exciton, and spin states leading to unique artificial quantum solids. Realizing such superlattices requires not only rational, mechanism-driven chemical synthesis of atomically-precise 2D crystals, but also careful optical spectroscopy and device studies for rigorous determination of fundamental properties and intrinsic limits. In this talk I will discuss our key prior achievements and emerging results towards the assembly of these unconventional superlattices. First, we show that innovative surface-treatments and precursor chemistries can dramatically alter the dimensionality, morphology, and defect level of 2D transition metal dichalcogenides (TMD) grown by chemical vapor deposition (CVD). Second, we demonstrate the promise of gas-phase methods for the synthesis of single monolayer 2D molecular lattices (e.g., metal-organic frameworks), and also demonstrate their response to chemical, optical, and electrical stimuli through device transport and scanning probe measurements. Finally, we show that the merger, through direct CVD deposition or exfoliation and transfer, of these 2D crystals yields unique heterointerfaces that can elicit photon upconversion, modulation of lattice phonons, and control of exciton dynamics. Ultimately, the unprecedented array of chemical, dielectric, and mechanical potentials that such superlattices can support open unique opportunities for breakthroughs in optics, sensing, information processing, and sustainability.

Epitaxial Mechanism of Two-Dimensional Materials on Crystalline Substrates YiWan, Cheng YangLi, Yu-MingChang and Lain-JongLi; The University of Hong Kong, Hong Kong

One key challenge with two-dimensional semiconducting transition metal dichalcogenides (2D-TMD) channel materials or insulating hexagonal boron nitride (hBN) for industry applications is the large-scale batch growth on substrates with continuous single crystallinity, and spatial homogeneity. To achieve large-area and grain boundary-free growth of 2D materials, it is critical to understand the fundamentals of the substrate-2D interaction to enable the mono-orientation of these 2D domains.
Taking a few examples including 2D TMD, hBN, and perovskites, we like to discuss the factors that control the epitaxy. Detailed analysis will be provided to illustrate the following points. (1) In the situation that 2D seeds strongly bind to the atomic substrates edges (eg. hBN on Cu(111); TMD on Ga_2O_3(100)), seed nucleation and orientation are controlled by the step edges. (2) In the circumstance that 2D seeds do not strongly bind to the step edges (eg. TMD on C- or M-sapphire; TMD on Ga_2O_3 (001)), the epitaxy of 2D is governed by the atomic structures (and symmetry) of the substrates. Hence, the reconstruction the surfaces of substrates to only a single type (symmetry) is necessary for the single-crystal epitaxy of monolayer TMDs without the aid of step edges. (3) Precursors may react with the substrate surfaces to change the substrate atomic structures and thus the orientation of 2D materials. For example, the surface sulfurization of sapphire or surface metallization of Ga_2O_3 drastically change the orientation preference. In summary, the substrate symmetry, step edges and chemical modification of substrates (or edges) need to be taken into consideration when reconstructing the substrates for successful epitaxial growth of 2D materials.

2:15 PM EL19.08.03
Metalorganic Chemical Vapor Deposition of Epitaxial MoS_2 and WS_2 on Group III-Nitrides ShaliniKumari, DorotaKowalczyk, ChenChen, NicholasTrainor, SeungH. Lee, TimMirabito, NicholasD. Redwing and JoanM. Redwing; The Pennsylvania State University, United States

Scalable vapor phase deposition methods are rapidly developing enabling epitaxial growth of transition metal dichalcogenides (TMDs) monolayer and few-layer films on wafer-scale substrates. C-plane sapphire has been the primary substrate used so far for TMD epitaxy as it is crystallographically compatible with the hexagonal TMD lattice, is thermally stable at high temperatures and is available in large area at low cost. However, the direct lattice mismatch between the TMDs and sapphire is large and while there is commensurability which reduces the effective mismatch, the lattice off-sets lead to translational line defects between coalescing domains. In contrast, the group III-nitrides (GaN and AlN) are nearly directly lattice matched to MoS_2 and WS_2 making them intriguing substrates for TMDs epitaxial growth. WS_2 and MoS_2 have a lattice mismatch of only 1.1 % and 0.8 % to the lattice parameter of GaN, whereas WS_2 and MoS_2 have a lattice mismatch of only 1.3 % and 1.6 % to the lattice parameter of AlN respectively. In addition, direct growth of TMDs on GaN opens up prospects for novel 2D/3D heterostructures for bipolar and hot electron transistors and optoelectronics.
In this work, we present the growth, structural, and optical properties of fully coalesced MoS_2 and WS_2 monolayer to few layer films grown on GaN and AlN epitaxial templates on sapphire via Metalorganic Chemical Vapor Deposition (MOCVD). Molybdenum hexacarbonyl ($Mo(CO)_6$), tungsten hexacarbonyl ($W(Co)_6$) and hydrogen sulfide (H_2S) were used as precursors in a N_2 and H_2 carrier gas for the growth of MoS_2 and WS_2 on 1 x 1 cm^2 GaN and AlN substates. The relative thermal and chemical stability of GaN and AlN can significantly affect the epitaxial growth of TMDs. For example, in the absence of NH_3, GaN begins to decompose at elevated temperatures in H_2 while AlN remains relatively stable. Therefore, for TMD growth on GaN, the samples were heated in N_2 to prevent decomposition and the growth temperature and flow rate/growth rate were tuned to prevent GaN decomposition and pit formation before the MoS_2/WS_2 covers the surface. In this study, the growth temperature was varied from 900 to 1000 ^oC, growth time from 10 to 25 minutes, and molybdenum and tungsten precursor flow rates from 0.0006 to 0.003 sccm whereas the H_2S flow rate was maintained at 400 sccm. All the growths were done with a moderate reactor pressure of 50 Torr using N_2 and H_2 as the carrier gas. AFM and FESEM were carried out to characterize the surface coverage and morphology of the layers. Spatially resolved Raman and photoluminescence spectroscopy were used to investigate the uniformity of the growth across the sample. The TMD films were continuous with thicknesses of mono- to few layers although pits were present in films grown on GaN at elevated temperature and reduced growth rate. The presence of A_{1g} and E_{2g} Raman modes for MoS_2 and WS_2 were observed at room temperature. The MoS_2 and WS_2 films exhibits strong photoluminescence at room temperature centered around 1.9 eV and 2 eV respectively. The structural, microscopic, and optical properties of the MoS_2 and WS_2 monolayers on GaN and AlN will be discussed in detail in the meeting. We emphasize the opportunities for the compatible integration of 2D/3D TMDs/III-V nitrides heterostructures without any transfer process by a fine-

tuned deposition, which can have wide implications for the performance of future electronic and optoelectronic devices.

Multiscale Structural Analysis of Epitaxially Grown 2D Layers using Four-Dimensional Scanning Transmission Electron Microscopy HanakoOkuno, DjordjeDosenovic, SamuelDechamps, MatthieuJamet and AlainMarty; CEA-Grenoble, France

Epitaxial growth is a route to achieve highly crystalline continuous 2D layers. In recent years, large scale epitaxial growth of graphene and various transition metal dichalcogenides (TMDs) have been demonstrated by many research groups. However, high quality layer production with expected electrical properties is still challenging due to the imperfection of nucleation control. For instance, slight misalignement and symmetrical crystal inversion in neighbouring nucleation sites result in domain junctions, at the stage of coalescence, containing a large number of atomic defects and which drastically degrades material quality. The presence of polymorphe, such as 2H and 1T‘ in the TMDs, also modifies their electronic properties.
In order to control growth process and to predict intrinsic properties of grown material up to wafer scale as a patchwork of defect structures, multiscale structural analysis should be accessible in routine way. X-ray diffraction (XRD) gives a precise information on material quality regarding the crystallinity and the angular distribution at mm scale, while scanning transmission electron microscopy (STEM) imaging offers today the capability to study the detailed local atomic structures such as vacancies, grain boundaries as well as the associated chemical composition at atomic scale. However, these techniques do not reveal complete material characteristics because of the gap in scale between the information obtained by different techniques. Four dimensional (4D)-STEM is a new acquisition technique allowing to simultaneously record 2D images in real and recoprocal spaces. Multiple information, from structure to electric field, at different scales can be reconstructed from signals appearing in diffraction pattern acquired at each pixel of the beam scan.
In this work, we demonstrate an analytical process using 4D-STEM to study epitaxial 2D materials grown in both laboratory and industrial scales. Orientation, polarity and phase maps in various TMD monolayers, such as WSe_2 and WS_2, are reconstructed at micron scale from 4D-diffraction datasets and directly correlated with both large scale XRD analysis and related atomic defect structures revealed by STEM imaging. This structural mapping technique allowed the localization of various domain junctions as well as quantitative information on their density. In addition, the technique was also applied in epitaxial vdW heterostructures for mapping local twist angles. The results show the capacity to construct structural overview of synthesized materials from large scale down to atomic scale, which provides reliable information necessary to develop high quality 2D materials and further to enable theoretical prediction of material properties basis on large-scale realistic structure models.

Understanding Salt-Promoted Metal Organic Chemical Vapour Deposition of Transition Metal Dichalcogenides JinfengYang, RyoMizuta, YeFan, VitalyBabenko and StephanHofmann; University of Cambridge, United Kingdom

Scalable integrated process pathways remain a key challenge for ultrathin 2D device materials particularly for potential opto-electronic device applications. For transition metal dichalcogenides (TMDC), the use of salts to enhance chemical vapour deposition (CVD) has become widespread, yet the underpinning understanding remains limited. We employ operando scanning electron microscopy (SEM) and environmental X-ray photoelectron spectroscopy (XPS) to systematically study the role of salt-based growth promotors. We focus on WS_2 as a model system and explore surface-based mechanisms linked to sodium tungstates, NaOH and NaCl on SiO_2 and sapphire substrates in conjunction with widely used gaseous (MO)CVD precursors. We report various hot salt substrate corrosion phenomena that lead to the substrate spreading of W intermediates and significantly influence the growth mechanisms. We can directly resolve the formation and wetting behaviour of liquid droplets and show that the growth scenario particularly for mono-layers is not following a vapour-liquid-solid (VLS) model. Holistic calibration of SE contrast allows us to reveal WS_2 nucleation and in-plane growth kinetics. Our discussion brings together the wider literature including mechanisms of 1D TMDC nanotube formation.

Modified Self-Flux Synthesis of Centimeter-Scale Transition Metal Dichalcogenides LukeHoltzman, MadisenHolbrook, NicholasOlsen, XiaoyangZhu, Abhay NarayanPasupathy, JamesHone and KatayunBarmak; Columbia University, United States

Two-dimensional transition metal dichalcogenides (TMDs) are a highly attractive class of materials due to their novel electronic and optoelectronic properties and the ability to use them as a platform for assembling heterostructures. Self-flux crystal growth of TMDs has been shown to grow bulk TMDs with the lowest defect densities of any synthesis technique, maximizing the ability to study their unique, intrinsic phenomena [1-3]. However, the current self-flux crystal growth method produces TMD crystals smaller than 1 mm^2 on average, making monolayer-exfoliation difficult and limiting applications to single devices. Additionally, these crystals are too small to use macroscopic exfoliation techniques such as gold-assisted exfoliation, which require crystals greater than 2 mm in diameter and can isolate entire monolayers from every layer of a bulk crystal. [4]
In this work, we use a modified flux-synthesis thermal cycle containing an optimized dwell temperature and temperature cycling Ostwald ripening to increase the crystal area of ultralow defect density TMDs by more than ten-fold. The crystal growth kinetics as a function of temperature are determined, enabling increased cooling rate steps and shorter synthesis times. An additional post-processing self-flux recrystallization step is added and further increases the crystal size of TMDs and reduces the defect density. Lastly, gold-assisted exfoliation is used to isolate several centimeter-long monolayers from one modified self-flux synthesis $MoSe_2$ crystal, displaying monolayer yields per crystal more than five orders of magnitude greater than traditional scotch-tape exfoliation techniques. These self-flux synthesis modifications provide a route towards reproducibly exfoliating ultralow defect density TMD monolayers at the centimeter scale with high yields, greatly increasing the scalability of high-quality self-flux TMD bulk crystals for mass production.

Wafer-Scale Fabrication of Extremely Narrow Nanowires of 2D Materials QuynhSam[1], QishuoTan[2], MehrdadKiani[1], XiLing[2] and JudyCha[1]; [1]Cornell University, United States; [2]Boston University, United States

Many van der Waals (vdW) layered two-dimensional (2D) materials host exotic transport phenomena such as topologically protected surface states[1] and quantum Hall effects[1] which exhibit strong size dependence at nanoscale dimensions.[2] When formed into 1D nanowires, additional materials property engineering via lateral confinement can be achieved.[3] The tunability of 2D materials with nanowire morphology makes them an attractive platform for studying fundamental physics and for use in next generation microelectronics; however, reliable fabrication methods that can produce narrow nanowires with high aspect ratios are currently lacking.[1]

Here, we report the thermomechanical nanomolding (TMNM) of bulk vdW layered materials to make nanowires with consistent crystal orientation, narrow widths under 40 nm, and high aspect ratios. In TMNM, elevated temperatures and pressures are used to extrude a material through a nanoporous mold to form nanostructures.[4] Until now, TMNM has been reported for metallic glasses and 3D crystalline materials to form 1D nanowires.[4] We demonstrate the use of this technique to successfully fabricate nanowires with widths ranging from 10 – 120 nm of four vdW layered materials: Te, In_2Se_3, Bi_2Se_3, and Bi_2Te_3. Atomic resolution scanning transmission electron microscopy (STEM) imaging shows the high crystalline quality of the molded nanowires. While the molding direction was perpendicular to the layer planes in the bulk crystal, crystal rotation occurs during TMNM such that the layers consistently lie along the growth axis of the molded nanowire. We find that the length of the nanowires increases with decreasing width during molding, suggesting that interfacial diffusion along the pores of the mold is the growth mechanism. This work expands the capabilities of TMNM as a straightforward approach to fabricate nanowires of 2D materials with uniform morphology and crystallographic orientation. Furthermore, lateral confinement of the nanowires afforded by TMNM provides an additional tuning knob for materials properties.

Effects of Nucleation Temperature on the Properties of Wafer-Scale Epitaxial WS_2 on Sapphire Grown by Metalorganic Chemical Vapor Deposition ChenChen[1], NicholasTrainor[1,1], ShaliniKumari[1,1], NicholasD. Redwing[1,1], YuxiZhang[1,1], AnujBisht[1], StephenRevesz[2], SyndaLabidi[2], MeghanE. Leger[1,1], ThomasV. McKnight[1,1], AndrewR. Graves[1], HebinLi[2], NasimAlem[1,1] and JoanM. Redwing[1,1]; [1]The Pennsylvania State University, United States; [2]Florida International University, United States

Wafer-scale epitaxial growth of single crystal TMD monolayers is of significant interest to advance 2D device applications. MOCVD is a promising approach for TMD growth on c-plane sapphire as it enables the use of high substrate temperatures (800-1000ºC) and chalcogen/metal ratios (10^3-10^5) which are beneficial for epitaxy. Previously we reported a multi-step process for MOCVD growth of WS_2 on sapphire which involves nucleation, ripening and lateral growth. The nucleation temperature was found to be crucial for achieving single orientation domains and coalesced layers with minimal inversion domain boundaries. In this study, we report the effects of nucleation temperature and film microstructure on the resulting optical and electrical properties of the monolayers.
Coalesced WS_2 monolayers were grown on 2" diameter c-plane sapphire in a cold-wall horizontal MOCVD reactor with an inductively heated graphite susceptor with gas-foil wafer rotation. $W(CO)_6$ was used as the metal precursor while H_2S was the chalcogen source with H_2 as the carrier gas at 50Torr reactor pressure. The multi-step process consisted of a 30sec nucleation at temperatures ranging from 800ºC to 950ºC followed by 10min ripening in H_2S, and then lateral growth for 20min at 1000ºC, which gives rise to a coalesced monolayer across the entire 2″ wafer. After growth, the substrate was cooled in H_2S to 300°C to inhibit the decomposition of the obtained WS_2 films.
A coalesced monolayer of WS_2 was achieved on 2" c-plane sapphire over the nucleation temperature ranges from 800ºC to 950ºC. AFM indicates that the WS_2 monolayers are fully coalesced, with a bilayer coverage of less than 20%. Interestingly, stripe-pattern contrasts due to variations in the adhesion of the WS_2 monolayer to the underlying sapphire were observed under FESEM and the density of stripes increased as the nucleation temperature was raised from 800ºC to 950ºC. In-plane XRD *phi*-scans confirm that the films are epitaxially oriented with respect to the sapphire over the nucleation temperatures from 800ºC to 950ºC with the (11-20) of WS_2 aligned with the (11-20) of a-Al_2O_3. The FWHM of both the *phi*-scan peak and *2theta*-scan peak of WS_2 decreased as the nucleation temperature was reduced. The sample nucleated at 800°C demonstrated the lowest FWHM of ~0.26° in the *phi*-scan peak, indicating larger crystalline domains and reduced in-plane rotational misorientation of the WS_2 domains compared to the higher temperature samples. Room temperature photoluminescence measurements of the films on sapphire reveal an increase in the PL peak position from 1.9eV to 2.0eV as the nucleation temperature was increased from 800°C to 950°C.
The variations in the structural and optical properties of the WS_2 films with nucleation temperature are attributed to differences in the extent of coupling of the WS_2 to the underlying sapphire. The WS_2 grown at 800°C nucleation temperature exhibits the strongest coupling to the underlying sapphire as evidenced by the narrow FWHM of the in-plane XRD *phi*-scan peak, the lack of stripe contrast from buckling in the FESEM image and the red-shift in the PL peak indicating residual strain in the layer. In contrast, the WS_2 grown at 950°C nucleation temperature exhibits weaker coupling consistent with buckling contrast in the FESEM image, a broader FWHM for the XRD *phi*-scan peak and a PL peak at 2.0eV. To test this hypothesis, the films were transferred from the growth substrates and onto sapphire to remove the coupling arising from epitaxy. For the transferred WS_2 film grown at 800°C, a substantial increase in the PL intensity and a blueshift in the PL peak position to 1.95eV were observed, indicating a reduction in strain within the film after the transfer process. Additional results correlating the structural and optical properties of the WS_2 monolayers to the transport properties of field-effect devices will be reported.

Large-Area Epitaxial Hexagonal Boron Nitride for Hydrogen Generation by Radiolysis of Interfacial Water JohannesBinder, AleksandraDabrowska, MateuszTokarczyk, KatarzynaLudwiczak, RafalBozek, GrzegorzKowalski, RomanStepniewski and AndrzejWysmolek; Faculty of Physics, University of Warsaw, Poland

Hydrogen is an important building block in global strategies toward a future green energy system. To make this transition possible, intense scientific efforts are needed, also in the field of materials science. Hexagonal boron nitride (h-BN) is a very promising candidate for such applications, as it has been demonstrated that micrometer-sized flakes are excellent barriers to molecular hydrogen. However, it remains an open question whether large-area layers fabricated by industrially relevant methods preserve such promising properties.

We address this issue and show results on the growth of epitaxial h-BN on 2-inch sapphire wafers by metalorganic vapour-phase epitaxy (MOVPE) [1-5], which is currently regarded as one of the most promising growth techniques. This technique allows to grow hBN layers, with thicknesses of tens of nm [1,3], and can serve as a substrate for the direct growth of van der Waals heterostructures on the wafer-scale [4].

In this work, we show that electron-beam-induced splitting of water creates hBN bubbles that effectively store molecular hydrogen for weeks [5]. The bubble formation can be observed in-situ in a scanning electron microscope, giving us the unique possibility to visualize the hydrogen generation process. Raman spectroscopy proves the presence of molecular hydrogen and experiments with heavy water provide evidence that hydrogen generation is triggered by the radiolysis of water captured at the van der Waals interface. By performing a stress test we could also demonstrate that H_2 remains in the bubble even after extreme wear and deformation (over 500 cycles of deflation and inflation by changing the ambient pressure), highlighting the suitability of our large-area epitaxial material for possible hydrogen storage applications.

Our findings show that epitaxial h-BN by MOVPE is not only a potential candidate for the growth of large-area van der Waals heterostructures and hydrogen storage but also holds promise for the development of unconventional hydrogen production schemes [5].

2D-3D Heterostructures for Low Power Logic and Memory Devices DeepM. Jariwala; University of Pennsylvania, United States

The isolation of a growing number of two-dimensional (2D) materials has inspired worldwide efforts to integrate distinct 2D materials into van der Waals (vdW) heterostructures. While a tremendous amount of research activity has occurred in assembling disparate 2D materials into "all-2D" van der Waals heterostructures and making outstanding progress on fundamental studies, practical applications of 2D materials will require a broader integration strategy. I will present our ongoing and recent work on integration of 2D materials with 3D electronic materials to realize logic switches and memory devices with novel functionality that can potentially augment the performance and functionality of Silicon technology. First, I will present our recent work on gate-tunable diode and tunnel junction devices based on integration of 2D chalcogenides with Si. I will extend that work to synthesizing high quality, homogenous phase 2D materials at back end of line compatible temepratures for logic applications. Following this I will present our recent work on non-volatile memories based on Ferroelectric Field Effect Transistors (FE-FETs) made using a heterostructure of MoS_2/AlScN and also introduce achieving ambipolarity and low contact resistance with a highly polar ferroelectric material.

SESSION EL19.09: Poster Session III: 2D Materials—Doping, Modification, Processing and Quantum Emitters

Surface Modifications and Hydrophilic Transformations of Hydrophobic InSe 2D Materials for Biological Applications ShreyasiSengupta[1], SwapnilB. Ambade[1], TanaL. O'Keefe[2], ChristyL. Haynes[2] and ZeevRosenzweig[1]; [1]UMBC, United States; [2]University of Minnesota Twin Cities, United States

Nanosheets are solid, layered two-dimensional nanostructures having properties unique and different from their bulk precursors, due to which they find potential applications in various fields. Our material of interest is InSe due to its many advantages, especially because it is an emerging material for electronic applications and is a direct bandgap semiconductor with high photoresponsivity. Usage of InSe and other 2D materials is expected to increase exponentially in the next decade. However, their unique morphology and ability to produce reactive oxygen species (ROS) can be detrimental to the environment. To address this environmental concern, our studies aim to understand the impact of surface chemistry modifications on the stability and interactions of these 2D materials with model membranes and bacterial organisms relevant to human health and the environment. Initially hydrophobic InSe nanosheets are synthesized by a facile kinetically controlled semi-bottom-up approach and are subsequently made hydrophilic and suitable for biological studies by surface modifications with different molecular ligands

having varying toxicity via physisorption or chemisorption. A comparative study of the toxicity profiles of the differently modified hydrophilic InSe nanosheets is performed on *Shewanella oneidensis* MR-1, an environmentally relevant gram-negative bacterium. The goal is to understand the post-use fate of these materials on their disposal to the natural aqueous environment and design surface modification strategies to make them safer and sustainable for extensive environmental use. From a fundamental science perspective, this study should increase the molecular-level understanding of the interactions between hydrophobic 2D materials and their hydrophilic adsorbates.

8:00 PM EL19.09.02
Correlation-Induced Magnetism in Substrate-Supported 2D Metal-Organic Frameworks BernardField, AgustinSchiffrin and NikhilMedhekar; Monash University, Australia

Two-dimensional (2D) metal-organic frameworks (MOFs) with a kagome lattice can exhibit strong electron-electron interactions, which can lead to tunable quantum phases including many exotic magnetic phases. While technological developments of 2D MOFs typically take advantage of substrates for growth, support, and electrical contacts, investigations often ignore substrates and their dramatic influence on electronic properties. Here, we show how substrates alter the correlated magnetic phases in kagome MOFs using systematic density functional theory and mean-field Hubbard calculations. We demonstrate that MOF-substrate coupling, MOF-substrate charge transfer, strain, and external electric fields are key variables, activating and deactivating magnetic phases in these materials. While we consider the example of kagome-arranged 9,10-dicyanoanthracene molecules coordinated with copper atoms, our findings should generalise to any 2D kagome material. This work offers useful predictions for tunable interaction-induced magnetism in surface-supported 2D (metal-)organic materials, opening the door to solid-state electronic and spintronic technologies based on such systems.

Physical Adsorption and Oxidation of Ultra-Thin MoS_2 Crystals YingchunJiang, ZihanLiu, HuiminZhou, AnjuSharma, JiaDeng and ChanghongKe; Binghamton University, The State University of New York, United States

The oxidation mechanism of atomically thin molybdenum disulfide (MoS_2) is critical to its nanoelectronics, optoelectronics and catalytic applications as these devices dissipate Joule heating and often operate in oxidative environments. Herein, we systematically investigate the oxidation of mono- and few-layer MoS_2 flakes in air with temperature of 23-525 °C and relative humidity of ~10-60% using atomic force microscopy (AFM), Raman spectroscopy and X-ray photoelectron spectroscopy. Our study reveals the formation of a uniform nanometer-thick physical adsorption layer on the surface of MoS_2, which is attributed to the adsorption of ambient moisture. This physical adsorption layer acts as a thermal shield of the underlying MoS_2 lattice to enhance its thermal stability and can be effectively removed by an AFM tip scanning in contact mode or annealing at 400 °C. Our study also shows that high-temperature thermal annealing and AFM tip-based cleaning result in chemical adsorption on sulfur vacancies in MoS_2, leading to p-type doping. Our study highlights the importance of humidity control in ensuring reliable and optimal performance for MoS_2-based electronic and electrochemical devices and provides crucial insights into the surface engineering of MoS_2, which are also relevant to the study of other two-dimensional transition metal dichalcogenide (TMD) materials and their applications.

8:00 PM EL19.09.04
Optothermal Properties and All-Around Encapsulation of Silicene CarloGrazianetti[1], Daya SagarDhungana[1], ChiaraMassetti[1,2], EleonoraBonaventura[1], EmilianoBonera[2], ChristianMartella[1] and AlessandroMolle[1]; [1]CNR-IMM, Italy; [2]Università degli Studi di Milano Bicocca, Italy

Xenes, the monoelemental family of two-dimensional (2D) materials, exhibit a variety of interesting physical properties with potential exploitation in nanotechnology [1]. Recently, 2D materials-based homo- and heterostructures, *e.g.* magic-angle twisted graphene and transition metal dichalcogenides van der Waals artificially stacked junctions, further provided additional momentum to this research field. In this framework, the realization of vertically stacked silicene-stanene heterostructures grown by molecular beam epitaxy turns out to be a viable route to access the properties of silicene [2]. Indeed, such a heterostructure scheme, where silicene is sandwiched in between an alumina encapsulation layer on the top surface and stanene on thin Ag(111) crystal at the bottom face, makes possible to step over the unavoidable interaction between silicene and silver substrate [3]. Therefore, the introduction of a stanene buffer layer enables to disclose the optothermal properties of silicene by means of power-dependent Raman spectroscopy [4], achieve a single-crystal silicene phase by means of template engineering [5], and develop an all-around encapsulation scheme to protect silicene in ambient conditions [6]. The photo-thermal Raman spectroscopy evidences the stark difference in the heat transport in silicene depending on the substrate, *i.e.* Ag(111) vs. stanene/Ag(111) [4]. The Ag substrate can be engineered by tin decoration, forming Ag_2Sn alloy, or by buffering the interface with a stanene layer, therein resulting in a promising way to master single crystal silicene layer on the cm^2-scale [5]. The insertion of a stanene layer at the bottom of silicene allows to remove the silver substrate stabilizing silicene, that can be easily gated, for example, via the on the top oxide. Moreover, a full 2D encapsulation scheme, where top and bottom faces of silicene are protected by 2D tin layers, gives rise to an atomically thin and cm^2-scaled membrane preventing degradation of silicene for months [6]. The all-around encapsulation of silicene thus constitutes an advancement for the silicene stability and encapsulation in ambient conditions and paves the way to further exploitation of silicene (but also all the Xenes) in flexible and wearable electronics [7].
The work is within the ERC-COG 2017 Grant N0. 772261 "XFab" and ERC-PoC 2022 Grant N. 101069262 “XMem”.

Graphene Origami: Evolution of the Morphology of Free-Standing Few-Layer Graphene in Plasma Synthesis Claudia-F.Lopez Camara, PaoloFortugno, MarkusHeidelmann, HartmutWiggers and ChristofSchulz; University of Duisburg-Essen, Germany

Since discovered, graphene has shown to be a very versatile material due to its unique properties, which makes it suitable to multiple applications, ranging from sensing to batteries. Even though free-standing graphene flakes have traditionally been synthesized using exfoliation techniques, interest on gas-phase synthesis is on the rise due to its suitability for process scale-up and for generating graphene with very low oxygen content. Yet, the growth of free-standing few-layer graphene (FLG) during plasma synthesis leads to a variety of morphologies, such as turbostratic graphene (typically less than ten graphene layers), and the growth mechanism is essentially unknown.

Using spatially resolved thermophoretic sampling directly from the area of the graphene formation zone for transmission electron microscopy (TEM) analysis, we studied the morphology of graphene flakes in different growth stages. Single-layer and few-layer graphene were observed, and a morphology pattern evolution was discerned depending on time and reaction conditions. Based on these investigations, we propose a folding-based growth and structure formation process, leading to a conceptual mechanism of few-layer graphene formation and growth, starting from initial round single-layer graphene to, eventually, carbonaceous nanoparticles. The edges resulting from the folding have also been investigated, revealing that graphene does not seem to break at the bends but fold similar to rolling up carbon nanotubes and without opening new reactive sites for further growth.

8:00 PM EL19.09.06
Breathable MOFs Layer on Atomically Grown 2D SnS_2 for Stable and Selective Surface Activation Ji-SooJang; Korea Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials (MoS2, SnS2, MXene, black phosphorus (BP), and graphene oxide) with intriguing physicochemical properties such as abundant reactive edge-sites, tunable electrical properties, and mechanical flexibility, have been developed for broad applications in chemical sensing, electrocatalysis, filtration membrane, and energy storage system.[1] Among various 2D materials, SnS2 (IV-VI A group), which is a semiconducting layered structure with a large bandgap of ~2.2 eV and has many advantages (low-cost, nontoxic, and environmental friendly properties), can be catered well into the broad applications.[2] Based on these interesting material properties of SnS2, 2D SnS2 is widely used as active surface reactor with rapid, sensitive, and selective surface reactivity to various molecules including ions, gases, and biomolecules. Even though the outstanding and exceptional characteristics of SnS2 has been proved in many previous studies, its poor stability due to oxidation and degradation issues under the ambient operation conditions limits the practical usage of SnS2.

In this work, we newly developed ‘Sandwich’ like hybrid materials platform, 2D SnS2 layer covered by uniformly porous ZIF-8, employing in-situ growing methods. First of all, the 2D SnS2 layer (1st layer) was directly grown on the Si based sensor substrate through ALD method, and as such, strong bonds between active material (SnS2 in this case) and the sensor substrate are

able to be formed. Then, the in-situ growing of ZIF-8 was followed on the heterogeneous SnS2 layers, so the defect free ZIF-8 covered the whole SnS2 layers. The top-side of ZIF-8 membrane and bottom-side SnS2 play critical role for molecular sieving and chemical detection, respectively. Due to the uniform pore distribution of ZIF-8 layer on the SnS2 sensing layer, H2O molecules can be reliably blocked by ZIF-8 breathable layer, while target NO2 molecules can selectively penetrate through the ZIF-8 layer. Therefore, our hybrid materials exceptionally showed high stability and selective surface activity from the chemical sensing case study and the underlying mechanisms were further investigated in the atomistic level using theoretical calculations.

8:00 PM EL19.09.07
High-Throughput Production of an Atomically Thin Nano-Dot Array for Enhanced Exciton-Exciton Interactions JeonginYeo[1], SeungjaeLim[2], TaewanKim[2], Jae-UngLee[2] and JoonkiSuh[1,1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Ajou University, Korea (the Republic of)

Monolayer transition metal dichalcogenides (TMDs) are an appealing material platform for investigating and manipulating excitonic properties in the atomically thin limit due to their intrinsic strong Coulomb interactions and alleviated screening effects. To date, a number of such studies have been conducted to determine the excitonic physics or control their dynamics by diverse experimental approaches including electrostatic gating, magnetic field manipulation and strain engineering. However, physically confined excitonic transport through nanostructuring is not handled yet. Herein, we introduce a high-throughput nanofabrication of laterally confined monolayer TMDs in a hexagonal array. The fabricated nanodots of monolayer TMDs are approximately 20 nm wide far below typical exciton diffusion length of monolayer TMDs. We then investigated their photoluminescence (PL) characteristics by performing a series of power, wavelength (2.25~2.82 eV), and temperature dependent measurements. We observed the unconventional emission in sub-20 nm WS_2 nanodots, which is presumably associated with the physically confined excitonic transport behavior and reconstructed band structure. This platform is suitable tool for understanding of confined quasi-particle transport behavior and size-dependent PL study, providing a broader insight for fundamental excitonic many-body interactions and related dynamics.

8:00 PM EL19.09.08
A Practical Hydrogenated Graphene Gas Sensor for CO2 Monitoring SolimarCollazo[1,1], SamuelEscobar[1,2], BradWeiner[1,1] and GerardoMorell[1,1]; [1]University of Puerto Rico at Río Piedras, Puerto Rico; [2]National Institute of Standards and Technology, United States

The development of a practical gas sensor is of great interest for monitoring toxic and non-toxic gases that might endanger our safety and wellbeing in different settings. Here, we present a gas sensor based on hydrogenated graphene for monitoring carbon dioxide (CO2). Hydrogenated graphene was synthesized using a single-step method directly onto an insulating substrate plated with gold. The material was characterized using Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), and X-ray diffraction (XRD). The interaction of the hydrogenated graphene with CO2 was systematically studied at different parts per million (PPM) to determine the detection limits of the sensor. Our results show that the hydrogenated graphene-based sensor is capable of sensing CO2 at mid-PPM levels with a CO2 responsivity of -176.21. The biosensor was also found to detect CO2 at low ppm values, making it suitable for use as a biosensor for aerobic cellular respiration and regular CO2 emission sensing. We have successfully developed a versatile and practical gas sensor based on hydrogenated graphene for CO2 monitoring. The sensor's detection limits, and responsivity make it suitable for a wide range of applications, including monitoring of CO2 emissions and aerobic cellular respiration. The simplicity of the synthesis method used also makes it a promising candidate for large-scale production.

SESSION EL19.10: Poster Session IV: 2D Materials—Epitaxial and Van der Waals Heterostructures
Session Chairs: Kibum Kang and Andrew Mannix
Tuesday Afternoon, November28, 2023

8:00 PM EL19.10.01
Van der Waals Heterostructures Containing Group-III Chalcogenides MichaelAltvater[1,2] and NicholasGlavin[1]; [1]Air Force Research Lab, United States; [2]UES, Inc., United States

The group-III chalcogenides are an emerging class of van der Waals semiconductors with potential for applications in electronics, optoelectronics, and photonics. Further, material properties such as work function and band gap vary dramatically as the material is thinned toward the 2D limit. In this talk, we present experimental studies of the electronic and optical properties of van der Waals heterostructures containing the layered group-III chalcogenides. We analyze the effect of charge transfer within the structure as a function of layer thickness and compare the electronic performance with the more common TMD-based heterostructure devices.

8:00 PM EL19.10.02
Self-Catalyzed Vapor-Liquid-Solid Growth of GaS Nanobelt YukihiroEndo, YoshiakiSekine and YoshitakaTaniyasu; NTT Basic Research Laboratories, Japan

Among group-III chalcogenides, which are atomic-layered semiconductors, GaS shows a large layer-number-dependent bandgap energy from 2.5 eV (bulk) to 3.4 eV (monolayer) corresponding to blue and ultraviolet light wavelengths, respectively [1]. This unique property makes it a promising material for photonic devices and water-splitting photocatalysts [2, 3] and also an important component for group-III chalcogenide heterostructures. Furthermore, 1D structures of 2D layered materials, nanobelt or nanoribbon, would enable novel quantum devices and nanodevice integration. In this work, we demonstrate the synthesis of GaS nanobelt by means of self-catalyzed vapor-liquid-solid (VLS) growth.
GaS was grown on a sapphire wafer by metalorganic chemical vapor deposition (MOCVD). Triethylgallium (TEGa) and diethylsulfide (DES) were used as Ga and S sources, respectively. VLS growth of 1D GaS-nanobelts occurs from Ga clusters, which can be formed under a Ga-rich surface growth condition obtained at high [TEGa]/[DES] supply ratios, while 2D GaS layers are grown at low [TEGa]/[DES] supply ratios. Thus, the dimension of the GaS structure can be controlled by MOCVD growth conditions.
To evaluate the optical quality of the GaS nanobelt, we fabricated a photodetector (width: 900 nm, thickness: 100 nm, channel length: 2 μm). A photocurrent was generated under light irradiation with photon energies larger than 2.5 eV (wavelengths shorter than 500 nm), corresponding to the bandgap energy of GaS. The dark current was lower than the detection limit of our measurement system. A high ON/OFF ratio (> 1000) at a wavelength of 400 nm was obtained at the applied voltage of 10 V. This good photoresponsivity indicates that the VLS-grown GaS nanobelt has a high enough quality for device operation. The development of high-quality 1D GaS nanobelt synthesis on a wafer opens up opportunities for group-III chalcogenide nanodevice applications as well as the exploration of novel quantum phenomena.

8:00 PM EL19.10.03
Engineered 0D-2D Heterostructure for Broad-Band Photodetectors Mukesh KumarThakur, AswinAsaithambi and IlkaKriegel; Istituto Italiano di Tecnologia, Italy

In the past decades, two-dimensional (2D) transition metal dichalcogenides (TMDs) like MoS_2, WS_2, WSe_2, etc., have drawn great research interest in various applications, such as phototransistors, light emitters, photocatalysis, solar cells, biomedical imaging, and many others due to their fascinating optical, electronic, and chemical properties. Although, monolayer (1L) TMDs, such 1L MoS_2, have a direct band gap, the atomically thin nature of the 1L TMDs leads to very low optical absorption (< 5 %, mainly in the visible range). Consequently, devices made of such materials suffer from low photoresponse (mA/W) and their spectral range is limited to the visible spectrum. AAdditionally, TMDs have many defect states and are very sensitive to O_2/H_2O, affecting the device response time, which is a major drawback of TMD-based photodetectors. Integration with light-absorbing nanomaterials, such as zero-dimensional (0D) nanocrystals (quantum dots, perovskites, etc.,) not only enhances photoresponse and spectral range, it also helps to passivate the defects in 2D materials, thereby improving the overall performance of the device.[1-3]
Here, we proposed two possible strategies to enhance the device performance of TMDs by coupling them with engineered 0D core-shell nanocrystals, such as InAs@ZnSe and $Sn:In_2O_3@In_2O_3$. In both cases, the resulting hybrid structures not only enhance the net absorption, they also help to build charge trap states, which allow efficient charge-transfer pathways for fast IR photodetection. The interaction is obtained through the spin coating of these 0D nanomaterials on the 1L TMDs, such as MoS_2 or WSe_2, which realizes the intimate and direct interfacing of 0D and 2D materials. I will also outline the impact of the surface ligands of such nanomaterials on the overall device performance and how selective excitation can give insight into the interaction mechanism between the two species. The spectroscopic results suggest the efficient charge transfer between 2D and 0D materials. For proof of concept, a photodetector device of these heterostructures is fabricated with improved photocurrent, detection range, and response time compared to the bare TMDs.
Key Words: 2D Materials, CVD, InAs, ITO nanocrystals, Infrared, Phototransistor

Moiré Excitons in WS_2-$MoSe_2$ Heterobilayers YaraGalvão Gobato[1], CaiqueSerati de Brito[1], AndreyChaves[2], M. A.Prosnikov[3], T.Wozniak[4], ShiGuo[5], IngridBarcelos[6], M. V.Milosevic[7], FreddieWithers[5], A.Beer[8], J.Fuchs[8], ChristianSchueller[8] and P.C. Christianen[3]; [1]Universidade Federal de São Carlos, Brazil; [2]Universidade Federal do Ceará, Brazil; [3]Radboud University, Netherlands; [4]Wroclaw University of Science and Technology, Poland; [5]University of Exeter, United Kingdom; [6]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil; [7]University of Antwerp, Belgium; [8]Universität Regensburg, Germany

Twisted van der Waals (vdW) heterostructures exhibit periodic variations, leading to a new type of in-plane superlattice known as moiré superlattice/pattern which modifies considerably the optical properties of excitons in transition metal dichalcogenides (TMD) vdW heterostructures. Here, we report on optical and magneto-optical properties of WS_2/$MoSe_2$ heterobilayers with twist angles around 0° and 60° under out-plane magnetic fields up to 20 T [1]. We observed two neutral exciton peaks in the PL spectra: the lower energy one exhibits a reduced g-factor relative to that of the higher energy peak, and much lower than the recently reported values for interlayer excitons in other vdW heterostructures such as WSe_2-$MoSe_2$. In addition, similar values of g-factors are obtained for samples with twist angles of approximately 0° and 60° which indicates a weak hybridization between the intralayer and interlayer excitons for this heterostructure. Furthermore, time resolved PL experiments reveal that the lifetimes of the moiré exciton emission peaks are much shorter (< 50 ps) than the values reported in the literature for the interlayer excitons in other TMD heterostructures (≈ 2 ns), which also indicates a weak exciton hybridization. The observed reduction of the g-factor value for the moiré exciton was explained by the quantized center-of-mass momentum of the moiré-confined exciton resulting in a exciton momenta value away from the exciton band edge. In general, our experimental and theoretical results provide evidence that such a discernible g-factor stems from the spatial confinement of the exciton in the potential landscape created by the moiré pattern, due to lattice mismatch and/or inter-layer twist in heterobilayers [1].

8:00 PM EL19.10.05
Fabrication of Graphene/WC/SiC Heterostructures and its Electronic Properties KoheiOtsuka[1], TakahiroIto[1], AkiraEndo[2] and WataruNorimatsu[3]; [1]Nagoya University, Japan; [2]University of Tokyo, Japan; [3]Waseda University, Japan

Graphene can be grown by thermal decomposition of SiC and other carbides, which means that we can easily fabricate graphene/carbide heterostructure [1]. In this study, we focus on tungsten carbide (WC) as the carbide. Recently, it is found that Hexagonal WC is one of the topological semimetals, and it has attractive properties such as Fermi-arc surface states, negative magnetoresistance, and dHvA oscillations [2, 3]. In graphene/topological semimetal heterostructures, nonlocal resistance originating from spin-polarized carriers has been observed, which is expected to be applied to spintronics [4]. Therefore, fabrication of graphene/WC heterostructures is expected to enable us to observe new electronic properties.
In this study, we fabricated graphene/WC/SiC heterostructure and investigate the electronic properties. Highly crystalline WC thin films were formed on 4H-SiC single-crystal substrates by pulsed laser deposition (PLD). Then, graphene was fabricated by thermal decomposition of the films. The fabricated graphene/WC/SiC samples were characterized by some measurements. The electronic state of the samples was measured by angle-resolved photoemission spectroscopy (ARPES). Transport measurements of WC/SiC and graphene/WC/SiC samples were also performed at low temperatures.

4H-SiC (000-1) single crystal substrate (5×5 mm^2, on-axis, CREE) was used as a substrate. The WC thin film was fabricated by the PLD method. Then, the substrate was heated at 1100°C for 10 minutes. The resulting WC thin film was heated at 1750°C for 10 minutes in a vacuum to fabricate graphene. Reflection high-energy electron diffraction (RHEED), atomic force microscopy (AFM), Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), transmission electron microscopy (TEM), ARPES, and low-temperature transport measurements were performed on the prepared samples.

From the High-resolution TEM images after WC deposition, we observed a WC thin film deposited on the SiC substrate with a thickness of about 7 nm. Analysis of the electron diffraction showed that the relationship of the orientation between hexagonal WC and SiC substrate was $(0001)_{WC}$//$(000\text{-}1)_{SiC}$ and $[11\text{-}20]_{WC}$//$[11\text{-}20]_{SiC}$.
ARPES measurements of the graphene/WC/SiC sample showed band dispersions of graphene and bulk WC. Furthermore, we observed a band near the Γ point of WC, which we cannot explain by the band structure of graphene and bulk WC. We think the band originate from the surface state of WC or the interface interaction between graphene and WC.
Transport measurements indicate that superconductivity of WC/SiC and graphene/WC/SiC sample. We estimated the transition temperature (Tc) of WC/SiC is about 1.8-2.2 K. We found that graphene/WC/SiC has smaller Tc than WC/SiC.

8:00 PM EL19.10.06
Quasi Van der Waals Epitaxy of Cadmium Telluride on 2D Materials EnguerrandTourard; CEA Leti, France

Cadmium teluride is a key material for many technologies, such as energy production or infrared sensing, which makes the growth of free standing (strain free) layers of CdTe of particular interest. In 2017, Kim et al demonstrated that it is possible to guide the growth of a material through one or few monolayers of 2D material, given that the polarity of the substrate below the 2D material is strong enough. This technique, called “remote epitaxy”, has been applied successfully to a wide range of III-V / 2D systems, such as the epitaxial growth of GaN on hBN / GaN substrate, or GaAs on Graphene / GaAs substrate. Epitaxially grown layers are then easily transferred and the 2D coated substrate can be re-used for future growths. Despite this great success with III-V materials, remote epitaxy of II-VI semiconductors hasn’t been studied much. From a purely theoretical point of view, CdTe with its higher ionicity than GaAs or GaN should be a good candidate for remote epitaxy. However, a transfer step is required to obtain 2D coated substrates, with its lot of difficulties (polymeric contamination, degradation of the 2D surface, oxidation of the substrate…), whereas high quality surface and interface are required to perform remote epitaxy.

Another approach to bypass the need of 2D material transfer would be to perform epitaxy on a reconstructed passivated surface. It has been proven recently (Jovanovic et al, 2020) that sapphire could act as a quasi van der Waals substrate for such a growth of CdTe via the in-situ formation of a monolayer of tellurium at the interface. In such a case, the substrate surface, free from dangling bonds, allows for an easy transfer of the epitaxially grown CdTe membrane. But, unlike with “remote epitaxy”, growth is not seeded by the polar substrate, and one can ask what is the impact on the crystalline quality of the epilayer?

In this communication, we will present the results of MBE grown CdTe film on both sapphire and graphene wet-transferred onto CdZnTe. The crystalline quality of the grown CdTe film is discussed based on SEM, AFM and X-ray diffraction. Graphene quality is checked out prior and after epitaxy based upon Raman spectroscopy. Additional XPS analysis were performed to evaluate substrate oxidation and graphene cleanliness. Results of CdTe layer removal and manipulation will also be presented.

8:00 PM EL19.10.07
Edge-Contacted In-Plane Mixed-Dimensional Heterostructures from Monolayer MoS_2 and Low-Dimensional Mo/Te Compounds HyeonkyeongKim, Young ChulKim, Yeong HwanAhn and YoungdongYoo; Ajou University, Korea (the Republic of)

Mixed-dimensional heterostructures formed by combining 2D materials and other dimensional (0D, 1D, and 3D) materials have attracted attention due to their hybrid structures. However, in-plane mixed-dimensional heterostructures have been rarely investigated. Here, we report a novel sequential chemical vapor deposition method for synthesizing in-plane mixed-dimensional heterostructures composed of monolayer MoS_2 and low-dimensional molybdenum/tellurium (Mo/Te) compounds. The composition, dimension, and phase of the Mo/Te compounds interfaced with the monolayer MoS_2 were determined by adjusting the Te flux and growth time. While in-plane 2D/1D MoS_2/Mo_6Te_6 and 2D/2D/1D MoS_2/2H $MoTe_2$/Mo_6Te_6 heterostructures were synthesized with a low Te flux, in-plane 2D/2D MoS_2/mixed 2H-1T’ $MoTe_2$ and 2D/2D MoS_2/2H $MoTe_2$ heterostructures were obtained with a high Te flux. We performed scanning photocurrent microscopy measurements for studying the transport properties and the electronic band structures of the devices fabricated with in-plane mixed-dimensional 2D/2D/1D MoS_2/2H $MoTe_2$/Mo_6Te_6 heterostructures. The composition-, dimension-, and phase-controlled synthesis method developed in this study will allow large-scale controlled fabrication of edge-contacted mixed-dimensional in-plane heterostructures.

8:00 PM EL19.10.08
Atomic-Layer-Deposited Wide Bandgap Metal Oxide Buffer Layers on the Eco-Friendly Thin Film Photovoltaics Cheng-YingChen[1], I-JuiHsieh[2] and PochunChen[2]; [1]National Taiwan Ocean University, Taiwan; [2]National Taipei University of Technology, Taiwan

In this work, atomic layer deposition (ALD) is conducted for growing Wide Bandgap Metal Oxides (ZnSnO) as buffer layers on p-type selenium (Se) absorbers, which was used in the first solid-state solar cell in 1883 and has a high absorption coefficient and mobility, making it a p-type absorber for wide energy gap (~1.8~2.0 eV) thin film solar cells. In addition, direct bandgap, earth-abundance, simple composition, non-toxicity, low melting point and environmental stability make Se inexpensive and developable for solar cells. However, in the n-type buffer layer perspective, so far, has not been found a suitable buffer layer for modulating conduction band offset (CBO) between n-type buffer layers and p-type Se absorbers.
The benefit for using ALD growth ZnSnO can be summarized the as following points: (1) ZnSnO is wide band gap material (~3.2eV); (2) Controllable of Zn and Sn ratio, which can intentionally modulate the CBO become spike type (i.e., 0<CBO<0.5 eV); (3) ALD can effectively growth larger scale of thin-film and precisely control the thickness. Finally, the result presented the $Zn_{1-x}Sn_xO$ (x=7%) under the optimization of ZnO and SnO ratio, the power conversion efficiency can be achieved at about 2.68%.

8:00 PM EL19.10.09
Coherently Stacked Van der Waals Semiconductor Heterostructures Jong YunChoi[1,2], Hyun JeCho[1,2], Suk-HoLee[1,2], GeonhoMun[1,2], Heon-SuAhn[1,2], Hwang-JungChang[1,2], HyunjinJung[2,3] and Moon-HoJo[1,2]; [1]Center for Van der Waals Quantum Solids, IBS (Institute of Basic Science), Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of); [3]Center for Artificial Low Dimensional Electronic Systems, Institute for Basic Science (IBS), Korea (the Republic of)

We report atomically coherent layer-by-layer epitaxial growth of MoS_2/WS_2 van der Waals (vdW) heterostructure with metal-organic chemical vapor deposition (MOCVD) which enables vertical stacking of atomically thin semiconductors without interlayer atomic mixing. Engineering the miscut angle of c-plane sapphire substrate, we first achieved the epitaxial growth of single crystalline WS_2 monolayer (ML) template as base layer. Single crystalline texture was confirmed by microscopies and transmission electron microscope (TEM) studies. Moreover, low energy electron diffraction (LEED) measurements at several different points perfectly exhibited 3-fold symmetry without any angle deviation. We also demonstrated coherent ML-by-ML epitaxial growth of MoS_2 on top of single crystalline WS_2 film. VdW epitaxy is kinetically controlled in the near-equilibrium limit, resulting in the tunable two-dimensional (2D) vdW electronic systems. Coherent monolayer stacking was verified by transmission electron microscope studies and optical characterization. Our AA'(2H) and AB(3R) stacked MoS_2/WS_2 heterostructures showed strong interlayer coupling. Furthermore, electronic and optoelectronic properties of coherent vdW heterostructures were obtained. Our work suggests synthetic material platform of various 2D coherent heterostructures for future application in electronic and photonic nano devices.

8:30 AM *EL19.11.01
Metalorganic Chemical Vapor Deposition of Wafer-Scale Transition Metal Dichalcogenide Monolayer and Heterostructures JoanM. Redwing; The Pennsylvania State University, United States

Wafer-scale synthesis of transition metal dichalcogenide (TMDs) monolayers is of significant interest for device applications to circumvent size limitations associated with the use of exfoliated flakes. Metalorganic chemical vapor deposition (MOCVD) has emerged as a promising technique for scalable synthesis of TMD films as it enables growth at high temperatures and chalcogen overpressures which are beneficial for epitaxy and provides good control over precursor flux which is necessary for the synthesis of heterostructures.
Our work has focused on MOCVD growth of epitaxial semiconducting TMDs (MoS_2, WS_2 and WSe_2) on 2" diameter c-plane sapphire substrates. Metal hexacarbonyls ($Mo(CO)_6$, $W(CO)_6$) and hydrides (H_2S, H_2Se) are used as precursors with H_2 as the carrier gas in cold-wall MOCVD reactor geometries. Pre-annealing the sapphire surface in H_2S or H_2Se modifies the nucleation behavior of TMDs on sapphire which is attributed to passivation of dangling bonds on the sapphire surface. Passivation of step terraces can drive nucleation to occur preferentially at step edges on sapphire leading to unidirectional domains and a concomitant reduction in mirror twin defects. In situ spectroscopic ellipsometry is demonstrated to be an effective real time monitor of TMD growth even at the sub-monolayer level which can be exploited to track surface coverage as a function of time under varying growth conditions. The ability to precisely control and modulate precursor flux during growth is used to synthesize in-plane heterostructures that enable localized exciton confinement and emission.

9:00 AM EL19.11.02
Structure and Phase Engineering of Novel Two-Dimensional Transition Metal Chalcogenides BijunTang and ZhengLiu; Nanyang Technological University, Singapore

Since the discovery of monolayer graphene in 2004, two-dimensional (2D) materials have attracted considerable attention owing to their potential applications in various fields such as optics, electronics, and catalysis. Numerous 2D materials have been developed in the past decade. Among them, 2D transition metal chalcogenides (TMCs) attract most of the attention, mainly attributed to their large spectrum of fascinating properties along with various crystal structures. In parallel with the discovery of new candidate materials and exploration of their unique characteristics, engineering 2D TMCs into designated structures and phases are also of great importance for meeting the requirement for different applications. In this talk, I will discuss how we use the chemical vapor deposition (CVD) method to engineer the structure and phase of 2D TMCs and as a result, to tune their electronic and magnetic properties. Several strategies will be particularly introduced including construction of heterostructure, alloying, phase-selective growth, and dimension tuning. Additionally, the feasibility and capability of using state-of-the-art machine learning (ML) techniques to guide the synthesis and engineering of 2D TMCs will also be discussed.

9:15 AM EL19.11.03
Growth of Width-Controlled Single Atomic Layer TMD Nanoribbons XufanLi and AvetikR. Harutyunyan; Honda Research Institute USA Inc., United States

Controlling the width of single atomic layer transition metal dichalcogenides (TMDs) offers additional degree of freedoms for engineering their properties aiming applications in fields for next generations of optoelectronics, quantum computing, communication, and sensing. However, direct width-controlled synthesis of TMD nanoribbons, especially for the appealing width range below 30 nm, remains challenging. Therefore, developing facile methods for their direct and controllable synthesis is of central importance. We present a new growth method for single and double atomic layer of TMD nanoribbons with width down to sub-10 nm. Nanoribbons are grown via precipitation from the pre-deposited nanoparticles via vapor-liquid-solid mechanism in which the nanoparticle diameter also controls the width of nanoribbon. We also present the evolution of electrical and optical properties of the nanoribbons with their width reduction due to the corresponding dimension confinement and the results of their performance in the quantum electronics, particularly as a single electron transistor and single photon emitter.

The Impact of Boron and Nitrogen Isotopes on the Properties of Hexagonal Boron Nitride JamesH. Edgar, EliJanzen and ThomasPoirier; Kansas State University, United States

Hexagonal boron nitride (hBN) is a two-dimensional dielectric material prized for its potential electronic, optoelectronic, and nanophotonic device applications. Here we describe how its properties are affected by changing its boron and nitrogen isotopes. hBN consists of 20% ^{10}B and 80% ^{11}B, and 99.6% ^{14}N and 0.4% ^{15}N when it is synthesized from sources with the natural distribution of isotopes (hBN^{nat}). Isotopic disorder is greatly reduced when hBN is synthesized using an isotopically enriched boron source, either ^{10}B or ^{11}B. Consequently, the phonon

polariton propagation length and lifetimes are increased by factors of eight and four times in monoisotopic hBN crystals. Due to reduced phonon scattering, the thermal conductivity is also increased, by as much as 50% to 650 $Wm^{-1}K^{-1}$ for $h^{10}BN$ at room temperature. Reducing the density of nuclear spin density motivates the synthesis of hBN with the ^{15}N isotope: ^{14}N and ^{15}N have nuclear spins of 1 and ½ respectively. Thus, the DC sensitivity of the boron vacancy V_B^- to magnetic fields is increased by a factor of four with $h^{10}B^{15}N$ over hBN^{nat}.

These hBN crystals with controlled isotope concentrations were grown at atmospheric pressure from molten metal solutions of nickel, chromium, and enriched boron in contacted with nitrogen gas at 1550 °C. By slow cooling (1-4 °C/h), hBN is synthesized and its crystals precipitate on the surface of the metal. This technique produces high quality hBN crystals, as indicated by their narrow E_{2g} Raman peak widths (<3 cm^{-1} for $h^{10}BN$) and strong photoluminescence intensities at energies great than 5.75 eV. This is a versatile, scalable technique for making high quality, large area, hBN single crystals with low residual impurity concentrations.

10:30 AM EL19.11.05
Optoelectronic Property of APCVD Grown 2D Non-Van der Waals Bi_2O_2Se Nanosheets SurajLakhchaura and AtikurRahman; Indian Institute of Science Education and Research (IISER), Pune, India

Bismuth oxyselenide has recently gained attention as a highly promising 2D material for next-generation digital electronics and optoelectronics due to its ultrahigh mobility, the moderate bandgap of 0.8eV, and exceptional environmental stability.Bi_2O_2Se-based field-effect transistors (FETs) have also shown excellent current on/ off ratios of $>10^6$ with an almost ideal subthreshold swing (≈65 mV dec^{-1}), which is essential for low-power logic devices. In this study, we have synthesized ultrathin single crystalline nanosheets of Bismuth oxyselenide using a Homebuilt Atmospheric Pressure Chemical Vapor Deposition system. We transferred as-grown samples to different substrates using a non-corrosive dry transfer method. We have fabricated a back-gated Bi_2O_2Se Field Effect Transistor and examined its electronic transport properties. Furthermore, our investigations into its optoelectronic properties revealed that our device demonstrated an ultrahigh responsivity of 1.16×10^6 A/W and detectivity of 2.55×10^{13} Jones. Our findings suggest that Bismuth oxyselenide is a promising material for applications in optoelectronics.

High Crystalline Quality $PtSe_2$ Films for High Frequency Optoelectronics PierreLegagneux and EvaDesgue; Thales Research & Technology, France

Transition metal dichalcogenides (TMDs) are very attractive two-dimensional materials for optoelectronic applications, due to their various and tunable bandgaps, to the strong light-matter interaction per 2D layer and to the possibility to transfer and integrate these 2D materials on CMOS or photonic platforms.
While the most well-known TMDs (MoS_2, WSe_2,…) exhibit a bandgap in the visible range, $PtSe_2$ is an original and remarkable TMD particularly adapted for optoelectronics in the infrared (IR) domain. It exhibits a bandgap varying from 1.2eV (monolayer) to 0.2eV (bilayer) and becomes semi-metallic from few layers to bulk. Thus, $PtSe_2$ absorption can be easily tuned to absorb IR light by varying its thickness from two to multilayers.
$PtSe_2$ is air stable and particularly adapted for high-frequency optoelectronics with a very high theoretical (4000 $cm^2/V.s$) and a high experimental (e.g. ~ 200 $cm^2/V.s$) carrier mobility at room temperature (Note that larger mobilities are reported in the literature which remain however difficult to measure due to the difficulty to estimate actual carrier concentration in semimetal multi-layered $PtSe_2$).
Due to its high intrinsic qualities, $PtSe_2$ is studied to fabricate high frequency photodetectors operating at the 1.55 µm telecom wavelength. Based on transferred thin $PtSe_2$ films grown by CVD, 17 GHz bandwidth photodetectors have been fabricated on a SiO_2/Si substrate and 35 GHz bandwidth waveguide photodetectors have been realized on a silicon nitride platform.
High frequency optoelectronics requires both efficient photodetection and high-speed transport and thus materials exhibiting high crystalline quality.
$PtSe_2$ has been synthesized by mechanical exfoliation, CVD, thermally assisted conversion and molecular beam epitaxy (MBE). To evaluate $PtSe_2$ crystalline quality, most groups have studied the full width at half maximum (FWHM) of the in-plane Eg Raman peak and shown that thinner is the Eg peak, higher is the crystalline quality and the electrical conductivity.
Here, we have studied the growth of high quality $PtSe_2$ by MBE on sapphire, which is a low cost, insulating substrate and have fabricated high frequency optoelectronic devices on 2 inches sapphire substrates. We show 8-nm thick $PtSe_2$ films exhibiting average FWHM Eg values as low as 3.7 cm^{-1} and electrical conductivities as high as 1.5 mS. Integrated in a coplanar wave guide, we demonstrated 1.55 µm photodetectors with a 60 GHz bandwidth and optoelectronic mixers exhibiting a flat response between 1 and 30 GHz. Optoelectronic mixing is a key technical enabler for future broadband and multifunctional RF systems such as radio-over-fiber communication systems, radar systems, and satellite payloads.
To further increase $PtSe_2$ crystalline quality, we are studying two methods: step-guided epitaxy and van der Waals epitaxy. Step-guided epitaxy on sapphire consists in growing on dedicated vicinal surfaces to favor the oriented nucleation of the crystals at the step edges (this method has been demonstrated by other groups for MoS_2 and WS_2 on sapphire). We will also show first results targeting van Der Waals (vdW) epitaxy of $PtSe_2$ on h-BN.

11:00 AM EL19.11.07
Reproducible Synthesis of Ultrahigh-Quality Graphene by Oxygen-Free Chemical Vapor Deposition XingzhouYan[1], JacobAmontree[1], ChristopherDiMarco[1], PierreLevesque[2], TehseenAdel[3], MadisenHolbrook[1], ChristianCupo[1], DihaoSun[1], KenjiWatanabe[4], TakashiTaniguchi[4], CoryDean[1], AngelaR. Hight Walker[3], KatayunBarmak[1], RichardMartel[2] and JamesHone[1]; [1]Columbia University, United States; [2]Université de Montréal, Canada; [3]National Institute of Standards and Technology, United States; [4]National Institute for Materials Science, Japan

Progress in translating advances in the growth of graphene films by chemical vapor deposition (CVD) to applications has been hindered by challenges in quality and reproducibility, as well as the lack of a simple model of growth kinetics. Here we show that eliminating trace oxygen leads to fast and highly reproducible CVD graphene growth. The dependence of growth rate on growth time, temperature, and CH4 pressure follow straightforward trends, while previously unobserved behavior is seen for H2 pressure. A compact kinetic model is constructed to describe the graphene growth behavior, which can be used to guide graphene synthesis. We confirm that ppm-level oxygen disrupts growth by etching the graphene edges, and map the boundary between growth and etching in the presence of H2. We demonstrate that trace oxygen causes two major sources of disorder in CVD-grown graphene: pinholes and amorphous carbon deposition. Finally, we grow epitaxial graphene on sapphire-supported Cu(111) films. The graphene shows few wrinkles, no evidence of amorphous carbon, and an ultra-low defect density. After dry transfer and device assembly, this graphene shows electrical transport behavior virtually indistinguishable from that of exfoliated graphene, both at room temperature and at low temperature.

11:15 AM *EL19.11.08
***In-Situ* TEM of Atomic Reconstructions in 2D Transition Metal Dichalcogenides**YichaoZhang[1], Chia-HaoLee[1], Ji-HwanBaek[2], HuijieRyu[2], GillianNolan[1], Gwan-HyongLee[2] and PinshaneY. Huang[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Seoul National University, Korea (the Republic of)

Scanning transmission electron microscopy (STEM) provides uniquely powerful tools to study the interfacial structure and transformations of 2D materials up to atomic resolution. Here, we utilize 2D multilayer stacks to create nanoscale laboratories for studying the atomic structure, structural transformations, and properties of 2D interfaces inside the STEM. We utilize graphene encapsulation in combination with a MEMS-based heating holder to conduct in-situ studies of solid-solid phase transformations and interfacial restructuring in 2D transition metal dichalcogenides. The graphene encapsulation protects the 2D materials from the vacuum environment of the STEM, enabling high temperature studies up to 1000°C. We use these structures to directly visualize the layer-by-layer phase transformation of $MoTe_2$ and the lattice reconstruction of 2D moirés.
First, we study the interfacial reconstruction mechanisms of twisted bilayer transition metal dichalcogenides ($MoSe_2$ and WSe_2) using *in situ* aberration-corrected STEM and dark-field transmission electron microscopy (DFTEM). We discover a new mechanism of local reconstruction from moiré patterns to parallel (3R) and/or antiparallel (2H) domains in twisted bilayer 2D transition metal dichalcogenides (TMDCs). Unlike previous reports, where the twist angle is altered by the rotation of a whole flake, we observe the nucleation and growth of commensurate domains through the formation and migration of grain boundaries. We capture the dynamic process of nucleation and growth of the aligned structure through a series of atomic resolution STEM images combined with atom-tracking analysis. These results provide new insights into the mechanisms of interlayer rotation at the atomic scale and potential methods for engineering the structure of moiré superlattices.
Second, we examine the atomic mechanisms of phase transitions of $MoTe_2$. $MoTe_2$ exhibits multiple structural and electronic phases at room temperature (2H, 1T', and T_d) that can be easily manipulated with different stimuli, making it a promising candidate for phase-change memories, high-performance transistors, and broadband photodetectors. We combine dark-field TEM and aberration-corrected STEM to image the phase transitions of few-layer $MoTe_2$ *in situ* from the micro- to atomic scales. We find that T_d-to-2H phase transitions initiate at the phase boundary at temperatures as low as 200-225 C, much lower than previously thought. The 2H-T_d interfaces propagate primarily along the b-axis of the T_d grain, producing an anisotropic, layer-by-layer phase transformation. These results should lead to new methods to manipulate the quantum and electronic properties within individual atomic layers.

SESSION EL19.12: Quantum Applications of 2D Materials

1:30 PM EL19.12.01
Giant Magnetoresistance of Dirac Plasma in High Mobility Graphene AlexeyBerdyugin[1,2], NaXin[1], JamesLourembam[1], PiranavanKumaravadivel[1], AlexanderKazantsev[1], ZefeiWu[1], CiaranMullan[1], JulienBarrier[1], AlexandraGeim[1], IrinaGrigorieva[1], ArtemMishchenko[1], AlessandroPrincipi[1], VladimirFalko[1], LeonidPonomarenko[3] and AndreGeim[1]; [1]The University of Manchester, United Kingdom; [2]National University of Singapore, Singapore; [3]The University of Lancaster, United Kingdom

The most recognizable feature of graphene's electronic spectrum is its Dirac point, around which interesting phenomena tend to cluster. At low temperatures, the intrinsic behaviour in this regime is often obscured by charge inhomogeneity but thermal excitations can overcome the disorder at elevated temperatures and create an electron–hole plasma of Dirac fermions. The Dirac plasma has been found to exhibit unusual properties, including quantum-critical scattering and hydrodynamic flow. However, little is known about the plasma's behaviour in magnetic fields. Here we report magnetotransport in this quantum-critical regime. In low fields, the plasma exhibits giant parabolic magnetoresistivity reaching more than 100 per cent in a magnetic field of 0.1 tesla at room temperature. This is orders-of-magnitude higher than magnetoresistivity found in any other system at such temperatures. We show that this behaviour is unique to monolayer graphene, being underpinned by its massless spectrum and ultrahigh mobility, despite frequent (Planckian limit) scattering. With the onset of Landau quantization in a magnetic field of a few tesla, where the electron–hole plasma resides entirely on the zeroth Landau level, giant linear magnetoresistivity emerges. It is nearly independent of temperature and can be suppressed by proximity screening, indicating a many-body origin. Clear parallels with magnetotransport in strange metals and so-called quantum linear magnetoresistance predicted for Weyl metals offer an interesting opportunity to further explore relevant physics using this well defined quantum-critical two-dimensional system.

1:45 PM EL19.12.02
Two-Fold Anisotropic Superconductivity in Bilayer T_d-$MoTe_2$ZizhongLi[1], ApoorvJindal[2], AlexStrasser[3], YangchenHe[1], DavidGraf[4], WenkaiZheng[4], KenjiWatanabe[5], TakashiTaniguchi[6], LuisBalicas[4], XiaofengQian[3], Abhay NarayanPasupathy[2] and DanielA. Rhodes[1]; [1]University of Wisconsin Madison, United States; [2]Columbia University, United States; [3]Texas A&M University, United States; [4]National High Magnetic Field Laboratory, United States; [5]NIMS, Japan; [6]Kyoto University, Japan

Non-centrosymmetric 2D superconductors offer an opportunity to explore superconducting behaviors with large values of anisotropy. Among the non-centrosymmetric families, T_d-$MoTe_2$ is a representative material because of its rich phases. Notably, T_d-$MoTe_2$ is the first 2D materials that demonstrated a coupling between ferroelectricity and superconductivity, and this ferroelctric switching can be simply controlled by electrical gating. Here, we will present on the superconducting behavior in bilayer T_d-$MoTe_2$ under the application of an applied magentic field along different directions in-plane and under differing displacement fields and doping densities. Importantly, we find that bilayer T_d-$MoTe_2$ has two-fold symmetric superconducting behavior as a function of in-plane magnetic field angle that maximizes along the a-axis, parallel to the mirror plane. The two-fold anisotropy is preserved in the entire superconducting region, even with the interaction of strong Rashba spin-orbit coupling, and we find that the two-fold symmetric superconductivity exists after the ferroelectric switching. Our findings generally agree with previously observed results in multilayer and monolayer T_d-$MoTe_2$ and the expected spin-orbit enhanced upper critical fields as found in DFT calculations.

2:00 PM *EL19.12.03
Few-layer 2M and T_d-TMDs: Topologically Nontrivial States, Superconductivity and Ferroelectricity ApoorvJindal[1], AmartyajyotiSaha[2], ZizhongLi[3], YangchenHe[3], TakashiTaniguchi[4], KenjiWatanabe[4], JamesHone[1], TuranBirol[2], RafaelFernandes[2], CoryDean[1], Abhay NarayanPasupathy[1] and DanielA. Rhodes[3]; [1]Columbia University, United States; [2]University of Minnesota, United States; [3]University of Wisconsin - Madison, United States; [4]National Institute for Materials Science, Japan

I will discuss our most recent results on superconductivity in bilayer T_d-$MoTe_2$, For bilayer T_d-$MoTe_2$ the influence of an electrostatic gate allows us to identify a unique superconducting state that relies on Fermi surface nesting between hole and electron pockets. As a result, we show that the superconducting state can be completely quenched by an electrostatic gate. Concomitant to this effect, ferroelectricity resulting from interlayer sliding is also present in bilayer T_d-$MoTe_2$, resulting in a hysteretic behavior of superconductivity with respect to an applied out-of-plane electric field. This behavior allows for the first investigations of how internal polarization might conflict with or enhance superconductivity in the two-dimensional limit. Time allowing, I will discuss our results on a similarly structured TMD in the few-layer limit, the topologically nontrivial 2M-WSe_2.

3:30 PM EL19.12.04
Van der Waals Josephson Junctions for 2D Superconducting Qubits JesseBalgley[1], XuanjingChu[1], JinhoPark[1], EthanArnault[2], MartinV. Gustafsson[3], JamesHone[1] and Kin-ChungFong[3]; [1]Columbia University, United States; [2]Massachusetts Institute of Technology, United States; [3]Raytheon BBN Technologies, United States

State-of-the-art superconducting qubits currently face numerous materials-limited roadblocks to increasing coherence times for fault-tolerant computing while shrinking form factors for scalability. Two-dimensional van der Waals (vdW) materials offer an ideal platform to circumvent these issues owing to their single-crystallinity, low defect density, and lack of dangling bonds. In particular, the vdW semiconductor WSe_2—whose band gap is ~5x smaller than that of vdW insulator hBN—can exhibit tunneling through ~10 layers, enabling Josephson junctions with exceptional tunnel barrier homogeneity and lower loss compared to deposition-grown junctions by confining fields in ultra-clean vdW interfaces while achieving 100x smaller qubit area. We characterize the electronic properties of vdW Josephson junctions with ultra-high-purity WSe_2 barriers and discuss their potential in small-footprint, long-coherence-time superconducting qubits.

3:45 PM EL19.12.05
Field-Free Superconducting Diode Effect in Fe(Se,Te) Van der Waals Josephson Junctions GangQiu[1,2], Hung-YuYang[1], LunhuiHu[3], HuairuoZhang[4], Chi-YenChen[5], YanfengLyu[6], PengDeng[1], SergiyKrylyuk[4], AlbertV. Davydov[4], RuixingZhang[3] and KangL. Wang[1]; [1]University of California, Los Angeles, United States; [2]University of Minnesota, United States; [3]The University of Tennessee, Knoxville, United States; [4]National Institute of Standards and Technology, United States; [5]National Sun Yat-sen University, Taiwan; [6]Nanjing University of Posts and Telecommunications, China

Iron-based high-Tc $FeTe_xSe_{1-x}$ (FTS) has been proposed to host unconventional superconductivity. Recent scanning probe and ARPES experiments imply spontaneous time-reversal symmetry breaking in FTS systems. In this work, we report the field-free superconducting diode effect in FTS van der Waals Josephson junctions (vJJ). Non-reciprocal superconducting critical current can be observed in the absence of external magnetic field, which directly manifests spontaneous time-reversal symmetry breaking in FTS systems. The polarity and efficiency of the diode effect are also stochastic, which can be randomly reset by performing a thermal cycle above the superconducting critical temperature Tc. This suggests the time-reversal symmetry breaking ordering is closely tied to the superconducting states. The stochasticity also provides insights into ferromagnetic domain behaviors of superconducting surface states.

4:00 PM EL19.12.06
2D-Material-Based Superconducting Quantum Devices XuanjingChu[1], JesseBalgley[1], JinhoPark[1], EthanArnault[2], MartinV. Gustafsson[3], JamesHone[1] and Kin-ChungFong[3]; [1]Columbia University, United States; [2]Massachusetts Institute of Technology, United States; [3]Raytheon BBN Technologies, United States

Two-dimensional van der Waals (vdW) materials are promising platforms for superconducting quantum devices due to their single-crystallinity, low defect density, and lack of dangling bonds. Additionally, vdW materials offer a novel knob of gate-tunable electronic properties, including carrier density and superconducting gap energy, and can be readily combined into quantum device heterostructures such as Josephson junctions (JJs). JJs made from vdW materials can boast homogeneity across large (~1000 μm2) areas making them practical as novel sub-THz JJ emitters whose frequency can be tuned with a gate voltage as opposed to changing the bias current. We characterize the dc and microwave electronic properties of vdW materials and show they are compatible with high-quality-factor superconducting quantum devices. We also present numerical calculations of the emitting properties of gate-tunable Josephson junctions based on vdW superconductors and semiconductors and show that they can meet desirable performance criteria, including narrow linewidths < 1 MHz and appreciable output power at the microwatt level.

4:15 PM *EL19.12.07
Probing Complex Many-Body Interactions in 2D Heterostructures JyotiKatoch; Carnegie Mellon University, United States

Two-dimensional (2D) materials provide unprecedented opportunity to engineer their physical properties by modification to the electronic structure utilizing external perturbations- strain, gating, adsorbates, defects, twist-angle, and interface engineering. This is expected to cause changes to the Hamiltonian describing the system and has resulted in exotic phenomena such as superconductivity, bound quasiparticles, topological states as well as magnetic phases, with implications for novel electronics and spin-device applications. In this talk, I will present our work on directly visualizing (without any assumption) the electronic structure of atomically thin systems utilizing *in-operando* angle-resolved photoemission spectroscopy with nanoscale spatial

resolution (nanoARPES) on 2D heterostructures and their fully functional devices. I will present the experiments which demonstrate on-demand tuning of the electronic band structure in atomically thin systems, such as transition metal dichalcogenides (TMDs) and graphene, by varying the twist-angle between the atomic layers and external dopants. Specifically, I will discuss the electric field tuning of the electronic interactions that result in van Hove singularity and flat bands in twisted bilayer graphene and twisted double bilayer graphene heterostructures. In addition, I will discuss our results where we observe the formation of quasiparticle polarons due to many-body interactions in graphene/TMDs heterostructures.

4:45 PM EL19.12.08
Polymer–Free Assembly of Van der Waals Heterostructures WendongWang[1,2], NicholasClark[1,2] and RomanGorbachev[1,2,2]; [1]National Graphene Institute, United Kingdom; [2]The University of Manchester, United Kingdom

2D heterostructures present an optimal approach for the synthesis of novel materials with highly adjustable properties, including electron topology and correlation effects. Currently, the prevailing method for constructing van der Waals heterostructures involves the "tear and stack" technique, wherein individual 2D layers are stacked using a polymer stamp. However, this approach easily traps contaminants at the heterostructure interface, leading to limitations in atomic cleanliness and electronic performance of the resulting heterostructures. To address this issue, we have developed a novel polymer–free stacking method that employs flexible, transparent, and thermally stable metallized silicon nitride membranes (SiN). These SiN membranes enable precise and rapid transfer of 2D flakes to desired locations in various environments, including air, argon glovebox, and ultrahigh vacuum, at elevated temperatures of up to 300°C. The elevated temperature during the fabrication process facilitates the removal of surface–absorbed contaminants from the 2D heterostructure interfaces. To showcase the merits of this polymer–free transfer technique, we successfully fabricated and assessed distinct heterostructures. In initial experiments, we achieved hBN/graphene/hBN heterostructures exhibiting remarkably bubble–free regions, accompanied by mobility values reaching 3×10^6 $cm^2V^{-1}s^{-1}$. Moreover, we demonstrated the fabrication of a more intricate LED structure with a bubble-free area 25x30 µm, completed within a mere 10–minute timeframe. Furthermore, a twisted monolayer/bilayer graphene on an hBN substrate displayed minimal variation in twist angles, with deviations of merely 0.016° over a length of 10 µm. Lastly, the SiN membrane method enables the large–scale transfer of 2D materials synthesized via chemical vapour deposition (CVD) from the growth substrate, devoid of any polymer involvement.

SESSION EL19.13: Poster Session V: 2D Materials—Characterization

8:00 PM EL19.13.01
Twist Related Structure-Property Correlations in h-BN/SiC Heterostructures AbhijitBiswas[1], RuiXu[1], Gustavo A.Alvarez[2], JinZhang[3], RobertVajtai[1], HanyuZhu[1], ZhitingTian[2], AngelRubio[3] and PulickelAjayan[1]; [1]Rice University, United States; [2]Cornell University, United States; [3]Max Planck Institute for the Structure and Dynamics of Matter and Center for Free-Electron Laser Science, Germany

Recently, “twistronics” in two-dimensional van der Waals (2D-vdW) materials and their heterostructures has become an emergent topic in materials science and condensed matter physics. Hitherto, ex-situ top-down mechanical stacking of individual monolayers of exfoliated single crystal 2D-vdW materials has been used for twistronics, which is technically challenging, non-trivial process, with the resultant interfacial impurity/contaminations. Therefore, future application of twistronics demands an alternative in-situ ultra-clean approach for the large-scale production of twisted nanomaterials.
Here we propose a simple and scalable alternative approach to investigate the twisted-interface-dependent properties in 2D-vdW nanomaterials. Two-dimensional hexagonal boron nitride (h-BN) thin films are grown directly on high in-plane lattice mismatched 3D silicon carbide (4H-SiC) substrate by using pulsed laser deposition (PLD), to explore possible twist-dependent structure-property correlations. In-depth investigations reveal that, concurrently, nanocrystalline h-BN exhibits unusually strong non-linear second-harmonic generation (SHG) and ultra-low cross-plane thermal conductivity. These properties are attributed to the inherent formation of twisted nano-domain edges between the 2D-vdW stacked h-BN nanocrystals with random in-plane orientations, exploited via their high in-plane lattice mismatch. Furthermore, first-principles time-dependent density functional theory (TDDFT) calculations reveal strong even-order optical non-linearity in twisted h-BN layers, supporting our observations.
Considering the uniqueness in growth and application-worthiness of h-BN, our work not only provides fundamental insights, but also demonstrates an alternate method for creating significant twisted-interface regions in directly deposited 2D nanocrystalline thin films (without the need of time-consuming, low-yield mechanical exfoliation processes with interfacial impurites), making it feasible to integrate the clean 2D twistronics into next-generation 3D materials devices.

8:00 PM EL19.13.02
Strain-Induced Stacking Order Change in Trilayer Graphene AdityaDey and HesamAskari; University of Rochester, United States

The layer stacking order plays a crucial role in the physical properties of two-dimensional van der Waals heterostructures. In graphene, stackings have garnered significant attention due to their potential impact on future applications, as demonstrated by the recent discovery of superconductivity in twisted bilayer graphene. Trilayer graphene, with its Bernal (ABA) and rhombohedral (ABC) stackings, has recently emerged as an intriguing system. ABC-trilayer graphene (ABC-TLG) is particularly noteworthy due to its fascinating opto-electronic properties, including Mott insulator behavior, superconductivity, and ferromagnetism. However, achieving stable ABC stacking in trilayer graphene presents challenges due to its lower thermodynamic stability compared to the more prevalent ABA stacking. To address this, a novel approach utilizing strain engineering is proposed and the underlying interfacial mechanics driving this stacking order change are investigated. The results demonstrate that the transition from ABA to ABC-TLG can be achieved at a critical strain magnitude of 0.55\%, resulting in a significant transformation of approximately 80\% of the configuration from ABA to ABC stacking. The stability and preservation of the obtained ABC stacking are examined, revealing the resistance of the transformed ABC-TLG region to transition into other high-energy states. Overall, this comprehensive approach provides a robust and controllable method for achieving stable ABC domains in trilayer graphene. The findings open up possibilities for the development of advanced electronic and optoelectronic devices, further advancing our understanding of stackings in two-dimensional materials.

8:00 PM EL19.13.03
Interface Structure of Fe-Intercalated Graphene/SiC (0001) Revealed by Atomic-Resolution Electron Microscopy RyotaroSakakibara[1], Tomo-oTerasawa[2,3] and WataruNorimatsu[4]; [1]Nagoya University, Japan; [2]Japan Atomic Energy Agency, Japan; [3]The University of Tokyo, Japan; [4]Waseda University, Japan

Thermal decomposition of SiC (0001) yields highly crystalline single-oriented graphene at the wafer scale [1]. There is a so-called buffer layer (BL) at the graphene/SiC interface, which is a reconstructed carbon layer on SiC (0001). It is possible to convert this BL to quasi-freestanding monolayer graphene by intercalation of a foreign element [2]. In this method, foreign atoms enter the BL/SiC interface to terminate the interfacial Si atoms, and the BL is decoupled from the substrate. The intercalated atoms are thus arranged in two-dimension and covered by graphene. The intercalation of the ferromagnetic element Fe can manifest intriguing physical properties such as perpendicular magnetic anisotropy and spin injection to graphene. Meanwhile, due to the affinity of Fe with Si and C, its intercalation is challenging. So far, several studies are reporting Fe intercalation in graphene/SiC [3]; however, the direct observation of its interface structure is missing. Here, we performed a uniform Fe intercalation and observed its interface structure at the atomic scale with cross-sectional transmission electron microscopy (TEM).

The uniform BL sample was prepared by annealing a single crystalline 4H-SiC (0001) substrate at 1500°C in an Ar atmosphere. Fe intercalation was carried out by vacuum deposition of Fe with a thickness of about 10 nm at room temperature, followed by annealing at around 660°C. The samples thus obtained were characterized by Raman spectroscopy (λ=532 nm), X-ray photoemission spectroscopy (XPS, hv=1486.6 eV), and TEM. The TEM observations were performed using a JEM-ARM200F-type microscope at an accelerating voltage of 200 kV. The thin specimen for TEM was prepared by the conventional Ar-ion thinning method.

From the Raman spectra of the sample, the BL was successfully converted to monolayer graphene. The Fe 2p spectrum of XPS suggests the presence of metallic Fe or Fe silicide on the sample surface, even after air exposure. A high-resolution TEM (HRTEM) observation of this sample revealed a layered contrast of graphene on the substrate surface. More importantly, uniform atomic layers of Fe were identified at the graphene/SiC interface by a high-angle annular dark field scanning TEM (HAADF-STEM) observation and energy dispersive X-ray spectroscopy (EDX) analysis. The number of these Fe layers was two to four over a wide range of observations. The interlayer distance between the first and second layers of Fe was ~2.4 Å. Such a structure has not been reported for Fe, Fe-oxide and Fe-silicide in their bulk form. In this Fe-intercalated graphene/SiC, modulation of the magnetic structure of Fe and spin injection to graphene can be expected.

8:00 PM EL19.13.04
Second-Harmonic Generation Imaging Microscopy with Ps Pulsed Lasers BitaRezania, VolkerBuschmann, ChristianOelsner and MariaLoidolt-Krueger; PicoQuant GmbH, Germany

Second harmonic generation (SHG) imaging microscopy is a nonlinear optical imaging technique that uses SHG as a contrast mechanism to produce high-resolution images. SHG occurs in materials with non-centrosymmetric crystal structures. Therefore, SHG imaging has been applied for characterization of 2D semiconductors, transition-metal dichalcogenides (TMDs) such as WS_2 and $MoSe_2$, lithium niobate crystals, PZT thin films, graphene, lanthanides, and even biological tissues. It provides information on the crystal lattice, assesses crystal quality and maps grain boundaries, defects, and mechanical strain. Furthermore, SHG imaging reveals the number of stacked layers as well as their orientation with respect to each other.

SHG imaging is commonly performed with a confocal laser scanning microscope using a high-power fs pulsed laser for excitation. In this study, we establish the use of high power ps pulsed lasers instead, with the aims of decreasing laser safety issues as well as reducing microscope complexity and cost. In addition, ps lasers offer high flexibility and tunability in terms of pulse duration, repetition rates, output power and external triggering.

We investigated two different 2D materials namely WSe_2 and MoS_2 on PDMS utilizing MicroTime 100 time-resolved confocal microscope. Reflection images and SHG images were acquired using a VisIR-1064 laser with 1064 nm wavelength, dimmed to laser class 3B and time-resolved photoluminescence (TRPL) images with 640 nm excitation.

The results set prove that ps pulsed lasers can replace fs lasers for SHG imaging. Moreover, the combination of ps lasers enables the collection of complementary datasets including reflection, SHG, TRPL and even two photon excitation (TPE) images collected from the same region of the sample using a single microscope setup. Thus, the optical properties of the materials can be characterized locally with several techniques to obtain a comprehensive understanding.

8:00 PM EL19.13.05
Imaging of Hyperbolic Plasmon-Phonon Polaritons in Twisted Double Bilayer Graphene AnnaLi[1], WilliamWilson[2], DanialHaei[2] and YueLuo[2]; [1]University of California, Berkeley, United States; [2]Harvard University, United States

Complex van der Waals heterostructures can be assembled, layer-by-layer, via the deterministic transfer of selected two-dimensional layered materials. The transfer method used offers a significant degree of control and precision enabling assembly of new composite materials with engineered optical properties. Here, we have fabricated twisted double bilayer graphene using a new transfer system with far greater spatial resolution (20 nm) than the previous systems at Harvard. We transferred mechanically exfoliated graphene and hexagonal boron nitride (hBN) with this transfer system (which uses a polymer stamp consisting of Polydimethylsiloxane (PDMS) and polycarbonate (PC)) to form hBN encapsulated, twisted double bilayer graphene at very small (~0.03 degrees) twist angles. The top capping layers of hBN was between 5–10nm thick, as verified using atomic force microscopy, and the bottom layers ranged from 10–20nm thick. These stacks were subsequently imaged using scanning near field microscopy in the mid-infrared range to observe the interference fringes from the system's "mixed" hyperbolic plasmon-phonon polaritons. Excited with a tunable QCL laser, we were able to study the dispersion relation and propagation behavior of the hybridized polaritons in twisted double bilayer graphene.

Measurement of Thermoelectric Properties of Semimetallic Polycrystal $PtSe_2$ Film with Temperature Dependence Jae WonChoi, No-WonPark, Gil-SungKim, Min-SungKang, YunhoKim, SeungwonYang and SangkwonLee; Chung-Ang University, Korea (the Republic of)

Hardness of measuring thermoelectonic properties of nm-scale thinckness thin film structure is one of the obstacles to research TMDC materials. We used a suspended bridge-type method and a strain gauge-controlled suspend platform to observe in-plane thermal conductivity and Seebeck coefficient of large-area platinum diselenide ($PtSe_2$) thin film. We founded influence about thermoelectric properties differency with thickness and christality changes. We observe the greatly suppressed in-plane thermal conductivity for 11-nm-thick polycrystalline $PtSe_2$ film as compared to that of exfoliated similar-thick in-plane single-crystalline $PtSe_2$ layer at 300 K. This reduction is attributed to the enhanced phonon scattering in polycrystalline $PtSe_2$ thin film. Our finding can pave the way toward an effective strategy for promising large-area TE energy harvesting devices with a high figure of merit in 2D semimetallic transition metal dichalcogenide materials.

8:00 PM EL19.13.07
Investigating the Trap-State Emission of CdTe Nanoplatelets TasnimAhmed and JustinR. Caram; University of California, Los Angeles, United States

Recently, two-dimensional II-VI semiconductor nanoplatelets (NPLs) have gained tremendous attention due to their exceptional photophysical properties including sharp emission spectra, tunable absorption and emission, large absorption cross section and giant oscillator strength etc. With the advancement of synthetic strategies, these NPLs now can be synthesized with controlled thickness even down to atomic precision. But while most of the progresses have been made with CdSe NPLs, the controlled synthesis of CdTe NPLs still remains challenging; even the detailed photophysics involving them remain unexplored. Here in this work we aim to synthesize CdTe NPLs with controlled thickness and decipher their carrier dynamics in single particle and ensemble level. With this aim we synthesized three monolayer NPLs which interestingly show a distinct excitonic emission and a broad emission band which can be related to trap states emission. The time resolved photoluminescence study reveal two distinct PL decay behavior when monitored at different probe wavelengths. The prolonged PL decay (>30ns) of the broad emission also suggests that it is related to trap emission. To dig deep into the mechanistic pathways of the photogenerated charge carriers, temperature dependent photoluminescence, single particle photoluminescence imaging and ultrafast pump-probe measurements are employed. Understanding the trap states nature will help us to find a key to manipulate them and these long lived trap states carriers can be utilized for their potential applications such as in photocatalysis.

8:00 PM EL19.13.08
Manipulating Charge Density Wave States in Lanthanum Tri-Telluride through Lithium Intercalation NatalieWilliams[1], ShiyuXu[1], SaifSiddique[1], RatnadwipSingha[2], JudyCha[1] and LeslieSchoop[2]; [1]Cornell University, United States; [2]Princeton University, United States

The rare earth tri-tellurides belong to a group of two-dimensional (2D) materials that possess intriguing quantum characteristics, including magnetic ordering, superconductivity, spin-density waves, and charge density waves (CDWs).[1] These properties hold significant potential for controlling electronic phases, making them appealing for applications in electronics and spintronics with specific advantages in memory devices and supercapacitors.[2]

Lanthanum tri-telluride, where lanthanum is the first element in the rare-earth series, exhibits a unidirectional CDW along the c-axis at room temperature. Here, we modulate the CDW order of lanthanum tri-telluride by electrochemically intercalating lithium into the gaps of the exfoliated flakes of lanthanum tri-telluride. Lithium intercalation imparts strain and electron doping to the host material, inducing changes in materials properties and even phase transformations.[3,4] We utilize in-situ Raman spectroscopy to investigate the structural alterations and CDWs of lanthanum tri-telluride flakes as consequence of lithium intercalation. These intercalation experiments hold the potential to uncover novel insights into the understanding of CDW states in rare earth tri-tellurides.

Tuning the Fermi Level of Graphene by Two-Dimensional Metals for Raman Enhancement NaZhang[1], KunyanZhang[2,3], WeiHu[4], RinuA. Maniyara[1], TimothyBowen[1], JonathonSchrecengost[1], ArpitJain[1], DaZhou[1], ChengyeDong[1], ZhuohangYu[1], HeLiu[1], NoelGiebink[1], JoshuaA. Robinson[1], ShengxiHuang[5] and MauricioTerrones[1,1,1]; [1]The Pennsylvania State University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States; [4]Qilu University of Technology, China; [5]Rice University, United States

Graphene-enhanced Raman scattering (GERS) offers great opportunities to achieve optical sensing with high uniformity and superior molecular selectivity. The GERS mechanism relies on the charge transfer between molecules and graphene, which is difficult to precisely manipulate through varying the band alignment between graphene and molecules. In this work, we leveraged a few atomic layers of metal termed 2D metal to precisely and deterministically modify the graphene Fermi level. Using CuPc as a representative molecule, we demonstrated that the Fermi level tuning can significantly improve the enhancement and molecule selectivity of GERS. Specifically, aligning the Fermi level of graphene closer to the highest occupied molecular orbital (HOMO) of CuPc results in a more pronounced Raman enhancement. Density functional theory (DFT) calculations of the charge density distribution reproduce the enhanced charge transfer between CuPc molecules and graphene with a modulated Fermi level. Extending our investigation to other molecules such as Rhodamine 6G, Rhodamine B, crystal violet, and F_{16}CuPc, we showed that 2D metal-enabled Fermi level tuning can preferentially improve the GERS for molecules with better band alignment with graphene, contributing to an enhanced molecule selectivity. This underscores the potential of utilizing 2D metals for precise control and optimization of GERS applications, which will benefit the development of high sensitivity, specificity, and reliability sensors.

Structural Phase Patterning of MoS_2ChristopherA. Barns[1] and ScottDietrich[2]; [1]West Chester University, United States; [2]Villanova University, United States

Finding ways to protect our technology from intellectual theft has become increasingly needed in recent years. While most people think of technology security in terms of software, many neglect the need to bolster the protection of our hardware. With the U.S. pushing towards being a lead innovator in metal-oxide semiconductor field-effect transistors (MOSFETs), our innovations must have built-in protection to negate any chance of being stolen through reverse engineering. To aid this endeavor, we propose an alternative method of making MOSFETs by utilizing the structural phases of molybdenum di-sulfide (MoS_2). Using a 30kV electron beam at 500pA, we expose MoS_2 flakes mounted on an SiO_2 substrate to a variety of electron beam doses to create patterns of its 1T metallic phase surrounded by the rest of its 2H semiconductor phase. Through this method, di-material logic gates are possible which will substantially fortify device security as a result.

8:00 PM EL19.13.11
Spectrally-Resolved Polarization-Resolved Multiphoton Fluorescence and Second Harmonic Imaging in Low-Dimensional Materials TolulopeAjuwon, ArikAhmed and SteveSmith; South Dakota School of Mines and Technology, United States

Low-dimensional materials, especially two-dimensional (2D) materials, can have significantly enhanced nonlinear optical coefficients. In particular, the second-order nonlinear polarizability $\chi^{(2)}$, an important materials parameter for the generation of entangled photon pairs via parametric downconversion, can be notably enhanced in monolayer materials. The relationship between this nonlinear susceptibility and multi-layer stacking, orientation and material defects can be revealed by spectroscopic, polarization-resolved imaging. A spectrally-resolved multi-photon induced fluorescence (MPIF) and second harmonic generation (SHG) imaging system, based on a closed loop piezoelectric stage, a transmission grating and an EMCCD is used to examine the nonlinear optical properties of low-dimensional materials. From the spectrally-resolved multiphoton emission, we form ratiometric images of select spectral bands, reducing sensitivity to variations in intensity caused by scattering or attenuation of the excitation beam. We visualize the spectrally-resolved MPIF and SHG in the two-dimensional (2D) material WSe_2 and demonstrate the correlation between the symmetry-induced suppression of SHG for even-numbered layers, where inversion symmetry is established, and the presence of edge and localized defect states on the finite-sized 2D flakes, revealed by variations in the MPIF. The polarization-resolved SHG in the single and multi-layer 2D material identifies the symmetry and orientation of the layers. The application of the methods to determine $\chi^{(2)}$ in other low-dimensional materials is also described.

Multimodal Raman, Photoluminescence & SHG Imaging of 2D Materials StuartThomson; Edinburgh Instruments Ltd., United Kingdom

Transition metal dichalcogenides (TMDCs) are exciting next-generation 2D semiconductors with versatile layer-dependent optoelectronic properties. The spatial characterisation of lab-grown TMDCs is crucial to understanding their unique optoelectronic properties and optimising film growth conditions. In this work, we present a multimodal imaging platform that combines optical widefield, Raman, photoluminescence and second harmonic generation imaging for the characterisation of 2D materials.

The imaging platform was used to characterise CVD grown WSe_2 crystals. Using Raman imaging, the presence of both monolayer and multilayer WSe_2 could be identified through a change in the intensity and peak position of the E^1_{2g} / A_{1g} phonon modes. Photoluminescence imaging confirmed the presence of monolayer WSe_2 with exciton emission at 780 nm, and identified two distinct multilayer regions in the centre of the crystal through changes in the photoluminescence wavelength and intensity. Finally, second harmonic generation imaging with femtosecond laser excitation was used to obtain the relative layer orientation of the multilayer domains in the WSe_2 flake.

Exploring the use of Earth-Abundant Layered Materials in 2D-Based Studies: From Natural Mines to Van der Waals Applications IngridBarcelos[1], Raphaelade Oliveira[1], YaraGalvão Gobato[2], RaulFreitas[1], HelioChacham[3], BernardoR. Neves[3], ChristianoJ. de Matos[4] and AlissonR. Cadore[5]; [1]Brazilian Synchrotron Light Laboratory, Brazil; [2]Universidade Federal de São Carlos, Brazil; [3]Universidade Federal de Minas Gerais, Brazil; [4]Universidade Presbiteriana Mackenzie, Brazil; [5]Brazilian Nanotechnology National Laboratory (LNNano), Brazil

Phyllosilicates minerals are an emerging class of naturally occurring layered insulators with large bandgap energy that have gained considerable attention from the scientific community. This class of materials has been explored recently at the ultrathin two-dimensional level due to their specific mechanical and optoelectronic properties, which are crucial for engineering novel devices. Phyllosilicates have lamellar structures and can be embedded into van der Waals heterostructures (vdWHs) due to the possibility of exfoliation down to monolayers and easy handling. Here, we will present a high throughput characterization of some naturally occurring layered phyllosilicates by employing several experimental techniques, first-principles calculations, and will demonstrate that these layered materials can be mechanically exfoliated down to their monolayer limit and combined in the different vdWHs[1-5]. Due to these properties, phyllosilicates minerals can be considered as promising low-cost nanomaterials for electronics, photonics, and optoelectronics future 2D-based device applications. We will also present features of these nanomaterials that are relevant to their use in potential 2D-based applications, discussing the major challenges in working with them. Consequently, our results establish the basis of further studies tunning phyllosilicates properties to desired studies. Therefore, we expect our work to stimulate further exploration of layered phyllosilicate materials and provide the foundation for novel nanotechnological applications.

Energy Harvesting using Few-Layer 2D Galena (galenene)R.Karthik[1], AppuSingh[1], P. R.Sreeram[1], PreetiL. Mahapatra[1], DouglasS. Galvao[2] and ChandraS. Tiwary[1]; [1]Indian Institute of Technology, India; [2]State University of Campinas, Brazil

Radiofrequency (RF) energy harvesting using 2D materials is receiving increased attention. In this work, we have demonstrated RF energy harvesting using 2D galena (galenene). Galenene was obtained from liquid exfoliation of bulk galena crystals (PbS), which is one of the naturally abundant metal chalcogenides, the primary ore of lead. Several characterization analyses, such as X-ray diffraction, atomic force microscopy, Raman spectroscopy, and XPS, were carried out to determine the physicochemical properties of the 2D galena structures. A galenene-based Schottky diode was fabricated, and the energy harvesting was demonstrated using a handheld radio transceiver with a carrier frequency of 140–170 MHz. The device extracts RF energy and produces an output DC voltage of a maximum of 1.8 volts and a corresponding output power of 38 mW at 150 MHz, and lights up an LED within a range of 100 cm. At 150 MHz, the device's power conversion efficiency was found to be 19%. DFT simulations were used to gain further insight into the galenene RF energy harvesting mechanism and support the experimental interpretations [1].

Monolayer Amorphous Carbon as a 2D Barrier UgurKaradeniz, ArtemK. Grebenko, ZhangHongji, LucasM. Sassi, AlenaA. Alekseeva, Chee-TatToh and BarbarosOezyilmaz; National University of Singapore, Singapore

Monolayer amorphous carbon (MAC) have emerged as a highly promising 2D material with exceptional properties. As the first amorphous 2D material, MAC possess a single atomic layer thickness and large area continuity over wafer scale. MAC can be synthesized conformally over a wide range of substrates at low temperatures (<300 °C). Its structure consists of complete in-plane sp^2 bonding and is free-standing at monolayer thickness. These unique attributes give MAC a range of properties that set it apart from its crystalline counterpart, graphene, and make it a compatible material for barrier applications.
This study presents research on the structural characterisation and barrier properties of atomically thin MAC films. By using laser-assisted chemical vapor deposition (LCVD), we successfully grew monolayer and multilayer MAC films, with precise control of the number of layers. By using Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), and atomic resolution transmission electron microscopy (TEM), we show that MAC amorphous layered structure remains identical regardless of thickness. Multilayer MAC were found to be fully sp^2 bonded and lacked long-range order, exhibiting a distribution of 5-9-member carbon rings.
In our investigations, we explore the potential applications of MAC across various fields as a 2D barrier layer. The direct conformal growth of MAC onto the target substrate ensures defect-free, continuous coverage over large areas. Combined with the absence of reactive grain boundaries, this gives MAC films its exceptional chemical and mechanical stability despite their sub-nanometer thickness. The stability of MAC films is highly advantageous for barrier applications, where materials must remain structurally intact and free from degradation despite being sub-nanometer thick. We demonstrate the use of MAC films as ultrathin barrier films for copper interconnects in integrated circuits to impede metal ion diffusion. The findings of this study highlight the exceptional properties of atomically thin amorphous materials to overcome existing material bottlenecks. Together with its technologically relevant growth conditions, there is immense potential for enhancing device performance and addressing prevalent technological challenges.

8:00 PM EL19.14.04
Rational Design of Two-Dimensional Reduced Siloxene Metal-Free Semiconductor for Enhanced Photocatalytic Performance NavDeepak, ShobhaShukla and SumitSaxena; IIT Bombay, India

This study investigated the photocatalytic properties of Reduced siloxene nanosheets for the removal of organic pollutants from wastewater. Reduction of Siloxene resulted in a decreased band gap from 2.7 to 2.3 eV, allowing for better absorption of visible light, and quenched photoluminescence, indicating increased efficiency in the utilization of absorbed light energy for photocatalytic reactions. The catalytic activity of the Reduced siloxene nanosheets was examined through the degradation of Methylene Blue (MB), following a pseudo-second-order model, and exhibited an adsorption capacity of 9.6 mg/g for MB. The results demonstrate that reduced siloxene nanosheets have significant potential as an efficient and effective catalyst for removing organic pollutants from wastewater. The reduction process induced changes in the band gap and photoluminescence quenching that contributed to a 78% increase in catalytic activity compared to the pristine Siloxene material (53%).

8:00 PM EL19.14.05
Large Area Phase Selection in Silicene by Interface Engineering Daya SagarDhungana[1], SimonaAchilli[2], ChiaraMassetti[3], ChristianMartella[1], CarloGrazianetti[1], GuidoFratesi[2] and AlessandroMolle[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Milano, Italy; [3]Università degli Studi di Milano-Bicocca, Italy

The synthesis of two-dimensional (2D) silicene by direct growth on Ag(111) substrate is usually qualified by the formation of multiple phases and domains, posing severe constraints on the spatial charge conduction towards a technological transfer of silicene to electronic transport devices. Here we engineer the silicene/silver interface by two different schemes, namely through decoration with Sn atoms, forming an 2D Ag_2Sn surface alloy (surface decoration scheme), or through an epitaxially grown silicene-stanene heterostructure with stanene buffering the substrate (heterostructure scheme) [1]. Based on in situ low energy electron diffraction (LEED) we observe that phase selection is obtained via the two interface engineering schemes. In details, a 4×4 and $\sqrt{3}\times\sqrt{3}$ single silicene phase are selectively stabilized in the surface decoration and heterostructure scheme, respectively. The two selected phases in both case separately, are well-distinguished by characteristic phase-sensitive Raman spectra taken after top encapsulation of silicene with a sequentially grown nanoscale Al_2O_3, and upon probing the surface by positional LEED and Raman scanning, they prove to be extended all over the whole growth area, namely on the cm^2 scale. Interface engineering by surface decoration also stabilizes the ordered growth of a $\sqrt{3}\times\sqrt{3}$ phase in the multilayer range, featuring a single rotational domain instead of the multiple domain formation upon direct growth. Theoretical *ab initio* models are used to investigate low-buckled silicene phases (4×4 and a competing $\sqrt{13}\times\sqrt{13}$ one) and various $\sqrt{3}\times\sqrt{3}$ structures, supporting the experimental findings [2]. Interface engineering with the heterostructure scheme is also functional to design an all-around encapsulation of silicene, entailing the top and the bottom face of silicene [3]. This processing step is structurally preparatory to extract the silicene from its native Ag substrate with no occurring environmental degradation (e.g. oxidation). Stabilization of Ag-free silicene is explained in terms of the sacrificial role played by the bottom stanene layer. Based on close Raman spectroscopy monitoring, we are able to certify the endurance of the silicene in the monthly scale.
Interface engineering of silicene as reported in Ref. [2] provides new and promising technology routes to manipulate the silicene structure by controlled phase selection and single-crystal silicene growth on a wafer-scale, and enables us to develop an encapsulation scheme for the silicene preservation when its native Ag substrate is stripped off so as to create the condition for a full exploitation of silicene in durable operational devices like transistors and piezoristors [4].

8:00 PM EL19.15.01
Growth of Hexagonal Boron Nitride (h-BN) Films under Low Pressure by Chemical Vapor Deposition (CVD) ThaisC. de Carvalho, Neileth JohannaS. Figueroa, Cesar AugustoD. Mendoza and Marcelo EduardoH. Maia da Costa; Pontificia Universidade Catolica Do Rio De Janeiro, Brazil

Hexagonal Boron Nitride (h-BN) is a two-dimensional (2D) material that shares structural similarities with graphene. However, unlike graphene, h-BN consists of a honeycomb lattice with alternating B and N atoms. It possesses the distinction of being the thinnest insulating material, exhibiting an electrical bandgap of 5.9 eV. Atomically thin h-BN films are crucial for the development of emerging applications involving 2D devices based on Van der Waals heterostructures. These films exhibit desirable properties, including high thermal stability, chemical inertness, and mechanical flexibility, enabling their utilization in diverse applications such as serving as a dielectric substrate for transistors, flexible nanoelectronics, and nano-capacitors. However, the production of large-area, high-quality monocrystalline h-BN using the chemical vapor deposition (CVD) method remains a significant challenge. The current study focuses on the synthesis of h-BN layers by employing the CVD method under low pressure, utilizing ammonia borane (AB) as a precursor to be deposited on Si (100) substrates. The objective is to overcome the existing obstacles and advance the fabrication of large-area, high-quality monocrystalline h-BN. Throughout the growth process, the precursor, ammonia borane (AB), was maintained at a temperature of approximately 95°C. Meanwhile, the substrate, in this case, was maintained at a much higher temperature of 1100°C. The gas atmosphere used during this process was a mixture of H_2 (flow of 2 sccm, standard cubic centimeters per minute) and Ar (100 sccm flow). The h-BN films undergo characterization using various spectroscopic techniques, including Raman spectroscopy, Atomic force microscopy (AFM), UV-visible spectroscopy, and X-ray photoelectron spectroscopy (XPS). The measured B:N ratio of the h-BN films obtained

in this study aligns well with the theoretical stoichiometric values of 1:1. The optical band gap of the hBN films grown on silicon substrate was determined to be 4.8 eV. Raman spectroscopy measurements were carried out and exhibited a peak at 1375 cm^{-1}, characteristic of the monolayer h-BN and corresponding to the E_{2g} vibration mode. The results showed that we were successful in the synthesis of h-BN films.

8:00 PM EL19.15.02
Synthesis and Properties of Atomically-Thin Width-Controlled TMD Quantum Nanoribbons XufanLi[1], SamuelWyss[2], BaichangLi[3], EmanuilYanev[3], YangLiu[3], YongwenSun[4], ZhiyingWang[3], MatthewC. Strasbourg[2], RaymondR. Unocic[5], YangYang[4], JamesHone[3], NicholasJ. Borys[2], P. JamesSchuck[3] and AvetikR. Harutyunyan[1]; [1]Honda Research Institute USA Inc., United States; [2]Montana State University, United States; [3]Columbia University, United States; [4]The Pennsylvania State University, United States; [5]Oak Ridge National Laboratory, United States

Width confinement and effect of edge structure add new freedoms for exploring exotic properties for already rich atomically-thin materials. Unique properties have already been discovered in graphene nanoribbons with width less than 5 nm. However, for transition metal dichalcogenides (TMDs), the effects by width confinement and edge structure have only been predicted in theoretical calculation due to challenges in synthetic methods to obtain nanoribbons with width less than ~30 nm. We develop a synthetic strategy to directly grow TMD nanoribbons with controllable width (down to sub-10 nm) and layers (single or double layer), from the pre-deposited seed nanoparticles. Width-dependent Coulomb blockade oscillation in the electron transfer behavior in the nanoribbons suggests formation of quantum-dot-like electronic states due to width confinement. Furthermore, combination of width confinement with strain engineering through sharp bending generates highly localized states in TMD nanoribbons, which is responsible for high purity, deterministic single photon emissions. The TMD nanoribbons add a new family of materials to the reservoir for future quantum electronics and photonics.

Room-Temperature Direct Growth of Wafer-Scale Transition Metal Dichalcogenide Films via Remote Plasma-Assisted Chemical Vapor Deposition JinaLee, Soo HoChoi, Seok Joonyun and Ki KangKim; Sungkyunkwan University, Korea (the Republic of)

Transition metal dichalcogenides (TMDs) offer potential solutions to address the challenges associated with silicon technology. To enable large-scale TMD film growth, chemical vapor deposition (CVD) techniques have been extensively studied. However, the transfer process required for device fabrication often degrades individual device performance and overall wafer reliability. In this work, we present a low-temperature, direct growth approach for TMDs using remote plasma-assisted chemical vapor deposition.
By employing hydrogen plasma, reactive precursor radicals are generated, enabling the growth of TMD films at temperatures as low as ~300°C. The thickness of wafer-scale TMD films can be easily controlled by adjusting the growth time. The direct growth of TMD films eliminates the need for transfer processes, preserving their uniform quality across the entire region, which is crucial for maintaining device performance.
Additionally, we demonstrate the successful growth of TMD films directly on high-k dielectric films such as Al2O3. This achievement opens up new possibilities for integrating TMDs with high-k materials, offering potential advantages for future device applications.
Overall, this work presents a low-temperature, direct growth method for TMDs using remote plasma-assisted chemical vapor deposition. The elimination of transfer processes and the ability to grow TMD films on high-k dielectric films contribute to improved device fabrication processes and enhanced device performance. This research lays the foundation for the scalable production of TMD-based devices, paving the way for the integration of TMDs into advanced electronic technologies.

8:00 PM EL19.15.04
On the Structural and Morphological of Graphene Layers Grown on Pt/Ti/SiO_2 by Hot Filament Chemical Vapor Deposition AngelaLuis Matos[1], TejB. Limbu[2], IvanCastillo[1], BalramTripathi[1], BradWeiner[3] and GerardoMorell[1]; [1]University of Puerto Rico at Río Piedras, Puerto Rico; [2]University of Houston-Clear Lake, United States; [3]University of Puerto Rico-Rio Piedras, Puerto Rico

Herein, we report large area single and bilayer graphene growth on Pt/Ti/SiO_2 substrate by hot filament chemical vapor deposition (HFCVD) with and without the assistance of Cu foil. The quality and the number of graphene layers deposited on the substrate were assessed by Raman spectroscopy, and X-rays photoelectron spectroscopy (XPS) analysis. Atomic force microscopy (AFM) was used for assessing the surface topography of the graphene films grown on the Pt/Ti/SiO_2 substrates. The microstructure and elemental analysis have been performed by Scanning electron microscopy (SEM), and Energy disperse spectroscopy (EDS). Our results show that bilayer layer graphene growth is facilitated by the presence of a copper foil placed nearby Pt/Ti/SiO_2 substrate, or by a relatively high filament temperature in the HFCVD reactor. Monolayer graphene grows only when no copper foil was placed nearby the Pt/Ti/SiO_2 substrate at a low filament temperature. Our approach paves a novel pathway towards the layer-controlled growth of graphene on Pt/Ti/SiO_2 substrate by HFCVD reactor for frontier applications.

8:00 PM EL19.15.05
Low Pressure Chemical Vapor Deposition of 1T-TaS_2 Films on Sapphire for Controllable Charge Density Wave Phase Transitions NicholasD. Redwing[1], NicholasTrainor[1], GabrielMartinez[2], DanielaR. Radu[2] and JoanM. Redwing[1]; [1]The Pennsylvania State University, United States; [2]Florida International University, United States

Metallic two-dimensional (2D) transition metal dichalcogenides such as TaS_2 can host charge density waves (CDWs), periodic modulations of electron density that arise in systems with strong electron-phonon coupling. CDWs can break crystal symmetry, mediate metal-insulator phase transitions and coexist with superconductivity. Furthermore, transitions between CDW phases can be tuned via strain, electric fields, etc. which can potentially be exploited for devices. Crystal disorder can inhibit CDWs, consequently, studies are typically carried out utilizing single crystal flakes exfoliated from bulk TMD crystals. Techniques to deposit large area, high crystal quality TaS_2 films are therefore needed to advance the field toward practical applications.

In this study, we report the synthesis and characterization of *1T*-TaS_2 films on c-plane sapphire using low pressure chemical vapor deposition (LPCVD). The growths were carried out at 100 Torr in a horizontal hot wall CVD reactor using $TaCl_5$ and sulfur powder as sources in a 5% H_2/Ar carrier gas mixture. The sulfur powder was placed upstream of the substrate in the quartz tube and was maintained at 150 °C. The $TaCl_5$ powder was contained within a stainless steel bubbler external to the reactor that was heated to 80 °C and maintained at a pressure of 110 Torr. The $TaCl_5$ was transported to the reactor by passing the H_2/Ar carrier gas at a flow rate of 100 sccm through the bubbler and was introduced downstream of the sulfur boat in the reactor via a separate quartz injector tube. The effects of reactor temperature, gas flow rates and reactor pressure on the uniformity, deposition rate and properties of the films were investigated. Temperatures greater than ~800 °C and low reactor pressures (100 Torr) were required to decompose the $TaCl_5$ via reaction with H_2 and minimize pre-reactions upstream of the substrate. AFM, Raman spectroscopy and X-ray photoelectron spectroscopy were used to characterize the films after growth. The Raman spectrum of films grown at 900 °C and 100 Torr and cooled rapidly after growth exhibited Raman modes at ~90, ~240 and ~380 cm^{-1}, consistent with the *1T* phase of TaS_2. Variable temperature Raman measurements are underway to investigate CDW phase transitions in the films.

Epitaxial Monolayer Growth of 2D ReS_2 via MOCVD HeewonPark[1,2], Yeon-JeongJang[1,2] and Moon-HoJo[1,2]; [1]IBS, Korea (the Republic of); [2]POSTECH, Korea (the Republic of)

We report monolayer growth of epitaxial van der Waals semiconductor ReS_2 on sapphire substrate. ReS_2, a member of transition metal dichalcogenide (TMDC), exhibits unique 1T' structure with large anisotropy. Metal-organic chemical vapor deposition (MOCVD) enables the synthesis of atomically thin semiconductor by precisely controlling vapor pressure. ReS_2 film and crystal could be obtained on sapphire substrate depending on the growth condition. Growth parameters such as temperature, pressure, and precursor supply affect the result of MOCVD growth. Material characterizations including Raman spectroscopy, atomic force microscopy (AFM), and x-ray photoelectron spectroscopy (XPS) were conducted to verify the quality of film and triangular crystals. Also, field effect transistors were fabricated to assess the mobility of polycrystalline ReS_2 film. We discuss polycrystalline nature of ReS_2 grown on insulating substrate due to its low in-plane symmetry and weak interlayer coupling between layers.

8:00 PM EL19.15.07
Growth of Superconducting Sr_2RuO_4 Thin Films via Thermal Laser Epitaxy BrendanD. Faeth[1], VarunHarbola[1], LenaMajer[1], HansBoschker[2], FelixHensling[1], WolfgangBraun[1,2] and JochenMannhart[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]Epiray Gmbh, Germany

Thermal laser epitaxy (TLE) is a novel technique for thin film deposition which employs continuous wave lasers to simultaneously heat both the substrate and elemental sources. This laser heating approach allows for evaporation or sublimation of nearly all elements from the periodic table, ultrahigh substrate temperatures exceeding 2000 C, and broad compatibility with process gases at a wide range of pressures from UHV up to 1 Torr, among other benefits. As a result, TLE dramatically expands the parameter space available for thin film synthesis compared to existing epitaxy techniques. However, to date it has proven experimentally challenging to achieve simultaneous control of multiple laser based elemental sources with the flux stability and

systematic fidelity necessary for the growth of ternary or multernary systems of interest such as complex oxides.
In order to establish the capabilities of TLE for the growth of such complex materials, we demonstrate here the successful epitaxial synthesis of several Ruddlesden-Popper phases of the Sr-Ru-O ternary oxide system via TLE. Near instant thermalization of both source elements and substrates from laser heating allows the process of thermodynamic phase control to be achieved rapidly during film deposition without the need for physical shuttering of sources. Additionally, we find that the "n=1" phase Sr_2RuO_4 can be reliably synthesized at substrate temperatures in excess of 1200 C and in a background environment of pure molecular oxygen, within an adsorption-controlled growth window that is inaccessible to conventional MBE approaches. We show that Sr_2RuO_4 films grown under these conditions demonstrate extremely high structural, electronic, and chemical quality, as evidenced by the appearance of superconductivity at relatively high critical temperatures. A detailed accounting of the experimental approach, growth thermodynamics and film characterization will be discussed.
This work not only demonstrates the feasibility of TLE for the synthesis of high-quality complex oxide thin films, but also suggests new routes to achieving thin film growth in other materials systems that remain as-yet inaccessible to conventional epitaxy techniques.

8:00 PM EL19.15.08
Barium Titanate Thin Film Remote Epitaxy using Graphene TemazuluS. Zulu, LarissaLittle and JuliaMundy; Harvard University, United States

Barium titanate (BTO) thin films present exciting opportunities for use in photonics due to their high refractive index (~ 2.4) and wide bandgap (> 3 eV) . We can integrate these films onto silicon to make scalable and efficient optical devices. In order to integrate the films onto silicon, we use remote Molecular Beam Epitaxy (MBE). In our process, we grow BTO films on a strontium titanate (STO) substrate with a graphene intermediate layer and then transfer the BTO films onto a silicon substrate. We first transfer graphene onto an STO substrate, then grow the BTO directly on the graphene layer. The weak Van Der Waals bond between graphene and the BTO thin film allows us to remove the film from the substrate and transfer it to a silicon substrate. We propose this as an alternative to growing directly on silicon using an oxide layer, which requires careful control of oxygen pressure to maintain epitaxial growth. Our method allows the barium titanate to grow in a single epitaxial orientation since we have a nearly lattice matched oxide substrate, and allows us to reuse the substrates. We propose that this could be a potentially straightforward, scalable, and efficient method for the nanofabrication of integrated barium titanate films on silicon.

8:00 PM EL19.15.09
Controllable Growth of Large Area P-Type MoS_2 with Transition Metal Doping using Confined Space CVD MuhammadSuleman, MinwookKim, Hyun-minPark and YonghoSeo; Sejong University, Korea (the Republic of)

2D Molybdenum Disulfide (MoS_2) has been used extensively as a semiconductor in recent years. Typically, MoS_2 demonstrates an N-Type Behavior as there are sulfur vacancies that are present in the material. However, the large-scale synthesis of P-Type MoS_2 and other 2D materials can still be challenging. Various methods can be used for doping the pristine MoS_2 to provide P-Type behavior and one of these methods is substitutional doping. Group VB Transition metals like Niobium (Nb), Vanadium (V) and Tantalum (Ta) can be used to achieve substitutional doping into the MoS_2 crystal lattice. In this work we have achieved P-Type behavior in CVD grown monolayer MoS_2 through a similar method. Moreover, the existence of doping atoms was confirmed by using XPS (X-ray photoelectron spectroscopy), EDX (Energy dispersive X-ray) and TEM (Transmission Electron Microscopy). The fabricated back gate FETs also confirm the behavior as a P-Type material. This proposed method for the synthesis of P-Type MoS_2 can have a lot of potential applications ranging from photodiodes, photodetectors, optoelectronics, field effect transistors, synaptic transistors, advanced materials heterostructures and energy harvesting.

8:00 PM EL19.15.10
Promoting Growth of Two-Dimensional Semiconductors by Preloaded Precursors MinsuKim[1], MinkyunSon[2], Ki-SeokAn[2] and SoonminYim[2]; [1]Kyonggi University, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

The recent implementation of alkali metal halide catalysts in the context of chemical vapor deposition (CVD) for synthesizing transition metal dichalcogenides (TMDs) has facilitated impressive growth of two-dimensional (2D) TMDs. However, there remains a need for further investigation into process development and growth mechanisms in order to amplify the impact of catalysts and comprehend the underlying principles. In this regard, a novel approach is proposed that involving the concurrent introduction of a metal source (MoO_3) and a salt (NaCl) through thermal evaporation. This technique yields notable growth behaviors, including enhanced 2D growth, regional selective growth, and expanded possibilities for diverse target materials. Employing a combination of sequential spectroscopy and morphological analyses, a comprehensive reaction pathway for MoS_2 growth is unveiled. Within this pathway, NaCl and MoO_3 react independently to generate intermediate compounds; Na_2SO_4 and $Na_2Mo_2O_7$. These intermediates play a crucial role in creating a conducive environment for 2D growth, characterized by augmented source availability and a liquid medium. Subsequently, through a self-assembly process, minute equilateral triangular grains amalgamate atop the liquid intermediates, culminating in the formation of substantial monolayer MoS_2 grains.
This investigation is poised to become a fundamental point of reference, offering insights into the principles underpinning salt catalysis and the evolution of CVD techniques for producing 2D TMDs.

8:00 PM EL19.15.11
Direct Synthesis of Twisted WSe_2 Multilayers by B_2O_3-Assisted Chemical Vapor Deposition JinwooKim and Gwan-HyoungLee; Seoul National University, Korea (the Republic of)

Moiré superlattices of stacked 2D layers have attracted a great attention, offering a unique platform for investigation of unprecedented quantum phenomena, such as superconductivity in twisted graphene bilayer and moiré excitons in twisted transition metal dichalcogenides (TMDs) bilayers. However, fabrication of twisted TMD bilayers still relies on a manual transfer process, which probably contaminates the interface of stacked layers and makes it difficult to precisely control the twist angle. Here, we present a direct synthesis method of twisted WSe_2 bilayers using chemical vapor deposition. We mixed small amount of B_2O_3 with the source materials to promote growth of WSe_2. In contrast to the WSe_2 grains produced by conventional CVD process, the WSe_2 grains grown in this work show the overlapping of neighboring grains, forming twist bilayer regions with various twist angles. Low-frequency Raman spectra of the twisted WSe_2 bilayers clearly shows the twist-angle-dependent layer breathing mode (LBM) and B_{2g} mode, indicating that the twisted bilayers have atomically clean van der Waals interface and no contamination. Our work shows a way to directly synthesize a large number of the twisted bilayers with different twist angles and provides a platform to investigate the twist-angle-dependent electrical and optical properties of the twisted bilayers.

8:00 PM EL19.15.12
Van der Waals Epitaxially-Grown Molecular Crystal Dielectric α-Sb_2O_3 for 2D Electronics HyunjunKim[1], HuijieRyu[2] and Gwan-HyoungLee[1]; [1]Seoul National University, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of)

In the forefront of nanoelectronics, two-dimensional (2D) materials have garnered substantial attention as prospective channel materials. This is due to their surface properties featuring free-dangling bonds, along with their exceptional mobility and the capacity for precise gate control at the atomic layer level. Nevertheless, the advancement of 2D electronics faces a hurdle in creating a seamless van der Waals interface, particularly in the direct growth of a high-k dielectric with a high degree of crystallinity on a 2D channel material. Here, we report van der Waals epitaxial growth of the molecular crystal dielectric α-Sb_2O_3 on graphene. The α-Sb_2O_3 nanosheets show a high breakdown field of 18.6 MV/cm for bilayers of 1.3 nm and decrease of the breakdown field with increasing thickness. We achieved equivalent oxide thickness (EOT) of 0.77 nm for 3L-Sb_2O_3 and as low leakage current as the DRAM limit of 1×10^{-7} A/cm^2 at a gate voltage of 1 V. The epitaxially grown Sb_2O_3 on graphene has two dominant orientation so that two types of grain boundaries (GB) with orientation angles of 0° and 60° are generated between aligned grains. The 0°-GB with well-stitched boundary shows higher electrical and thermal stabilities than 60°-GB with disordered boundary. Our work shows a method to epitaxially grow the molecular crystals on 2D materials and a great potential of molecular crystals for van der Waals dielectric in 2D electronics.

SESSION EL19.16: Applications of Wafer-Scale 2D Materials—Photonics

8:30 AM *EL19.16.01
Harnessing Exciton Dynamics for Tunable Polarization Conversion and Switchable Polarized Narrowband Emission SamuelK. Seah[1], SouvikBiswas[1], JoesonWong[1], HamidrezaAkbari[1], SupavitPokawanvit[2], Wei-Chang DavidYang[3], HuairuoZhang[3], ClaudioU. Hail[1], MeirGrajower[1], KenjiWatanabe[4], TakashiTaniguchi[4], FelipeJornada[2], AlbertDavydov[3] and HarryA. Atwater[1]; [1]California Institute of Technology, United States; [2]Stanford University, United States; [3]National Institute of Standards and Technology, United States; [4]National Institute of Materials Science, Japan

Light-matter interactions in anisotropic layered and two-dimensional semiconductors such as black phosphorus enables exploration of novel optical confinement phenomena at the atomic scale. Active polarization control, which has diverse applications in optical imaging, sensing, and computing, arises from the electrically tuneable crystalline anisotropy of black phosphorus (BP) which creates a mechanism for polarization modulation. I will discuss metasurfaces combined with van der Waals heterostructures incorporating twisted BP layers which open up further degrees of freedom in polarization conversion, and increases the polarization state tuning range to nearly half the Poincaré sphere. In other recent work, we discovered that certain edges of monolayer black phosphorus act as sites for localization and quantum confinement of quasi-1D excitons, resulting in discrete edge excitonic spectral emission lines with a nearly 10x reduction in linewidth relative to the surrounding 2D bulk. Integration of edge excitons into a gate-tunable heterostructure revealed a highly symmetric gate-dependence, enabling voltage-controlled turn-on/turn-off of polarized radiative emission.

9:00 AM EL19.16.02
Tunable Interlayer Excitons in Organic-Inorganic Van der Waals Heterostructures AurelieChampagne[1,2], OlugbengaAdeniran[3], TomojitChowdhury[4], MengyuGao[4], JiwoongPark[4], ZhenfeiLiu[3] and JeffreyB. Neaton[1,2,5]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Wayne State University, United States; [4]The University of Chicago, United States; [5]Kavli Energy NanoScience Institute, United States

Interfacing transition metal dichalcogenides (TMDs) into van der Waals heterostructure bilayers with type-II level alignment has led to recent reports of interlayer excitons with large binding energies, long lifetimes, and signatures of exciton condensation at elevated temperatures [1–4]. Atomically flat two-dimensional molecular crystals (MC) on TMD monolayers is an emerging interfacial quantum materials platform with tunable level alignment, exciton binding energies, and photoluminescence, given the heightened sensitivity of the organic layers to their environment [5]. In addition to non-local adsorbate/substrate screening, free charge carrier screening is particularly relevant in MC-TMD bilayer heterostructures, and controllably altering these distinct modes of screening can lead to new phenomena. Using a dielectric embedding ab initio GW plus Bethe-Salpeter equation (GW-BSE) approach [6], we compute energy level alignment as well as neutral excitations at MC-TMD interfaces (MC = PDI or PTCDA ; TMD = MoS_2 or WS_2), exploring new emergent optical transitions, such as those associated with interlayer excitons characterized by electrons and holes separated between the MC adsorbate and the TMD, respectively. Combining the GW-BSE approach with a new model we have developed that reduces computational cost with no loss of accuracy [7], we further explore how the presence of free charge carriers can screen the electron-hole interactions and modify the quasiparticle energy level alignment and interlayer excitons.

This work is supported by the Center for Computational Study of Excited-state Phenomena in Energy Materials (C2SEPEM) and the Theory of Materials FWP at LBNL, funded by the US Department of Energy (DOE) under contract No. DE-AC02-05CH11231. Computational resources are provided by the National Energy Research Scientific Computing Center (NERSC).

9:15 AM EL19.16.03
Extremely Anisotropic Few-Atom-Thick Organic-Inorganic Bilayers with Wafer-Scale Uniformity TomojitChowdhury[1], FauziaMujid[1], AurelieChampagne[2], CeLiang[1], PatrickKnüppel[3], NathanGuisinger[4], JeffreyB. Neaton[2], Kin FaiMak[3] and JiwoongPark[1]; [1]Univeristy of Chicago, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Cornell University, United States; [4]Argonne National Laboratory, United States

Thin films featuring extreme optical anisotropy are an ideal platform that enables efficient light sensing, harvesting, and display functionalities. However, realizing large-scale thin films with controllable and predictable optical anisotropy remains a major challenge due to two formidable experimental hurdles. First, the non-triviality of producing high-quality large area thin films while preserving their global anisotropic response. Second, the lack of direct experimental evidence linking the films' structures and their anisotropic properties. In this talk, we introduce large-scale and highly crystalline few-atom-thick organic-inorganic bilayers (BL) comprising single-layer two-dimensional molecular crystals (2DMC) atop transition metal dichalcogenide (TMD) monolayers. By leveraging the design flexibility in non-covalent molecular crystals, we grow diverse BLs that exhibit fully deterministic linear dichroism, which is tunable within a 50% range as we vary the 2DMC structures. Through comprehensive optical and high-resolution scanning probe microscopies and analyses, we establish a direct correlation between the molecular unit cells' structures and the observed optical anisotropy. Intriguingly, temperature-dependent polarized optical imaging and spectroscopy unveil the existence of a highly anisotropic excitonic species in the BL, which is distinct from both the pristine molecular and TMD excitons, even under the substantial dielectric screening by the TMD monolayer.
To gain insights into the nature of this anomalous excitonic species, we employ ab initio GW Bethe-Salpeter equation (BSE) calculations, which reveal a strong correlation between the electrons and the holes within the BL. This correlation gives rise to an anisotropic and significantly delocalized Wannier-like interlayer exciton that exhibits high sensitivity to the structure and composition of the 2DMC. These results underscore the potential of our organic-inorganic BL as an excitonically rich platform enabling the discovery of novel light-matter interactions beyond the confines of traditional covalent 2D materials. We will conclude this talk with an outlook on the prospects of creating exotic hybrid 2D systems, that includes the molecular analogue of the moiré superlattice.

9:30 AMBREAK

10:00 AM EL19.16.04
Interfacial Optical Sensing of Ferroelectricity in Freestanding Perovskite Oxides with Monolayer WSe_2JaehongChoi[1], KevinCrust[2], LizhongLi[1], Jae PilSo[1], KenjiWatanabe[3], TakashiTaniguchi[3], HaroldY. Hwang[2], JieShan[1], Kin FaiMak[1] and GregoryFuchs[1]; [1]Cornell University, United States; [2]Stanford University, United States; [3]National Institute for Materials Science, Japan

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) can be easily integrated with other functional materials such as ferroelectric materials due to their lack of dangling bonds. Also, owing to their atomic thickness, electronic and photoluminescence (PL) properties of 2D TMDs can be modulated by external perturbations, which opens new avenues for quantum sensing and tunable optoelectronic devices. In this work, we integrate monolayer WSe_2 with a free-standing $BaTiO_3$ (BTO) membrane and studied the ferroelectricity induced PL modulation in WSe_2. Perovskite oxide BTO has strong spontaneous polarization and moderate coercive field, but their epitaxial mother substrates often limit the range of device structures. Recent studies showed that BTO can be separated from its substrate by using a sacrificial oxide layer. By using this method, BTO is released from the substrate and transferred to a Si-based substrate. We pick up BTO membranes with an appropriate size by using a stamping method and fabricate a field effect device where the BTO polarization can be switched and sensed simultaneously with monolayer WSe_2 in-situ. We observe that the relative density of charge carriers in changesas the polarization switches, and this gives rise to the PL intensity modulation. The relative emission intensity of neutral excitons and trions show gate dependent hysteresis, which confirms that WSe_2 senses and optically reads out the ferroelectricity in BTO.

This work is supported by AFOSR MURI (FA9550-18-1-0480).

10:15 AM EL19.16.05
Revealing Photophysical Properties of 2D $BA_2MAPb_2I_7/MoS_2$ Type-II Heterostructures AlpYilmaz[1], F. GoncaAras[1] and AydanYeltik[1,2]; [1]TOBB University of Economics and Technology, Turkey; [2]UNAM − Institute of National Nanotechnology Research Center, Bilkent University, Turkey

Optoelectronic devices based on type-II heterojunction semiconductors have great potential to provide high-performance characteristics due to their superior charge separation capabilities[1]. Various type-II heterostructures have been studied to date by using different semiconductor materials[2,3], among which 2D organometal halide perovskite single crystals (OHPSCs) have recently gained intensive interest owing to their significant properties such as high absorption coefficient, adjustable bandgap, and high charge carrier mobility[4]. Single-layer transition metal dichalcogenides (TMDs) have been also used in optoelectronics due to their high carrier mobility, direct bandgap, flexible structural properties, and high stability[5]. However, by including two promising candidates of these material categories, the photophysical properties of $BA_2MAPb_2I_7$/monolayer-MoS_2 type-II heterostructure have not been studied yet. Herein, we studied the optical properties of $BA_2MAPb_2I_7$/monolayer-MoS_2 heterostructures for the first time. Detailed investigations were carried out using μ-PL and μ-Raman spectroscopies along with various other characterization techniques. 2D OHPSCs were synthesized via the solution temperature lowering method and 2D OHPSCs of different thicknesses, from atomic to multilayer thicknesses, were produced using the mechanical exfoliation method. Furthermore, the large-area continuous monolayer MoS_2 film was synthesized via the chemical vapor deposition method with a glass-assisted approach for the first time. PDMS-based dry-transfer method was used to produce the $BA_2MAPb_2I_7/MoS_2$ heterostructures. When excitation was performed with a 532-nm laser source, the PL intensities of both the MoS_2 and OHPSCs decreased compared to those of the bare materials due to type-II band alignment in the heterojunction region. We also report that the photophysical properties of the $BA_2MAPb_2I_7$/monolayer-MoS_2 type-II heterostructures are able to be controlled depending on the 2D OHPSC layer thickness. The fundamental insight is provided for the heterojunction materials investigated in this study for use in high-performance optoelectronic applications.

10:30 AM EL19.16.06
Low-Power Optical Control of Two-Dimensional Magnets TiXie[1], JieruiLiang[1], HasithaS. Arachchige[2], DavidMandrus[2] and ChengGong[1]; [1]University of Maryland, United States; [2]The University of Tennessee, Knoxville, United States

A magnetic material, while dressed with different spin configurations, can host a variety of emergent phenomena such as chiral domain walls, skyrmions, and Majorana fermions. Traditional preparation of various spin textures in magnetic films by transforming an already established spin pattern demands intensive energy to cause spin flipping or domain wall motion. In contrast, engineering the phase transition kinetics potentially opens up new avenues to achieve desired spin configurations. The two-dimensional (2D) layered magnets, owing to the ultra-thinness, allow the magnetism control by various external stimuli, among which optical approaches promise non-destructive manipulation, both locally and globally. In this talk, I will introduce how we demonstrated a low-power optical control of 2D magnets. By perturbing the phase transition kinetics, we found that optical incidence on the order of tens of microwatt per micrometer can effectively control magnetic domain formation, and the orientation of the magnetic domain is highly dependent on optical helicity. Our low-power optical operation paves the new avenue to efficiently engineer 2D spin textures for a plethora of emergent quantum phenomena.

SESSION EL19.17: Scalable Processing for 2D Materials

1:30 PM *EL19.17.01
Manufacturing 2D Materials at Large Scale and High Spatial Selectivity ZakariaAl Balushi; University of California, Berkeley, United States

The multitude of 2D materials in regard to composition, crystal structure and layer thickness leads to a variety of material properties covering all of the components necessary to address voltage, interconnect, energy, and dimensional scaling issues in a variety of applications. For 2D materials to be technologically competitive, it is imperative to develop manufacturable materials deposition protocols at low temperatures and at any location on demand without wafer transfer processing. In this talk, a low temperature spin coating process will be discussed to form transition metal dichalcogenides at low temperatures using a modified spin coating technique from low decomposition temperature molecules. Furthermore, to achieve spatial selectivity of grown 2D materials, this talk will also describe a novel process to spatially measure and modulate the surface energy of van der Waals surfaces at growth temperatures to achieve selective area growth of 2D materials into a variety of form factors.

2:00 PM EL19.17.02
Light Emission from Megasonically Solution-Processed MoS_2 Nanosheet Films VinodK. Sangwan, SonalV. Rangnekar, MengruJin, MaryamKhalaj, BeataM. Szydlowska, AnushkaDasgupta, LidiaKuo, HeatherKurtz, TobinJ. Marks and MarkC. Hersam; Northwestern University, United States

Electroluminescence (EL), the conversion of an electrical current into light, is the basis of ubiquitous technologies including lighting, displays, and data communication. Recently, two-dimensional (2D) monolayer semiconductors have been widely studied in the context of electroluminescent devices due to their tunable photonic and electrical properties. Specifically, transition metal dichalcogenides (TMDs) show a direct band gap at the monolayer scale, strong light-matter interactions, tightly bound excitons, trions, and multi-excitons that can be controlled by strain and doping. Layered TMDs are also amenable to solution-processibility for printed optoelectronics with high carrier mobility and mechanical flexibility in printed active layers. Furthermore, stacking arbitrary 2D materials in van der Waals heterojunctions has enabled a variety of light-emitting devices, including lateral p-n homojunctions, vertical p-n heterojunctions, and quantum well structures. On the other hand, a light-emitting capacitor (LEC) achieves light emission through bipolar carrier injection using an alternating-current (AC) gating scheme that avoids stringent materials selection for matching contact metals and is less sensitive to morphological nonuniformity in the semiconductor. However, challenges in isolating optoelectronic-grade monolayer TMDs using scalable liquid-phase exfoliation have thus far precluded the realization of large-area EL devices.

Here, we overcome these challenges and demonstrate EL in large-area solution-processed molybdenum disulfide (MoS_2) nanosheet films. Monolayer-rich MoS_2 ink is produced through electrochemical intercalation followed by megasonic exfoliation (i.e., sonication at megahertz frequencies) that has recently been shown to yield high-performance visible and near-infrared photodetectors.[1,2] The MoS_2 ink is used to produce large-area, percolating nanosheet films for AC-gated transient-EL devices in a metal-insulator-semiconductor-metal geometry. Characteristic monolayer MoS_2 photoluminescence (PL) and EL spectral peaks at 1.88-1.90 eV are observed in thick MoS_2 films with the emission intensity increasing with film thickness over the range of 10-70 nm. A vertical LEC geometry produces highly uniform EL in large-area devices, thus confirming that megasonically exfoliated MoS_2 monolayers retain their direct bandgap character in electrically percolating thin films. This work establishes the potential of megasonicated 2D monolayer inks as an additive manufacturing platform for flexible, patterned, and miniaturized light sources.

A Scalable Route for Composition-Tunable Transition Metal Dichalcogenide Nanosheets RebekahWells[1], NicolasDiercks[1], VictorBoureau[1], SimonNussbaum[1], MarcEsteve[1], MarinaCaretti[2,1], HannahJohnson[2,1] and KevinSivula[1]; [1]Ecole Polytechique Federale de Lausanne, Switzerland; [2]Toyota Motor Europe, Belgium

The alloying of 2D TMDs is an established route to robust semiconductors with continuously-tunable optoelectronic properties. However, a major obstacle in commercializing large-area, thin devices based on alloyed TMD nanosheets is their large-scale production.[1]

In this presentation we describe major advances that address this issue. Firstly, we describe a new powder-based, solution processable method to produce high quality 2D TMD nanosheets using a pre-annealing step and electrochemical intercalation/exfoliation.[2] Compared to traditional methods (i.e., ultrasonication), 2D TMD nanosheets produced using our method show ameliorated optoelectronic properties owing to high aspect ratios and low defect densities. Next, we demonstrate how this innovative method can be adapted to afford production of ternary ($Mo_{0.5}W_{0.5}S_2$, $Mo_{0.5}W_{0.5}Se_2$, MoSSe, WSSe) and quaternary ($Mo_{0.5}W_{0.5}SSe$) alloyed TMD nanosheets from commercially available, pure-phase bulk TMD powders. We provide evidence of the atomic mixing within the nanosheets using atomic resolution scanning transmission electron microscopy (STEM) in combination with integrated differential phase contrast (iDPC) for the metal and chalcogenide atoms, respectively. Furthermore, we show that control over the final composition of the nanosheets can be exerted by tuning the feed ratios of the TMD powders. Accordingly, we examine the unique optoelectronic properties that arise as a function of the chemical composition of the alloy. Notably, the phenomena observed are consistent with nanosheets produced *via* chemical vapor deposition (CVD) and related methods, suggesting that this versatile method is an economically viable solution for making alloyed 2D TMD nanosheets. Indeed, the ability to produce controllably alloyed TMD nanosheets in large quantities is critical for the inexpensive production of next-generation, large-area optoelectronic devices.

In order to transform our exfoliated materials into large-area, thin films, we report the further advancement of our preparation methods toward a continuous roll-to-roll deposition of TMD-based thin films from nanosheet dispersions using a liquid-liquid self-assembly technique.[3] We demonstrate reproducible printing of 100mm wide TMD nanosheet films on plastic substrates.

Thus, the advances presented here represent a comprehensive route towards large-area, tunable, and fully solution-processable 2D TMD-based devices.

Permeation Mechanisms Through 1 nm Thin Carbon Nanomembranes AndreyTurchanin; Friedrich Schiller University Jena, Germany

Molecular thin carbon nanomembranes (CNMs) synthesized by electron irradiation induced cross-linking of aromatic self-assembled monolayers (SAMs) are promising 2D materials for the next generation of filtration technologies [1, 2]. Their unique properties including ultimately low thickness of ~1 nm, sub-nanometer porosity, mechanical and chemical stability are attractive for the development of innovative filters with low energy consumption, improved selectivity and robustness. However, the permeation mechanisms through CNMs resulting in, *e.g.*, an ~1000 times higher fluxes of water in comparison to helium have not been yet understood [1]. Here we report a study of the permeation of He, Ne, D_2, CO_2, Ar, O_2 and D_2O using mass spectrometry in the temperature range from room temperature to ~120 °C. As a model system, we investigate CNMs made from [1",4',1',1]-terphenyl-4-thiol SAMs. We found out that all studied gases experience an activation energy barrier upon the permeation which scales with their kinetic diameters. Moreover, their permeation rates are dependent on the adsorption enthalpy on the nanomembrane surface. These findings enable us to rationalize the permeation mechanisms and establish a model, which paves the way towards the rational design not only of CNMs but also of other organic and inorganic 2D materials for energy-efficient and highly selective filtration applications [3].

Topological Characterization of 2D Polymers and Thin Nanofilms: TEM Imaging Processing and Computational Analysis Yu-MingTu, XunGong, QuienMichelle and MichaelS Strano; Massachusetts Institute of Technology, United States

Recent research has shown an increased interest in the development of polymers that can extend covalently in two dimensions. This type of material has the potential to combine the mechanical strength and in-plane energy conduction of conventional two-dimensional (2D) materials with the low densities, synthetic processability, and organic composition of their one-dimensional counterparts. 2D polymers and materials possess unique properties such as ultra-thinness, well-organized pore structures, and high chemical stability, making them highly attractive for a range of applications, including nanotechnology and devices. One promising area of research involves altering the 2D layered structure of these materials to create barriers through staggered platelet stacking or perm-selective separation membranes via aligned pore structures. Nevertheless, comprehensive studies are required to validate the 2D formation and layered stacking structure, which necessitates combining material characterization techniques and computational tools.
In our recent study, we designed and synthesized a 2D polyaramide-1 (2DPA-1) using irreversible polycondensation chemistry. This approach offers mechanical processability and high chemical stability, making it an ideal candidate for further investigation. Our current work focused on exploring how the 2DPA-1 polymer molecules, which are covalently linked by interlayer hydrogen bonds, can be realigned into highly organized nanofilms using various techniques such as solvent retreatment, spinning coating, drop-casting, and scotch tape exfoliation. To analyze the resulting 2D structure, we used a combination of transmission electron microscopy (TEM) imaging and computational processing tools. These tools enabled us to examine the ultra-thinness sheet-like structure (0.4 nm thickness) and estimate possible 2D platelet orientation and layered structure. The image processing tools also allowed for high throughput structural analysis of 2D platelets and polymers. Overall, our study provides insights into the potential of 2D materials and highlights the importance of combining material characterization techniques and computational tools to fully understand their properties and potential applications

3:30 PM EL19.17.06
Production and Characterization of Phosphorene Nanoribbons (PNRs) EvaAw[1], LorenPicco[2,3,4], OliverD. Payton[2,3,4], StacyR. Moore[3], FengfeiZhang[1], AdamJ. Clancy[1], ThomasS. Miller[1] and ChristopherA. Howard[1]; [1]University College London, United Kingdom; [2]Bristol Nano Dynamics Ltd., United Kingdom; [3]University of Bristol, United Kingdom; [4]Active Nano Mapping NNUF, United Kingdom

In our fast-paced technological world, the demand for more powerful yet smaller devices has fueled the need for nanomaterial innovation. To meet this demand, precise chemical doping techniques can be employed to tailor the properties of low-dimensional materials and facilitate their integration into functional films, electrodes, and spin-based electronics.

Phosphorene nanoribbons (PNRs), a newly synthesized nanomaterial by our research group at UCL [1], are predicted to exhibit exotic properties, including the Seebeck effect, tunable layer-dependent electronic, optical and ionic transport properties. Recent experiments have demonstrated room-temperature magnetism [2] in PNRs and their ability to enhance hole mobility in solar cells [3]. By combining the flexibility and unidirectional properties of nanoribbons with the high surface area and anisotropic properties of 2D phosphorene sheets, PNRs are expected to exhibit high conductivity due to the 2D confinement of electronic movements and edge effects.

My talk focuses on the synthesis of PNRs using a two-step method. Firstly, black phosphorus is intercalated with alkali metal ions, followed by exfoliation to form stable liquid dispersions of PNRs with few-layer thicknesses and 4-50 nm widths uniform along their lengths [4]. This scalable approach allows us to isolate high quality individual PNRs from bulk black phosphorus. In collaboration with Bristol Nanodynamics Ltd., I am using a recently developed conductive high-speed atomic force microscopy (HS-AFM) to characterise the local charge distribution of PNRs [5].

HS-AFM is an advanced characterization technique which allows for high-resolution data acquisition and real-time video observations across large surface areas. This technique enables simultaneous topography and conductivity measurements, providing valuable insights into the spatial maps of conductivity. By analyzing these maps, we can derive insights on how the electronic band structure of PNRs varies with the number of layers and bifurcations.

SESSION EL19.18: Advances in Novel 2D Material Synthesis
Session Chairs: Sanjay Behura and Andrew Mannix
Friday Morning, December1, 2023
Hynes, Level 3, Room 309

8:00 AM EL19.18.01
Correlated SKPM and TERS Imaging of Janus MoSSe Monolayers and MoSSe-MoS_2 Vertical Heterostructures TianyiZhang[1], AndreyKrayev[2], HongweiLiu[1,3] and JingKong[1]; [1]Massachusetts Institute of Technology, United States; [2]HORIBA Instruments Inc, United States; [3]The Hong Kong University of Science and Technology, Hong Kong

We report correlated scanning Kelvin probe microscopy (SKPM) and tip enhanced Raman scattering (TERS) imaging of Janus MoSSe monolayers and MoSSe-MoS_2 vertical heterostructures (VHS) obtained by replacing the top sulfur layer of monolayer MoS_2 with selenium atoms via a plasma-assisted room-temperature atomic-layer substitution (RT-ALS) approach. MoSSe crystals were transferred to gold to improve the efficiency of TERS measurements. Unlike their conventional Raman counterparts, TERS spectra of MoSSe featured a strong A_1^2 mode, possibly due to the preferential enhancement of the out-of-plane modes favored in the gap-mode TERS. We observed a sharp drop of the intensity of A_1^2 mode in the VHS of MoSSe-MoS_2 that naturally occurred during the Janus conversion of multilayer islands sporadically occurring in larger monolayer MoS_2 crystals. The work function of these vertical heterostructures is drastically different from the monolayer Janus MoSSe material which makes SKPM technique an excellent tool for visualizing VHS. Besides, rather unexpectedly, we observed splitting of the A_1^1 mode of MoSSe both in the Janus monolayers and in their VHS, we will discuss possible reasons for this splitting.
SKPM imaging of multiple crystals confirmed high microscopic uniformity of the S-Se substitution and the lack of damage to the original MoS_2 crystals except for occasional etching of the grain boundaries in twin symmetry crystals. At the same time, TERS imaging revealed that the width and the spectral position of A_1^2 peak may vary drastically at the nanoscale which implies local nanoscale variations of the stoichiometry of Janus material.
Finally, in this study we found that 785 nm excitation provides the strongest TERS response on Janus MoSSe when compared to 633 nm, 671 nm or 830 nm excitations. This observation should be very helpful for future TERS studies on Janus TMDs and their vertical heterostructures.

8:15 AM EL19.18.02
Characterization and Engineering of 2D vdW Magnets Hosting 1D Magnetic Chains using Scanning Transmission Electron Microscopy (STEM) EugenePark[1], JohnPhilbin[2], JoshuaSanchez[1], ConnorOcchialini[1], HangChi[1], ZhigangSong[3], AlexandreFoucher[1], JoachimD. Thomsen[2], JulianKlein[1], ZdenekSofer[4], PrinehaNarang[2] and FrancesM. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]University of California, Los Angeles, United States; [3]Harvard University, United States; [4]University of Chemistry and Technology Prague, Czechia

Van der Waals 2D magnetic materials have emerged as a novel platform that offers unique optoelectronic, magnetic, and quantum properties.[1] Such low-dimensional spin systems have vast potential in applications such as spintronics and nanoscale magnetic devices. The ability to engineer the structure and defects with respect to magnetic, optical, and electronic properties is critical. For example, using individual spins to encode many-body Hamiltonians can allow quantum simulation to be carried out on vdW heterostructures composed of 2D magnets. Out of the wide range of 2D van der Waals magnets, 2D magnets with high structural anisotropy are relatively unexplored, making such materials intriguing and helpful for both fundamental research and device design. For instance, the highly anisotropic character could deliver additional degrees of freedom like 1D magnetism that we can harvest in 2D vdW materials.

Here, we examine the structural properties of two kinds of 2D magnets hosting 1D chains of magnetic atoms. Using scanning transmission electron microscopy (STEM), we characterize structural properties such as the alignment of magnetic chains between layers with atomic resolution. We also explore the nature of defects and the possibility of controlling defect location using the STEM electron beam.[2,3] To reduce beam damage when imaging few layer materials, the sample was encapsulated in graphene to constrain the movement of atoms. By parametrizing a model spin-Hamiltonian based on density functional theory calculations, we predict the spin structure that develops from the chain arrangement of the magnetic atoms in this material. We discuss measurements to verify theoretical calculations using instruments such as vibrating sample magnetometry and photoluminescence. Lastly, we engineer the 2D magnet via electron beam irradiation to modify the structure of 1D spin chains and predict magnetic properties and spin structure using atomistic magnetic simulation.

Hybrid Pulsed Laser Deposition Growth of Group IVB Dichalcogenides MythiliSurendran, HuandongChen, ShantanuSingh, AmirAvishai, BoyangZhao, Yu-TsunShao and JayakanthRavichandran; University of Southern California, United States

Group IVB transition metal dichalcogenides (TMDCs) (MX_2: M=Ti, Zr, Hf and X =S, Se, Te) have high calculated room temperature electronic mobilities (5-10 times higher than MoS_2) making them promising materials for electronic applications[1]. However, they remain as the least explored amongst all the layered TMDCs largely due to the synthesis challenges to achieve large area high-quality thin films. TMDC thin films are mostly grown using chemical vapor deposition, although molecular beam epitaxy, metal-organic vapor deposition, pulsed laser deposition (PLD) [2, 3] and several other techniques have been exploited. High temperatures of about 1000°C are typically required to grow group IVB TMDCs as they consist of refractory metals such as Zr and Hf, resulting in high defect densities in these films. Moreover, they have a high propensity to oxidize at these high temperatures, thus affecting the electronic properties.

Here, we report a hybrid PLD approach wherein we employed organo-sulfur precursors as sulfur source (as an alternative to H_2S) to grow chalcogenide thin films. To demonstrate the efficacy of this approach, we have demonstrated epitaxial growth of Group IVB TMDCs such as TiS_2 (semimetallic), ZrS_2 and HfS_2 (semiconducting) [4, 5]. Structural and electrical characterization, along with low temperature transport studies reveal low defect densities and high carrier mobilities in these thin films. The synthesis challenges during the realization of refractory metal-based chalcogenides will be discussed in detail. This novel method enables growth temperatures as low as 500°C and opens up new opportunities to investigate the fundamental properties of Group IVB chalcogenides and realize the predicted electronic and optoelectronic applications.

Electrically Driven Ion Dynamics with Negative Differential Resistance in Alkali Ions Intercalated 2D-Layered Metal Oxide GichangNoh[1,2], JeonghoKim[2], Han BeomJeong[3], YooyeonJo[1], Min-kyungJo[2], EoramMoon[2], MingyuKim[2], EunpyoPark[1], In SooKim[1], Chul-HoLee[4], Hu YoungJeong[3], KibumKang[2] and Joon YoungKwak[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Ulsan National Institute of Science and Technology, Korea (the Republic of); [4]Seoul National University, Korea (the Republic of)

Ion-based electronics provide a platform to explore unique physical properties and have extensive applications in the design of bio-nano interface and bio-mimetic devices. 2D-layered materials, thanks to their ability to easily accommodate ions between their layers, emerge as an ideal choice for these ion-based electronic platforms. To realize systematic ion control in 2D-layered materials, it's crucial to ensure stable spatiotemporal reactions of ions on demand. However, substantial hurdles persist during device fabrication and operation based on ion intercalation, including the need for external force during the intercalation process, the challenge of maintaining thermodynamic stability with ions, and the management of structural distortions during ion migration. Here, we introduce the intrinsic stable potassium ion (K^+) intercalated 2D-layered MnO_2 (2D K-MnO_2) by the metal-organic chemical vapor deposition (MOCVD) method. Thermodynamically, the layered structure of MnO_2 with the intercalated potassium ion and H_2O has the lowest Gibbs free energy among the other phases, resulting in spontaneous intercalation during the growth process. Potassium ions intercalated into the van der Waals gap of layered MnO_2 can easily move under the external bias, and this electrical-driven ion movement causes the reversible phase transition to Mn_3O_4. Especially, the phase transition of Mn_3O_4 and the lattice distortion by over-concentrated potassium ions form a high Schottky barrier that presents dominant negative differential resistance (NDR). We designed a device with multi-channels of the 2D K-MnO_2 to apply simultaneous signals with various conditions and successfully proved that the spatial and temporal potassium ion controls the gradual conductance changes with NDR behavior. Moreover, we imitated the biological voltage-gated potassium channels based on NDR-related conductance change and applied the long-term & short-term plasticity to the associative learning. Our approach to NDR-based ionic motion of 2D K-MnO_2 shows not only a new concept of the dynamics of ion devices but also the high applicability for ionic activities in the human body.

9:00 AM *EL19.18.05
Developing and Integrating Atomically Thin Metals, Semiconductors and Insulators JoshuaA. Robinson; The Pennsylvania State University, United States

The last decade has seen an exponential growth in the science and technology of two-dimensional materials. Beyond graphene, there is a huge variety of layered materials that range in properties from insulating to superconducting. Furthermore, heterogeneous stacking of 2D materials also allows for additional "dimensionality" for material and device engineering. In this

talk, I will discuss recent breakthroughs in two-dimensional atomic layer synthesis, properties, and integration toward advancing devices relevent to the semicondcutor industry. This includes novel 2D heterostructures and the realization of unique 2D allotropes of 3D materials (e.g. 2D metals, nitride, oxides) based on a novel synthesis method, dubbed confinement heteroepitaxy (CHet). By shrinking traditional metals to atomically thin structures, we find that their properties are completely different than their bulk counterparts, lending themselves to unique quantum and optical applications not possible before.

10:00 AM EL19.19.01
Electrical Detection of the Flat Band Dispersion in Van der Waals Field-Effect Structures GabrielePasquale[1], EdoardoLopriore[1], ZheSun[1], KristiansCernevics[1], FedeleTagarelli[1], KenjiWatanabe[2], TakashiTaniguchi[3], OlegYazyev[1] and AndrasKis[1]; [1]EPFL, Switzerland; [2]Research Center for Functional Materials, National Institute for Materials Science, Japan; [3]International Center for Materials Nanoarchitectonics, National Institute for Materials Science, Japan

The emergence of the field-effect transistor transformed contemporary technologies. Of paramount significance to the effective operation of such devices is the minimal current leakage between the source and gate electrodes. These currents have traditionally been considered detrimental, hindering the flow of electrical charge through the channel. Consequently, for more than seven decades, leakage currents were perceived as lacking any valuable insights beyond their role in improving performance and transistor design. This research delves into the examination of gate leakage currents, specifically tunneling currents, in field-effect devices utilizing thin layers of InSe channels. InSe, known for its exceptional electrical and optical properties, as well as its distinctive band structure, exhibits a flat-band dispersion at the valence band edge, which may give rise to emergent phenomena [1]. However, determining the energy position of the flat band in a field-effect device has traditionally required costly and impractical methods. Therefore, our study focuses on analyzing tunneling currents in gated structures composed of a few layers of InSe and their relationship with ambipolar transport and photoluminescence measurements. Notably, we observe a shift in tunneling mechanisms due to the presence of the van Hove singularity at the flat band. To validate our findings, we explore tunneling currents as a reliable means of determining the position of the flat band, even at room temperature. Our study offers a fresh outlook on the enduring enigma, presenting an alternative framework for comprehending leakage currents in field-effect devices.

10:15 AM EL19.19.02
2D Materials Integration with Silicon as 2D-3D Heterostructure Architecture Enabled by Quantum Tunneling TaraJabegu, NingxinLi, AishaA. Okmi and SidongLei; Georgia State University, United States

In-line with the concept of three-dimensional (3D) hybrid integration, the combination of silicon-based circuits with two-dimensional (2D) material-based device architectures has emerged as an appealing topic. This fusion holds the promise in innovative electronics and optoelectronics with novel functions, higher integration level, fast speed, and many other benefits that are intangible in conventional designs. Nonetheless, the integration of silicon and 2D materials in a 3D configuration encounters a problem of substantial contact resistance. Earlier investigations suggested that the presence of van der Waals gap and in-gap states could be responsible for the poor contact. In this study, we present an alternative approach to enhance contact quality. In essence, instead of eliminating the van der Waals gap between silicon and 2D materials, we treat the gap as a quantum tunneling barrier and manage to increase the quantum tunneling efficiency. By tuning the Fermi-surface alignment and minimizing the charge carrier momenta mismatch, we effectively reduce the contact resistance between silicon and graphene achieving nearly ideal ohmic contact. Furthermore, we characterize the phonon-assisted inelastic transport process on this silicon-graphene interface and demonstrate its positive effects in enhancing the contact conductivity. This research provides a feasible and versatile approach for high-quality 3D-2D contact fabrication towards the hybrid integration of dissimilar materials with advanced functionalities in the field of electronics and optoelectronics.

1:30 PM EL19.20.01
Impact of Thermal Annealing on the Interaction of Monolayer MoS_2 on Au StephanieD. Lough[1], JesseThompson[1], DarianSmalley[1], RahulRao[2] and MasahiroIshigami[2]; [1]University of Central Florida, United States; [2]Air Force Research Laboratory, United States

We have investigated the impact of thermal annealing on the interaction of single layer MoS_2 and Au using Raman Spectroscopy. Au-assisted exfoliation results in single layer MoS_2 which has weakly- and strongly-coupled regions where the strongly-coupled regions are n-doped and relatively unstrained while the weakly-coupled regions are p-doped and tensile strained. The observed nanoscale inhomogeneities may result in Au contacts having a large variability in performance. Our data also show that monolayer MoS_2 starts to decouple from Au at above 100 °C, becoming fully decoupled above 200-250 °C. This indicates that monolayer MoS_2 produced by Au-assisted exfoliation may be more easily transferred off Au at high temperatures. Our results also show that the overall areal coverage of strongly-coupled regions does not increase by thermal annealing while the degree of hybridization becomes more inhomogeneous at annealing temperatures above 100 °C.

1:45 PM EL19.20.02
Photoluminescence Quenching in N-Heterocyclic Carbene Functionalized Tungsten Dichalcogenide Mixed-Dimensional Heterostructures AnushkaDasgupta[1], RafaelLópez-Arteaga[1], IqbalB. Utama[1], TumpaSadhukhan[2], S. CarinGavin[1], XiWan[1], WeiWang[3], BrendanKerwin[1], RiddhiAnanth[1], AlbertVong[1], NathanielStern[1], GeorgeSchatz[1], XuedanMa[3], EmilyWeiss[1] and MarkC. Hersam[1]; [1]Northwestern University, United States; [2]SRM Institute of Science and Technology, India; [3]Argonne National Laboratory, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) are promising candidates for quantum optoelectronic devices due to their pronounced valley physics and excitonic properties. One approach to modulate these properties is to modify 2D TMDs with carbon-based ligands.[1] Among carbon-based ligands, the strong σ-donor character, stability, and structural tunability of N-heterocyclic carbenes (NHCs) has prompted investigations of NHC coordination to various atomically flat metal surfaces and metal nanoparticles. Here, we discuss the optical properties of WS_2 and WSe_2 monolayers functionalized with NHCs via a solvent-free route and an air-stable precursor. The deposition of NHCs on the 2D TMDs results in a significant room-temperature photoluminescence (PL) quenching. Moreover, low-temperature PL measurements (T = 3.9 K) show quenching of the WS_2 and WSe_2 excitonic emission and a shift of the defect bands to lower energies. The extent of both effects is tunable by altering the N-substituents of the NHCs as well the thickness of the deposited organic layer. The resulting mixed-dimensional heterostructures are further characterized by X-ray photoelectron spectroscopy, atomic force microscopy, and time-of-flight secondary ion mass spectrometry to elucidate the nature of the functionalization process. The observed PL quenching is consistent with a charge transfer process from defect states introduced by chalcogen vacancies to midgap states introduced by the carbene layer, as predicted from first-principles density functional theory calculations. Overall, these results demonstrate that carbene functionalization is an effective pathway for modifying

the optical properties of 2D TMDs.

Computational Design of Plasma Process for High Purity Layer Thinning of 4-In MoS_2MuyoungKim[1], ChangminKim[1], Hyeong-UKim[1], DaewoongKim[1], TaesungKim[2] and Woo SeokKang[1]; [1]Korea Institute of Machinery and Materials, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Two-dimensional molybdenum disulfide (MoS_2) has attracted huge attention for next-generation nanoelectronics due to its unique physical and chemical properties. Among the fascinating characteristics of MoS_2, a tunable bandgap according to the thickness is necessary for on-demand engineering of future electronics. In this respect, the precise layer control of MoS_2 has been a long-standing desire, but prior studies encountered critical challenges such as poor scalability, surface roughening and impurities. This work aimed to achieve ultrahigh purity and precision in wafer-scale layer thinning of MoS_2 by plasma processes: plasma-enhanced chemical vapor deposition (PECVD) and reactive ion etching (RIE). The 4-inch MoS_2 was synthesized by PECVD, and the as-deposited layers were peeled off by RIE with a computationally screened gas mixture. For the computational screening, the plasma-induced surface chemistry was explored using first-principles calculations that offered atomic insights on reaction energetics and the associated orbital interaction. Through the process optimization, layer-by-layer thinning of MoS_2 was confirmed in 4-inch wafer, where mono- or bilayer was evenly removed for each RIE cycle. Additionally, there were no damages in atomic structure and chemical impurities. The combined computational screening-experimentation accelerates the process development and provides concrete understanding on underlying physics in manufacturing process.

Plasma Electron Irradiation Etching (PEIE) of Two-Dimensional Materials YunjoJeong[1], Jong-BaePark[2], EunjinChoi[1], Dae ChulKim[2], SukangBae[1], Young-WooKim[2] and JangyupSon[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute for Fusion Energy, Korea (the Republic of)

Two-dimensional layered materials (2DLMs) have garnered significant interest due to their versatility and the potential for investigating practical applications such as flexible electronics, molecular filters, etc. In maximizing the versatility of 2DLMs, various attempts have been made to tailor their properties for desired applications, such as inducing mechanical deformation, modifying their surface chemistry, and investigating the change in their thickness-dependent properties such as bandgap energy, mechanical strength, and optical transmittance.
Although significant progress has been made in maintaining control over mechanical or chemical states of 2DLMs, precise control over their thickness remains a challenge. Currently, most research has focused on mono- or few-layer 2DLMs; however, while such research allows for a thorough understanding of the various properties of 2DLMs, practical application of 2DLMs is contingent upon achieving capacity for arbitrary manipulation of their thickness at the multilayer scale. Conventional approaches to control over the thickness of 2DLMs include bottom-up approaches such as chemical vapor deposition and top-down approaches such as chemical etching via plasma, wet etchants, etc. Although such approaches are relatively effective, they inherently exhibit tradeoffs such as defects and sample contamination. Here, we introduce a novel approach to achieving precise etching of two-dimensional materials at the nanometer scale. A modified plasma electron annealing method, originally designed for the recrystallization of amorphous Si [1], was employed to achieve highly precise control over the vertical dimension of exfoliated BN crystals. Characterization via Raman spectroscopy and atomic force microscopy (AFM) confirm successful thinning of BN, and an in-depth investigation via AFM of the surface roughness of the BN after the plasma electron treatment reveals that the remaining BN lattices remain undamaged. This work paves new potential for the investigation of 2DLMs at the multilayer level, opening up novel opportunities for their industry-friendly applications.

Interface Band Engineering for High-Performance 2D Field-Effect Transistors Chul-HoLee; Seoul National University, Korea (the Republic of)

Two-dimensional (2D) semiconductors such as transition metal dichalcogenides (TMDs) have emerged as promising materials for implementing beyond-CMOS electronics due to excellent gate coupling and immunity to short-channel effects at the ultimate scaling. In addition, owing to a van der Waals layered structure, they hold great potential for non-conventional electronics capable of heterogeneous integration and deformation. To achieve high-performance 2D field-effect transistors (FETs), it is highly required to control the electronic states and energy band profiles at various heterointerfaces among the semiconductor channel, the gate dielectric, and metal electrodes. In this talk, I will present two types of proof-of-concepts 2D FETs enabled by interface band engineering: 1) modulation-doped FETs (MODFETs) and 2) metal-semiconductor FETs (MESFETs). In a MODFET, we demonstrated remote modulation doping in the type-II band-modulated channel, enabling us to achieve high mobility by suppressing dopant-induced charge impurity scattering. The 2D MESFETs were also demonstrated using the Fermi-level pinning-free metal Schottky gate, whose device characteristics approach the Boltzmann switching limit.

Tailoring Localized Excitons and Their Light-Matter Interactions with Nanoscale Structure in 2D Semiconductors NicholasJ. Borys[1,2]; [1]Montana State University, United States; [2]MonArk NSF Quantum Foundry, United States

Strain-induced localization of excitons is important for many conventional and quantum optoelectronic devices that are based on layered two-dimensional (2D) semiconductors. For example, single-photon emitters in single-layer WSe_2 (1L-WSe_2), which are potential platforms for solid-state quantum light sources, occur in nanoscale regions of localized tensile strain that produce excitonic potential energy wells. In these regions and the surrounding vicinity, excitons funnel to the strained region of lowest energy. The resulting interplay between reducing the energy, spatially localizing, and hybridizing the exciton with defect states is hypothesized to be integral to the formation of quantum emitters. Understanding these phenomena and their roles in the formation of quantum emitters necessitates investigations that directly probe the intrinsic nanoscale structure-property relationships of strain-localized emitters and identify systematic differences between emitter populations of different systems. The latter focus is crucial to quantitatively assess how different approaches to generate the local strain such as random nanobubbles, deposition on nanofabricated pillars, or nanoindentation affect the quality and properties of the resulting quantum emitters.
This talk will highlight two recent studies by our group of strain-localized emitters in 2D semiconductors. In the first, nanobubbles of 1L-WS_2 and 1L-WSe_2 on gold films are found to provide a unique background-free system in which to correlate strain-localized states with nanoscale structure. Using room-temperature steady-state and time-resolved spectroscopy, individual localization centers within single nanobubbles can be identified and counted. The occurrence of single or multiple emitters within an individual nanobubble correlates with its structure, demonstrating that strain-engineering of exciton localization in 2D materials necessitates nanoscale precision. Ongoing work is extending these correlated measurements to cryogenic temperatures to probe how the number of localization sites correlates with the number of quantum emitters formed. In the second study, we statistically compare the steady state properties and excited state dynamics of localized exciton-based quantum emitters formed in a variety of systems of 1L-WSe_2 that vary the generation of local strain, the defect density in the 1L-WSe_2, and the surrounding dielectric environment. Of the systems probed arrays of metallic stressors with high-quality flux-grown 1L-WSe_2 are found to systematically produce the most homogeneous quantum emitter populations. Combined, the two studies uncover key structure-property relationships for 2D semiconductor quantum emitters and aim at identifying which combination of strain generation, surrounding dielectric environment, and nanophotonic engineering is best suited to optimize emitter performance.

4:00 PM EL19.20.07
Photoluminescence Emission Properties of Scrolled Monolayer MoS_2C. AbinashBhuyan[1,2], Kishore K.Madapu[2], SumanPaul[3] and SandipDhara[1,2]; [1]Indira Gandhi Centre for Atomic Research, A CI of Homi Bhabha National Institute, India; [2]Indira Gandhi Centre for Atomic Research, India; [3]Attocube Systems AG, Germany

Three-atomic thin monolayer MoS_2 (1L-MoS_2) attracted a great deal of attention among the research communities because of their interesting optoelectronic properties [1]. By thinning down the layers from bulk to monolayer, MoS_2 becomes a direct bandgap material with an optical gap at 1.81 eV. Because of the band nesting effect, the 1L-MoS_2 absorbs ~10% of incident light in the visible range [2]. However, photoluminescence (PL) emission from the bilayer is four orders lower than monolayer because of the transition to an indirect band gap which arises at K-point. Interestingly, by stacking multiple monolayers can enhance the light-matter interaction leading to enhanced absorption of incident light. Moreover, rolling a large-area monolayers will make a new 1D structure of material called scrolled 1L-MoS_2. The scrolled 1L-MoS_2 shows higher on-state current in field-effect transistor devices [3]. The demand for scrolled 1L-MoS_2 is increasing because of their use in compact and miniaturized 2D electronic devices.[4] In this context, we fabricated scrolled 1L-MoS_2 by using the solvent, ethanol solution. The solvent extracts the heat during its evaporation causing a decrease in the Gibbs free energy in the planar form, which modifies the planar into scroll structure, to compensate the energy dissipated in evaporation. The fabrication of scrolled 1L-MoS_2 is confirmed by optical microscopy and the field emission scanning electron microscopy. The images (not shown in the figures) reveal a perfect rolling of a planar structure to form a scrolled structure. Raman study confirm the number of layers in the planar and scrolled form of 1L-MoS_2. PL spectra of both monolayer and scrolled 1L-MoS_2 are dominated at A-exciton emission, 1.81 eV [2]. It is interesting to observe the PL intensity enhancement by nearly five times. The observed PL enhancement is attributed to the increase in the number of layers in the scrolled structure. Our PL emission result is further supported by the absorption measurement. We observe more than two times enhancement in

the absorbance. Such scrolled structures can be used in the fabrication of compact 1D optoelectronic devices using 2D materials.

Rapid Detection of Atomically Thin Semiconductors using Automated Photoluminescence Mapping JuriG. Crimmann[1], MoritzN. Junker[1], YannikM. Glauser[1], NolanLassaline[1,2], GabrielNagamine[1] and DavidJ. Norris[1]; [1]ETH Zurich, Switzerland; [2]Technical University of Denmark, Denmark

Transition metal dichalcogenides (TMDs) are two-dimensional (2D) layered semiconductors that have been studied for various applications, ranging from transistors to single-photon emitters. While multilayered TMDs have an indirect band gap and are commonly used in electronics, TMD monolayers are integrated in optoelectronics since their direct band gap enables efficient light emission. Such atomically thin sheets are often obtained through mechanical exfoliation, followed by manual inspection using a brightfield microscope. However, this process is time-consuming, relies on user experience, and is prone to human error. Here we report a fully automated approach for identifying TMD monolayers using photoluminescence microscopy. Our technique reduces the time spent per sample by more than a factor of 20 and identifies WSe_2 and MoS_2 monolayers with close to 100 % accuracy. We anticipate that our approach will improve fabrication efficiency and enhance the quality of atomically thin optoelectronic devices such as photovoltaics, photodetectors, and light-emitting diodes.

Bilayer Graphene Based Heterostructures for Quantum Information Science ChristophStampfer[1,2]; [1]RWTH Aachen University, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Graphene and bilayer graphene (BLG) are attractive platforms for quantum electronics, quantum circuits and quantum information science in general. This has motivated substantial efforts in studying quantum dot (QD) devices based on graphene and BLG. The major challenge in this context is the missing band-gap in graphene, which does not allow to confine electrons by means of electrostatics. A widely used approach to tackle this problem was to introduce a hard-wall confinement by etching the graphene sheet. However, the influence of edge disorder, turned out to be a roadblock for obtaining clean quantum devices. The problem of edge disorder can be circumvented in clean BLG, thanks to the fact that this material offers a tunable band-gap (up to 120 meV) in the presence of a perpendicularly applied electric field, a feature that allows introducing electrostatic soft confinement in BLG.
Here we present gate-controlled single and double quantum dot operation in electrostatically gapped BLG [1-6]. We show a remarkable degree of control of our devices, which allows the implementation of gate-defined electron-hole and electron-electron double-dot systems [1], where single-electron occupation becomes possible [2]. Also in the single dot regime, we reach the very few electron/hole regime, extract excited state energies and investigate their evolution in a parallel and perpendicular magnetic field [3]. We will show data on ultra-clean BLG quantum dots allowing investigating the spin-valley coupling in bilayer graphene [4], the electron-hole crossover and the high symmetry between electron and hole states [5]. Finally, we will show data on BLG quantum dots allowing investigating the spin [6] and valley lifetimes. Our work paves the way for the implementation of spin and valley-qubits in graphene.

Large-Area Epitaxial Growth of α-In_2Se_3 and its Layer-Dependent Nonlinear Optical Properties LeiXu, XiaotianZhang, ZhenhuaWu and MingtaoYan; Shanghai Jiao Tong University, China

Non-volatile memories based on ferroelectric materials is one of the most competitive next-generation memories due to its low power consumption, fast read and write speed, non-volatility, and compatibility with CMOS manufacturing processes. However, the critical dimensions of conventional ferroelectric thin films as well as the depolarization and leakage current in conventional ferroelectric dielectrics limit the development of ferroelectric memories. On the other hand, recent development of field effect transistors based on two-dimensional ferroelectric semiconductors offers great potential to outperform conventional ferroelectric memories, in which the polarization states are stored in the semiconducting channels to bypass the limitations of conventional ferroelectric materials. Among all phases of In_2Se_3, two-dimensional α-In_2Se_3 with non-centrosymmetric structure possesses both intercoupled in-plane (IP) and out-of-plane (OOP) ferroelectricity in monolayer, which exhibits great application prospects such as non-volatile memories devices, memristors, and artificial intelligence synapse. However, the coexistence of multiple phases during the growth of In_2Se_3 thin films remains as a challenge to growing uniform and pure α phase In_2Se_3 in a large area and meeting the requirements of large-scale integration.
Herein, we demonstrate the synthesis of large-are α-In_2Se_3 monolayer and multilayer films via both chemical (CVD) and physical (PVD) vapor deposition methods. Characterization techniques such as Raman spectroscopy, piezo-force microscopy (PFM), high-resolution transmission electron microscopy (TEM) and second harmonic generation (SHG) were carried out to identify the single phase and high crystallinity of the films. In particular, we notice that the SHG signal intensity of PVD-grown α-In_2Se_3 decrease gradually with the increase of layers, which is the opposite trend to CVD-grown α-In_2Se_3. This indicates a homostructure of α-In_2Se_3 films was formed in our CVD process compared to the vertical heterostructure of α/β-In_2Se_3 generated from our PVD process. We test the durability of our ferroelectric films. The α-In_2Se_3 films maintained the polarization for more than 30 minutes under PFM measurement and the films remained active after 2 months exposure to the air.Finally, we transfer the sample onto Au/Si substrate to study the polarization switching behavior of CVD and PVD-α-In_2Se_3 under external electric field by conduct atomic force microscope (CAFM).

Mechanism of In-Plane Thermal Rectification in Semi-Stochastic Grain-Size Graded Graphene structures SimantaLahkar and RaghavanRanganathan; Indian Institute of Technology Gandhinagar, India

Thermal rectifiers preferentially conduct heat in one direction, and can potentially open up novel technological frontiers of applications such as thermoelectric power generation using thermal diode bridge, thermal logic circuits, and advanced thermal management devices for micro-electronics and atomic clocks, if they can be realized with adequate efficiencies. Compared to bulk materials, two-dimensional (2D) materials could offer a wide range of design strategies for generating and tuning thermal rectification (TR) behavior. The realization of practical thermal rectifiers relies significantly on a sound understanding of the underlying mechanisms of asymmetric heat transport. However, the in-plane thermal rectification in 2D materials like graphene having directional gradients of grain sizes, which could potentially exhibit an interplay of multiple mechanisms, has remained elusive. In fact, understanding the heat transport mechanisms in polycrystalline graphene, which are more practical to synthesize than large-scale single-crystal graphene, could potentially allow a unique opportunity to combine with other defects and designs for effective optimization of the thermal rectification property. In this work, we investigated the thermal rectification behavior in periodic atomistic models of polycrystalline graphene whose grain arrangements were generated using different probability distribution functions in order to have different gradient grain size distributions along the in-plane heat flow direction. We employed the centroid Voronoi tessellation technique to generate realistic grain boundary structures for graphene. The reverse non-equilibrium molecular dynamics simulations method was

used to calculate the thermal conductivity and rectification of the structures equilibrated at different stress and temperature conditions. Additionally, detailed phonon mapping was carried out to understand the underlying mechanisms based on the fluctuation-dissipation theory in order to understand the critical structural descriptors that determine the degree of asymmetric heat flow in graded polycrystalline graphene.

9:00 AM EL19.21.04
Intercalation-Exfoliation of MoS_2 with Evaporable Stabilizer to Obtain High-Yield Monolayers Inks for Printable Photodetectors BarbaraY. Martin[1], TylerDavidson-Hall[1], NathanYee[1], NicholasWilson[2], TeriSiu[2], ManilaOzhukil Valappil[2], MichaelPope[2], JianyingOuyang[1], NeilGraddage[1] and JianpingLu[1]; [1]National Research Council Canada, Canada; [2]University of Waterloo, Canada

Photodetectors are electronic devices which convert light into an electrical signal. Printable, flexible and low-cost photodetectors are in high demand as these devices can be used in a variety of applications such as cameras for smartphones, medical sensors, night vision or even ambient light sensors.
Transition Metal Dichalcogenides (TMDs) possess strong light emission and absorption in the visible and near-infrared wavelength range, making them very attractive materials for optoelectronic applications. Molybdenum disulfide (MoS_2) is a multilayer 2D material that can be exfoliated to obtain monolayers, this material is also characterized by multiple crystalline phases. With this variety of structures, it is possible to adjust the band gap of MoS_2 from an indirect band gap at 1.29eV to a direct band gap at 1.8eV. Moreover, metallic or semi-conductor monolayers can also be obtained.
Chemical vapor deposition can be used to produce semi-conductor monolayer TMDs with controllable synthesis. However, large scale, and low-cost production is very difficult with this technique. Intercalation followed by liquid-phase exfoliation is a powerful technique to produce defect-free monolayers in large-quantities. However, reproducible printable inks with high concentration of TMD monolayers are more difficult to achieved. Another challenge to obtaining good quality TMD inks for printable photodetectors is the necessary to use a large amount of insulating stabilizer (such as PVP or ethyl cellulose).
Our work focuses on the development of highly concentrated MoS_2 inks for printable photodetectors. This ink was made by a new intercalation-exfoliation process, an easily evaporable stabilizer was used to replace PVP, and a cascade centrifugation step was added to the process to achieve a highly efficient monolayer size selection (90% of the flakes have less than 3 layers).

9:15 AM EL19.21.05
Effect of Several Growth Parameters on Graphene Growth on Four Types of Supported Cu Films using Cold Wall CVD and Perspective on Growth Mechanism of Graphene from Scaling Functions of Graphene Island Size Distribution ShantanuDas[1,2]; [1]Intel Corporation, United States; [2]Arizona State University, United States

In this work, I will present results from a series of studies using a custom-automated LabVIEW controlled graphene growth method in a custom-modified multi-chamber UHV chamber transformed into a cold wall CVD system. The controlled experimental approach allowed careful study of effect of several growth parameters on graphene growth on Cu. A systematic, in depth study of graphene in industrially preferred cold wall CVD has potential to shed light on studies of other single layer 2D materials.

Graphene growth was explored on solid electrodeposited, recrystallized, sputter deposited and liquid Cu films supported on W or Mo refractory substrates under ambient pressure using Ar, H2 and CH4 mixtures. Among these films, electrodeposited Cu film was chosen to study the effect of total flow rate, CH4:H2 ratio and dilution of the CH4/H2 mixture by Ar at a fixed substrate temperature of 1000 °C and total pressure of 700 Torr, on the nucleation density and average size of graphene crystallites. The resulting morphological changes correspond with those that would be expected if the precursor deposition rate was varied at a fixed substrate temperature for physical deposition using thermal evaporation. The evolution of graphene crystallite boundary morphology with decreasing effective C deposition rate indicates the role of edge diffusion of C atoms along the crystallite boundaries, in addition to H2 etching on graphene crystallite shape. The results indicate that graphene grown on Cu films using cold wall CVD follows a classical two-dimensional nucleation and growth mechanism. Following nucleation at the earliest growth stages, isolated crystallites grow, impinge and coalesce to form a continuous layer. During the pre-coalescence growth regime, the size distributions of graphene crystallites exhibit scaling which is a function of island area, graphene coverage, average island area and areal density. For graphene grown on Cu surfaces that have been annealed in a reducing Ar+H2 ambient, excellent data collapse onto a monotonically decreasing universal Avrami scaling function is observed irrespective of graphene coverage, surface roughness or Cu grain size. This result is interpreted to indicate attachment limited growth and desorption of C-containing species. Graphene grown on Cu surfaces that were annealed in a nonreducing environment exhibits a qualitatively different bimodal scaling function indicating diffusion-limited growth with a lower attachment barrier combined with C detachment from the graphene edges.

Graphene growth on molten Cu films supported on custom-designed Mo substrates demonstrate a similar 2D nucleation and growth mechanism. The study also explores the orientation of graphene islands on molten Cu. The roles of temperature gradient, chamber pressure and rapid thermal heating in C precursor-rich environment on graphene growth morphology on thin sputtered Cu films are explained. A comparison of graphene growth on electrodeposited Cu vs recrystallized Cu is also shown.

The growth process and the observed results are instructive for the burgeoning graphene industry. Due to the similarities between the growth mechanism of graphene synthesis using cold wall CVD and hot wall CVD, the considerable knowledge base relevant to hot wall CVD can be exploited for graphene growth using the relatively less-explored cold wall CVD. I also anticipate that applying the study of pre-coalescence size distribution method to other 2D material systems may be useful for elucidating atomistic mechanisms of film growth that are otherwise difficult to obtain.

9:30 AM EL19.21.06
MoS_2/Graphene Heterostructure with Silver Nanoparticles Deposited on the Surface for Nitrogen Dioxide Sensor Applications JihunSim and WoojongYu; Sungkyunkwan University, Korea (the Republic of)

Even small quantities of toxic gases can have fatal implications. In the case of NO2 gas, even at concentrations as low as 100ppm, it can prove lethal to humans, causing inflammation and burns upon direct exposure. NO2 is a prominent air pollutant found in the atmosphere, known for its detrimental effects on health and its significant contribution to air pollution issues. Therefore, early detection of NO2 gas leaks plays a crucial role in ensuring the safe use of NO2 gas, necessitating the development of fast and accurate detection technologies.In this particular study, researchers successfully fabricated an efficient gas detection sensor by utilizing two-dimensional materials such as MoS2 and Graphene to create a semiconductor/metal heterostructure. By incorporating a layer of silver (Ag) through sputtering on the surface of these two-dimensional materials, the adsorption of NO2 gas was induced. Two-dimensional materials, with their high aspect ratio and extensive surface area, exhibit immense potential for enhancing sensing capabilities. Using this sensor based on two-dimensional materials, the researchers were able to detect NO2 gas even at ultra-low concentrations, starting from as little as 1ppm up to 50ppm. Notably, at a concentration of just 1 ppm, the sensor exhibited a remarkable resistance change of nearly 20%.
These findings underscore the boundless opportunities offered by two-dimensional material-based sensors, suggesting that by exploring alternative coatings beyond silver (Ag), it may be possible to target and detect a broader range of gases.

9:35 AM EL19.21.07
Two-Dimensional Van der Waals Lateral Heterostructure with V-Doped MoS_2 and WS_2Whan KyunKim[1,2] and WoojongYu[3]; [1]Department of Semiconductor and Display Engineering, Sungkyunkwan University, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of); [3]Department of Electrical and Computer Engineering, Sungkyunkwan University, Korea (the Republic of)

In this study, we present the fabrication of a two-dimensional van der Waals (vdW) lateral heterostructure, achieved via a solution-based chemical vapor deposition (CVD) process. This methodology opens up avenues for designing devices with novel and unique properties. Our fabrication strategy exploits the differential synthesis temperatures of MoS_2 and WS_2; the former occurring at a lower temperature than the latter. By leveraging this phenomenon, we successfully constructed an in-plane lateral junction through the one-step CVD process, which entailed sequential growth of each material at different temperatures. In addition, substitutional doping of vanadium (V) was implemented in the CVD growth process. Initially, V-doped MoS_2 was synthesized at 700 °C, followed by the epitaxial growth of V-doped WS_2 from the edge of V-doped MoS_2 at 800°C. This approach ensured the preservation of a hexagonally packed plane and facilitated the formation of an atomically clean and sharp interface between V-doped MoS_2 and V-doped WS_2. In MoS_2 and WS_2, each crystallizing at distinct temperatures, the extent of vanadium (V) doping varies correspondingly. Notably, WS_2, which exhibits a higher crystallization temperature, demonstrated a V doping concentration nearly twice that of MoS_2. This disparity in doping concentrations brought about an intriguing shift in the V-WS_2 semiconductor behavior from its inherent n-type to p-type, while V-MoS_2 remained an n-type semiconductor. Therefore, by utilizing this distinctive property, it becomes feasible to fabricate a vdW lateral PN heterostructure. Our results not only present an efficient fabrication approach for electronic devices but also open up possibilities for creating unique structures like magnetic PN junctions.

9:40 AM EL19.21.08
Potential, Scope and Limitations of Liquid Interface Assembly as a Technique for Synthesizing 2D Thin Films MediniPadmanabhan and NicholasWeber; Rhode Island College, United States

Solution fabrication of large-area thin films with 2D materials is an active field of study. In this work, we disperse natural graphite and MoS_2 flakes at a heptane-water interface. Individual

flakes spread out and arrange themselves as a thin film at the interface, which is then transferred to a glass substrate. This technique allows us to combine the light absorbing properties of MoS_2 with the high conductivity of graphite to make composite films which exhibit photoconductivity. We observe that the flakes like to arrange themselves in a single layer and resist stacking. The conductivity of the resulting film is correlated with its porosity, much like a percolation network of resistors. We find that the technique, while very effective in spreading out these 2D materials into a single layer, does not help with exfoliation at the atomic scale.

9:45 AM EL19.21.09
Mechanical Nanomanipulation of Water Confined in a Naturally Occurring Water-Hybrid 2D System Raphaelade Oliveira[1,2], AlissonR. Cadore[2], HelioChacham[1], RaulFreitas[2], KlausKrambrock[1], AngeloMalachias[1] and IngridBarcelos[2]; [1]UFMG, Brazil; [2]CNPEM, Brazil

Water is the matrix of life and its confinement in nanocavities and flow through nanocapillaries are central topics from geophysics to nanotribology. Water in nanoscale media can show distinct elastic and viscosity behaviors, presenting exquisite properties such as low dielectric constant [1]. A more recent development in the emergence of nanofluidics is the ability to fabricate artificial nanocapillaries for water transport through van der Waals (vdW) assembly of atomically-thin two-dimensional (2D) materials, such as hexagonal boron nitride and graphene [2]. Although the engineering of these nanocapillaries can be beneficial in controlling specific properties, there is plenty of natural water-based heterostructures barely explored so far. These water-hybrid 2D systems intercalate water layers in the lamellar structure of naturally occurring vdW materials that can show unprecedented and highly tunable properties for nanotechnology applications.
Hydrous minerals act as natural nanocavities for water transport on Earth, which is essential to biochemical processes with cycling of nutrients and elements. In this scenario, phyllosilicate minerals emerge as an abundant class of hydrous minerals that are wide band gap insulators. They can be exfoliated down to monolayers due to their lamellar structure that stacks silicon oxide tetrahedral layers with (Al,Mg)-octahedral layers with O/OH at the vertices [3]. Some specimens of phyllosilicates can be pillared by ions, such as clays, or further octahedral layers, such as chlorites. They present the unique ability to absorb water by confining water layers in the interlamellar space, being water-hybrid 2D systems of natural occurrence.
Theoretical studies suggest that the electrostatic charge distribution due to the presence of substitutional ions in the structure of phyllosilicates modulates how water confines between its layers [4]. Within the barely explored group of chlorite phyllosilicates, we can identify clinochlore as the specimen that favors higher incorporation of interlamellar water due to its more complex structure. In a previous works, we observed a contribution about 14%wt attributed to the presence of water/hydroxyl ions in clinochlore by quantitative analysis [5]. This expressive water-related amount suggests clinochlore as one of the most suitable natural platforms for water confinement in 2D systems among phyllosilicate minerals. However, the hydration of phyllosilicates by interlamellar water intercalation is not a well understood process besides its importance in several fields.
In the forefront of advancing our understanding of nanoconfined water in 2D systems, we will present the nanoimaging of interlamellar water in ultrathin exfoliated clinochlore by infrared scattering-type scanning near-field optical microscopy. We observed a striation pattern for the nanoconfined water capillaries in clinochlore that changes the overall dielectric properties of the system and, consequently, its surface potential probed by Kelvin probe force microscopy. As a unique result, we performed the nanomanipulation of confined interlamellar water in clinochlore by atomic force microscopy in contact mode. By applying a constant local force between the tip and the sample during the scanning, it was possible to drain practically all the fluid from the analyzed area in a controlled manner, changing the clinochlore surface potential. This pioneering result allows the multifunctionalization of these natural water-hybrid 2D system for catalytic applications, sensing, microfluidic devices, and patterning of biomolecules in 2D systems.

How's Your Interface?RodneyS. Ruoff; Ulsan National Institute of Science and Technology, Korea (the Democratic People's Republic of)

The type of interface(s) formed between adjacent materials **A** and **B** can vary depending on **A** and **B** and parameters such as temperature and pressure—among others. Qualitative terms such as “chemisorption” (covalent bonding) and “physisorption” (van der Waals bonding and perhaps including H-bonding for some but not others) are used to describe bonding present at the interface. I will discuss several interfaces that interest me and my team—and how I think about these interfaces as providing opportunities for the growth of certain types of carbon and related (such as BN) materials. *We appreciate support from the Institute for Basic Science (IBS-R019-D1).*

11:00 AM *EL19.22.02
Three Theory Insights in 2D Growth, and Two Ideas in 2D Ferroelectrics BorisI. Yakobson; Rice University, United States

(1) Why the 2D transition metal dichalcogenides grow better if salt is added to the mix? First-principles calculations of the atomistics behind-the-scenes, from the eutectic effect to gas-phase chemistry, reveal the mechanisms and suggest ways to better “cooking recipes” [Z. Liu et al. Nature, 2018: **556**, 355 || J.ACS Nano, 2021: **15**, 10525 || JACS, 2022: **144**, 7497]. (2) How to ensure that the produced 2D-layers are coveted single crystals and not a patchwork of inverted domains, disrupted by the grain boundaries? Vicinal plane substrates’ surface steps dictate the direction of 2D nucleation by virtue of edge-epitaxy. Theory reveals the key role of structural complementarity [Nano Lett. 2019: **19**, 2027], and thus predicts which substrates work best, e.g. for h-BN [T.-A. Chen et al. Nature, 2020: **579**, 219 || Appl. Mater. Today, 2023: **30**, 101734]. (3) This edge-step epitaxy offers a way to produce free, weakly-bonded borophene on insulator [ACS Nano, 2021: **15**, 18347], a potential breakthrough in the field, if experimentally realized.
(1`) We explore with DFT a hetero-bilayer of realistic 2D components: ferroelectric In_2Se_3 and the β-Sb (known for its strong spin−orbit coupling). The $\pm\boldsymbol{P}$ of the In_2Se_3 induces distinctly different electronics in the bilayer: if $\boldsymbol{P}$ points “inward”, it is a trivial insulator; switched “outward”, its state is nontrivial topological, $Z_2 = 1$ — inviting future multifunctional devices’ applications [Nano Lett. 2021: **21**, 785].
(2`) In another example, the often-overlooked (blocked by the substrate) flexibility of 2D materials leads to unexpected behavior of the ferroelectrics. Introduced “ferro-flexo” coupling $\sim P \times k$ in the Ginzburg-Landau-Devonshire j^4-energy, allows one to predict the spontaneous curvature k_s and the rise of Curie temperature, domain wall width, etc. for InP, $CuInP_2S_6$ and In_2Se_3. Polarization switches do bend the layer, converting electrical signal to movement as an actuator, with efficient work-cycle [ACS Nano, 2023: **17**, 5121].

Tuesday Morning, November28, 2023
Hynes, Level 3, Room 301

10:30 AM *EL20.01.01
The Physics and Chemistry of Redox-Based Memristive Switching in Metal Oxides RainerWaser[1,2], StephanMenzel[1] and ReginaDittmann[1]; [1]Forschungszentrum Julich, Germany; [2]RWTH Aachen University, Germany

Redox-Based Resistive Switching Memories (ReRAM), also called *nanoionic* memories or *memristive* elements, are widely considered to provide a potential improvement beyond the limits of current memory technology with respect to write speed, write energies, and scalability as well as an energy-efficient approach to neuromorphic computing concepts.
In this talk, fundamental aspects of the physics and chemistry (lattice disorder, ionic and electronic transport processes, interface reactions and phase formation) of these elements will be presented [1]. In particular, the polarity of the switching (eightwise or counter-eightwise) and the geometry (conducting filament vs. area dependent switching) will be discussed. Furthermore, the ultra-high non-linearity of the switching kinetics of redox-based resistive switching devices will be outlined with an emphasis on the so-called valence change mechanism (VCM) typically encountered as a bipolar switching in metal oxides, but also mentioning the electrochemical metallization (ECM) cells as well systems which may show both aspects. The involved electrochemical and physical processes can be either electric field/voltage enhanced or accelerated by a local increase in temperature due to Joule heating.
The major strands of neuromorphic computing, namely the computational neuroscience for decoding the human brain, the computing-in-memory and the artificial neural networks for pattern recognition, will be worked out. And the different requirements on memristive elements to be applied in these strands will be discussed.

11:00 AM EL20.01.02
Thermodynamic Origin of Nonvolatility in Resistive Memory JingxianLi and YiyangLi; University of Michigan, Ann Arbor, United States

Resistive memory or memristor is a highly potential memory and computing unit for next-generation information storage, in-memory computing, and neuromorphic computing. Valence change memory (VCM) is a promising memristor that stores information through the distribution of oxygen vacancy point defects in transition metal oxides.

The ability to store and retain information is a critical function of nonvolatile memory. It is widely believed non-volatility in resistive memory is a result of the slow diffusion kinetics of oxygen vacancies. In this work, we combine materials characterization, device measurements, ab initio, and continuum modeling and show instead that information retention results from phase separation that results from materials thermodynamics. We definitively show for the first time that the amorphous refractory metal oxides undergo spinodal decomposition into two phases with different metal to oxygen ratios. Moreover, the stability of this spinodal decomposition controls whether a resistive memory cell will be able to retain information over time.

By applying phase separation, a foundational principle of materials science, to the field of resistive memory, we explain for the first time why these materials are able to function as nonvolatile memory. We further highlight the critical importance of considering nonideal thermodynamic interactions such as phase separation for future electronic materials dominated by point defects.

11:15 AM EL20.01.03
Fully Transient Simulation of Filament-Type Switching Operations in Unipolar and Bipolar Memristors by Combining Electrothermal and Phase-Field Models DongmyungJung[1], ChanhooPark[1], Ki-HaHong[2] and YongwooKwon[1]; [1]Hongik University, Korea (the Republic of); [2]Hanbat National University, Korea (the Republic of)

Transient simulation of memristors where conductive filaments (CFs) dynamically evolve according to an electric field and temperature is a challenging subject. In the case of the valence

change mechanism (VCM), the matrix and CFs can be regarded as two distinct phases, the high and low resistance phases (HRP and LRP), respectively. The HRP is stable. On the other hand, the LRP with a uniform concentration of defects is metastable. Therefore, the LRP spontaneously goes back to the HRP after some time, which explains the data retention. In many simulations of the memristor device, the defect migration was described by drift and diffusion (DD). In this case, a CF with a high defect concentration should start to dissolve immediately after forming or set because there is no electromigration at zero electric field and only diffusion by concentration gradient exists. Also, the closer to the outer part of the CF, the lower the defect concentration. In other words, the DD equation alone cannot explain the existence of the LRP with a uniform defect concentration.
Phase-field model (PFM) is the most efficient to deal with a system where two distinct phases, LRP and HRP, are spatially mixed. We coupled the PFM with the electrothermal model along with defect generation and annihilation dynamics and successfully established a fully transient simulation of the forming, reset, and set operations of the VCM-based memristor. Using our model, both unipolar and bipolar switching can be simulated for the same active material by just changing boundary conditions that are bias conditions and interface properties with an electrode. It was shown that in the case of unipolar switching a CF evolves mainly by the generation and annihilation of defects whereas in the case of bipolar switching a CF evolves mainly by the electromigration of defects.
In our I-V curve simulation, the higher compliance current, the thicker CF as experimentally observed. Note that our simulation does not define any specific filament region in the model geometry. Only initial defects are randomly assigned. Also, the successive pulse operations were simulated for synapse applications. Most interestingly, the effects of the interval length between pulses could be observed. The CFs can evolve for the time when no pulse is applied, which is to reduce the interface energy for total energy minimization. As a result, a longer pulse interval resulted in better linearity in the long-term depression curve. More details and the results of our simulation will be shown in the actual presentation.

11:30 AM *EL20.01.04
Fusion of Solid-State Ionics and Electronics to Advance Neuromorphic Technology KazuyaTerabe, TakashiTsuchiya and TohruTsuruoka; NIMS, Japan

For the further development of today's information society, hardware-oriented artificial intelligence (AI) systems, such as terminal equipment and brain computers that operate with low power consumption and small size, are expected to be developed. To realize such software-independent AI hardware, devices that realize various functions and performances, such as memristive and neuromorphic characteristics, are required. To this end, it is important to actively develop not only conventional semiconductor devices with properties suitable for digital arithmetic processing, but also new-concept devices operating on different principles. One of these is a new group of devices developed by fusing solid-state ionics and electronics. These devices operate by controlling the transport of ions and vacancies as well as electrons and holes in solids. Consequently, the transport of ions (vacancies) and the associated electrochemical phenomena can be used to control the local composition of device materials and even reconstructing the hetero-interface structure at will. In other words, it is the device nanoarchitectonics that is achieved by controlling ion transport. (named ionic nanoarchitectonics)[1]. This ionic nanoarchitectonics enables the control of various physical properties of device materials, and this control can create interesting devices with new functions and performance not found in conventional semiconductor devices. To date, we have. have created many devices with diverse functions using ionic nanoarchitectonics [1-4]. These devices include atomic switches, decision-making devices, artificial synaptic devices [5], solid-state electrical double-layer transistors, artificial vision [6], physical reservoir devices [7] and so on. Ion nano-architectonics, based on the fusion of solid-state ionics and electronics, is a promising method to enhance neuromorphic technology.

Memristors and Arrays for Analog Computing with High PrecisionJ. JoshuaYang; University of Southern California, United States

The analog data deluge issue nowadays call for multipurpose analog computing platforms with great reconfigurability and efficiency, namely, field programmable analog arrays (FPAAs).[1] FPAAs as the analog counterpart of field programmable digital arrays (FPGAs) open opportunities for fast prototyping analog designs as well as efficient analog signal processing and neuromorphic computing. Memristors may be the ideal building blocks for FPAAs if they are truly analog with many conductance levels, not just for lab-made devices, but more importantly, devices fabricated in foundries. We have recently demonstrated 2048 conductance levels, a record among all types of memories, achieved with memristors in fully integrated chips with 256x256 memristor arrays monolithically integrated on CMOS circuits in a standard foundry.[2] We have unearthed the underlying physics that previously limited the number of distinguishable conductance levels in memristors and developed electrical operation protocols to circumvent such limitations. These results reveal insights into the fundamental understanding of the microscopic picture of memristive switching and provide approaches to enable high-precision memristors for various applications.

Resistance Switching in Silicon Oxide for Memory and Computing Applications AdnanMehonic, DovydasJoksas, WingH. Ng, NikolaosBarmpatsalos and AnthonyJ. Kenyon; University College London, United Kingdom

The increasing demand for computing power has brought to light the limitations of current CMOS-based technologies and Von Neumann architecture. To address this, alternative paradigms like memristor-based accelerators have emerged. In this presentation, I will discuss resistance switching in silicon oxide (SiOx) based ReRAM devices and explore pathways for improving device performance. Additionally, I will present the rationale and challenges associated with utilising memristive crossbar arrays as analogue hardware accelerators. Two algorithmic approaches are presented to tackle inherent issues in memristor-based systems. The first approach involves utilising committee machines during inference [1], while the second approach explores non-ideality-aware training of memristor-based artificial neural networks (ANNs) [2].

2:30 PM *EL20.02.03
Bioinspired In-Sensor Computing for Artificial Vision YangChai; The Hong Kong Polytechnic University, Hong Kong

According to the projection by Semiconductor Research Corporation and Semiconductor Industry Association, the number of sensor nodes exponentially increases with the development of the Internet of Things. By 2032, the number of sensors is expected to be ~45 trillion, which will generate >1 million zettabytes (10^{27} bytes) of data per year. The massive data from sensor nodes obscure valuable information that we need it most. Abundant data movement between sensor and processing unit greatly increases power consumption and time latency, which poses grand challenges for the power-constraint and widely distributed sensor nodes in the Internet of Things. Therefore, it urgently requires a computation paradigm that can efficiently process

information near or inside sensors, eliminate redundant data, reduce frequent data transfer, and enhance data security and privacy. We propose bioinspired in-sensor computing paradigm to reduce data transfer and decrease the high computing complexity by processing data locally. By using two-dimensional (2D) semiconductors, we demonstrate the in-sensor computing at the device and array levels. The unique sensory response characteristics of 2D semiconductors lead to computing functions at sensory terminals. In particular, bioinspired device characteristics enable the fusion of the sensor and computation functionalities, providing a way for intelligent processing sensory information.

3:30 PM *EL20.02.04
Valence Change Memristive Devices for Bio-Inspired Information Pathways AnnaLinkenheil, JonasSchneegaß, BenjaminSpetzler, ZhansongGeng, KristinaNikiruy, TzvetanIvanov, FrankSchwierz and MartinZiegler; Technische Universität Ilmenau, Germany

Memristive devices have attracted considerable attention in the electronic device community due to their inherent memory effect, which allows them to mimic the function of biological synapses. As such, they are a key building block for realizing artificial neural computing schemes in hardware, so-called neuromorphic systems. However, there are various neuromorphic architectures with different requirements for memristive devices, requiring optimization of electrical properties and materials as well as the technological framework for each specific application.

This talk will discuss the challenges and prospects of memristive devices for neuromorphic computing in general and several selected examples. Valence-change-based memristive devices are presented, and it will be discussed how their properties can be tailored by systematic design variations for applications in neuromorphic computing architectures. Furthermore, it is shown how the resistance change of memristive devices affects the dynamics of networks and how network dynamics influence network connectivity. Important requirements for memristive devices will be discussed, and it will be shown how a new way of information processing beyond current approaches can open a new bio-inspired pathway toward the construction of cognitive electronics.

This work was partially funded by the Carl-Zeiss Foundation via the Project MemWerk and the German Research Foundation (DFG) through the Collaborative Research Centre CRC 1461 "Neurotronics – Bio-Inspired Information Pathway".

4:00 PM EL20.02.05
Electroforming-Free Threshold Switching in Polycrystalline $ErMnO_3$ Films Based Two-Terminal Devices RongWu[1,2], FlorianMaudet[1], Thanh LuanPhan[1], WassimHamouda[1], VeereshDeshpande[1] and CatherineDubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Freie Universität Berlin, Germany

Rare-earth hexagonal manganites h-$RMnO_3$ (R=Y, Er, Ho to Lu) have been extensively studied as multiferroic materials in the last 15 years. The study of non-volatile unipolar resistive switching behavior in polycrystalline $YMnO_3$ was reported, indicating that h-$RMnO_3$ may be promising candidates for memristive devices owing to their intriguing ferroelectric domain pattern - vortex lines where six-fold domains merge [1], [2].
In this work, we report the first demonstration of volatile resistive switching behavior observed in polycrystalline $ErMnO_3$ thin films. The devices exhibit a repeatable unipolar threshold switching behavior. To fabricate the devices, 60 nm-thick $ErMnO_3$ thin films were deposited on Pt-coated Si wafers using RF sputtering. Subsequently, a post-deposition annealing process was carried out at 750 °C in N_2, resulting in the formation of polycrystalline $ErMnO_3$ thin films with mixed orthorhombic and hexagonal crystalline phases. Further engineering was realized through a subsequent thermal treatment at 400 °C in air. Top Pt electrodes were then patterned. The two-terminal Pt/$ErMnO_3$/Pt devices exhibit high endurance (>10^4 cycles) and low variability. To gain a clear understanding of the physical origin of the threshold switching and to open a path for potential applications, a detailed structural study (X-ray diffraction, Raman spectroscopy, X-ray photoelectron spectroscopy, scanning electron microscopy) and extensive electrical characterization (current-voltage and voltage-current measurements including as a function of temperature, conductive atomic force microscopy) were performed. We propose a physical model to explain the observed threshold switching effect and current controlled negative-differential resistance behavior. Our model involves trap-assisted and thermally-activated Poole-Frenkel conduction, along with local Joule heating effects. We will discuss how the engineering of the microstructure, specifically the inclusions of minor orthorhombic phase within the hexagonal phase, plays a crucial role in achieving the threshold switching behavior. These devices hold great promise as candidates for building spiking neurons in leaky integrate-and-fire (LIF) neuron circuits [3].

4:15 PM EL20.02.06
Oxygen Tracer Diffusion in Substoichiometric Hafnium Oxide for Resistive Memory DongjaeShin[1], JingxianLi[1], KarstenBeckmann[2], AntonV. Ievlev[3] and YiyangLi[1]; [1]University of Michigan, United States; [2]State University of New York Polytechnic Institute, United States; [3]Oak Ridge National Laboratory, United States

Resistive memory are highly promising candidates for neuromorphic computing due to their ability to retain a constant resistance state over time. Hafnium oxide-based memristors in particular have shown exceptional retention stability, exceeding 10 years at 85ºC. It is believed that this retention stability is a result of slow oxygen vacancy migration; however, there exists substantial discrepancy between the experimentally measured device retention time and the characteristic oxygen diffusion time of HfO_2. In this work, we measure the oxygen ^{18}O tracer diffusion of different HfO_x thin films with different metal-to-oxygen ratios. We found that sub-stoichiometric hafnium oxide exhibits ~1-3 orders of magnitude lower diffusivity compared to stoichiometric HfO_2. We show that the retention time of Hafnia memristors can be approximated by the diffusion time when we use this lower oxygen diffusivity of the substoichiometric oxide, resolving the question of why Hafnia memristors are able to retain state.

4:30 PM *EL20.02.07
New Mechanism in Ohmic VCM Devices - Prospective and Challenges ShaochuanChen[1], TengZhang[2], HeinrichHartmann[3], AstridBesmehn[3], YuchaoYang[2] and IliaValov[3,4]; [1]RWTH Aachen University, Germany; [2]Peking University, China; [3]Research Center Juelich, Germany; [4]Institute of Electrochemistry and Energy Systems, Bulgaria

Functionalities, propertis and stability of memristors are determined by three main factors – physico-chemical processes materials and operation scheme, where the first two factors are inherently related. It is a of highest priority of the ongoing research to improve memristors in several important aspects including multi-functional use, variability, state stability and degenerative processes. A way to progress in fundamental aspect understandings and applicatoins is to achieve understanding and control over the physical processes involved in the formation of different resistive states and based on this knowledge to design reliable materials system being with predictable and adjustable properties. Several important aspects of the operation principles have been relieved, such as effects of protons and ambient moisture, interface interactions, migration of cations believed to be immobile, nanobattery effect, influence of the capping layers and film thicknesses etc.
In this work, we present a new mechanism observed in ohmic oxide memristors that allows for significant improvement of the device characteristics and stability. The switching performance depends on materials used for electrodes, their electrochemical activity and redox potential. We found that not Schottky barrier is necessary to swithc the devices and reach relibale operation. TI*n situ* TEM analysis have shown that contribution of different ionic species is responsible for two distinctive switching mechanisms that in turn determine the performance. Based on this knowledge we were able to design devices showing multiple functionalities and with significantly improved characteristics.

SESSION EL20.03: Poster Session
Session Chairs: Yiyang Li and Radu Sporea
Tuesday Afternoon, November28, 2023
Hynes, Level 1, Hall A

8:00 PM EL20.03.01
Flexible and Disposable Paper-Based Optoelectronic Physical Reservoir Devices HiroakiKomatsu, NorikaHosoda and TakashiIkuno; Tokyo University of Science, Japan

Wearable sensor devices that use physical probes such as light and electric potential to monitor health conditions are widely used in the biomedical field. To classify and predict health

conditions, the acquired data needs to be transmitted to an AI system in the cloud. The communication of such a large amount of data involves issues such as network load and communication speed. One of the methods to solve these issues is that we allow the sensor itself to have AI functions, such as physical reservoir (PR) devices. We believe that in-sensor optoelectronic PR device, which has (1) response times that match the time scale of biological signals (0.1-100 s), (2) flexibility, and (3) disposability, is one of the ideal frameworks to realize intelligent sensors. However, because the response times of the optoelectronic PR devices reported so far are several tens of milliseconds, it difficult to handle biological signals [1,2]. Moreover, flexibility and disposability have also not been addressed.
In this study, we fabricated an optoelectronic PR device that satisfy three requirements mentioned above. Our device is composed of ZnO nanoparticles (NPs)-embedded cellulose nanofiber (CNF) freestanding film. The film was prepared by spray deposition of CNF aqueous solution dispersed with ZnO NPs (average diameter: 25 nm)[3]. Patterned Au electrodes were formed on the film surface. We demonstrated a pattern recognition using ultraviolet (UV) light input pulses. To verify that it works as a PR device, the film was exposed to UV pulsed light encoded with 4-bit patterns (pulse width: 50-500 ms, wavelength: 365 nm), and the photocurrent was measured.
Under the UV pulsed light irradiation, the film showed the rise and decay time constants of 6.4 s and 3.4 s, respectively, indicating that our films have a time scale compatible with biomedical applications. Furthermore, the maximum photocurrent was increased with increasing the number of pulses when the UV light was repeatedly irradiated. This phenomenon indicates that our films exhibit the short-term memory required for reservoir devices. To demonstrate the AI performance, handwritten digit recognition was conducted using MNIST databases. Our device showed accuracy of 88%. Therefore, it was demonstrated that our films can be used as a PR device. In addition, handwritten digit recognition using our film with a bending radius of 9.5 mm and 16.1 mm showed almost no change in accuracy compared to the flat condition. Thus, it was demonstrated that our film can be used in the bent state. In this session, we will describe the results of pattern recognition in the bent state and introduce the possibilities of disposability.

Organic Neuromorphic Electronics for Emulating and Interfacing Biological Systems PaschalisGkoupidenis; Max Planck Institute for Polymer Research, Germany

Harnessing the exceptional efficiency of the brain in information processing at the technological level can be condensed in the terms “artificial intelligence” and “neuromorphic computing”. A popular approach in artificial intelligence is the representation of information processing aspects found in biological systems with artificial neural networks (ANNs). This approach is based on executing algorithms, that loosely represent the function of the nervous system, on traditional computer architectures. Over the last decade, the field of artificial intelligence (AI) has demonstrated an enormous potential for complex processing and efficient computing. However, concepts of AI are mainly based on digital operating principles, while being part of an analogue world with great diversity in signaling. Moreover, AI still lacks the efficiency and computing capacity of biological systems. Alternatively, neural functions can be directly emulated with non-conventional devices, circuits and architectures. This hardware-based paradigm of brain-inspired processing is known as neuromorphic electronics.
In this talk, various neuromorphic devices will be presented that are based on organic mixed conductors, materials that are traditionally used in bioelectronics. A prominent example of a device in bioelectronics that exploits mixed ionic-electronic conductivity phenomena is the organic electrochemical transistor (OECT). Organic neuromorphic electronics based on OECTs have the ability to emulate efficiently and with fidelity a wide range of bio-inspired functions including synaptic plasticity and neuronal dynamics. The presence of a global electrolyte in an array of devices also allows for the homeostatic control of the array. Global electrical oscillations can be used as global clocks that phase-lock the local activity of individual devices in analogy to the global brain oscillations. Moreover, “soft” interconnectivity through the electrolyte can be defined, a feature that paves the way for parallel interconnections between devices with minimal hard-wired connections. Finally, practical demonstrations will be shown, highlighting the potential of organic materials in robotics, neuromorphic sensing and biointerfacing.

8:45 AM EL20.04.02
Proton-Based Electrochemical Random Access Memory using Nickel (Oxy)Hydroxide AndrewJ. Jalbert and YiyangLi; University of Michigan, United States

In-memory computing using analog resistive memory cells can be substantially more efficient than digital computing. Electrochemical random-access memory (ECRAM) using protons or oxygen vacancies are a highly promising solution. Nickel Hydroxide is an electrochromic material that can be switched between two phases: $Ni(OH)_2$ (Hydroxide) and NiOOH (Oxyhydroxide) upon the insertion or removal of protons. In this work, we investigate the use of Nickel (Oxy)Hydroxide as a proton-based ECRAM material. We show that this material is able to switch resistance states in a linear and analog fashion by electrochemically shuttling protons through an alkaline electrolyte media at room temperatures. Importantly, this ECRAM cell is also able to retain information over time, providing the potential for long-term, nonvolatile, and analog information storage.

9:00 AM EL20.04.03
Investigation of Drain Bias Stress Effect on IGZO TFTs Based Charge Storage Neuromorphic Circuits UngCho, MinseungKang, JaehyeonKang, HyeongjunSeo and SangbumKim; Seoul National University, Korea (the Republic of)

Charge storage type neuromorphic synapse circuits such as 2T0C, 3T1C and 6T1C have recently emerged as alternatives to nonideal nonvolatile memories for on-chip training of deep neural networks, particularly in terms of linear and symmetric weight updates [1]. Utilizing amorphous InGaZnO (a-IGZO) thin film transistors as update transistors instead of traditional Si CMOS enables long data retention and low power consumption due to their superior low leakage characteristics [2]. However, the reliability of the IGZO TFTs remains a critical challenge, particularly regarding oxygen vacancies in the active channel, gate insulator, and channel/gate insulator interface [3]. While previous research has extensively studied stability problems under positive bias stress (PBS), negative bias stress (NBS), and hot carrier stress (HCS), investigations on the impact of drain bias stress (DBS) on IGZO TFTs are limited. During the off-state, where no programming occurs and weights are maintained in the storage capacitor, the update transistors are exposed to drain and off-state gate bias stress. The off-state accounts for the majority of time in the operational scenario in charge storage type neuromorphic circuits, thus highlighting the significance of DBS stability analysis. This study focuses on investigating the effect of DBS at the transistor level, modeling degradation and unveiling its mechanisms. Furthermore, the impact of DBS on IGZO TFTs based charge storage neuromorphic circuits was assessed using the proposed model.
Electrical measurements were conducted to assess the reliability at the unit transistor level. The evaluation of gate bias stress, including both PBS and NBS, revealed little degradation in terms of threshold voltage (Vth), subthreshold swing (SS), and on-current. On the other hand, during the evaluation of drain bias stress, Vth and SS demonstrated little change, while a noticeable on-current degradation was observed. Additionally we simulated the off-state by applying both drain bias and negative gate bias simultaneously, it was observed that the greater the negative bias, the more significant on-current degradation occurred. Complementary measurements, including capacitance-voltage measurements and the evaluation of transistors with various dimensions, were performed in order to elucidate degradation mechanisms and indicate the physical meaning of degradation through a stretched exponential model. The degradation model parameters, such as the time constant of electron trapping and the saturation point of current degradation, demonstrate an increased degradation with more negative gate bias. Using the proposed degradation model, the weight change of 3T1C neuromorphic circuits after cycling endurance could be successfully predicted. Furthermore, the impact of DBS on training and inference accuracy was investigated. Leveraging the knowledge gained from this study enables the design of more reliable IGZO TFTs based neuromorphic circuits and their operation, advancing the development of robust and efficient neuromorphic systems.

Electrolyte and Neurotransmitter Dependency of Long-Term Plasticity in Biohybrid Synapses FrancescaSantoro; Forschungszentrum Jülich/RWTH Aachen University, Germany

The replication of neural information processing in electrical devices has been extensively studied over the years. The paradigm of parallel computing, which allows information to be simultaneously detected, processed and stored, is required for numerous applications in many fields. In the case of brain-computer interfaces, another important requirement is the suitability of the device for communication with cells. Organic electrochemical transistors (OECTs) based on PEDOT:PSS are used for this purpose due to their ionic-to-electronic signal transduction and biocompatibility [1]. Many works have demonstrated the reproduction of neural plasticity mechanisms, such as short-term facilitation and long-term potentiation. In each device, the physical mechanism of transduction may be different, but it is known that the electrolyte plays a key role in the functioning of these devices, as it provides the ions responsible for the chemical transmission of information. Focusing on long-term memory, this can be reproduced in the OECTs with the oxidation of the neurotransmitter, as in the case of the biohybrid synapse [2]. It is crucial to understand the influence of the electrolyte composition on the memory effect of the device, as long-term modulation is based on a change in the ionic balance between the electrolyte and the organic polymer. For this reason, the influence of some of the most used electrolyte compositions on neurotransmitter-mediated long-term plasticity was analyzed in this work. The interaction of electrolytes with dopamine oxidation was investigated by means of the cyclic voltammetry technique, and the effect on channel conductance was studied by applying pulses of different amplitude and duration as gate voltage of the transistors. It was shown that long-term memory can be hidden under certain conditions, such as the presence of Mg2+ and Ca2+ in the electrolyte. This electrolyte-dependency plasticity should be considered when the OECT is used in a biological environment in which a large number of molecules of a different nature, in addition to neurotransmitters, are present. The next step in this analysis involves the effect of the electrolyte in more neurotransmitter-sensitive OECTs, with micrometer-sized channel area.

More is Different: Physical Computing Discovery ElliotJ. Fuller; Sandia National Laboratories, United States

The heterogenous integration of novel materials with existing technology is critical to beyond Moore computing paradigms. Digital computation based upon silicon has relied heavily on a reductionist hierarchy, wherein the system can be reduced to simple rules and elements can designed separately. However, this hierarchy collapses when novel materials are integrated into physics-based compute paradigms to due to the twin difficulties of complexity and scale. Physical compute systems must be co-designed. In 1972, the physicist Philip W. Anderson coined the term, “more is different” to describe emergent phenomena that occur in complex systems where entirely new properties appear, especially where symmetries are broken[1]. Here I will discuss experimental work on building complex physical systems that execute computational kernels, for example outer product updates[2], and how these systems are “different” from their digital counterparts. Next, I will demonstrate how models can be used to predict the evolution of simple neuromorphic learning systems when operated under certain constraints[3]. These models break down when phase transformation (or symmetry breaking) occurs and the collective behavior of an ensemble of interacting elements is expected to exhibit emergent phenomena. Finally, I will discuss the development of a computing discovery platform to study emergent materials behavior, wherein rapid synthesis, characterization, and integration of new materials into compute arrays enables studying compute outcomes at scale (>1,000 interacting elements).

CMOS-Compatible Electrochemical Synaptic Transistor Arrays for Deep Learning Accelerators JinsongCui[1], FufeiAn[1], YuxuanWu[1], JiangchaoQian[1], SaranPidaparthy[1], Jian-MinZuo[1,2] and QingCao[1,2]; [1]University of Illinois, United States; [2]University of Illinois at Urbana-Champaign, United States

In-memory-computing architectures based on memristive crossbar-arrays can enhance the computing efficiency for deep-learning with massive parallelism. However, to fulfill their potential, the core memory devices must be capable of providing high-speed and symmetric analog programing with small variability, compatible with silicon technology, and scalable into nanometer-size footprint. We present an electrochemical synaptic transistor, built with CMOS-compatible metal oxides and operating by shuffling protons within a symmetric gate stack, to meet all these stringent requirements. It can be monolithically integrated with silicon transistors to form pseudo-crossbar arrays where parallel, precise, and symmetric programming of the channel conductance can be executed with gate-voltage pulses. High-speed programing with frequency approaching megahertz, endurance above 100 million read-write pulses, and device critical dimensions down to 150×150 nm^2 have all been realized.

11:00 AM EL20.05.03
Nonvolatile Electrochemical Random Access Memory using Phase Separation VirgilJ. Watkins, DianaKim, LaszloCline and YiyangLi; University of Michigan, United States

Analog neuromorphic computing can decrease the energy consumption of data-intensive tasks like machine learning by orders of magnitude through conducting matrix vector multiplication using Ohm’s and Kirchoff’s Laws. Electrochemical random access memory (ECRAM) stores and switches analog resistance states by electrochemically modulating the concentration of oxygen vacancies in a transition metal oxide. Unfortunately, most ECRAM devices are volatile and revert to equilibrium, with retention times orders of magnitude lower than the typical 10 year, 85C requirement. In our work we develop a nonvolatile ECRAM cell using tantalum oxide. Our core innovation is the use of phase separating materials in the miscibility gap. In this configuration, all resistance states have the same chemical potential, thereby eliminating the driving force for volatility. This result not only exceeds the expected 10 year lifetime, but can provide a memory cell with potentially indefinite retention at elevated temperatures.

11:15 AM EL20.05.04
Electric Field Regulated High Thermal Rectification Ratio using Ferrocenyl Terminated Molecular Junction XingfeiWei and RigobertoHernandez; Johns Hopkins University, United States

Conventional silicon-based electronic devices have electron conductance rectification ratios greater than . This magnitude was achieved in molecular electric diode composed of ferrocenyl (Fc) terminated self-assembly monolayers (SAMs) developed by the Nijhuis group [*Nature Nanotech 12, 797–803 (2017)*]. Perhaps surprisingly, the largest thermal rectification ratio reported so far in materials and devices is at the magnitude of near 1. Applying the same electrostatic attraction mechanism seen by the Nijhuis, we have found in atomistic simulations that ferrocenyl terminated molecular junctions can also achieve high thermal rectification ratio. In the forward bias case, the top electrode is negatively charged, the Fc group is positively charged, and the strong electrostatic force drag the Fc group closer to the top electrode and thereby enhances thermal conductance. In the backward bias case, the Fc group is charge neutral, and the electrostatic force between the Fc groups and the top electrode is weak and thereby reduces thermal conductance. We will report the distance between the two electrodes, the partial charge on the Fc group, the electric field magnitude, and the number of SAM molecules affecting heat transfer. The implications of this work for developing next-generation phononic devices will also be discussed.

Volatile and Non-Volatile Memristive Technologies Implementing Tunable Dynamic and Relaxation for Spiking Neural Networks SabinaSpiga; CNR-IMM, Italy

Hardware spiking neural networks (SNNs) are currently attracting an increasing interest towards low-power computing systems for edge applications, such as the ones relying on smart analysis of sensory signals in real time. Taking inspiration from brain computation, which processes information with temporal structure, it is desired that also neuromorphic chips compute with dynamics, encompassing devices and circuits able to compute and elaborate information over multiple time scales. In current CMOS-based neuromorphic chips, the integrative functions and temporal dynamics are mainly implemented by capacitors. Anyway, they hardly provide in the system time constants over ms or tens of ms, and their capacitance density is difficult to be scaled-up without occupying large silicon area. Within this framework, memristive technologies have recently shown great promise to substitute or complement CMOS circuits in hardware SNNs, with key role in providing novel and compact dynamical elements which can mimic the neuronal and synaptic features, and are able to extend the time domain of the computing system. Our work focuses on memristive technologies capable of exhibiting tunable dynamics, integrative functions and relaxation effects which can span up to seconds or longer, up to the non-volatile behavior. The devices are based on the structure $Ag/SiO_x/Pt$ or $Ag/Al_2O_3/SiO_x/Pt$ stacks and the switching mechanism relies on the formation and dissolution of a silver-based filament shorting the two electrodes. The filament can be unstable and exhibits a relaxation behavior once the programming voltage is removed. In the ON, low resistance state, it is also possible to achieve conductance modulation as a function of the input stimuli. We will show that the devices show dynamic behaviors over multiple time scales which originate from an interplay of accumulation and relaxation effects, and the overall features can be controlled by programming conditions and material engineering.

Enhancing Memory Retention of FAB Compatible ECRAM Devices using an Ion Blocking Layer NirTessler[1], SeonukJeon[2] and JiyongWoo[2]; [1]Technion-Israel Institute of Technology, Israel; [2]Kyungpook National University, Korea (the Republic of)

Traditionally, the only ions allowed or welcomed by the microelectronic industry are those that act as fixed dopants. The issue of mobile ions became welcome primarily due to the memristor technology however, thin film transistor technologies benefit from them too. The electrochemical (transistor) random access memory (ECRAM) is emerging as a promising building block for multi-level neuromorphic computing. Using FAB-compatible materials we construct the ECRAM using CuOx as the gate and ions source (Cu+). The morphology of the HfOx gate insulator layer is finetuned to render it ion transporting such that it can act as a uniform electrolyte layer. Lastly, the channel material is WOx with tungsten metal as the source/drain contact.
While there are several reports of ECRAM devices, the operation mechanisms are not fully known/understood thus withholding progress of this field. Using the Sentaurus device simulator by Synopsis, including the hydrogen diffusion module, we simulate the mixed ionic electronic operation of the device. We have recently reported that by fitting the simulation to the device performance we could identify the potentiation mechanism (i.e., insulator charging) and the occurrence of copper plating that takes place under high Cu+ ion flux (as in fast charging of Li batteries).[1]
In the first part of the talk, we will expand on the chemical-physics details of the ECRAM device mentioned above. Next, we will present a new device architecture where an ion-barrier layer is introduced and is shown to enhance memory retention. The third device structure is where we remove the WOx layer and study the ionic-electronic conduction of a modified HfOx layer. Using the above three device architectures in conjunction with the mixed ionic-electronic device simulation we reveal the role of the two memory mechanisms: a) Electric field-activated ion transport and b) Structure-induced trapping by ion-barrier layers.

Probabilistic Computing using Metal Nanoparticles-Embedded Mott Threshold Switches for True Random Number Generator YewonSeo, YunkyuPark and JunwooSon; Pohang University of Science and Technology, Korea (the Republic of)

VO_2 threshold switch, which undergoes a insulator-to-metal transition above a threshold voltage, shows promise as a candidate for stochastic switching due to its capacity to determine the overall electrical transition in devices through the percolative formation of metallic filaments [1]. However, geometric evolution of the switchable (metallic or insulating) domains significantly influences the stochastic switching in VO_2; the performance of VO_2 based stochastic devices (e.g., true random number generators) could be tuned by the evolution of metallic domains in the insulating matrix and random formation of conducting filaments [2].

Here, we achieve drastic enhancement of intrinsic stochastic operation under pump-probe procedure in Pt-nanoparticle-embedded VO_2 (Pt-VO_2) two-terminal devices. In particular, metallic Pt nanoparticles enable an extension of memorization time from pump pulse, which enhances probability of certain selection to show random firing of on/off (1 or 0) states under probe pulse; the extended recovery time to the insulating state presents a wide range of options in terms of probe voltage amplitude and delay time, thereby enhancing the randomness of the switching behavior upon application of the second probe pulse. Moreover, this device has the advantage of high speed (667 kbits/s), low power consumption (12 nJ/bit), high endurance (>105200 bits), and mass production, which is key requirement to realize true random number generator (TRNG). Therefore, our result provides a new strategy to improve stochastic switching characteristics in Mott threshold switches for high performance TRNG.

Aubergine to Blackberry: Nature Derived Chromophores to Mimic Photosensitive Neurons in Human Eye MaximShkunov[1], AimeeSweeney[1,1], AnnelotNijkoops[1,2], LeslieAskew[1], ManuelaCiocca[2] and LuisaPetti[2]; [1]University of Surrey, United Kingdom; [2]Free University of Bozen-Bolzano, Italy

Visual information processing in vertebrates begins with light detection by the eye's retina cone and rod cells. Tri-colour cones, typical for primates, respond to blue, green and red/yellow spectral bands, whereas rods cell are extremely sensitive to low light intensities, providing grey-scale vision. Mimicking behaviour of these cells with optoelectronic devices opens up opportunities for neural stimulation, artificial retina, superhuman vision devices, and self-powered optical sensors. Nature is also rich in conjugated, organic semiconductor molecules, with various bandgaps, thus offering colour-specific responses in the visible spectral range.
In this work we explore fruit- and vegetable-derived conjugated chromophores from various berries, including raspberry, blackberry, elderberry, blueberry, as well as aubergine, beetroot, red cabbage and spinach, targeting photo-induced response in three spectral bands, red, green and blue. Self-assembly binding properties of these molecules allow to build chromophores-decorated TiO2 nano-porous structures inspired by dye-sensitised solar cell technologies. We demonstrate photo-capacitor devices employing the chromophores, interfaced with biological electrolyte (phosphate buffered saline), showing spiking photocurrent (photovoltage) response under low-intensity pulsed light excitation.
Absorption spectra of chromophores were found to be in the visible part of the spectrum, with chlorophyll derived from spinach peaking at 440 nm, and with anthocyanins and betalains chromophores' peaks at around 520 nm. The photocurrent spectral response of the samples was correlated with that of absorption; however, some spectral shifts were observed. Photo-current response signals were clearly present for all samples, with magnitude from few tens to hundreds of nA when exposed to pulsed-light flash cycles with a pulse length of few tens of milliseconds. This is comparable to typical biological response times. The results suggest that nature- derived conjugated chromophores present feasible environmentally-friendly semiconductors for opto-stimulated devices with colour-selectivity. They also produce photo -current and -voltage responses corresponding to hyperpolarisation and depolarisation of cell membranes associated with neurons' spiking behaviour.

Tuning the Relaxation Time of Diffusive Memristors for Neuromorphic Applications QiangfeiXia; University of Massachusetts, United States

A diffusive memristor is a volatile resistance switch with a metal/oxide/metal structure. It goes to a low resistance state when an electrical stimulus is applied and automatically relaxes back to its original high resistance state if the stimulus is removed. The switching behavior is attributed to the formation and rupture of a localized conducting channel within the oxide layer. Because of their structural similarity with biological ion channels, diffusive memristors have been successfully used to emulate typical synaptic and neuronal behavior such as spike-timing-dependent plasticity, leaky integrate and fire, etc. However, a remaining issue of the diffusive memristor is the non-uniform and non-controllable relaxation time (the time it takes to go from low to high resistance states), which limits the wide-range adoption of such devices in large arrays for real-world problems. In this work, we designed and fabricated diffusive memristors with uniform and tunable relaxation times. We adopted a double oxide switch layer that led to an over ten-fold improvement in the cycle-to-cycle uniformity. By connecting the device to different resistors, we tuned the relaxation time up to three orders of magnitude. This controllable and uniform relaxation process was utilized to generate the time surfaces in the hierarchy of time surface (HOTS) algorithm for pattern recognition.

4:00 PM EL20.07.02
Characterization of Crystallization Kinetics in Phase-Change Materials using Indirectly Heated Phase-Change Memory and its Application to One-Shot Weight Transfer InhyukChoi, MinseungKang, WonseokChoi and SangbumKim; Seoul National University, Korea (the Republic of)

Phase-change memory (PCM) exhibits notable advantages such as non-volatility, fast operating speed, scalability, and high reliability, making it a promising candidate for analog synaptic devices in neuromorphic computing. However, challenges related to nonlinearity and asymmetry in weight modulation need to be addressed [1]. Consequently, weight modulation predominantly relies on the gradual crystallization process, as amorphization through a melt-quench process induces abrupt changes in weight values [2]. In the context of off-chip training, concerns regarding nonlinearity and asymmetry can be alleviated since the weights pre-trained by the software can be accurately transferred to the PCM synaptic array using an iterative program and verify scheme [3]. However, it is noteworthy that this iterative scheme is not energy-efficient and can potentially accelerate the endurance failure of PCM devices.
In contrast to conventional PCM structures that employ self-heating of phase-change materials, indirectly heated PCM structures utilizing externally generated heat have been suggested for high-reliability memory devices [4] and RF switches [5]. Here, for the first time, we propose the application of indirectly heated PCM as an energy-efficient and highly reliable one-shot weight transfer device through a single programming pulse with a simultaneous verify process. To ensure precise weight transfer, a comprehensive understanding of the crystallization process occurring within the device is crucial. Indirectly heated PCM itself can be used to characterize the crystallization kinetics [6], enabling faster heating rates close to device operation and broader temperature ranges encompassing melting points compared to previous characterization studies using differential scanning calorimetry (DSC), a laser with transmission electron microscope (TEM) analysis, and other device-based approaches [7-9]. After optimization through finite element method (FEM) simulation, we fabricated an indirectly heated PCM device designed to achieve a uniform temperature distribution in the phase-change material. Crystallization properties, including crystallization temperature, time, and activation energy, were measured over a wide temperature range for various phase-change materials exhibiting either nucleation-dominated or growth-dominated crystallization. For growth-dominant materials, growth rates spanning several orders of magnitude were estimated in conjunction with calibrated FEM simulations. Additionally, we will discuss the crystallization characteristics and device structures that need to be considered to enhance the energy efficiency and accuracy of one-shot weight transfer in indirectly heated PCM devices.

Mechanisms in Gadolinium-Doped Gallium Nitride for Future Computing and Quantum Applications VishalSaravade[1,2], ChuanleZhou[3], Zhe ChuanFeng[2], BenjaminKlein[2] and IanT. Ferguson[2]; [1]Pennsylvania State University, United States; [2]Kennesaw State University, United States; [3]Missouri University of Science and Technology, United States

Characterizations and mechanisms in gadolinium-doped gallium nitride (GaGdN) that can enable its applications for future neuromorphic and quantum computing will be presented. Gallium nitride (GaN) has been a well-investigated compound semiconductor for power devices, LEDs, photodetectors, and neutron detection applications. However, spintronic properties of GaN have either not been found to be suitable for future quantum computing applications or have not been well explored. In this work, the results obtained and mechanisms observed and identified in GaGdN indicate the potential suitability of GaGdN for spintronic applications. Monocrystalline GaGdN thin films were deposited on sapphire substrates by metal-organic chemical vapor deposition (MOCVD). Two Gd precursors were used to observe the variations in the properties with different metal-organic sources. GaGdN grown using a $(TMHD)_3Gd$ precursor showed Anomalous Hall Effect (AHE) based on a carrier-mediated mechanism due to carrier-hopping and metallic conduction. GaGdN grown using a Cp_3Gd precursor exhibited Ordinary Hall Effect (OHE) indicating no signs of spin polarizations. A key difference between the $(TMHD)_3Gd$ and Cp_3Gd precursors is that $(TMHD)_3Gd$ precursor contains oxygen in its organic ligand. In order to clearly understand the mechanisms for spin properties in GaGdN, GaGdN grown using Cp_3Gd source were implanted and doped with oxygen and carbon. As-grown Cp_3Gd that showed OHE, after O or C implantation showed AHE, which is a sign of spin polarization. Resistivity of GaGdN from Cp_3Gd source increased after O or C-implantation increasing which indicates the introduction of O- and C-induced deep interstitial states. The n-type carrier concentration reduced upon implantation, which indicates that these energy states are acceptor-type. Annealing was done to stabilize the O- and C-dopants in GaGdN from Cp_3Gd. After annealing, AHE signal in GaGdN:O reduced in smoothness but the resistivity decreased and the carrier concentration increased. On the other hand, annealed GaGdN:C showed a smoother AHE signal, an increased resistivity, and a reduced carrier concentration. X-ray diffraction (XRD) measurement showed that O and C stabilize in GaGdN:O and GaGdN:C at interstitial sites and render the AHE. The nature of crystallographic incorporation and effects of annealing on the spin-related properties of GaGdN:O and GaGdN:C were different even though both showed room temperature AHE. The mechanism in GaGdN for room temperature spintronics is carrier-mediated and is activated by O or C-induced deep interstitial acceptor energy states. Insights into these mechanisms can aid the further developments in III-Nitrides for future heterogeneous computing, machine-learning devices, neuromorphic computing, and quantum applications.

Integration of Ag-CBRAM Crossbars and Mott ReLU Neurons for Efficient Implementation of Deep Neural Networks in Hardware DuyguKuzum, JaeseoungPark, YuhanShi and SangheonOh; University of California, San Diego, United States

In-memory computing with emerging non-volatile memory devices (eNVMs) has shown promising results in accelerating matrix-vector multiplications (MVMs). However, activation function calculations are still being implemented with general processors or large and complex neuron peripheral circuits. Here, we present the integration of Ag-based conductive bridge random access memory (Ag-CBRAM) crossbar arrays with Mott ReLU activation neurons for scalable, energy and area-efficient hardware implementation of deep neural networks (DNNs). We develop Ag-CBRAM devices that can achieve a high ON/OFF ratio and multi-level programmability. Compact and energy-efficient Mott ReLU neuron devices implementing rectified linear

unit (ReLU) activation function are directly connected to the columns of Ag-CBRAM crossbars to compute the output from the weighted sum current. We implement convolution filters and activations for VGG-16 using our integrated hardware and demonstrate the successful generation of feature maps for CIFAR-10 images in hardware. Our approach paves a new way toward building a highly compact and energy-efficient eNVMs-based in-memory computing system.

Describing the Analog Resistance Change of HfO_x Neuromorphic Synapses Fabia FarlinAthena and EricM. Vogel; Georgia Institute of Technology, United States

At the forefront of memristive device research, significant attention is paid to the understanding of resistance variations in Titanium/Hafnium Oxide (Ti/HfO_x) synapses. These changes are typically dictated by a thin-oxide barrier, a result of oxidation and reduction within a Hafnium-rich conducting filament [1, 2, 3, 4]. Yet, despite a broad understanding of these principles, direct experimental investigation of the conducting filament proves notably complex. Consequently, crucial physical attributes and processes, such as the exact location of the barrier, the temporal fluctuations in thickness during analog pulsing, and the influence of temperature on the current, remain elusive and demand a more thorough elucidation.

We aim to take a step forward to unravel these intricacies by utilizing a compact model rooted in Trap-Assisted-Tunneling and Ohmic transport principles. This model has demonstrated significant value in shedding light on the mechanisms of analog switching in HfO_x synapses. It not only accurately mirrors the experimentally observed current-voltage relationship, but also faithfully reproduces its sensitivity to temperature changes.

In deploying this model, we have been successful in extracting the barrier heights during analog pulsing. These data align with a barrier situated adjacent to the reset anode [5, 6]. Our findings are supported by an independent Finite Element Analysis simulation using COMSOL Multiphysics® that incorporates the migration of oxygen vacancies.

The proposed model's utility has been further amplified by its capacity to estimate the barrier's thickness in response to the analog pulses. It is able to simulate the evolution of the current-voltage relationship from the low resistance state to the high resistance state by simply modulating the thickness of the barrier.

In summary, this work enables us to delve deeper into the relationship between the physical characteristics of the HfO_x synapses and the analog switching dynamics.

Atomic Layer Deposition of WO_x-Doped In_2O_3 for High-Performance BEOL-Compatible Transistors ChanyoungYoo[1,2], BalreenSaini[2], JonathanHartanto[2], FeiHuang[2], CristianR. Arens[2], JohnD. Baniecki[1], WilmanTsai[2], BaylorB. Triplett[2] and PaulMcIntyre[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States

The semiconductor industry has undergone a revolution over the last five decades, driven by Moore’s statement on dimensional scaling. However, the challenges for continued area scaling via lithographic patterning and the memory bottleneck limit the efficiency of computing. A new paradigm of improved energy efficiency, high bandwidth, and low latency on-chip memory access can be achieved by using 3D computing architectures with monolithic integration of logic and memory devices at high density (M3D, Monolithic three-dimensional). To realize M3D integration in future computing, fabricating high-performance thin film transistors and memories under back-end-of-line (BEOL) compatible conditions having a limited thermal budget (<400ºC maximum temperature) must be addressed.
Metal oxide semiconductors incorporating In_2O_3, have received significant attention as they possess high mobility, high I_{ON}/I_{OFF} ratio, ultra-scaled gate length, and sufficient drive currents. Doping In_2O_3 with several mole % tungsten oxide to form “IWO” has been reported to improve the threshold voltage stability of these semiconductor channel materials. However, currently reported film deposition for IWO is limited to sputtering, which cannot grow conformal films on topographically complex surfaces. This limitation becomes critical when utilizing these films as channel materials in gate-all-around or FinFET structures, which inherently possess 3D geometries. To address the increasing demand for high on-current, the shift towards 3D structures is necessary.
Consequently, we use the 3D-compatible atomic layer deposition (ALD) method to deposit IWO by adjusting the cycle ratios for In and W precursors and the oxidant co-reactant, enabling precise control over the doped film composition. We demonstrate deposition of IWO (1~4 mol% WO_X) films using ALD and fabricate both bottom- and top-gated thin film transistors with a 3-nm thick IWO channel in a BEOL-compatible process with a maximum temperature of less than 250ºC. The 1 mol% WO_X-doped IWO transistor exhibits exceptional performance characteristics, including a subthreshold slope of 65 mV/decade, a high $I_{D,sat}$ of 70 (W=12, L=1.5) at V_{DS}=1.0 V and V_{GS}=2.0 V, and remarkable stability under bias stress. The transistor showed negligible hysteresis and maintained excellent threshold voltage (V_{th}) stability under negative and positive bias stress conditions (ΔV_{th} = -0.06, and +0.1 V, respectively, at an electric field of 4.2 MV/cm for 1000 seconds). This V_{th} stability under bias stress highlights the reliability of ALD-grown IWO for ferroelectric field-effect transistors and its potential to enable high-performance monolithic 3D integrated devices.

Metal-Oxide NeoHebbian Synapses for Scalable Learning DmitriStrukov, TinishBhattacharya, Sai SukruthBezugam, ShubhamPande and EwelinaWlazlak; University of California, Santa Barbara, United States

Backpropagation through time (BPTT) algorithm is commonly used for learning and modeling temporal data. The algorithm applies the BP technique on the unrolled recurrent neural network T (~ up to 1000) times for T-step-long input sequences. Hence, enormous energy and time are spent on training such an effectively T-layer-deep network. Recently suggested e-Prop learning algorithm addresses this inefficiency by taking inspiration from biologically-plausible three-factor rules. E-prop synaptic weights are adjusted using locally stored information from pre- and post-synaptic neurons, avoiding resource-taxing network unrolling. Hence, such an algorithm is naturally suited for (in-memory, analog) neuromorphic hardware that could drastically reduce training time and energy.

In my talk, I will discuss recent work on “neoHebbian” synapses essential for an efficient eProp algorithm hardware implementation. Such synapses feature two state variables - a neuron coupling weight and an “eligibility trace” for updating the weight. Several design options were considered to implement these features, including implementations based on single-state variable and multiple-state variable metal-oxide resistive switching devices and utilizing temperature as a state variable. I will conclude my talk by discussing promising research directions at material and device levels for improving the performance of such synapses.

Investigation of Connection Strength Modulation Between the Artificial Neuron Devices Based on 2D hBN Threshold Switching RRAM YooyeonJo[1], GichangNoh[1], EunpyoPark[1], Min JeeKim[1], Yong WooSung[1], Dong YeonWoo[1], Dae KyuLee[1] and Joon YoungKwak[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University of Science and Technology, Korea (the Republic of)

The brain-inspired neuromorphic computing has attracted many researchers to solve the von Neumann bottleneck problems of conventional computing systems [1-2]. Various emerging materials and structures have been proposed to emulate the performance of biological neurons and synapses successfully. In particular, 2D materials-based memristors have been investigated by many researchers because of their excellent electrical performance, simple structure, and small device scale as promising building blocks of neuromorphic computing [3-5]. Although many artificial synaptic devices based on 2D materials-based memristors have been reported, there are very few reports in artificial neuron research, which is one of the key components in neuromorphic computing systems. Also, the integration of developed artificial neuromorphic devices based on emerging materials is an essential field of research to verify the performance of an artificial neural network (ANN) on the system level and successfully demonstrate large-scale ANN hardware [6-7].
In this study, we fabricated the threshold switching resistive random-access memory (RRAM) based on 2D multi-layer hBN film to mimic the behavior of the biological neuron for neuromorphic computing. The fabricated device was composed of Au/Ti bottom and Au/Ag top electrodes, respectively. The fabricated volatile memristor showed the highly-reliable resistance switching characteristics with 0.22 V of the average set voltage even at 110 fA of compliance current. Additionally, it showed a huge ON/OFF ratio over 3×10^6 at 0.1 V of reading voltage. The threshold switching characteristics were well maintained with the different series resistors from 100 kΩ to 10 MΩ. We evaluated the switching speed of the fabricated device via an AC response experiment. The 100 kΩ series resistor was connected to protect the device from a breakdown. As a result, it showed 22.7 and 30.9 μs of ON and OFF time, respectively.
The leaky-integrate-and-fire (LIF) neuron behaviors were demonstrated with the fabricated device and passive components. According to the RC time delay and the input pulse amplitude, the number of output spikes of the artificial neuron could be modulated, resulting in tailoring the artificial neuron properties to the desired performance for various applications. Lastly, we integrated the two artificial neurons to demonstrate the biological neural networks. The two LIF neurons were connected via a synaptic resistor as a biological synapse. Depending on the resistance (connection strength between the neurons), the number of output spikes of the post-synaptic neuron was modulated. We believe that our experimental results pave the way for the development of large-scale neural network hardware in the future.

Low-Temperature Liquid Metal Printing for Sustainable Fabrication of 2D Oxide Electronics WilliamJ. Scheideler, AndrewB. Hamlin and SimonA. Agnew; Dartmouth College, United States

Low-thermal budget fabrication of metal oxide semiconductors could unlock these materials' potential for emerging applications in sensing, computing, and memory devices via 3D heterogeneous integration with CMOS electronics. Towards that goal, we present a low-temperature, energy-efficient approach to deposit high performance two-dimensional (2D) metal oxides and heterostructures. Our approach consists of continuous liquid metal printing (CLMP) driven by Cabrera-Mott oxidation of liquid metal alloys, for depositing of 2D oxide layers as thin as 1 nm and multilayers 10's of nm. The simplicity of this vacuum-free CLMP process mitigates the need for high capital expenditure equipment and eliminates use of toxic gases. Metal oxidation is thermodynamically favorable, allowing rapid growth kinetics at the millisecond time-scale for wafer scale deposition in less than 2 seconds at temperatures from 200 °C down to 120 °C for back-end-of line (BEOL) applications as well as flexible electronics.
We present a study of the physics of liquid metal printing of 2D binary and ternary oxides based on alloys of In, Ga, Zn, and Sn by utilizing rapid film thickness measurements based on spectroscopic reflectometry. We investigate the limits of printing speed and model the influence of speed and print temperature on 2D oxide growth kinetics and crystallinity as determined from XRD. Finally, we apply CLMP to assemble heterostructures with 1 nm-level precision for enhancing modulation doping at 2D oxide interfaces, resulting in exceptionally conductive (> 500 S/cm) printed conductive oxide layers.

Self-assembled computing nanoarchitectures based on interacting nanoobjects have been recently proposed as biologically plausible substrates for neuromorphic computing [1,2]. In these nanonetworks, functionalities arise from the emergent behavior of the system that rely on collective phenomena. Here, we report on NW networks as versatile substrate for physical (*in materia*) computing. We show that the emergent behavior in these complex networks arise from resistive switching phenomena in single network elements, as revealed by investigating switching properties of single NW and single NW junctions. The emergent spatio-temporal dynamics of these nanoarchitectures in multiterminal characterization is shown that can be exploited for neuromorphic-type of data processing and represent versatile substrates for the implementation of unconventional computing. In the framework of physical reservoir computing (RC), we report on the computing capabilities of these networks by considering different computing tasks such as pattern recognition, time-series prediction and speech recognition. A combined experimental and modeling approach will be discussed, and a theoretical framework based on graph theory to describe complex nanonetworks will be discussed. Going beyond the concept of two terminal measurements, we report on experimental evidence of memory engrams (or memory traces) in NW networks, i.e., physicochemical changes in biological neural networks supposed to endow the representation of experience stored in our brain. Results show that these networks represent a versatile substrate for computing, allowing both encoding and consolidation of information in the same physical substrate, paving the way for a development of new *in materia* computing paradigms.

Robust and Reliable Computation using Heterogeneous Devices and Circuits GiacomoIndiveri; ETH Zürich, Switzerland

For many practical tasks, that involve real-time processing of sensory data and closed-loop interactions with the environment, conventional artificial intelligence neural network accelerators cannot match the performance of biological ones.
Neuromorphic intelligence aims to emulate the principles of computation of animal brains, exploiting the physics of computation of electronic and memristive devices.
Similar to their biological counterparts, neuromorphic devices and circuits are affected by variability and inhomogeneities.
In this talk I will present brain-inspired methods and strategies to achieve reliable and robust computation using an unreliable and inhomogeneous computing substrate, and present examples of neuromorphic systems that use these methods to solve edge-computing and sensory processing applications.

2:00 PM *EL20.10.01
Sustainable Fabrication of Nanoscale Memories Based on Molecular Materials and Nanogap Electrodes DimitraG. Georgiadou; University of Southampton, United Kingdom

Nanotechnology is widely used in electronics to further miniaturise electronic components. Nanomaterials have played a major role in this, as they possess many attractive inherent properties derived from their low dimensionality. However, nanoparticles and self-assembled monolayers are usually processed from solution and they are difficult to be implemented with high yield in large area electronics. On the other hand, two-terminal electronic devices commonly comprise a generic metal/semiconductor/metal structure in a vertical (sandwich) configuration. This poses restrictions in the device fabrication when nanomaterials are involved, as the quality of the film is often compromised due to the small scale of the nanomaterials that do not guarantee uniform, continuous and pinhole-free film formation. A solution to this is offered by lateral devices, where the two metals are placed on the same plane and separated by a gap, which is filled by the semiconductor. If this gap is small enough, comparable to the dimensions of the materials used, the nanomaterials can effectively bridge this gap and connect the two electrodes electrically without causing a short-circuit.

Adhesion lithography (a-lith) is a nanopatterning technique with reduced manufacturing energy as compared, for example, with e-beam lithography, that allows the fabrication of asymmetric nanogap metal electrodes at a low cost and with high throughput on a variety of rigid and flexible substrates of arbitrary size. We have so far demonstrated ultra-high speed (GHz) Schottky diodes (1) and fast photodetectors (2) as well as multi-bit and ferroelectric memories (3) based on different solution-processed semiconductors and a-lith patterned electrodes separated by a <10 nm gap.

Herein we present different classes of molecular materials, based on the polyoxometalate and Pb-free perovskite families, which are successfully implemented in nanoscale memory applications. Our results indicate that multi-state memory behaviour is within reach with polyoxometalate materials, while we also present molecular self-assembly approaches to better control the resistive switching at the nanoscale. Since only a few electrons are required to function, these devices hold promise for low power consumption and high-speed operation. Furthermore, we show that the combination of coplanar nanogap electrodes with Bi-based perovskites holds great promise for achieving low power consumption and fast switching speeds, while their planar geometry facilitates a light-controlled operation, enabling both analogue tuning of resistance states and elimination of sneak currents in the array configuration.

This work paves the way to the development of a new form of greener devices and systems that merge photonic, electronic and ionic effects, bringing new prospects for in-memory computing and artificial visual memory applications.

Hexagonal Si and Ge Polytypes as Optoelectronic Materials MartinKeller[1], AbderrezakBelabbes[1,2], JürgenFurthmüller[1], FriedhelmBechstedt[1] and SilvanaBotti[3,1]; [1]Friedrich Schiller University Jena, Germany; [2]Sultan Qaboos University, Oman; [3]Ruhr University Bochum, Germany

The group IV elements silicon and germanium crystallize in cubic diamond structure under ambient conditions and feature indirect bandgaps. Therefore they cannot emit light efficiently and are not applicable in active optoelectronic devices. Under high pressure, however, as well as using different growth techniques, several Si and Ge polymorphs, have been observed. Lonsdaleite Ge as well as Ge-rich hexagonal alloys have even been found to have a direct bandgap and strongly emit light with varying frequency. Thus hexagonal systems have become of great interest for potential optical emitters that may be integratable with CMOS technology. We have performed extensive ab initio studies of the energetic, structural and electronic properties as well as oscillator strengths of the hexagonal Si and Ge polytypes 2H, 4H and 6H using Density Functional Theory and approximate quasiparticle treatments, and trends between the different geometries are analysed. The results for cubic and hexagonal Si and Ge agree excellently with existing experimental findings. The electronic structures point to promising optical properties.

2:45 PM *EL20.07.01
Impact of Phase-Change Memory Nonidealities on Analog In-Memory Computing Deep Learning Accuracy NingLi[1,2]; [1]Lehigh University, United States; [2]IBM Research, United States

Among the emerging approaches for deep neural network (DNN) acceleration, compute-in-memory (CIM) in crossbar arrays using non-volatile memories (NVMs) is very promising for achieving high execution speeds and high energy efficiency. Phase change memory (PCM) is one of the most promising candidates for analog CIM – particularly for inference using previously-trained DNN weights. However, when NVMs are used in analog mode, devices will exhibit nonidealities compared to a perfect analog resistor, limiting the computing accuracy. These nonidealities for PCM devices mainly include resistance drift, read noise, limited memory window, and various device failures due to fabrication yield and limited device endurance and retention. In this presentation, I will talk about our study on the impact of these nonidealities on the analog CIM deep learning accuracy.

We systematically varied PCM memory window, resistance drift, and read noise, and studied their impact on the accuracy of large neural networks of various types and with tens of millions of weights.[1] We show that the DNN accuracy can be improved by the PCM with reduced read noise, even if the memory window is also reduced. However, there is a limit on the memory window, below which the accuracy drops significantly. DNN inference accuracy decreases over time due to the PCM resistance drift. However, the long-term accuracy loss can be minimized using an optimized mapping of weights to unit cells with multiple PCMs representing weights of varying significance. The energy efficiency dependence on the resistance drift was also studied [2]. There are tradeoffs and correlations between PCM device characteristics, which we used to identify the device optimization space to achieve better short term and long-term accuracy.

In addition, there are typically some failed devices of various types in NVM CIM chips, due to nonperfect fabrication yield and device failure over time. We studied the impact of these different types of failed devices on the analog CIM accuracy for various DNNs.[3] We find that larger networks with fewer reused layers are more tolerable to failed devices. Devices stuck at high resistance states are more tolerable than devices stuck at low resistance states. To improve the robustness of DNNs to defective devices, we developed training methods that add noise and corrupt devices in the weight matrices during network training and show that this can increase the network accuracy in the presence of the failed devices. Our approach is based on a single generic training and a subsequent mapping of the weight to any chip with unknown failed device locations.

In summary, we systematically studied the impact of nonidealities of PCMs on the DNN accuracy, using the PCM devices fabricated at IBM [1] and the hardware-aware simulation tool [4] developed at IBM Research. We proposed a few methods, including optimization of device specification, optimized weight mapping, special hardware aware training, to enhance the DNN performance.

3:45 PM *EL20.11.01
Recent Progress in Developing Next Generation Neuromorphic Devices Based on Ferroelectric Hafnia by the U.S. Army Research Laboratory AndreuGlasmann[1,2], SinaNajmaei[1], WendySarney[1], AlexMazzoni[1], JustinPearson[1] and MatthewChin[1]; [1]U.S. Army Research Laboratory, United States; [2]Boston University, United States

In this presentation, I will present on the research progress by the U.S. Army Research Laboratory (ARL) in creating a framework for maturing emerging non-volatile memory devices based on ferroelectric hafnia for integration into front- and back-end CMOS neuromorphic integrated circuits. Next generation edge applications require a dramatic shift in computing paradigms, which utilize new electronic devices and circuit architectures to address the increasing power demands of enabling cognitive sensing and autonomy in extreme environments. Ferroelectric hafnia exhibits promising attributes, such as scalability, sub-nanosecond switching, back-end-of-the-line (BEOL) and front-end-of-the-line (FEOL) CMOS-compatibility, and good endurance that make it a promising candidate to address these needs.

In this presentation, I will discuss our material and device efforts in developing BEOL 2D ferroelectric field effect transistors. Our research demonstrates that within the CMOS compatible thermal processing envelope the ferroelectric landscape of HZO shows unique characteristic that have significant implications on the neuromorphic device properties of FeFETs. We examine these properties by integrating HZO into BEOL 2D WSe2 based-FeFET device architectures, a prototypical van der Waals system, and verify their robust synaptic plasticity within a 3.5 order of magnitude conductive range. These discoveries highlight a roadmap for material processing, dimensional scaling, and integration of HZO-based FeFETs.

I will further discuss our complementing activities that focus on creating the design and simulation tools required for integration of FeFETs into CMOS. In this effort we seek to develop a framework for multiscale modeling of ferroelectric-based devices. To that end we will focus on our efforts in developing a physics-based compact device model for three-terminal ferroelectric field effect transistors. The model has been designed with explicit support for transient analysis to capture time-dependent polarization switching dynamics down to nanosecond scale with multiple types of ferroelectric domains. In the presentation, we will discuss the model's calibration against experimental data and use in optimizing the design of a ferroelectric-metal field effect transistor (FeMFET). Finally, we conclude with future direction of the work, including how we intend to couple this model to a Monte Carlo analysis framework to feed into neural network-level hardware simulations of neural accelerator crossbar architectures.

4:15 PM EL20.11.02
Wake-Up of Ferroelectric HZO Films -- Towards a BEoL Compatible Wake-Up Free Material DavidLehninger, AyseSünbül, AnantRastogi, PratikBagul, ShouzhuoYang, KonradSeidel and MaximilianLederer; Fraunhofer IPMS, Germany

The discovery of ferroelectricity in thin doped hafnium oxide films has revived interest in the concept of ferroelectric (FE) memory. Zirconium-doped hafnium oxide (HZO) crystallizes at low temperatures (400°C and below), making this material interesting for back-end-of-line (BEoL) implementation. Metal-FE-Metal (MFM) capacitors are critical building blocks for the realization of BEoL-compatible FE memory concepts. Located in the BEoL, they can be connected to either the gate or drain of a standard logic device to realize a one transistor-one capacitor (1T1C) FE field effect transistor (FeFET) or a 1T1C FE random access memory (FeRAM), respectively. [1]
Since its discovery, researchers have made great efforts to improve important properties of hafnium oxide-based ferroelectrics, such as remanent polarization, endurance, retention, imprint, and wake-up. Typical approaches include, but are not limited to, the investigation of different dopant elements, dopant concentrations, film thicknesses, and stacking options such as interface/electrode materials and superlattice structures.
While much progress has been made, certain issues, such as wake-up, remain challenging. Wake-up is the opening of the initially pinched polarization versus electric field hysteresis loop, which leads to a gradually increasing remanent polarization during field cycling until saturation. Since memory applications require stable polarization, an initial field cycling ("wake-up") is necessary. However, the need for this wake-up makes the realization of hafnium oxide based FE memories more complex and reduces the maximum number of endurance cycles. Therefore, a wake-up-free material would be highly desirable.
Several theories have been proposed to explain the wake-up effect. These theories can essentially be summarized as follows [2]: (i) defect redistribution, which reduces internal bias fields and promotes the depinning of domain walls, (ii) defect redistribution and subsequent stabilization of the orthorhombic phase ("field-induced phase transformation"), and (iii) 90° domain wall motion ("ferroelastic switching").
The wake-up effect of FE-HZO films could be mitigated by: (i) using mesa-etched test structures [3]; (ii) reducing the number of defects and carbon contamination by applying longer ozone pulses durations during the atomic layer deposition process [4]; (iii) interface engineering by plasma treatment [5] or epitaxial growth [6].
Herein, we investigate the effect of post-deposition annealing temperature, film stoichiometry, film thickness, and co-doping on the wake-up characteristics of FE HZO films embedded in MFM capacitors. Several structural and electrical characterization techniques, such as X-ray diffraction and polarization versus electric field measurements, are applied to obtain a comprehensive overview. The goal is to present a BEoL-compatible material stack with significantly reduced wake-up without compromising other important parameters such as remnant polarization and reliability.

4:30 PM EL20.11.03
Cryogenic Characterization of Polarization Switching in Ultra-Thin Ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ Capacitors BalreenSaini[1], ChanyoungYoo[2], FeiHuang[1], JohnD. Baniecki[2], WilmanTsai[1] and PaulMcIntyre[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The demand for smaller, faster, and more energy-efficient logic and memory devices is continuously increasing, leading to a heightened requirement for new materials that can be scaled down dimensionally and that are compatible with CMOS fabrication processes. A material system that shows promise for nonvolatile memory applications is HfO_2-based ferroelectrics. Since the discovery of ferroelectricity in HfO_2 thin films, research in this area has surged due to their potential as nonvolatile memory elements in 1 transistor-1 capacitor ferroelectric random-access memory (FeRAM) and in ferroelectric field-effect transistors (FeFET). Many of these research efforts have focused on reducing the programming voltage, improving reliability at lower operating voltages, and, in some cases, achieving compatibility with back-end-of-line (BEOL) process temperatures. However, compared to traditional perovskite-based ferroelectrics, there is a less comprehensive understanding of the domain-switching mechanisms involved in programming the polarization of these fluorite-type ferroelectric materials.
The metastable assembly of phases typically present in as-fabricated HfO_2-based thin films exhibit a field-induced phase evolution at room temperature that can result in the increase (wake-up) or decrease (fatigue) of the remnant polarization with switching cycles. Other mechanisms such as domain depinning and charged defect redistribution with field cycling are also reported to cause the observed polarization evolution with field cycling (endurance). The extent to which various proposed mechanisms for polarization evolution can contribute to experimental observations will depend on their activation energies. In the present work, we explore the effect of measurement temperature on the functional properties of ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ (HZO) capacitors to further our understanding of the atomistic mechanisms responsible for the observed endurance characteristics. To carry out this investigation, we utilize a cryogenic probe station, which has the capability for measurements over a range of temperatures, as low as 10 K.
We examine HZO capacitors with different thicknesses (ranging from 4 nm to 10 nm) with Mo and TiN electrodes. A decrease in remnant polarization is observed for all samples as the measurement temperature is decreased to 10 K. This polarization reduction is recovered by increasing the temperature back to room temperature, suggesting reduction in the thermally activated domain wall motion at low temperatures. Polarization hysteresis (P-V) measurements for capacitors with pristine state pinched loops at room temperature show a negligible pinching effect at cryogenic temperatures. A positive-up-negative-down (PUND) pulse scheme is utilized to separate the polarization switching current from the displacement current. Frequency-

dependent and electric field-dependent endurance measurements are performed to further elucidate the possible contributions of different switching mechanisms to the observed temperature dependence of polarization switching.

4:45 PM EL20.11.04
$Hf_{0.5}Zr_{0.5}O_2$ Based Ferroelectric Memories for Applications Down to Deep Cryogenic Temperatures HeorhiiBohuslavskyi[1], KestutisGregorios[1], MikaPrunnila[1] and SayaniMajumdar[2]; [1]VTT Technical Research Centre of Finland, Finland; [2]Tampere University, Finland

Since the last decade, extensive studies on HfO_2-based ferroelectric devices have been carried out to unlock their applications in high-density, low-power, and high-speed electronics, and most importantly in non-volatile memories and logic circuits. Emergence of HfO_2-based ferroelectric memories has its origin in the CMOS compatibility and scalability potential, therefore bringing the prospect of easy integration with the existing foundry processes [1]. Among ferroelectric hafnia, Zr-doped HfO_2 (HZO) has received most attention due to its low crystallization temperature, making it a suitable candidate for CMOS back-end-of-line (BEOL) integration. More recently, memories operating at cryogenic temperatures became a topic of high interest due to their potential applications in high-performance computing, quantum computing and space technologies [2]. To realize the memory devices functional down to deep cryogenic temperatures with reasonably low power dissipation, understanding of fundamental device physics and proper material engineering are of vital importance. Previously, perovskite oxide based ferroelectric tunnel junctions, when cooled down to low temperatures, were demonstrated to have several key parameters improved as compared to room temperature operation, featuring higher on/off ratio, faster switching and improved endurance [3]. In terms of HZO-based capacitors or junctions, a few recent papers reported operation down to low temperatures [4-6]. However, a comprehensive understanding of the cryogenic physics and properties of HZO devices within the wide temperature window from 300 K down to 4 K temperatures as well as the optimization of interfaces and material stack for cryogenic operation are currently missing. In the present work, we report high remnant polarization from quasi wake-up free $Hf_{0.5}Zr_{0.5}O_2$ thin film devices together with state-of-the-art endurance down to deep cryogenic temperatures [7]. The HZO films, grown and annealed under CMOS BEOL-compatible conditions, were characterized within the 300 – 4 K temperature range with a particular focus on the analog switching properties of the films. Finally, we evaluate the overall performance of our HZO devices as cryogenic memories aiming at optimizing the domain dynamics control for achieving high classification accuracy of in-memory computing circuits [7,8].

Vector Matrix Multiplication with 2D Materials MarioLanza; King Abdullah University of Science and Technology, Saudi Arabia

Most artificial intelligence systems are based on artificial neural networks (ANNs), which are normally implemented in traditional silicon microchips. These microchips contain complementary metal-oxide-semiconductor (CMOS) circuits that realize different operations, including mathematical operations, digital-to-analogue and analogue-to-digital conversion, and transimpedance amplifiers. One of the most critical operations in ANNs is the vector matrix multiplication (VMM), but realizing it with traditional CMOS circuits consumes too much time and energy. Using crossbar arrays of memristors is much more efficient because the VMM is done in parallel via Ohm's law and Kirchhoff's law. In the past few years, multiple studies presented VMM based on memristive devices made of metal-oxides and phase-change materials. Here we present the first VMM operation using two-dimensional (2D) layered materials, and discuss its advantages and challenges compared to traditional memristive materials.

11:00 AM *EL20.12.02
Improved Microcontact Printing of Choline Oxidase using a Polycation-Functionalized Zwitterionic Polymer as Enzyme Immobilization Matrix MingZhao[1,2], BrendaHuang[1], YanCao[1] and HaroldMonbouquette[1]; [1]University of California, Los Angeles, United States; [2]Massachusetts Institute of Technology, United States

Electroenzymatic sensors typically rely on specific oxidase enzymes to catalyze oxidations of the target analyte to produce hydrogen peroxide (H_2O_2) that is oxidized or reduced at an underlying electrode at moderate potential to give a current signal. Development of microelectrode array (MEA) microprobes for multiple detection through selectively deposit multiple different enzymes onto specific microelectrode sites is in great demands.

Enzyme deposition and immobilization on microelectrode surfaces is most commonly achieved by manually loading a mixture of enzyme, bovine serum albumin (BSA), and glutaraldehyde (GAH) as crosslinker on the electrode surface. However, the manual approach becomes problematic when the MEA feature size is in the micrometer range. In previous work, we demonstrated the use of microcontact printing (μCP) for creation of multianalyte sensing microprobes by patterning two different enzyme/BSA mixtures onto selected, distinct sites on a MEA and subsequent crosslinking with GAH vapor. Although this accomplishment demonstrates the potential of MEAs for recordings of multiple neurochemicals simultaneously *in vivo* with high spatiotemporal resolution, the use of enzyme/BSA mixtures in aqueous solution as the "ink" has important disadvantages. Since the BSA protein behaves as a globular particle in solution that contributes little to the viscosity of the "ink", imprinted enzyme patterns tend to be so thin that low sensitivity results or problematic surface spreading and low spatial-resolution deposits occur when higher enzyme loading is attempted. For the application described in this work, excessive spreading of "ink" deposits is highly undesirable as it can lead to contamination of adjacent microelectrodes less than 100 μm away resulting in sensor crosstalk. As these problems are inherently related to ink properties, there has been a need for a new formulation that provides high adhesion to substrate, stronger intermolecular forces for higher viscosity and yet similar functionality as BSA to enable enzyme immobilization through covalent crosslinking.

While great strides have been made in modifying "ink" properties to achieve high resolution patterns, the focus has been on creating very thin layers of chemicals or proteins on substrates via covalent attachment. In this report, we designed a novel graft polymer, poly(2-methacryloyloxyethyl phosphorylcholine)-*g*-poly(allylamine hydrochloride) (PMPC-*g*-PAH), which serves as an alternative enzyme immobilization matrix to BSA that enhances the capability and efficiency of enzyme transfer to microelectrode surfaces via μCP. The zwitterionic polyphosphorylcholine moieties of the graft polymer serve to enhance surface hydrophilicity, the free amine groups provide functional groups for crosslinking with GAH vapor, and the polymer itself increases solution viscosity so as to curtail undesirable "ink" spreading. The minimization of ink surface spreading enables longer stamp alignment times, enhanced control of enzyme loading for better sensor performance, as well as potentially minimizing immune response that would improve long-term stability *in* vivo.

Architectures and Circuits for Analog-Memory-Based Hardware Accelerators for Deep Neural Networks (Invited) HsinyuTsai; IBM Almaden Research Ctr, United States

Analog non-volatile memory (NVM)-based accelerators for Deep Neural Networks (DNNs) can achieve high-throughput and energy-efficiency by computing multiply-accumulate (MAC) operations using Ohm's law and Kirchhoff's current law on arrays of resistive memory devices [1]. In recent years, energy-efficient, weight-stationary MAC operations in analog NVM memory-array "Tiles" were demonstrated in hardware with Phase Change Memory (PCM) devices integrated in the backend of 14-nm CMOS [2, 3]. Competitive end-to-end DNN accuracies can be obtained with the help of hardware aware training, accurate weight programming, and sufficiently linear MAC operations in the analog domain [4].

In this paper, I describe architectural and circuit advances for such Analog NVM-based accelerators and specialized digital compute units, designed to accelerate Transformer, Long- Short-Term-Memory (LSTM), and Convolution Neural Networks (CNNs). A highly heterogeneous and programmable accelerator architecture that takes advantage of a dense and efficient circuit-switched 2D mesh to exchange vectors of neuron-activation over short distances in a massively parallel fashion [5] is presented. Based on a 14-nm inference chip consisting of multiple arrays of PCM devices, the impact of memory materials on the accuracy and performance of these systems will be discussed.

The author would like to thank colleagues at IBM Research Almaden, Yorktown, Albany, Zurich and Tokyo for their contributions to this work and the IBM Research AI HW Center.

Design and Development of Ultrathin All-Solid-State Flexible Polymer Batteries DavidPatrun, ZiyaadAytuna, ThomasFischer and SanjayMathur; University of Cologne, Germany

The design and development of lightweight flexible polymer batteries have gained significant attention in recent years due to their potential to revolutionize portable electronics, wearable devices, and energy storage systems. To achieve the goal of thin all-solid-state batteries, an innovative design principle is necessary. Various fabrication techniques, such as electrospinning and blade coating processes, have been explored to produce flexible battery electrolytes with high structural integrity and mechanical stability. In the development of flexible polymer batteries, the selection of suitable electrode materials is crucial. Various metal oxides and composite materials have been investigated for their electrochemical performance, stability, and flexibility. Surface modification has been achieved by nanoscale deposition techniques such as plasma-enhanced chemical vapour deposition (PECVD). These nanostructuring strategies have been employed to enhance the electrochemical properties, promote ion transport, and increase the overall energy density of the battery.

Carbon-Based Inks Formulations for Screen-Printed Planner Flexible Micro-Supercapacitor Devices NikitaDey; Indian Institute of Technology Kharagpur, India

The increasing demand for high-performance energy storage devices, driven by advancements in flexible and smart technology like wearable electronics, has led to a need for smaller and more efficient solutions. To address this, the use of printing technology and functional inks have emerged as a promising manufacturing pathway. These technologies offer benefits such as high deposition rates, minimal material waste, scalability, and the ability to produce high-resolution patterns. This study emphasises on the fact that carbon-based inks have emerged as a game-changing technology for printed flexible electronics, offering numerous benefits such as affordability, processability, high conductivity, and flexibility. This presents new possibilities for sustainable ink formulations and the fabrication of screen-printed patterns for applications in sustainable energy. Optimizing various parameters such as ink rheology, mesh pore size, mesh design, and squeegee motion are crucial for fabricating electrodes tailored to specific applications. In the pursuit of developing screen printable carbon-based ink, we have explored a diverse range of binder solvent pairs to cater to our specific requirements. Our experimentation involved employing various combinations, including Ethyl cellulose (EC) paired with terpineol, carboxymethyl cellulose (CMC) paired with deionized water (DI), and ceramic binder such as glass water. It was found that, EC-based inks with terpineol is superior for micro-supercapacitor because they are less corrosive, easy to print, and also their insolubility in water ensures heightened longevity and durability. This also opens up possibility of using water-based gel electrolyte. On the other hand, CMC-based and glass water-based inks are soluble in water, rendering them less durable with a shorter lifespan. Also, glass water-based inks are corrosive which might damage the printed fabric mask. In addition to the quality of the ink, the design of the devices was found to significantly impact the energy storage performance. Therefore, a range of different device designs was employed to study their effects. The comparative analysis of the ink quality, and device designs yield valuable insights into the development of efficient and durable screen-printed planner flexible micro-supercapacitor devices. The abstract also addresses the opportunities and challenges associated with printing these carbon based materials, for micro-supercapacitors and micro-batteries on an industrially viable scale. By exploring these possibilities, this work aims to contribute to the development of high-quality and scalable solutions for next-generation wearable smart electronics.

Atomic Layer Deposition on 1D Nanomaterials for Electrochemical Applications JanM. Macak[1,2]; [1]University of Pardubice, Czechia; [2]Brno University of Technology, Czechia

One-dimensional nanomaterials – materials with one dimension outside the nanoscale, further noted as 1D NMs – represent a class of very important nanomaterials with continuously increasing importance. Due to their intrinsic features, unique properties and diversity of functionalities, they count among the most widely studied materials nowadays. While considerable research efforts have been spent to synthesize various 1D NMs (e.g. nanopores, nanotubes or nanofibers), limited efforts have been devoted to surface modification and property tailoring of these materials.
However, it is their surface that comes into direct contact with various media (air, gases, liquids, solids) and influences the reactivity, stability and biocompatibility of these materials. The surface and aspect ratio (defined as their diameter to length ratio) influence the performance of these materials in various applications. Considering these facts, it is more relevant to tailor the surface of these materials and to be able to influence their properties and reactivity at the nanoscale, rather than to deal with tailoring their own bulk material composition.
The focus of this presentation is on the modification of two types of 1D nanomaterials – nanotubes and nanofibers. Numerous techniques can be utilized for this purpose, such as for example wet chemical or physical deposition techniques. However, it is only the Atomic Layer Deposition (ALD) that is capable of really uniform and homogenous coating of these 1D nanomaterials, in particular those of very high-aspect ratio.
The presentation will be mainly focused on modification of TiO_2 nanotube layers and various nanofibers of different aspect ratios via ALD for electrochemical applications.
Experimental details and some very recent application examples in photocatalysis, catalysis, sensors, batteries, etc. [1-10] and structural characterizations of these modified materials will be discussed.

SESSION EN01.02: Anode Materials for Lithium-ion Batteries—Challenges and Opportunities
Session Chair: Jan Macak
Monday Afternoon, November27, 2023
Hynes, Level 2, Room 200

1:30 PM *EN01.02.01
How Building Batteries for Robots Enabled Pressure Free Lithium Anodes and Instantly Rechargeable 850 Wh kg^{-1} Catholytes for Electric Aircraft JamesH. Pikul; University of Wisconsin–Madison, United States

This talk will cover new approaches for powering robotic systems across scales. Starting with microbatteries made for tiny robots, we will show how molten salt manufacturing and 3D printing enable 3-4X improvements in battery energy density and pressure-free lithium anodes. We will then move to larger systems where new chemistries and bioinspired design led to 10X improvements in macroscale robot operation time and long-range, instantly-rechargeable electric aircraft.

Current lithium (Li) metal pouch cells require high external pressures of 69 to 1,000 kPa and have huge volume increases of 39 to 220% after cycling, which makes them incompatible with small and flexible robotic applications because the clamping systems required to apply the pressure eliminate any energy or flexibility benefits. This talk will demonstrate swelling-free and pressure-free Li metal anodes with 1580 mAh cm^{-3} capacity enabled by polymer gyroid microlattices that allow 3D control of the molecular interaction between Li, polymer, and electrolyte. The geometry augments the chemical functionality to realize dense Li growth through complex 3D printed geometries by maximizing the Li volume fraction, polymer-Li-electrolyte contact, and manufacturability. Stable Li deposition was realized at a practical areal capacity of 5 mAh cm^{-2} in 10 minutes. A 308 Wh kg^{-1} anode-free pouch cell (2.1 Ah) incorporating a polymer gyroid had 80.2% capacity retention after 226 cycles, and the cell swelling was below 7%. Over 860 cycles were achieved when the pouch cell was prepared with 2.6 times excessive Li.

As robots and electric machines get bigger, they present increasing energy storage challenges. For example, the energy densities required to electrify aviation, heavy machinery, and robots (~1,000 Wh kg^{-1}) seem insurmountable with current battery architectures based on solid intercalation materials (250 Wh kg^{-1}), but animals can store ~2,000 Wh kg^{-1} and operate continuously. The clear gaps in energy density and operational capability between machines and animals motivate new ways to extract electrochemical energy via bioinspired designs. The last part of this talk will report an electrochemical stomach that near-continuously powers electric aircraft and robots by ingesting small molecules as beverages and converting that chemical energy to electricity by pairing them with metals. We demonstrate a 10.4 Ah stomach that delivers an energy density of up to 850 Wh $kg_{stomach}^{-1}$ at 192 A $kg_{stomach}^{-1}$ and restores the chemical energy in 1 minute. The stomach powered a commercial quadcopter and doubled the flight time of the manufacturer's state-of-the-art batteries. Owing to the diversity of small molecules, we tailor beverages to enable 1,447 Wh kg^{-1} discharge energy density or fire-safe energy storage.

2:00 PM EN01.02.02
MOF-Derived Fe, N Co-Doped Porous Carbon Polyhedrons (Fe-N-C) for High-Performance Lithium-Ion Battery Anode Materials KaiyiQin; Northeastern University, China

The lithium storage performance and structural stability of anode materials have a significant influence on the capacity performance and cycling stability of lithium-ion batteries. Despite the cost, conductivity, non-toxicity, and non-polluting advantages of graphitic carbon materials, their cycle stability is compromised by volume changes during lithium storage. Additionally, the theoretical capacity of 372 mAh/g is no longer sufficient to meet the growing demand for high-capacity LIBs. Metal-organic frameworks (MOFs) and their derivatives have emerged as promising anode materials for LIBs due to their tunable structure, high surface area, and high porosity. In this study, we successfully synthesized Fe, N co-doped carbon materials (Fe-N-C) with exceptional properties by calcination and co-doping Fe and N elements into a ZIF-8 precursor. Scanning electron microscopy (SEM) results revealed that the morphology of the synthesized samples was identical to that of ZIF-8. X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) analyses confirmed the successful co-doping of Fe and N into the carbon material. The porous structure provided a buffer for volume changes and improved cycling performance. After 300 cycles at a current density of 500 mA/g, the Fe-N-C anode exhibited charge and discharge specific capacities of 538 mAh/g and 543 mAh/g, respectively. The co-doping of Fe and N enhanced the conductivity and rate performance of Fe-N-C, resulting in excellent cycling stability. This study demonstrates the exceptional electrochemical activity and potential of Fe, N co-doped carbon polyhedrons for high-performance lithium-ion batteries. Carbonization of metal-organic frameworks and co-doping with Fe and N elements represents a promising strategy to enhance the electrochemical performance of graphitic carbon anode materials.

2:15 PM EN01.02.03
Enhancement of Cycling Performance by use of Li Anode with Additive Leaching-Type Polymer Layer for Lithium Metal BatteriesOHMyung-keun and Dong-WonKim; Hanyang University, Korea (the Republic of)

Rechargeable lithium batteries using lithium metal as an anode are attractive candidates for high energy density power sources in portable electronic devices and electric vehicles, because lithium metal offers a high specific capacity (~3,862 mAh g^{-1}) and possesses a low reduction potential. However, the development of rechargeable lithium metal batteries has been hindered by the high reactivity of lithium metal with liquid electrolytes and the occurrence of dendrite growth during charge and discharge cycles. Therefore, it is essential to form the stable solid electrolyte interphase (SEI) on lithium metal to prevent lithium dendrite growth and minimize side reactions of liquid electrolyte. Recently, various additives have been investigated to form a stable SEI layer on Li metal. However, during repetitive charge and discharge process, the additives in the electrolyte can be gradually depleted, resulting in capacity fading. In this work, we developed additive leaching-type polymer layer containing excessive amounts of additives that form the stable SEI layer. The additives can be stored in the polymeric layer, continuously released to the electrolyte during the repeated cycling. Electrochemical analyses such as linear sweep voltammetry and cyclic voltammetry were investigated, and the Li/Li symmetric cells

showed the regulation of lithium deposition with small overpotential. The cycling performance of lithium metal batteries employing additive leaching-type polymer layer was evaluated with high nickel NCM cathode. Furthermore, characterization techniques such as cyclic voltammetry, X-ray photoelectron spectroscopy, ^{7}Li nuclear magnetic resonance, and electrochemical impedance spectroscopy were employed to analyze the release behavior of additives and investigate the mechanisms associated with released additives for improvement of cycling performance.

2:30 PM EN01.02.04
Structure Tailoring and Material Modification of the Thick Cathode for Fast Charging and Long Lifespan Li-S Batteries YuxuanZhang[1], Han WookSong[2] and SunghwanLee[1]; [1]Purdue University, United States; [2]Korea Research Institute of Standard and Science, Korea (the Republic of)

It is urgent to develop both affordable and sustainable batteries with high energy density and fast charging speed to alleviate the range anxiety of electric vehicles.[1,2] The lithium-sulfur (Li-S) system is especially attractive because of its high theoretical specific energy (around 2600 W h kg^{-1}), low cost, and low toxicity. However, the application of sulfur cathodes to date has been hindered by several obstacles, including low active material loading, low electronic conductivity, shuttle effects, and sluggish sulfur conversion kinetics.
Herein, we combine a material-agnostic approach based on the asymmetric cathode structure design with a controllable vapor-deposited polymer to realize fast charging Li-S batteries with high sulfur loading.[3] Specifically, the active materials and the tortuosity of the cathode were tailored by the 3D printing (stereolithography technique), which distributed in an inhomogeneous way to compensate for the gradient distribution of Li ions originated in the cathode depth direction, leading to less polarization in the electrode scale. The as-printed cathode is then sintered at 900 °C in an N_2 atmosphere to generate a carbon skeleton (i.e.: carbonization of resin) with intrinsic carbon defects. The structure design and defects engineering are expected to synergistically create favorable sulfur conversion conditions and mitigate the polarization in thick electrodes. The oCVD technique is leveraged to produce a conformal coating layer to eliminate shuttle effects for the elongated battery life. In-situ XRD diffractograms show a distinguishable difference between the printed cathode and the 2D planer cathode with similar mass loading, confirming an eminent sulfur conversion kinetic condition.
Overall, the customized cathode delivered 820 mAh g^{-1} at 4 C with a mass loading of 8.3 mg cm^{-2}, and the cathode with oCVD polymer showcased high-capacity retention (85% after 300 cycles), which indicates high mass loading with elevated sulfur utilization ratio, accelerated reaction kinetics, and stabilized electrochemical process have been achieved on the sulfur cathode by implementing this innovative cathode design strategy. The results of this study suggest a promising way of employing structural optimization and material modification for the higher energy and power density battery.

8:00 AM *EN01.03.01
Flexible and Durable Batteries for Wearable Sensors Ana ClaudiaArias; University of California, Berkeley, United States

On skin detection of vital signs and biomarkers, a non-invasive approach, holds tremendous significance for evaluating the body's response to physical activity and clinical diagnostics. When integrated into wearable devices, flexible sensors offer several advantages, including continuous data acquisition, high performance, and cost-effectiveness. Powering such devices while maintaining their mechanical properties has driven active innovation in the field of wearable compliant batteries. Incorporating additional functionalities often compromises the energy storage capacity of these devices, resulting in lower gravimetric or volumetric capacity compared to commercially available batteries. Maximizing the energy density of wearable batteries remains a crucial goal. Most demonstrations in this field rely on lithium-ion battery chemistry, which often includes toxic and/or flammable components. Thus, designing non-toxic systems utilizing abundant and disposable materials is of utmost importance. We have developed an electrode composite with an interpenetrated binder network, enabling a flexible battery with energy density comparable to commercial AA alkaline batteries. Wire-shaped batteries based on helical band springs will be presented, demonstrating resilience to fatigue and the ability to maintain electrochemical performance over 17,000 flexure cycles. Intrinsically safe and non-toxic silver-zinc (Ag/Zn) and zinc-manganese dioxide (Zn/MnO2) battery chemistries are employed in our work.

8:30 AM EN01.03.02
A Solar-Powered Optogenetic System for Long-Term, Wirelessly-Controlled Neuromodulations JaejinPark, KyubeenKim, Tae SooKim and Ki JunYu; Yonsei University, Korea (the Republic of)

Optogenetics has revolutionized neuroscience by enabling the manipulation of neural activity using light-sensitive proteins to modulate brain function. To facilitate advanced neuromodulation in freely moving animals, various optical stimulation devices have been developed. Presently, wireless optogenetic devices predominantly utilize either coil-powered or battery-powered systems. Battery-powered systems necessitate frequent battery replacements, which can cause stress for the animals. Furthermore, recharging the batteries requires the charger to be located within a specific area. Coil-powered systems, on the other hand, require a structure that wraps around the animal's cage to provide power, limiting their operation to confined spaces where such a setup is established. In addition to these constraints, specialized techniques like impedance matching with expensive, bulky equipment such as radiofrequency (RF) generators are essential for operating these systems.

On the contrary, an innovative wireless solar-powered optogenetic device (WSOD) takes advantage of light energy to autonomously charge and operate. This remarkable feature eliminates the need for spatial restrictions, enabling the experimental subject to move freely without confinement. Additionally, the WSOD functions independently without relying on external components such as an RF generator or amplifier. To harness sufficient power from diverse light sources, including sunlight and lamps, we have implemented highly efficient flexible InGaP/GaAs tandem solar cells, which are incredibly thin (< 5 μm). The solar cell has an impressive power conversion efficiency of 18 % and a wide spectral range from 300 nm to 900 nm. This outstanding efficiency allows the WSOD to operate continuously for more than 80 minutes with just a 10-minute charging period during daylight hours. The fully assembled WSOD incorporates these photovoltaic cells with a power management system and Bluetooth technology on a flexible substrate, enabling control via a smartphone application. Furthermore, the WSOD allows multiple connections to numerous devices from a single mobile device, facilitating in vivo experiments in diverse environments and with various subjects.

To demonstrate these capabilities, we performed optical stimulation in the secondary motor cortex (M2) region of a transgenic mouse brain, observing subsequent locomotion behavior. Through quantitative analysis, we identified compulsive circling behaviors and increased velocity during the stimulation period. Furthermore, we demonstrated the long-term stability of the WSOD by observing no significant differences in locomotion behavior over a month-long duration. This study introduces a wirelessly rechargeable optogenetic device powered by solar energy, facilitating wireless charging without any spatial constraints. The pivotal advantage of this system lies in its ability to naturally recharge during the course of regular activities, eliminating the need for bulky and expensive equipment like RF generators or amplifiers. With this feature, we are moving closer to the ultimate objective of developing wireless optogenetic devices that enable the completely unrestricted behavior of the subjects.

8:45 AM EN01.03.03
Enhancing Single Electrode Triboelectric Generators via Charge Trapping Layer Integration Wei-LinWu, Cheng-YuShih, Yen ShuoChen and Fu-HsiangKo; National Yang Ming Chiao Tung University, Taiwan

With the rapid development of internet of things (IoTs), the increasing need of self-power sensor is expected. Triboelectric generator (TEG) has become a promised candidate in mechanical stimuli sensing(1, 2), which is distinguished from several conventional sensors in that it doesn’t need any extra power source.
The triboelectric effect can be explained by Maxwell's equations and involves both contact electrification and electrostatic induction. In contact electrification, two dissimilar materials come

into contact and exchange charges, resulting in a potential difference between them. In electrostatic induction, an external electric field polarizes the charges in a material, creating a potential difference between two regions of the material. However, the insufficient output performance of triboelectric generators hinders their widespread application. To enhance the energy-harvesting capabilities of these generators, we are focusing on device structures(3), surface topography(4), and material selection(5).
In this paper, we introduce the charge storage layer to optimize device structure. For the purpose to increase the surface charge by raising the bulk charge, the low mobility polymer is inserted between friction layer and metal plate as charge storage layer. Then, polydimethylsiloxane (PDMS) as friction layer with micro-pyramid structure to increase the surface area and pressure sensitivity. We choose polydimethylsiloxane (PDMS) and polytetrafluoroethylene (PTFE) to be the friction double layer for the reason of low cost, high flexibility, and great output performance. The output voltage of dual layer triboelectric generator can achieve 150 V, which is eight times higher than the triboelectric generator without charge storage layer.

Keywords: triboelectric effect; charge storage layer; energy harvesting; pyramid structure

Understanding Interplay of Cycling Conditions on Li-Ion Battery Performance for EVTOL Applications AnujBisht, RuhulAmin and IliasBelharouak; Oak Ridge National Laboratory, United States

The advancement of improved energy storage systems has garnered significant attention in Electric Vertical Takeoff and Landing (EVTOL) applications. To ensure optimal performance and safety of onboard batteries, comprehending their behavior under varying charging/discharging protocols and environmental conditions is crucial. This work provides a comprehensive evaluation of commercial Li-Ion batteries for EVTOL applications, with a specific focus on their response to different charging/discharging strategies and mechanical vibrations encountered during flight. Controlled experiments are conducted to explore the effects of rapid cycling on battery performance, encompassing lifespan, capacity, and internal resistance. Additionally, the impact of mechanical vibrations on battery behavior is assessed to identify potential challenges for onboard batteries. The study's results reveal intriguing insights into the interplay between temperature, vibration, and battery performance, bridging the gap between battery performance and EVTOL applications. This work contributes to the wider adoption of electric aerial transportation, promising a greener and safer future for urban mobility.

Conductive Polymers at The Nexus of Innovation: Empowering Nanogenerators and Smart Interactive Wearables RodrigoF. Martins[1], GuilhermeFerreira[1], SumitaGoswami[2], ElviraFortunato[1] and SumanA. Nandy[1]; [1]Universidade Nova de Lisboa, Portugal; [2]Almascience, Portugal

Conducting polymers have emerged as versatile materials with transformative potential in two key domains: nanogenerators and smart interactive sensor applications for wearable substrates. This abstract explores the exciting advancements and synergistic possibilities created by integrating conducting polymers into these cutting-edge technologies.
In the realm of nanogenerators, conducting polymers are being investigated as a functional element because of their remarkable electro-mechanical properties. Good electrical conductivity, coupled with mechanical flexibility, makes them ideal for smart wearable applications. This abstract delves into the principles of energy conversion, highlighting the ability of conducting polymers to convert mechanical energy, such as vibrations or pressure, into electrical energy. This breakthrough has far-reaching implications, powering wearable electronics, Internet of Things (IoT) devices, and remote sensors, ultimately reducing our reliance on traditional energy sources.
Shifting focus to wearable substrates, conducting polymers unveil a new era of smart, interactive sensor applications. These polymers are seamlessly integrated into textiles, cellulose substate, foam, enabling the development of large area of wearable markets such as garments, healthcare, defense, sports, transportation that can sense a wide array of stimuli. From monitoring physiological parameters to tracking environmental conditions and enabling user interactions, conducting polymer-based sensors provide real-time data acquisition and actionable insights. Furthermore, the synergies between nanogenerators and interactive sensors powered by conducting polymers are being explored. Wearable devices can harness energy from user movements and ambient vibrations to sustain continuous sensor operation. This integration not only enhances the autonomy of wearable devices but also enables novel functionalities such as self-powered biosensors and adaptive clothing. As this abstract demonstrates, conducting polymers represent a bridge between the worlds of energy harvesting and wearable technology. Their remarkable properties and adaptability promise a future where self-sustaining, sensor-rich wearables seamlessly integrate into our daily lives, revolutionizing how we interact with technology and our environment. This abstract serves as an invitation to explore the dynamic landscape of conducting polymer applications, fostering innovation and advancements in nanogenerators and smart interactive wearables.

9:30 AM EN01.03.06
A Low-Cost Self-Powered Sensor-Network System for Renewable Gas Transportation Infrastructure System Powered using Energy Harvesting YaaqoubMalallah[1], TiffanyNguyen[2], CallanHall[2], RajinderS. Deol[2], HenamS. Devi[3], MadhusudanSingh[3] and IoannisKymissis[2]; [1]Kuwait Institute for Scientific Research, Kuwait; [2]Columbia University, United States; [3]Indian Institute of Technology Delhi, India

Hydrogen is one of the most important fuels for a sustainable and renewable energy economy. One of the challenges with working with hydrogen, however, is that it requires the use of well-sealed pipelines due to its very fast diffusivity, flammability, and chemical reactivity leading to complication during incorporation of sensors in the delivery and distribution network. There is also a huge interest in examining the blending of hydrogen with natural gas, in which the hydrogen concentration is controlled to stay below 20 % to prevent embrittlement of the metal components commonly used in natural gas containment and transportation networks. Incorporation of sensors is especially important for these hydrogen supply infrastructures. It has been shown that a number of contaminants in the hydrogen supply can be especially harmful for fuel cell applications. In particular, epoxies commonly used in building components such as assembling fuel systems, sensors, and pipelines can foul fuel cell membranes and lead to a dramatic loss in energy delivery and irreversible damage to the fuel cell systems. Our proposed design will use a mechanical energy harvesting approach which will stimulate a high-quality factor (Q) resonator on the inside of the pipe without the need to penetrate the walls of the pipe system. Such sensors could also report on the pressure in hydrogen fuel pipelines, measure flow, and monitor the blending ratio in natural gas/hydrogen mixed delivery systems. Acoustic communication is also used to transmit information between the sensing and communication base unit, eliminating the need for pipe penetrations and risk of leaks, embrittlement, etc. Meanwhile, the sensor package will be powered with piezoelectric, solar, and flow of gas as wind energy harvesting systems. Piezoelectric energy harvesting using materials like PVDF and KNN (Potassium Sodium Niobate) was performed on a stainless-steel sheet through mechanical vibrations of a speaker. The resonance frequency that the PVDF sheet vibrates most readily and efficiently was successfully analyzed and recorded through multiple isolation techniques. In order to observe the resonance frequency, five different methods were implemented into the experiment to reduce noise. Visually, the resonance frequency can be seen from 180 Hz to 220 Hz. The experimental results confirm the visual resonance frequency and reveals external factors that can affect the resonance of the piezoelectric material. We were able to transmit and receive signals through the metallic pipeline at 200 kHz to 500 kHz using PVDF sensors for communication purposes. The power received through 4 mm thick solid iron pipe was 5 %, which is enough to transmit bytes of sensor data from inside the metallic pipe that acts as a Faraday cage. Meanwhile, our lab scale prototype for the energy harvesting systems generated about: 0.02 W for piezoelectric, 2 W for solar, and 0.8 W for wind. A large industrial scale version will be more economically viable.

Implementing Bimetallic Metal Organic Framework for High Performance Asymmetric Supercapacitors SatnamS. Mattu and AbhayDeshmukh; Rastrasant Tukadoji Maharaj Nagpur University, India

Metal organic frameworks (MOFs) are used in various fields like gas absorption, catalysis, energy storage, and conversion as well as in the field of luminescence. As compared to Metal organic frameworks, Bimetallic metal organic frameworks show enhanced and synergistic effects and thus can be used widely for the development of commercial energy storage devices, especially supercapacitors. In this work the synergistic effect of cobalt and aluminum bimetallic MOF is studied as electrode material for supercapacitors by electrodeposition method. This Co-Al MOF exhibits a specific capacitance of 1014.08 Fg-1 at a current density of 40 Ag^{-1} in 1 M KOH in three electrode system. The asymmetric device of Co-Al MOF as the positive electrode and carbon cloth as a negative electrode is also manufactured which exhibits high specific capacitance of 124.26 Fg^{-1} at a current density of 0.25 Ag^{-1}. Apart from a good specific capacitance, Co-Al bimetallic MOF as a device also exhibits a great cycling stability of 93 % capacitance retention even after 12000 cycles. We have such a good specific capacitance in 1 M KOH alkaline electrolytes for both 2 electrodes as well as three electrode systems which is remarkable in the field of supercapacitors. The observed results shows that this work can be used further to make an asymmetric hybrid supercapacitor in the future.

Ultraflexible and Stretchable Monocrystalline Silicon Solar Cells for Wide Ranging Deployment NazekEl-Atab; King Abdullah University of Science and Technology, Saudi Arabia

Flexible and stretchable solar cells are of importance for state-of-the-art applications such as solar powered vehicles, wearables, buildings and robots, among others. While organic materials show good flexibility and stretchability, however, they generally show low efficiencies and stabilities. In terms of inorganic materials, silicon has been the material of choice in the photovoltaic industry due to its low cost, availability, low toxicity and maturity of the manufacturing process. Nevertheless, silicon is rigid and when thinned down to achieve flexibility, the material becomes brittle and the mechanical resilience of the cell is degraded. Moreover, the efficiency of the cells gets degraded too as the active material that absorbs light is thinned down. In this talk, I will discuss a corrugation technique that allows the transformation of rigid silicon solar cells into their ultra-flexible and stretchable version without thinning down the original thickness of the silicon and without degrading the normalized efficiency of the cells. The corrugation technique is based on creating alternating grooves with different shapes, resulting in interconnected islands of silicon using interdigitated back contacts. The different corrugation patterns enable different flexing and stretching capabilities, specific weight and output power which allows customization based on the application requirements. The technique allowed for the world-record flexible and stretchable inorganic solar cells which can be bent down to 140 µm radius and stretched up to twice their original size without degradation in the original normalized efficiency.

11:00 AM EN01.04.02
Intrinsically Stretchable Organic Solar Cells on Crack-Free Substrate/Electrode Platform under 40% Strain YeonjeeJeon, SeungbokLee and Jung-YongLee; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

The increasing demand for off-grid power sources in soft robotics and wearable electronics has sparked considerable interest in stretchable organic solar cells (SOSCs). However, the brittleness of materials used in traditional solar cells makes them susceptible to cracks even under mild strain, limiting their application in wearable devices. To overcome this limitation, intrinsically stretchable organic solar cells (IS-OSCs) have emerged as a promising solution. They offer advantages, including omnidirectional stretchability, seamless integrability, and compatibility with conventional manufacturing processes. In our study, we revealed that the mechanical failure of IS-OSCs under strain can be traced back to the PH1000 layer. Cracks originating from the PH1000 layer subsequently propagate to the photoactive layer, resulting in a decrease in power conversion efficiency (PCE) in the IS-OSCs under strain. To achieve crack-free IS-OSCs under human body elongations as high as ~40%, we propose a double-locked substrate/transparent electrode platform. To enhance the adhesion of the most fragile layer, the PH1000 layer, we developed techniques to enhance both physical and chemical adsorption, including surface treatment of the substrate and cross-linking between the substrate and modified PH1000. Remarkably, our double-locked system sustained strains exceeding 40% without developing cracks, while the untreated PH1000 film exhibited cracks at a strain level of 20%. Our double-locked IS-OSCs achieved an initial PCE of 10.2%, demonstrating significantly enhanced mechanical robustness, with nearly double the ε_{PCE70} (44%) compared to the control device (24%), where ε_{PCE70} represents the strain at which 70% of the initial PCE is retained[1]. Additionally, our IS-OSCs maintained 90% of the initial PCE even after undergoing 1,000 stretch-release cycles under a 10% strain.

11:15 AM EN01.04.03
A Wearable Sweat Sensor Powered by a Flexible Perovskite Solar Cell JihongMin[1], StepanDemchyshyn[2], MartinKaltenbrunner[2] and WeiGao[1]; [1]California Institute of Technology, United States; [2]Johannes Kepler Universität Linz, Austria

Continuous monitoring of physiochemical biomarkers using wearable sensors has the potential to revolutionize personalized healthcare. While sweat sensing has emerged as a promising method for continuous biochemical screening, ensuring a sustainable power supply remains a challenge. Previous energy harvesting modules, such as biofuel cells and triboelectric nanogenerators, have relied on exercise-induced power and sweat generation, limiting their applicability to fitness monitoring. In this study, we propose a flexible perovskite solar cell (FPSC) powered autonomous sweat sensor that efficiently harvests energy from ambient light, enabling continuous and sustainable sweat monitoring throughout the day, even during sedentary activities. The wearable device integrates a long-term reusable FPSC and electronic system, alongside a cost-effective and replaceable microfluidic biosensor array produced through inkjet printing technology. The FPSC features a record-breaking power conversion efficiency (PCE) of 31% under indoor illumination conditions. Its exceptional performance is attributed to the incorporation of α-methylbenzylamine (MBA) as an organic spacer in the quasi-2D perovskite absorber layer, enhancing defect passivation and overall device functionality. Furthermore, the FPSC exhibits high durability, withstanding thousands of rigorous bending cycles, making it suitable for wearable applications. Its maintains a high power output under a wide range of illumination conditions, including dim indoor lighting, ensuring uninterrupted operation during various activities throughout the day. Our battery-free device was validated for on-body use by continuously extracting sweat and capturing real-time cross-calibrated sweat biomarker levels (glucose, sodium, pH, skin temperature, and sweat rate) throughout the day over 12 hours under various lighting conditions and daily activities raning from outdoor resting to indoor exercise.

11:30 AM EN01.04.04
Are Luminescent Solar Concentrators Worth the Effort?TomiBaikie[1], BenjaminDaiber[2], NeilGreenham[1], AkshayRao[1] and BrunoEhrler[2]; [1]University of Cambridge, United Kingdom; [2]AMOLF, Netherlands

Luminescent Solar Concentrators (LSCs) are devices that capture and concentrate light using a transparent matrix doped with chromophores. LSCs have the potential to outperform other light concentration technologies due to their ability to concentrate diffuse light and reshape the solar spectrum to match the optimum spectral characteristics for photovoltaic (PV) technology. This study compares different LSC technologies, including solar windows, within a simulated real-world environment and outlines the potential impact of upcoming LSC technologies to determine their commercialization potential.

We utilised a calendar year of real-world solar spectrum data from Boulder and Amsterdam and combined it with a machine learning model, a ray-tracing algorithm and recombination current diode model to determine the potential power efficiencies from different luminescent solar concentrators (LSC) configurations.

11:45 AM EN01.04.05
Enhancing Solar Energy Conversion Efficiency in Interfacial Evaporation Technology using Graphite Nanoflakes/Polydimethylsiloxane Composite Anh TuanNguyen, SumanChhetri and WoochulLee; University of Hawaii at Manoa, United States

Carbon-based materials such as graphite, graphene, and carbon nanotubes have been shown as a promising high-performance photothermal materials for the application in interfacial evaporation technology. In this study, we prepared a flexible graphite nanoflake (GnF)/polydimethylsiloxane (PDMS) composite with varying amounts of GnF from 1 to 10 wt%. It was found that the GnF/PDMS composite's photothermal property was optimized at 3 wt% of GnF, resulting in excellent total solar absorption of 94.8 %. As proof of concept, GnF/PDMS composite was coated on polyurethane (PU) foam to create a floatable interfacial water evaporator. Under 1 sun illumination, the coated PU with 1 wt% of GnF/PDMS composite yields an evaporate rate of 1.14 $Kg/m^{-2}h$ with solar-vapor conversion efficiency of ~68 %. With the promising photothermal effect, the GnF/PDMS composite can also be used in various solar-powered applications, including desalination and purification.

Graph-Theory-Guided Design of Self-Assembled Biomimetic Composites for Batteries and Supercapacitors NicholasA. Kotov[1,2]; [1]University of Michigan, United States; [2]Imperial College London, United Kingdom

Multifunctional, structurally versatile, and resource conscious materials represent the critical bottlenecks of nearly all modern technologies. These problems were being addressed using blueprints and inspiration from living tissues and organisms. However, their design is dominated by the empirical reproduction of simple organizational patters. The ever-increasing demands for materials performance, requires more complex structures and patterns.

This talk will show that, it is possible to transition from inexact approach of replicative nanocomposites to exact biomimetic material design using graph theory (GT). This change enables creation of multiscale architectures that are equal or more complex than original prototypes and display a combination of properties essential for lightweight energy sources critical for energy storage devices and other applications critical for sustainability.

The GT description of nanostructures developed for chiral nanoassemblies can be extended to nacre-like and cartilage-like nanocomposites, representing two large families of lightweight multifunctional nanocomposites used in energy devices. Stress, charge, and mass transport characteristics of materials from aramid nanofibers (ANFs) as well as other nanoscale fibers can be directly related to GT-based structural parameters. These findings enabled a new generation of Li- and Zn-based batteries for robotics and aviation.

In order to related the performance characteristics of the energy storage devices to the structure of complex biomimetic materials, a set of topometric parameters combining parameters from topological and physical space can be introduced, Specifically, high *nodal degree* and *volumetric nodal density* combined with low *Ohm centrality* and high *Freundlich nodal density* of networks from carbon nanotubes grown on top of carbonized aramid nanofibers engender composites with failure-resilient deformations, stress-adaptable charge transport, minimal dead volume, and high affinity to lithium polysulfides. The battery performance data demonstrate direct relation to the cyclic and capacity performance of Li-S batteries.

The latest work in this direction will include biomimetic composites for supercapacitors. These devices utilize self-assembled particles with virus-like spiky geometry that reveal topologically enhanced charge storage.

Recent Progress on V2O5 Based Electroactive Materials: Synthesis, Properties and Supercapacitor Application AdilAlshoaibi; King Faisal University, Saudi Arabia

The concerns of sustainable energy rely on highly efficient renewable energy sources and effective storage devices. Supercapacitor is practically reliable energy storage devices with rapid charging rate, high power density, simple setup, and good stability. Electrode materials have significant impacts o the performance of supercapacitors. Therefore, finding highperforming electroactive material is a critical concern of the area. Herein, the recent progress of vanadium pentoxidebased electroactive materials for supercapacitor application has been reviewed. Vanadium pentoxide is a potential electroactive material for supercapacitor due to its mixed oxidation states, eco-friendliness, low cost, high capacitance, and high energy density. But, poor conductivity and low cyclic stability are major drawbacks of the oxide which affect its electrochemical properties. This review points out different strategies of mitigating such limitations. Finally, future perspectives on V2O5-based electroactive materials for supercapacitor application have been highlighted.

2:15 PM EN01.05.03
Okra-Derived Hierarchical Porous Structured Activated Carbon Tuning with Metal-Oxide for Advanced Supercapacitors EktaMajhi and AtulS. Deshpande; Indian Institute of Technology Hyderabad, India

A hybrid supercapacitor is designed to fulfill the need for power and energy density by utilizing the composite of activated carbon and metal oxide. Naturally abundant bio-waste (Okra) has been explored to develop porous activated carbon for supercapacitors due to their easy availability, excellent specific surface area, a wide range of micro and mesopore structures giving extremely high performance, and a cost-effective synthesis approach. The bio-waste precursors have excellent microstructural properties, heteroatoms, and mineral content, which outline their subsequent effect on electrochemical performances. Moreover, the surface modification of carbon materials depending upon the pre-processing, carbonization, and etching by chemical activation method is explored, showing the impact on the capacitance. The electrode material is synthesized by freeze-drying biomass precursor followed by carbonization, acid treatment, and one-step activation. Its physicochemical properties are studied by characterization techniques like FESEM, EDS, XRD, Raman, TEM, BET, FTIR, XPS, and TGA analysis. Here, hierarchical honeycomb-structured porous activated carbons giving high surface area were synthesized from okra biowaste by the combination of chemical treatment and heat treatment at different temperatures, facilitating ion penetration and ion diffusion on the electrode-electrolytes interface, and the abundant macropores can serve as ion-buffering reservoirs. Transition metal oxide is synthesized by co-precipitation technique, having a unique characteristic. The electrochemical measurements CV, GCD, EIS, and cyclic stability tests are performed in an electrolyte solution using a carbon-metal oxide composite electrode, giving ultra-high specific capacitance and cyclic stability with high energy and power density. Here in this work carbon matrix is enriched with co-doped heteroatom facilitating the pseudo behavior with the enhancement of electrical conductivity and its hierarchical porous structure, providing easy accessibility to the electrolyte ions. The charge storage mechanism is explored in detail better to understand the dependence between physiochemical and electrochemical properties. Accordingly, we can tune the properties for individual applications. This work provides a facile, scalable synthesis route to get okra-derived activated carbon and transition metal oxide to achieve outstanding super-capacitive performance without compromising energy density.

2:30 PM EN01.05.04
Green Fabrication of Flexible Supercapacitors by using Silk Biomaterials XuelianLiu, NicholasOstrovsky-Snider, MarcoLo Presti, TaehoonKim, JeffRoshko and FiorenzoOmenetto; Tufts University, United States

Energy storage devices that are eco-friendly, high-performance, and flexible are needed for integration into wearables, smart sensors, and implantable medical devices. The raw materials used in such devices determine both their performance and ecological impact. Here, we describe the process of assembling supercapacitors using three distinct silk fibroin (SF)-based composite biomaterials and carbon electrode materials. Photo-crosslinkable SF (Sil-MA) hydrogel, SF-polydopamine (SF-PDA), and SF bioplastic have been used to create a gel electrolyte, electrode binder, and encapsulation respectively. Together, these elements form a mechanically and electrochemically robust skeleton for bio-friendly energy storage devices. Combined with carbon materials, symmetric supercapacitors were built with methods that minimize energy consumption and the device's carbon footprint. The devices can achieve capacitance over 200 mF cm^{-2} at a charge-discharge current of 10 mA cm^{-2} with 94% capacitance retention after 20000 cycles. Moreover, the devices can be stretched, bent, twisted and compressed with minimal influence on the electrochemical performance.[1]
The SF biomaterials and green fabrication methods developed can also be applied to other aqueous electrochemical energy storage systems such as zinc-ion hybrid supercapacitors. The tough SF hydrogel can provide additional benefits to zinc anode by protecting it from the formation of dendrites and corrosion by-products.[2] This strategy for the use of SF biomaterials may open a route for the development of eco-friendly energy storage devices that can be integrated into future wearable and biomedical systems.

Strong and Highly Ionic Conductive Ionogel for Wearable Solid State Supercapacitor HongliZhu, RuobingBai, YingWang and ZhengxuanWei; Northeastern University, United States

To follow the pace of the high-speed development of wearable electronic devices, the mechanical and electrochemical performances of the corresponding flexible and stretchable solid state energy storage devices need to be further improved. As a kind of solid polymer electrolyte for wearable energy storage devices, ionogel is a promising candidate exhibiting a broad stability window, exceptional mechanical performance, exceptional thermal stability, and low vapor pressure. Nevertheless, it is difficult to simultaneously enhance the mechanical and electrochemical performances of ionogel. In this work, we constructed an ionogel using polymerized poly (acrylic acid) and polyvinyl alcohol interpenetrating polymer networks as the host material and injecting 1-Ethyl-3-methylimidazolium dicyanamide ionic liquid as a filling solvent. Adequate contorted polymer chains and abundant reversible hydrogen bonds within the network aided in energy dissipation during tensile and compression, contributing to the exceptional mechanical properties. The improved electrochemical performances of ionogel result from the development of ion transfer kinetics. In particular, the subsequent ions impregnation and solvent exchange procedures modified the network structure and elevated the ion concentration in the ionogel. Concurrently, ionic liquid occupied in the networks rendered this ionogel with an outstanding stability of volume, mass, and ionic conductivity under conditions of low relative humidity. After

a series of treatments, this ionogel performed a remarkable strain of 2500 %, an exceptional ionic conductivity of 3.18 S/m at room temperature, and a virtually constant weight, volume, and ionic conductivity over about forty hours at a relative humidity of 20%. Sandwiching this ionogel electrolyte using electrospun polyacrylonitrile-based carbon fibers electrodes, a solid-state supercapacitor exhibited remarkable areal capacity, outstanding power density, and exceptional energy density. As a result, we synthesized a novel ionogel that breaks long-standing confinement while simultaneously exhibiting expected mechanical and electrochemical properties, thereby promoting the development of ubiquitous solid-state energy storage devices.

3:30 PM *EN01.05.06
Flexible/Stretchable Supercapacitors for Powering Integrated Sensors of Wearable Patch Devices Jeong SookHa; Korea University, Korea (the Republic of)

In accordance with the miniaturization of personal wearable electronics, there has been extensive effort to develop high performance flexible/stretchable energy storage devices for powering integrated active devices. Supercapacitors are expected to achieve this purpose owing to their simple structures, high power density, and cyclic stability. As integrated wearable powering devices, supercapacitors are required to have stability over mechanical deformation such as bending and stretching due to body movements in addition to high electrochemical performance. The application of flexible/stretchable supercapacitors can be expanded further through the introduction of additional novel functionalities.

In this talk, we will introduce our recent works on the fabrication of high performance flexible/stretchable supercapacitors and their application as integrated energy storage devices to power various sensors in stretchable patch devices. In particular, our design strategy to fabricate the stretchable array of supercapacitors using serpentine and liquid metal interconnections as well as the intrinsically stretchable supercapacitors will be discussed. Finally, we will demonstrate our currently developed flexible/stretchable supercapacitors with novel functionality of self-healing, temperature tolerance, biodegradability, shape memory, and electrochromic display for advanced wearable patch devices with high durability, environmental friendliness, and color-changing display.

4:00 PM EN01.05.07
Sustainable Approaches for 1D Supercapacitors and Triboelectric Devices based on Functionalized Carbon Fiber Yarns LuisPereira[1,2]; [1]FCT NOVA, Portugal; [2]AlmaScience, Portugal

Carbon fibers (CFs) are versatile materials for energy harvesting and storage applications, particularly when focusing on wearable device applications. They present a combination of some unique properties, such as suitable electrical conductivity and mechanical strength, being also lightweight.
Stretch-broken carbon fiber yarns (SBCFYs) can be used as current collectors to fabricate 1D fiber-shaped supercapacitors (FSCs) using regenerated cellulose-based electrolyte. The areal-specific capacitance reaches 433.02 μF cm^{-2} at 5 μA cm^{-2}. The maximum achieved specific power density is 0.5 mW cm^{-2}, at 1 mA cm^{-2}. The 1D FSCs possess a long-life cycle, 92% capacitance retention after 10000 charge/discharge cycles. The specific capacitance can be improved through functionalization of CFs with MoS_2 nanosheets, reaching 58.6 F g^{-1} at 1 mV s^{-1} with a power density of 15.17 W g^{-1} and energy density of 0.5 mWh g^{-1}.
Functionalization of CF by introducing functional groups or nanoparticles onto the fiber surface is also crucial in optimizing power conversion efficiency in energy harvesting devices, such as triboelectric ones. We propose triboelectric generator yarns (TEG yarns) with axially grown ZnO nanorods using a new method for depositing PDMS directly onto conductive carbon yarns. The in-situ PDMS curing method allows the fast formation of a uniformly thick coating over functionalized CFs. Single-electrode configuration TEG yarns were developed, and their electrical output was optimized by precisely adjusting the PDMS layer thickness and by changing the chemical and physical nature of the SBCFYs surface, reaching a power density of 74.1 μW cm^{-2}. We demonstrate that electrodeposited cellulose nanocrystals layers can replace ZnO nanorods in improving local polarization, which results in an increase of 100% of the TEGs electrical output to around 142.7 μW cm^{-2}.
Both SBCFYs supercapacitors and triboelectric devices can be hand-stitched onto fabrics showcasing the practicality and versatility of the prepared 1D CFs energy harvesting and storage devices to power the future generation of wearables electronics.

4:15 PM EN01.05.08
Hierarchical Nanostructure of Carbon Decorated Metal Organic Framework for Low Cost Aqueous Al-Ion Supercapacitors ShyamalShegokar, PujaDe and AmreeshChandra; Indian Institute of Technology Kharagpur, India

A novel strategy of incorporating conducting additive to enhance the performance of ZIF-67 based Al-ion supercapacitors is presented. The porous ZIF-67 and composites of ZIF-67 with different forms of carbon viz., rGO and CNS were synthesized by a simple co-precipitation method. Physiochemical characterizations like XRD, BET, FTIR, etc. were performed to confirm the successful synthesis of ZIF-67 and its composites. The electrochemical behaviour of the as-synthesized materials were studied using three electrode measurements. Amongst all the synthesized materials, composite of ZIF-67 with rGO performed best due to increased electrical conductivity and higher specific surface area. Further, electrolyte modification was carried out using 6mM KFCN as redox additive and all the synthesized composites were tested again. Here, the specific capacitance of ZIF-67_rGO composite enhanced to 346 Fg^{-1} at 1 A g^{-1} current density which was nearly two times the value exhibited by pristine ZIF-67. It also delivered good cycling stability with excellent coulombic efficiency of 89% and 95% after 1000 cycles, at 5 A g^{-1} current density, respectively.

Metal–Organic Framework Based Ultrafine-Fe1-xS-Nanoparticle-Confined Het-Erodimensional Anode and Hierarchical 3D Porous Carbon Cathode for Perfor-Mance Maximization of Sodium-Ion Hybrid Capacitors Jong HuiChoi and Dong WonKim; KAIST, Korea (the Republic of)

While being the most popular, lithium-based energy storage devices have issues of geological distribution and rarity in the earth's crust. Due to their abundance, sodium ion-based hybrid capacitors (SIHCs) are drawing significant attention as an alternative. However, the sluggish kinetics and low capacities of their anode and cathode need to be overcome. Here, we report a strategy to realize ultrahigh-performance SIHCs anode and cathode electrode materials derived from metal-organic frameworks (MOFs). Facile carbonization of MIL-100(Fe) precursor and subsequent sulfidation process generated ultrafine pyrrhotite nanoparticles in the carbon matrix. The embedded fine particles exhibited outstanding rate performance due to the reduced size effect. Moreover, heteroatom-rich cathode materials were synthesized via the pyrolysis of ZIF-8. The subsequent KOH activation maximized the surface area and constructed a porous structure to the cathode material. High capacity was achieved due to pseudocapacitance that was induced by abundant surface heteroatoms. As a result, the SIHC device that was composed of the as-synthesized anode and cathode materials exhibited ultrahigh energy density (>200 Wh/kg) and power density (>19,000 W/kg). This study suggests a novel design strategy for realizing high-performance SIHCs.

SESSION EN01.06: Poster Session: Material Approaches to Harvest, Store and Deliver Energy Across Unconventional Applications I

Flexible and Fast Chargeable Lithium-Ion Battery Based on Percolative Network-Based Electrospun Nickel Microfibers and Electrosprayed Nanotextured Anode Materials DaekyuChoi and Hong SeokJo; Sungkyunkwan University, Korea (the Republic of)

High-performance flexible energy-storage devices have great potential as power sources for portable and wearable electronics. The major obstacle for developing such next-generation flexible batteries is the absence of flexible electrodes that can simultaneously meet high stability, high energy-density, and fast charging features. In this study, we present a novel approach employing an electrospun nickel microfiber (NiMF)-based flexible current collector. Not only does the current collector developed here show high mechanical properties, high electrical conductivity, and lightweight design, but the percolative network thereof also enables high flexibility and fast-charging speed with high stability. For the anode coating material, the mixture of lithium titanium oxide (LTO), carbon nanotubes (CNTs), polyvinylpyrrolidone (PVP), and polyvinylidene fluoride (PVDF) with a mixing ratio of 85:5:1:9 was used. In particular, the use of the electrostatic spraying method herein enabled the manipulation of the coating-thickness, -uniformity, and -texturing of the anode material being deposited on the randomly-entangled individual NiMFs. In case of the NiMF-based LTO electrode, despite being coated with the same loading mass of active materials, its total weight was only 25 mg because of an extremely low weight of the NiMF current collector relative to its volume. On the other hand, the Ni foil-based LTO electrode had a total weight of 475 mg. This difference in weight enabled the NiMF-LTO electrode to achieve a significant energy-density increase of more than 20 times compared to the Ni foil-LTO electrode. The resistance of the NiMF-LTO electrode was measured to be 6.3 Ω, which was significantly lower than that of the Ni foil-LTO electrode, which was 261 Ω. In addition, the NiMF-LTO electrode showed a 1.5% change in resistance after 100 cycles of bending test, while

the Ni foil-LTO electrode yielded a large change of 10% with the formation of cracks. In the half-cell test, as increasing the current rate (C-rate) from 0.1 to 2 C and subsequently reducing to 1 C, the corresponding discharge capacity (C_{dis}) of the NiMF-LTO case decreased from 166 to 75 mAh/g, followed by a recovery to 145 mAh/g, showing a high retention rate of 99.5%. In contrast, the C_{dis} of the Ni foil-LTO case exhibited a significant decrease from 165 to 4.5 mAh/g and then recovered to 10.5 mAh/g, showing a lower retention rate of 37%. Moreover, the NiMF-LTO case demonstrated a high stability with a capacity decay rate of only 0.05% over 100 cycles at 1 C. This advancement was attributed to the low impedance possibly identified by the charge transfer and ion transfer resistances (R_{ct} and R_{it}). At 0.1 C, the R_{ct} of the NiMF-LTO electrode-based half-cell was measured to be 142 Ω, lower than that of the Ni foil-LTO case (297 Ω). This difference indicates that the percolative structure of the NiMF-LTO electrode facilitated the efficient transportation of lithium ions from the electrolyte to electrode. Furthermore, the R_{it}, corresponding to the concentration gradient of lithium ions within the electrode, was measured to be 100 mΩ for the NiMF-LTO case, while that measured from the Ni foil-LTO case was higher as 704 Ω. This also indicates that the high uniformity and texturing (or surface area) of the LTO layer electrosprayed on the NiMFs enhanced the ion diffusion rate within the electrode. The approach and materials employed here are expected to show great promise for developing next-generation flexible batteries with offering high and stable electrochemical and mechanical features.

The Power of Stress—A DFT Approach to Mitigate Fuel Cells Poisoning MohamedMahrous; The American University in Cairo, Egypt

Fuel cells are a promising alternative to traditional power sources due to their high efficiency and low environmental impact. However, the problem of carbon monoxide (CO) poisoning remains a significant challenge for fuel cell technology. In this study, we propose to use density functional theory (DFT) calculations to investigate the effects of stress on the electrodes to mitigate the adsorption of CO on its surface. We will employ DFT simulations to study the changes in the metal's electronic and structural properties under different stress and CO concentration levels. By analyzing the combined effects of stress and CO on the metal, we will identify optimal stress levels for mitigating CO poisoning and provide insights into the underlying mechanisms.

$FeMoO_4$ Nanoparticles as Functional Negative Electrode Material for High Performance Supercapacitor Devices over a Wide pH Range AyaM. Mohamed[1,2], HebaM. El Sharkawy[3,2], MohamedRamadan[2] and NagehK. Allam[2]; [1]Cairo University, Egypt; [2]The American University in Cairo, Egypt; [3]Egyptian Petroleum Research Institute, Egypt

Rational design of functional negative electrode materials with wide potential window, high capacitance, high rate capability, cost- effectiveness, and durability in various electrolytes is a grand challenge to realize the fabrication of high-performance supercapacitor devices. We report the successful synthesis of β-FeMoO4 nanoparticles and their utilization as a negative electrode in supercapacitor devices over a wide pH range. The morphology, elemental, and surface analysis of the fabricated β-$FeMoO_4$ are characterized via FESEM, EDS, and the N_2-adsorption/desorption techniques. Moreover, the elemental composition and the crystal structure of the fabricated $FeMoO_4$ are elucidated using XPS and XRD analyses. Upon analyzing its electrochemical performance as a supercapacitor electrode in 2 M KOH, the fabricated β-FeMoO4 reveals remarkable specific capacitance of 600 F g^{-1} at 1 A g^{-1}. The charge storage mechanism is elucidated in detail, revealing mixed surface capacitive-pseudocapacitive mechanism. Besides, the assembled asymmetric supercapacitor device utilizing Ni-Cu-P as the cathode (positive pole) and β-FeMoO4 as the anode (negative pole) displays superior specific energy and specific power of 40.75 Wh Kg^{-1} and 850 W kg^{-1}, respectively.

8:00 PM EN01.06.04
Optimized Fabrication of Bimetallic ZnCo Metal−Organic Framework at NiCo-Layered Double Hydroxides for Multiple Storage and Capability Synergy All-Solid-State Supercapacitors AyaM. Mohamed[1,2], DohaM. Sayed[1,2] and NagehK. Allam[2]; [1]Cairo University, Egypt; [2]The American University in Cairo, Egypt

Rational design and structural regulation of hybrid nanomaterials with superior electrochemical performance are crucial for developing sustainable energy storage platforms. Among these materials, NiCo-layered double hydroxides (NiCo-LDHs) demonstrate an exceptional charge storage capabilities owing to their tunable 2D lamellar structure, large interlayer spacing, and rich redox electrochemically active sites. However, NiCo-LDHs still suffer from sever agglomeration of their particles with limited charge transfer rates, resulting in an inadequate rate capability. In this study, bimetallic ZnCo-metal organic framework (MOF) tripods were grown on the surface of NiCo-LDH nanowires, which significantly reduced the self-agglomeration and stacking of the NiCo-LDH nanowire arrays, offering more accessible active sites for charge transfer and shortening the path for ion diffusion. The fabricated hybrid ZnCo-MOF@NiCo-LDH and its individual counterparts were tested as supercapacitor electrodes. The ZnCo-MOF@NiCo-LDH electrode demonstrated a remarkable specific capacitance of 1611 F/g at 2 A/g with an enhanced rate capability of 66% from 2 to 20 A/g. Moreover, an asymmetric all solid-state supercapacitor device was constructed using ZnCo-MOF@NiCo-LDH and palm tree derived activated carbon (P-AC) as positive and negative poles, respectively. The constructed device can store a high specific energy of 44.5 Wh/Kg and deliver a specific power of 876.7 W/Kg with outstanding Columbic efficiency over 10,000 charging/discharging cycles at 15 A/g.

8:00 PM EN01.06.05
Surface Facet Controlled Zinc Metal Anode for High Performance Aqueous Zinc Ion Energy Storage System HeeBinJeong[1], JohnHong[1], Dong IlKim[1], Hyeong SeopJeong[1] and SeungNamCha[2]; [1]Kookmin University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Several issues exist with the current organic electrolyte based electrochemical energy storage system, including the lack of metal resources, thermal expansion problems, and toxicity. In contrast, aqueous Zinc (Zn) ion batteries (AZIBs) have garnered substantial attention due to their abundance in resources and the cost-effectiveness and environmental friendliness of their electrode materials. Additionally, a water-based electrolyte solution can act as a successful block layer, thereby improving thermal stability. However, the use of a water medium can result in the formation of Zn dendrites on the Zn metal anode. The protruding structure of these dendrites can damage the separator and short-circuit the cell. Moreover, the generation of hydrogen and corrosion caused by parasitic surface reactions on the native passivation layers of Zn metal anodes pose significant problems, leading to decreased cycling stability of AZIBs. Therefore, the properties of the Zn metal surface should be well-tailored to address these issues. In this work, we proposed the use of a highly active acidic etching process on the Zn metal anode to increase the effective surface area and control the surface facet for favorable and smooth Zn deposition and stripping. Without any heat treatment, a mere 2-minute etching time can effectively create a closely spaced array within the etched grooves, resulting in a preferential (002) crystal plane orientation on the Zn metal anode. The high surface area can provide more active sites on the Zn metal anode. Moreover, the tailored (002) surface orientation can ensure the continuous deposition of planar zinc metal during the charge-discharge process, which can minimize the growth of protruding Zn dendrites. According to the suggested highly active acidic etching process, the electrochemical performance was greatly improved in terms of stability, specific capacity, and symmetric cell cyclability. Our results demonstrate that using acid-etched planar zinc foils as the anode can effectively increase the electroactive surface area, suppress hydrogen evolution reactions, and inhibit dendrite formation on the Zn metal anodes. As a result, the Zn anode symmetry cell showed long and stable cyclability for 250 hours at both current densities of 3 mA cm^{-2} and 1 mAh cm^{-2}. Moreover, in the full cell configuration with the α-MnO_2 cathode, the full cell displayed a long cycle life with a capacity retention of 73 % for up to 150 cycle at current density 0.5A/g. This acid etching process has a significant advantage of being short and simple in the experimental process compared to previously reported studies, thus providing new opportunities for stable and high-performance AZIBs.

8:00 PM EN01.06.06
High Performance Lithium-Sulfur Batteries by Ultrathin Mixed Ionically-Electrically Conductive Interlayer via Solution Shearing HyunminPark, DonghyeokSon and StevePark; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

In an endeavor to mitigate the low energy density associated with lithium-ion batteries, lithium-sulfur batteries (Li-S batteries) have emerged as a prominent area of research due to their considerably high theoretical capacity of 1675 mA h g^{-1}. The utilization of sulfur as a cathode material confers several advantages to Li-S batteries, including the non-toxicity and abundant availability of sulfur, which can be obtained as a byproduct of crude oil refining. Despite the considerable potential of Li-S batteries, their commercialization has been hindered by the shuttle phenomenon, primarily caused by soluble lithium polysulfide (LiPS) intermediates (Li_2S_x, $4 \leq x \leq 8$). Numerous efforts have been made to address this issue, including the utilization of sulfur host materials with diverse functions such as electrocatalysis, adsorption, and facile electron transfer. Nevertheless, these approaches do not provide a fundamental solution as they fail to prevent the dissolution of sulfur into the electrolyte in the form of polysulfides during repeated charging and discharging. Therefore, it is recommended to develop a functional separator or interlayer that can reactivate inactive sulfur and suppress the shuttle phenomenon. Particularly, the introduction of an interlayer that acts as an additional barrier to the diffusion of soluble LiPSs has been regarded as a more direct, efficient, and scalable strategy to alleviate the shuttle phenomenon compared to modifying the cathode. Nonetheless, unresolved concerns regarding existing interlayers necessitate additional scholarly exploration. Firstly, the utilization of transition metal compounds (e.g., metal oxides, sulfides) as interlayers, capable of chemically adsorbing soluble LiPSs without a conductive carbon-based material, results in low initial discharge capacity and inadequate utilization of sulfur due to low electrical conductivity. Secondly, the overall energy density is diminished due to insufficient thickness and weight of the interlayers. Lastly, Blade casting and vacuum filtration methods for interlayer production have limitations hindering uniformity and large-area thinness. Consequently, scalable approaches for fabricating ultrathin and homogeneous interlayers on a large scale are imperative for the practical application of interlayers in Li-S batteries. In this study, we have successfully developed a large-area (10 cm × 10 cm), ultrathin (750 nm), and lightweight (0.182 mg cm^{-2}) mixed ionic-electronic conducting CNP interlayer comprising carbon nanotubes (CNTs), Nafion, and poly(3,4-ethylenedioxythiophene):polystyrenesulfonate (PEDOT:PSS) with 1-ethyl-3-methylimidazolium tetracyanoborate ionic liquid counter-ion exchange via a scalable solution shearing technique. The CNP interlayer effectively suppresses the shuttle phenomenon through the synergistic segregation effect, facilitated by the ion-conductive Nafion that induces electrostatic repulsion towards negatively charged soluble polysulfides, as well as the supplementary adsorption effect towards soluble polysulfides exhibited by CNTs and PEDOT. Additionally, the CNP interlayer demonstrates high electrical conductivity through counter-ion exchange with

an ionic liquid, thereby enabling facile reactivation of inactive sulfur as a secondary current collector. Impressively, the lithium-sulfur pouch cell with the CNP interlayer achieves a high discharge capacity of 1029 mA h g^{-1} and exhibits stable cyclability over 20 cycles, even under lean electrolyte conditions (5 µl mg-1) and high areal sulfur loading (5.3 mg cm^{-2}). The scalable strategy to fabricate a shuttle-suppressing interlayer using solution shearing and counter-ion exchange guides future advancements in lithium-sulfur battery interlayers.

A Promising Approach Towards the Commercialization of Lithium Sulfur Batteries: Prelithiated Graphene MahmudTokur[1,2]; [1]Sakarya University, Turkey; [2]NESSTEC Energy & Surface Technologies A.S., Turkey

Lithium-sulfur (Li-S) batteries are a promising candidate technology for high-energy rechargeable batteries due to their advantages of abundant materials and inherently high energy [9]. However, the practical applications of Li-S batteries are challenged by several obstacles, including the low sulfur utilization and poor lifespan, which are partly attributed to the shuttle of lithium polysulfides and lithium dendrite growth during cycling [12]. The shuttling of polysulfide ions between the electrodes in a Li-S battery is a major technical issue triggering the self-discharge and limiting the cycle life. [11]. A stable lithium anode is essential for maintaining the good cycle stability of Li-S batteries in practical applications [13]. To address these lithium-related issues, various carbon materials, including graphite and graphene, have been investigated as suitable lithium hosts to use as anode materials for Li-S batteries [9]. Prelithiation is a crucial strategy to compensate for the lithium needs of the system when using lithium-free active materials, but most of the prelithiation reagents developed so far are highly reactive and sensitive to oxygen and moisture, making them difficult for practical battery application. In this study, prelithiated graphite and graphene-based anode materials are obtained by the galvanostatic charging method to improve the performance of Li-S batteries and compare the electrochemical properties, especially in terms of capacity retention and rate capability. According to the results, graphene showed better performance due to its high lithium storage capacity and fast lithium-ion diffusion rate. A pouch cell was assembled with prelithiated graphene anode showing an energy density of about 360 Wh kg^{-1} in the first cycle and protected its specific capacity of 60% after 100 cycles in a liquid-based Li-S battery.
Keywords: Lithium Sulfur Battery, Prelithiation, Graphene Anode

A New Strategy for Hexagonal Boron Nitride Coating on Zinc Metal Anode for High-Performance Zinc Ion Batteries Dong IlKim, HeeBinJeong and JohnHong; Kookmin University, Korea (the Republic of)

The high demand for new electrochemical storage systems with high energy densities and operational stability has driven recent studies on aqueous zinc-ion batteries (AZIBs). AZIBs, which consist of aqueous electrolytes and electrode materials, are promising alternatives to flammable organic batteries. However, further research efforts on Zn metal anodes are still required due to issues such as the formation of protruding Zn deposition morphology (Zn dendrites) and parasitic reactions, including hydrogen evolution reactions between the Zn metal anode and the water electrolyte. These issues can reduce the high-efficiency electrochemical cycling of AZIBs. Therefore, finding a proper protective layer for the Zn metal is crucial to reduce the direct nucleation sites of Zn dendrites, provide high mechanical strength to the Zn anode, and improve selectivity and uniformity at the electrode surface during the charge-discharge process.
Here, we present the first report on utilizing bulk hexagonal boron nitride (h-BN) layers as a promising coating for the Zn metal anode. The thin and uniform bulk h-BN coating reduces the nucleation radius of Zn dendrites, resulting in uniform Zn stripping and deposition. Furthermore, h-BN is a two-dimensional (2D) material with superior insulating properties, making it highly desirable. In particular, the h-BN layers can serve as effective energy barriers, preventing electron tunneling from the Zn metal to the electrolytes. This can minimize the parasitic surface reactions on the surface of the Zn metal anode.
In this study, we propose a practical coating method using commercial h-BN powders, which allows for uniform deposition on the Zn metal anode over a large area. Through the optimization of the coating process and h-BN layer thickness, the Zn/h-BN symmetry cells exhibited a reduced overpotential (29 mV) and extended lifespan (over 250 hours) at a current density of 1 mA cm^{-2} during the deposition and stripping processes. Additionally, a full cell configuration of Zn/h-BN//α-MnO2 was fabricated to demonstrate its electrochemical performance. The Zn/h-BN//α-MnO2 full cell displayed a high electrochemical performance of 345 mAh g^{-1} at a current density of 0.1 A g^{-1}, with long-term cyclability of 75.4% after over 500 cycles at a current density of 0.5 A g^{-1}. This simple and effective coating method utilizing h-BN materials represents a promising approach towards the commercialization of Zn-ion batteries.

8:00 PM EN01.06.09
High Performance Metal Halide Batteries Enabled by Electrolyte Optimization LiliangHuang, WenjunZhu and IvanSitu; Sidus Energy Limited, United States

As one of the most promising energy storage devices, the Li-ion battery has witnessed tremendous success and growth over recent decades.1 As society transitions into a carbon-neutral era,2 there becomes an urgent need for the development of novel cathode materials, whose cost and performance significantly impact the future widespread application of Li-ion batteries. The recent development of metal halide cathodes enables deviation from conventional intercalation chemistry and thus greatly expands the chemical space for high-performance cathodes.3-4 To date, lithium halide-based batteries with excellent energy density and rate performance have been developed, but cycling lifetime and self-discharge are still a challenge in their commercialization.3-6 Herein, we demonstrate that electrolyte optimization can serve as a promising strategy to address these issues. Specifically, we show that increasing the lithium salt concentration in ether-based electrolytes is beneficial for cycling and stationary stability through alleviating the detrimental side reactions introduced by the metallic lithium as well as the shuttling of lithium halides. Further incorporating fluorinated solvents into the electrolyte can increase not only the electrolyte ionic conductivity but also the columbic efficiency. Moreover, in contrast to the conventional notion that carbonate solvents are incompatible with Li metal anodes, we discover a unique synergy between certain carbonate and ether-based solvents, resulting in significantly improved battery performance. Finally, enabled by this improved electrolyte design, we have successfully prepared pouch cells with good cycling lifetime and higher energy density than commercial cells.

An Asymmetric Moisturizing 3D Foam with High Deformability for Complementary Energy Harvesting via Moisture-Induced Electric and Triboelectric Generator GwanhoKim and CheolminPark; Yonsei University, Korea (the Republic of)

Moisture-induced electric generators (MEGs) have emerged as promising candidates for next-generation energy conversion. However, existing MEG devices face limitations such as low current and voltage outputs, high moisture dependence, and lack of mechanical robustness. In this study, we introduce a novel 3D asymmetric moisturizing deformable MEG device that exhibits exceptional mechanical performance and simultaneously harnesses power from both MEG and triboelectric nanogenerator (TENG) effects. Our device combines an organo-ionic hydrogel infusion within the lower section of a 3D melamine foam substrate, coated with 2D conductive MXene ($Ti_3C_2T_x$) and hydrophilic poly(vinyl alcohol), resulting in superior water capturing and rapid ion transport capabilities. Notably, this device operates efficiently across a wide range of temperatures (-20 to 60 °C) and relative humidities (20 to 90% RH). Leveraging the negative surface charge of MXene, positive ions from salts and water in the organo-ionic hydrogel are preferentially selected, enabling continuous power generation with a maximum open-circuit voltage and short-circuit current density of 0.32 V and 877 µA cm^{-2}, respectively. Additionally, the upper layer of our device generates a high voltage (~80 V) through contact electrification with a perfluoroalkoxy alkane film over ~30,000 cycles. The integration of MEG and TENG components yields a high-power output (~83 µW cm^{-2}), showcasing the device's practical potential for emergency exit sign applications by leveraging the distinctive characteristics of MEG's direct current and TENG's alternating current.

High Voltage Generated by Moving Drops PravashBista[1], AaronRatschow[2], Hans-JürgenButt[1] and StefanA. Weber[1,3]; [1]Max Planck Institute for Polymer Research, Germany; [2]Technische Universität Darmstadt, Germany; [3]Universität Stuttgart, Germany

Water drops sliding on insulating, hydrophobic substrates can become electrically charged [1–3]. Despite many decades of research, this spontaneous electrification of moving drops is still far from being understood. By precisely measuring charge and voltage, we found that moving water drops accumulate a voltage of several kilovolts after sliding for just a few centimeters. To enable an efficient utilization of this simple electric energy generation mechanism, a detailed and quantitative understanding of the underlying physical process would be required. Using a simple electrostatic model, we show that the drop voltage is fundamentally connected to the properties of the electrostatic double layer at solid-liquid interfaces. The observation of high drop voltages will have important implications for energy harvesting applications, as well as droplet microfluidics and electrostatic discharge protection.

Ultra-Flexible Li-Ion Batteries using High Mass-Loading Polymer-Rich Thick Electrodes Nigussh. Hatsey[1,2], Hye-MiSo[1], AreumKim[1], MinsubOh[1] and SeungminHyun[1,2]; [1]Korea Institute of Machinery and Materials (KIMM), Korea (the Republic of); [2]University of Science and Technology (UST), Korea (the Republic of)

Flexible batteries have been the research of interest due to various applications of Internet of things (IoT), soft robots and wearable electronics. For the development of advanced electronics, flexible batteries with high energy density and mechanical stability are essential. However, conventional electrodes are limited to achieve both flexibility and high energy density of batteries. In this work, we developed novel electrode structure to fabricate ultra-flexible Li-ion battery with high energy density. This novel electrode structure was fabricated through reinforcing thermally induced polymer-rich electrode by stainless-steel (SS) fiber current collector. The polymer-rich electrode made through thermally induced phase separation (TIPS) process was suggested for flexible thick electrode. The SS fiber current collector was prepared by a facile method from a bundle. The combination of the polymer-rich electrode and SS fiber current collector enabled structural flexibility and mechanical stability. The electrochemical property and mechanical properties of the battery with the novel electrode were analyzed by comparing with battery of polymer-rich electrode coated on conventional metal foil current collector. The battery with LiNiMnCoO2 thick-film electrodes with SS fiber electrodes showed high rate capability. At 2C rate, the specific capacity of foil electrode is 60 mAh g^{-1} and that of the SS fiber electrode is 135 $mAhg^{-1}$, which is two times higher. Moreover, up to 12 $mAhcm^{-2}$ high areal capacity is attained using about 1 mm thick electrode with SS current collector. Electrochemical performance of high mass-loading pouch-type battery after 2000 bending cycles also showed very high retention of specific capacity. The structural flexibility and mechanical reliability of the novel electrode structure enables to make flexible batteries with high energy density.

8:00 PM EN01.06.13
Sulfur Cathode Integrating Nanoscale Carbon-Layered Mesoporous Silica Particles for Prolonged Cycle Life of Lithium-Sulfur Batteries Sun HyuKim, Ji YangLim, Si WonChoi, SandeulRyoo, Hye RanKim and YongjuJung; Korea University of Technology and Education, Korea (the Republic of)

Lithium-sulfur (Li-S) batteries have garnered significant attention as a promising energy storage system owing to the high energy density and high natural abundance of sulfur. Nonetheless, their practical application has been slowed down by limited cycle life attributed to soluble polysulfide species generated on discharge. The migration of these dissolved polysulfide ions towards the lithium anode gives rise to the formation of inert materials on its surface. The solubility of polysulfides is necessary for the discharge-charge process of the sulfur cathode, so it is inevitable to effectively confine them within the cathode to protect the diffusion phenomena of polysulfide out of cathode. Several approaches have been proposed, such as the utilization of sulfur-infiltrated carbon nanotube (CNT) films. However, the macro-porous structure of CNTs limits their ability to effectively accumulate polysulfides. Another strategy involves incorporating ordered mesoporous silica (OMS) as an additive to mitigate the diffusion of polysulfides, yet OMS lacks long-term stability as a polysulfide reservoir. To address these limitations, this study introduces a novel solution for effectively immobilizing polysulfides. It entails the synthesis of carbon-layered OMS (c-OMS) through surface-selective polymerization inside silica mesopores, followed by carbonization. Comparing the performance of the sulfur-CNT cathode with c-OMS to that of the sulfur-CNT cathode alone, the former demonstrates a significantly enhanced capacity (942 mAh/g) and superior cycle stability (91% retention after 100 cycles). These outcomes underscore the advantageous surface properties of c-OMS, which exhibit a high chemical affinity for electrolyte solvents. This research presents a promising approach for enhancing the performance of Li-S batteries by effectively addressing issues related to polysulfide dissolution and confinement.

8:00 PM EN01.06.14
A Nonconductive Mesoporous Carbonaceous Material as a New Sulfur Host for Low-Cost and Viable Lithium–Sulfur Batteries Si WonChoi, Hye RanKim, Ji YangLim, Sun HyuKim, Je YeonKim and YongjuJung; Korea University of Technology and Education, Korea (the Republic of)

Li-S batteries have gained significant attention in recent years due to their high theoretical energy density, cost-effectiveness, and the abundant availability of sulfur active material. However, the practical implementation of Li-S batteries faces various challenges that need to be overcome. Many researchers believed that one of the prominent obstacles lies in the low electrical conductivity of sulfur, which hampers the overall performance of the batteries. From this perspective, a range of methodologies aimed at enhancing the electrical conductivity of sulfur electrodes have been scrutinized.
Incorporating sulfur int conductive matrix has been regarded as a commonly employed approach to improve electrical conductivity. Extensive research has been conducted on the utilization of porous conductive materials such as carbon nanotubes, graphene, carbon black, as well as conducting polymers. These materials have been found to facilitate efficient electron transport within the sulfur cathode, resulting in improved rate capability and cycling stability.
Contrary to prevailing trends, a recent study has presented a novel approach using nonconductive ordered mesoporous silica (pOMS) as a host material. This study focuses on the unique sulfur reaction mechanism, where molecular sulfur is converted to polysulfides through a charge transfer process at the solid-solution interface during discharge. The study demonstrates outstanding long-term cycle stability and high capacity retention, challenging the conventional notion that conductive materials are essential for improving battery performance. This utilization of a nonconductive inorganic host, instead of conductive frameworks like porous carbons, represents a significant departure from current research trends in the Li-S battery community. However, the fabrication process of pOMS is known to be complex and cumbersome, limiting its widespread implementation.
To address this issue, we propose using a nonconductive mesoporous carbonaceous material as a sulfur host. Typically, this material is fabricated at temperatures below 500 °C through a pyrolysis process of organic polymers under inert gas flow conditions. The resulting materials treated at low temperatures possess abundant polar functional groups on their surface, which can interact with polysulfides. The sulfur cathode with nonconductive carbons exhibits remarkable improvements in reversible capacity and cycling properties.

Innovative Li-S Batteries Comprising a Sulfur-Free Carbon Electrode and a Separator with Elemental Sulfur Ji YangLim, Hyun WooKim, Si WonChoi, Sun HyuKim, SandeulRyoo and YongjuJung; Korea University of Technology and Education, Korea (the Republic of)

Lithium sulfur (Li-S) batteries have emerged as a promising next-generation rechargeable battery owing to the potential advantages of sulfur, a cathode active material, such as high theoretical capacity, low-cost and high natural abundancy. However, Li-S batteries suffer from various performance problems which should be tacked for mass production, including capacity degradation during cycling due to the diffusion of polysulfides, poor rate capability associated with intrinsic chemical reactions between polysulfides, and high self-discharge property. To address these issues, the carbon-sulfur (C-S) composites concept has been presented in which active sulfur materials are embedded in the pore structure of carbon frameworks. The C-S composites have proved to be highly beneficial for mitigating polysulfide diffusion out of cathode, resulting in substantial performance improvements. However, it has been revealed that (1) the increased performance of the C-S composites stems from their high capability to confine active materials within the porous structure of carbon hosts; (2) the intimate contact between carbon and sulfur is not essential for functioning a sulfur cathode. It has been found from intensive studies that sulfur particles participate in discharge process via solution electrochemistry: a small amount of solid sulfur is dissolved in the electrolyte through chemical equilibria between solid sulfur and dissolved sulfur, and sulfur molecules in the solution are electrochemically reduced to polysulfides at the interface of carbon and an electrolyte solution upon discharge. Based on this finding, we present an innovative Li-S battery comprising a sulfur-free carbon cathode and a microscale sulfur-layered separator or a sulfur-incorporated separator. Notably, these cells normally function and demonstrate excellent performances in terms of reversible capacity, rate capacity, and cycling stability. as all sulfur materials on the separator are consumed. We believe that this approach offers a new paradigm for a rational design of high-performance Li-S batteries and could be widely applied for enhancing the energy density of Li-S batteries.

8:00 PM EN01.06.16
Zeolitic Imidazolate Framework -8–Based Passive Daytime Radiative Cooling Paint for Energy-Efficient Cooling HangyuLim, JaeinPark, DongwooChae, JisungHa and HeonLee; Korea Uiversity, Korea (the Republic of)

Owing to increasing energy consumption, especially for cooling, as well as climate change and the emergence of new industries, there is a growing demand for new cooling technologies to replace the existing systems that consume a large amount of energy and contribute to environmental pollution. To overcome these problems, radiative cooling can be utilized, which uses the optical properties of materials to achieve cooling without emitting pollutants or consuming energy. Paint is the most practical form for the application of a radiative cooling material. Therefore, we fabricated a passive daytime radiative cooling (PDRC) paint using a polyurethane binder and zeolitic imidazolate framework (ZIF)-8 powder. The ZIF-8 powder was synthesized in an environmentally friendly manner using deionized water as the solvent, and the resulting paint had a reflectance of 94.9%, an emissivity of 94%, and a cooling power of 113

W/m2. Actual temperature measurement results showed that the paint cooled the surroundings by an average of 5.7 °C and up to 8.1 °C during the daytime. As a result, ZIF-8–based PDRC paint is capable of cooling below room temperature and is expected to reduce the energy used for cooling and alleviate environmental pollution in various fields, such as building exteriors.

Photocatalytic Reductive C–C Coupling Driven by Light-Induced Electron Transfer/Phase Migration of a Redox Mediator in a Biphasic Solution RenItagaki[1,2], AkinobuNakada[1,3], HajimeSuzuki[1], OsamuTomita[1], Ho-CholChang[4] and RyuAbe[1]; [1]Kyoto University, Japan; [2]JSPS Reserch Fellow DC1, Japan; [3]PRESTO/JST, Japan; [4]Chuo University, Japan

Natural photosynthesis establishes highly efficient molecular-conversion reactions driven by solar light energy, based on the combination of ingenious parts, such as light capturing, charge separation and migration, and catalysis in the reaction center. In addition to extensive studies on artificial photosynthetic systems mimicking the natural system, photoredox catalysis has recently had great impact on the field of photochemical organic synthesis. In any case, photoinduced electron transfer from/to electron donor(s)/acceptor(s) is a key initial step. One of the most important issues in the construction of highly efficient artificial photocatalytic systems is to suppress undesired backward electron transfer that decreases total efficiency. Herein, we developed a new photocatalytic system using biphasic solution media to mitigate such backward charge recombination. Two-immiscible solution composed of water and 1,2-dichloroethane (DCE) was employed with ferrocenium/ferrocene (Fc^+/Fc) electron mediator. The change in dissolubility of Fc^+/Fc (hydrophilic/hydrophobic) by photocatalytic electron transfer is expected to play an important role for the spatial charge separation to suppress the backward electron transfer. We demonstrated photocatalytic reductive coupling of benzyl bromide by utilizing the photoinduced inter-liquid phase migration of Fc^+/Fc; suppressing the undesired backward charge recombination significantly.
Visible-light irradiation to a biphasic solution that composed of water and DCE solution containing an Ir(III)-photosensitizer, Fc, and benzyl bromide (Bn-Br) facilitated the reductive coupling of Bn-Br to dibenzyl (Bn_2). Given the energy diagrams of the photosensitizer and Fc, the Fc should act as an electron donor for the photoexcited Ir(III)-photosensitizer. The reduced Ir(III) complex has an enough potential for one-electron reduction of benzyl bromide forming Bn_2. Importantly, Fc^+, generated by photooxidation, migrates to the aqueous phase due to the drastic change in its partition coefficient compared to that of Fc. On the other hand, visible-light irradiation to the same solution without water phase did not give any product. This finding indicates that the phase migration of Fc^+ across a biphasic solution suppresses the unfavorable backward charge recombination, which enables the photoreduction of Bn-Br. The results on the coupled phase migration/photoinduced electron transfer prompted us to further investigate design principles in order to improve the efficiency of this photocatalytic reaction. The co-existence of anions can further modify the driving force of phase migration of Fc^+ depending on their hydrophilicity; the best photocatalytic activity was obtained with 99% yield after continuous photocatalysis for 90 min in the presence of $NBu_4^+Br^-$ compared to 25% one without additive. Thus, the liquid-liquid phase migration of the mediator results in effective charge separation, which leads to facilitate the reduction of Bn-Br in the DCE phase.

Boosting Energy-Harvesting Performance of PVDF Nanofiber-Based Piezocomposite using Metal-Free Organohalide Crystals KiyongKim, HoiminKim and Joo-HongLee; Sungkyunkwan University, Korea (the Republic of)

Polyvinylidene fluoride (PVDF) has been widely studied in the field of self-powered active implantable medical devices (AIMDs). Because it has decent piezoelectricity, which is required for sensing various body signals, biocompatibility, and mechanical flexibility. To enhance the polar β-phase of PVDF, which is associated with its piezoelectric behavior, the incorporation of inorganic piezoceramics into PVDF has been a commonly considered approach. The physicochemical interfacial interaction between PVDF and these piezoceramics enables the non-polar α-phase of PVDF to be transitioned to the polar β-phase, resulting in the improved piezoelectric response with a high piezoelectric coefficient (d_{33}). In recent studies, although metal-based piezoceramics, such as lead zirconate titanate (PZT), barium titanate (BTO), and lead magnesium niobate (PMN), have been effective in enhancing the piezoelectric properties of the resulting PVDF-based piezocomposite, they showed limits in terms of mechanical flexibility, biocompatibility, and cytotoxicity, which are important for developing industrially viable AIMDs. In this study, we develop an ultra-thin and flexible piezocomposite by incorporating the metal-free organohalide crystals into the PVDF matrix using the electrospinning process. The electrohydrodynamic spinning process facilitates the interfacial attraction between the polymer chain and the organohalide crystals, which promotes the alignment of the β-phase of PVDF. Herein, 1,4-diazabicyclo[2.2.2]octane (DABCO)-NH_4I_3, which is the metal-free organohalide crystals having ABX_3 molecular structure with hexagonal crystal system and consists of one-dimensional chains of face-sharing $(NH_4)X_6$ octahedra separated by organic cations, was used. Compared to the bare PVDF electrospun nanofibers, DABCO-NH_4I_3-incorporated PVDF electrospun nanofiber exhibits a significantly improved piezoelectric response with showing a high d_{33} value of 202 pC/N. The enhanced β-phase of the PVDF nanofibers was examined using the grazing-incidence wide-angle X-ray scattering (GIWAXS) technique. Its high biocompatibility was also demonstrated by the cell viability test using fibroblast cells. The piezoelectric nanogenerator (PENG) fabricated using the piezoelectricity-enhanced nanofibers yields an outstanding energy-harvesting performance with a maximum output voltage of ~ 80 V, which is 10-fold higher than that observed from the bare PVDF nanofiber-based PENG. Since the DABCO-NH_4I_3-incorporated PVDF nanofibers developed here not only have high biocompatibility and flexibility but also show enhanced piezoelectric behaviors, it is expected to show great potential in the field of self-powered AIMDs.

8:00 PM EN01.06.19

Highly Efficient, Flexible and Self-Healable Moisture-Driven Energy Harvester based on 2D Vanadium Pentoxide Nanosheets KundanSaha and SameerSonkusale; Tufts University, United States

The ubiquitous source of atmospheric moisture brought about a fascinating research avenue of extracting atmospheric water to generate sustainable electricity. Energy may be extracted from ambient moisture with obvious and substantial advantages. This point-of-use technology provides a decentralized alternative to meet the energy needs in isolated off-grid places. Unlike traditional energy generators which predominantly rely upon fossil fuel, moisture-induced energy generators can extract energy from moisture in a sustainable and eco-friendly way. Herein, we demonstrated a self-healable moist electric generator (MEG) based on vanadium pentoxide (V_2O_5) 2D nanosheet membranes. Lamellar membranes of V_2O_5 nanosheets have been shown to be excellent cation conductors and excellent materials for harvesting energy from ambient moisture. Ultra-thin 2D nanosheets of V_2O_5 was obtained by treatment of bulk V_2O_5 crystals with hydrogen peroxide. V_2O_5 nanosheet membrane was fabricated by vacuum-assisted filtration of 2D V_2O_5 nanosheets dispersion over a PTFE support membrane. The V_2O_5 membrane was easily peeled off from the support membrane on drying to obtain a flexible and freestanding V_2O_5 membrane. The V_2O_5 membrane consisting of percolated nanofluidic channels was sandwiched between a bottom solid copper foil and a perforated copper foil as the bottom electrode. The top electrode is perforated for exposure to atmospheric humidity. As the atmospheric water molecules come in contact with the V_2O_5 surface, an open-circuit voltage of 0.5 Volts and a short-circuit current of 0.3 microamperes is generated. The generated voltage and current is attributed to the preferential flow of cations through the V_2O_5 nanochannels. The exposed surface and edges of V_2O_5 nanosheets have a high negative surface charge which results in the splitting of water molecules into H_3O^+ and OH^- ions. An electrical double layer (EDL) is established at the V_2O_5/water interface which selectively permits H_3O^+ ions through the channels. The mobile ions of the EDL transport through the nanofluidic channels creating a gradient between the two electrodes, resulting in a constant potential difference between the top and bottom electrodes which is harvested as electric current. The MEGs can be easily connected in parallel or series to enhance the current and voltage respectively. We demonstrate ten MEGs connected in series to power small electronic devices such as calculators and humidity meters. One of the key features of the V_2O_5 MEG is its ability to repair any physical damage to the active material owing to the water-assisted healing characteristics V_2O_5 membrane.

Flexible Energy-Dense Li-Ion Batteries based on Super-Lightweight and Highly Flexible Metal-Coated Fabrics WanchengYu, JianShang, LeiWang and ZijianZheng; The Hong Kong Polytechnic University, China

Flexible Li-ion batteries (FLIBs) are in urgent demand but the balance of flexibility and energy density of the battery is a great challenge. Hundreds of works reported flexible Li batteries fabricated by special structure design or soft materials. However, getting flexibility always leads to lower energy density because of the introduction of inactive weight or volume. Hence, we proposed a new type of flexible, super-lightweight, and three-dimensional current collector, metal-coated fabrics (MCFs). They can be employed in large-scale fabrication and roll-to-roll production. By replacing the Cu foil with Cu-coated fabrics (CuCF), the energy density is increased by 10%. MCFs also show advantages on the flexible applications. For the MCF-based pouch cell, after 1,000 bending cycles at the bending radii of 5 mm and 2 mm, the capacity retention is higher than 90%. The fb_{FOM} of the LIB made with MGFs reaches over 50, outperforming industrial flexible LIB and most reported flexible LIB made with soft current collectors. Since MCFs are prepared with cost-effective materials and a highly scalable process, they are promising, from a commercial viability point of view, to replace metal foils as current collectors in a wide variety of energy storage industries.

Energy Harvesting with Fiber based Triboelectric Laminates for Wearable Devices ArtisLinarts, LinardsLapčinskis, KasparsMalnieks and AndrisSutka; Riga Technical University, Latvia

Triboelectric nanogenerators (TENG) are intriguing energy harvesting devices that convert mechanical energy into electricity and could power small portable devices or charge batteries [1]. Herein, we develop a broad and scalable approach to introduce volumetric dipoles into TENGs and break the surface charge paradigm by generating layer-by-layer triboelectric laminate structures from sequential electrospinning of large and small polymer fibers. When large fibers are electrospun onto smaller fibers, the interface between the laminate layers will slip, leading to internal contact electrification. In contrast, when small fibers are electrospun onto large fibers, they form an interpenetrated network with tight binding, creating a nonslip interface. This combination of ordered interfaces leads to parallel dipole moments being formed within the bulk volume of the laminate leading to an effective macroscopic dipole being formed. Increasing the total number of layers within a laminate, of the same total volume, leads to a linear relationship between charge and layer number. Most importantly we demonstrate that this concept not only works for laminates made of 2 different polymers but from identical polymer as well. We also show that exploiting triboelectric laminates in TENG devices can enhance their current

output by 40 times. We believe that this concept will be widely used in the future for designing wearable devices with low power demand.

Engineering Polymer Interfaces Toward Controlling Triboelectric Surface Charge for Wearable Systems KasparsMalnieks, AndrisSutka, ArtisLinarts and LinardsLapčinskis; Riga Technical University, Latvia

Developing pathways and materials that efficiently convert ambient energy from the environment into electricity is critical to powering distributed sensing networks, wearable and implantable electronics, and other Internet of Things (IoT) devices.[1] Mechanical and kinetic motions exist everywhere in our society, from human movement, blood flow, railway vibrations, car vibrations, rain fall bicycle motion, geological activity, or even simply water flowing through pipes. This abundance of motion has led to an explosion of research in small–scale mechanical energy harvesters.The goal of these mechanical energy harvesting technologies is to extract electrical energy from an otherwise stable material and convert it into useable electricity. Adding functionality where a certain material can also harvest heat and/or light can also boost energy generation and reduce energy loss.[2] Generally, such harvesting is practical to autonomously power low-energy devices (μW–mW).
Triboelectric energy harvesting devices, or so called triboelectric nanogenerators (TENG), have recently gained momentum for mechanical energy harvesting to power autonomous microdevices and portable electronics. Polymer-based TENGs can be easily fabricated from cheap, lightweight, flexible, and abundantly available materials. In comparison to piezoelectric, ferroelectret, and piezoelectrochemical principles, TENGs do not require costly materials or processes to enable energy harvesting, although significant developments are overcoming some difficulties in some piezoelectric polymer systems.
In our research within the field of TENG, we have explored the intricate nature of triboelectric charging in polymers and elucidated various strategies for enhancing the performance of TENGs. Our investigations into triboelectric surface charge engineering have encompassed a range of material factors operating at the nanoscale. Key factors we have examined include:
Triboelectrification Mechanisms: We have delved into the mechanisms underlying triboelectrification, which encompass mass transfer, ion transfer, and electron transfer processes.
Effect of Surface Roughness: Our studies have investigated how surface roughness influences charge generation, shedding light on its crucial role in TENG performance.Temperature Influence: We have explored the impact of temperature on charge generation, providing valuable insights into optimizing TENG operation under varying environmental conditions. Influence of Fillers: Our research has examined how the presence of fillers within polymers affects charge generation, uncovering strategies to enhance TENG efficiency.
Adhesion and Surface Properties: We have analyzed the interplay of adhesion and surface properties in charge generation, emphasizing their significance in TENG design. Polymer Chemistry and Bond Energy: Our investigations have considered the role of polymer chemistry and bond energy in triboelectric charging processes, offering a comprehensive view of material design.Collectively, these multifaceted aspects have culminated in the development of a flexible wearable triboelectric nanogenerator capable of achieving remarkable results, including a peak power output of 24 mW m^{-2} and energy generation of 4.5 mJ. This underscores the potential for harnessing TENG technology in wearable applications and beyond.

Redox-Targeting Approach with Hard Carbon and Biphenyl Semi-Liquid Electrode for Enhancing Energy Density in Seawater Batteries DowanKim and YoungsikKim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Renewable energy sources such as solar, wind, and wave power are growing in importance due to concerns about fossil fuels and climate change. To make these sources reliable, energy storage systems (ESSs) are essential. Among ESS designs, Seawater Batteries (SWB) stand out as the next generation of large-scale ESSs, utilizing the abundant Na+ ions in seawater and an open cathode design for high theoretical energy density. SWB requires specific anode materials and liquid electrolytes due to the presence of a solid electrolyte (NASICON) that separates the anode and cathode. Unlike traditional batteries, SWB's liquid electrolyte requires a narrow electrochemical stability window only for the anode, allowing electronic conductivity without the risk of short circuits. Previous studies have used Na metal, solid anodes, and liquid anode materials in SWB. While sodium metal can provide high volumetric energy density, it suffers from limited cycle life. Solid-state anodes face electrode stacking challenges that limit energy density improvements. Liquid anodes such as sodium-biphenyl fill the cell efficiently, but offer lower volumetric energy density. Nevertheless, the use of a liquid anode with high cyclability made it possible to realize the most reliable seawater battery and it became the most widely used. To address the energy density challenge, a concept called "Redox-targeting" from redox flow battery systems has been applied to SWB. This approach incorporates semi-liquid active materials in a powder state and redox-mediated electrolytes in a liquid state, forming a semi-liquid electrode (SLE) configuration. Sodium-biphenyl (Na-BP), with ionic and electronic conductivity, and hard carbon (HC) were used as active materials for the HCBP SLE electrode. For Na-BP and HC, the overlapping response voltage bands were confirmed by the dQ/dV plot to confirm the amount of available capacity. After confirming the reaction mechanism of the HC used by the galvanostatic intermittent titration (GITT) method, it was found that the intercalation reaction could be involved, which could be confirmed by ex-situ TEM images. The electrochemical properties were then evaluated in a seawater half-cell system using sodium ferrocyanide as the cathode material and were confirmed to be 11.1 mAh cm^{-2} for over 500 cycles (5000 hours). Using this approach, successful mass production of HCBP SLE and its application in seawater batteries has achieved, indicating the potential for industrial utilization.

8:00 PM EN01.06.24
Additive Manufacturing of Bearing Inspired TENGs for Integrated Energy Storage MurathanCugunlular, OnurDemircioglu, MelihO. Cicek, DogaDoganay, Mete BatuhanDurukan and HusnuE. Unalan; Middle East Technical University, Turkey

With the recent advancement in soft, flexible, and wearable devices, the need for innovative energy sources increases rapidly to overcome the energy needs for such devices. The capabilities of conventional energy storage devices may be insufficient to meet the energy needs of these devices. The solution to this problem may be to improve the performance of storage devices or their integration with energy harvesters. These harvesters include photovoltaics, piezoelectric, electromagnetic, and triboelectric nanogenerators (TENGs). Among these devices TENGs stand out with their unique features such as adaptability, simple-structure, high power density and integrability to modern devices. However, there are some problems that hinder the widespread applicability of TENGs. One of these problems is the breakdown voltage of the air, which acts as a barrier to obtain high power density. Recent studies suggests that the use of lubricants can increase this breakdown voltage while providing polarization between electrodes to improve their performance. In this work, an innovative, bearing inspired TENG (Bi-TENG) design was explored using polylactic acid (PLA) fused deposition modeling. The effect of lubricant and rotation speed on the performance of Bi-TENG was investigated. A peak power of 20 μW was obtained from the fabricated Bi-TENGs and the addition of lubricant was found to increase power by 110% compared to non-lubricated Bi-TENG. The fabricated TENG was also used to charge energy storage devices to demonstrate its use in wearable applications.

SESSION EN01.07: Stretchable Batteries—Fabrication and Mechanical Challenges
Session Chairs: Mihai Duduta and Carmel Majidi
Wednesday Morning, November29, 2023
Hynes, Level 2, Room 200

8:15 AM *EN01.07.01
Design and Fabrication of Stretchable and Transparent Rechargeable Batteries MarkusNiederberger; ETH Zurich, Switzerland

The main task of a battery is to store energy and supply power to electronic devices. Although the areas of application for batteries have expanded massively in recent years - from portable devices to e-mobility and stationary storage options - the basic structure of the battery has hardly changed: It consists of two electrodes with electrolyte and separator, which are housed in a more or less rigid casing. Compared to batteries, portable electronic devices are constantly changing their design, depending on fashion and consumer tastes, but also with the intention of implementing new mechanical properties that make the devices flexible, rollable, stretchable or perhaps even transparent. For fully integrated systems that contain the battery and thus do not require wiring to an external power source, the batteries must have similar physical properties, which requires a complete rethink of battery design, but also allows for certain trade-offs in electrochemical performance [1].
In this talk, examples of the design and fabrication of a stretchable lithium-ion battery [2] and a transparent and stretchable zinc-ion battery [3] will be presented and discussed. In the Li-ion battery, all components (current collector, anode and cathode, electrolyte and packaging) were stretchable, making the battery flexible and twistable. The current collector was fabricated by depositing Ag microflakes as a conductive layer on a stretchable carbon-polymer composite. Anode (pre-lithiated V_2O_5) and cathode ($LiMn_2O_4$) powders were sprayed onto the silver flakes. A polyacrylamide 'water-in-salt' hydrogel was used as the electrolyte, which exhibited high ionic conductivity and excellent stretchability. The full cell battery worked even at a high strain of

50%. The second example concerns a transparent and stretchable Zn-ion battery with two electrodes featuring a hexagonal grid structure deposited on a polydimethylsiloxane (PDMS) substrate with a polyacrylamide (PAM) hydrogel electrolyte. In both electrodes, Au nanowires (NWs) were used as current collectors together with Zn for the anode and α-MnO_2 for the cathode. For the full cell battery, the PAM hydrogel was sandwiched between aligned films of PDMS+Au NWs/Zn and PDMS+Au NWs/α-MnO_2, showing a high transmittance of 73% and 65% at 550 nm without and with 50% strain, respectively. The battery provided a capacity of 176.5 mA h g^{-1} after 120 cycles under varying strain conditions up to 50%.

8:45 AM EN01.07.02
Mechanical Failure Modes and Effect on Electrochemical Performance for Conventional $LiCoO_2$ Electrodes for Flexible Li-Ion Batteries KyungbaeKim, RobertoMartinez and CandaceK. Chan; Arizona State University, United States

As the demand for flexible electronic devices like wearables and foldable gadgets increases, it becomes necessary to develop appropriate components such as flexible batteries. While there has been progress in flexing entire battery cells during electrochemical cycling, further research is needed to understand how mechanical failure affects individual battery components, especially the electrodes, after flexing. In this study, we intend to highlight how characteristics of various lithium cobalt oxide (LCO) electrodes, such as particle size and mass loading differences, impact mechanical failure during flexing. This will entail an analysis of bending diameters corresponding to curvature angles and flexing duration, as well as studying the electrochemical performance of the electrodes after repeated bending (up to 3000 times) at diameters of 100, 50, and 25 mm. The mechanical strength (cohesion and adhesion properties) of the bent electrodes was evaluated through peel and scratch tests after undergoing flexing under different bending conditions. Optical and scanning electron microscopy were used to observe the mechanical failures on the surface and cross-section of the peeled and scratched electrodes after bending. The findings reveal that using a smaller LCO particle size can improve the durability of flexible electrodes, while high mass loadings cause formation of distinctive pore distribution with microcracks that propagate across the cross-sectional microstructure. Additionally, certain electrode microstructures can allow for mitigation of the deleterious effect of bending on the discharge capacity obtained at different C-rates.

9:00 AM EN01.07.03
Spiral Ribbon Inspired Coaxial Fiber Li-Ion Battery ThierryDjenizian; Ecole des Mines Saint-Etienne, France

The challenging needs of energy storage at millimeter scales for wearable technologies and IoT grow persistently, driving the development of integrable micro-power sources that can be realized owing to innovative investigations in chemistry of materials, battery architectures, and microfabrication processes. Here, we propose a new design in the family of flexible coaxial fibrous Li-ion batteries by successfully adopting the unidirectional spiral winding method to achieve multilayered tubules of all the cell components. Such a coaxial fibrous Li-ion batteries device showing high energy storage capability is millimeter thin, highly flexible, and functions effectively without compromising the whole electrochemical performance of the battery. The full cell delivers a specific capacity of 104 µAh /cm at a 0.1C rate with nearly 100% coulombic efficiency and is further capable of being operated at various charging rates. The co-axial fiber battery was then modified later to spiral flexible battery with excellent stretchability.

9:15 AM *EN01.07.04
Integration of Stretchable Batteries and Printed Circuit Board SoojinPark; Pohang University of Science and Technology, Korea (the Republic of)

Stretchable electronics have been considered as a key technology in wearable and implantable medical devices. Although substantial advances have been made in key stretchable components, a stretchable electronic platform that integrates a stretchable power source and a stretchable printed circuit board (SPCB) has been a great challenge. Here, we propose an intrinsically stretchable electronic device platform powered by a stretchable film battery so that the platform can be used stand-alone. The stretchable battery is used as a substrate for manufacturing device platforms where SPCB is printed and directly connected through via holes, thereby enabling an increase in integrated devices density. To achieve intrinsically stretchable battery and high-performance circuit board, we designed a novel design concept of stretchable, self-healable, and pressure sensitive polymer composite. The platform is water-proof and maintains its stable electrical performance under extreme physical deformations. As a proof of concept, we demonstrate the integration of LEDs on the platform that can operate at large biaxial strain (125%) underwater.

SESSION EN01.08: Energy Transducers—From Harvesting to Actuation
Session Chair: Mihai Duduta
Wednesday Morning, November29, 2023
Hynes, Level 2, Room 200

10:15 AM *EN01.08.01
Soft Matter Transducers for Energy Harvesting and Electrochemical Actuation with Liquid Metal CarmelMajidi; Carnegie Mellon University, United States

Liquid metal alloys like eutectic gallium-indium (EGaIn) have attracted tremendous attention over the past decade for their use as microfluidic circuits encapsulated in soft elastomers. Applications include strain gauges, pressure sensors, mechanically tunable antennae, and highly stretchable electronics. However, in recent years, there's been increasing interest in extending liquid metals to applications in energy harvesting, energy storage, and electrochemical actuation. In this talk, I will review recent contributions from my research group in exploring the development of soft matter transducers that utilize EGaIn as electrodes for these emerging applications. This will include new classes of soft material architectures for stretchable batteries, triboelectric energy harvesting, and thermoelectrics. In addition, I will present efforts to use these EGaIn-based material systems to create wearable devices that can power body mounted electronic devices using energy harvested from body heat or motion. Lastly, I will discuss our latest work on exploiting the influence of electrochemical reactions on the surface tension of EGaIn droplets to create soft actuators. Inspired by the architecture of sarcomeres in natural muscle tissue, these actuators contract in response to low voltage stimulation. Where possible, I will relate experimental analysis of these soft actuators to underlying principles in fluid mechanics and elasto-capillary interaction.

10:45 AM EN01.08.02
Bringing the Performance of Conventional Thermoelectric Energy Harvesters to Unconventional Form Factors: Direct Laser Printing of Large-Area Inorganic Thermoelectric Materials on Flexible Plastic Foil YuanTian, IsidroFlorenciano Cano, HeyiXia and FranciscoMolina-Lopez; KU Leuven, Belgium

Thermoelectric generators (TEGs) are gaining increasing attention as a renewable power source that can generate electricity from abundant waste heat in the environment. As such, TEGs can easily complement batteries and expand their lifespan by facilitating recharging instead of periodic replacement. However, some of the emerging fields that demand urgently new energy solutions, such as wearables and soft robotics, also imposes challenging mechanical properties and form factors like tolerance to repeated bending, conformability to curved surfaces and large area. Despite their high performance, traditional inorganic thermoelectric (TE) materials are brittle and expensive to integrate in a large-area device. On the other hand, the reported efforts to fabricate flexible and low-cost printed TEGs based on polymers yielded lackluster outcomes due to low performance. In this presentation, we will combine the best of both worlds by showing how high-performance inorganic TE materials can be directly printed on flexible substrates and over large areas. Printing techniques are known for their scalability, minimal material waste, and capabilities to achieve intricate designs. While printing (from melts or solutions) belongs mostly to the realm of organic materials, laser-based additive manufacturing is becoming common for the manufacturing of inorganic bulk parts. However, the extreme high temperatures potentially occurring during laser scanning discourage the use of laser printing for patterning materials directly on flexible substrates, e.g. plastic foil. In this presentation, we will show the selective-laser sintering of a film of Bi_2Te_3 that is blade-coated from a slurry onto a polyimide substrate. The laser scanning parameters are carefully selected to achieve a high thermoelectric performance, while ensuring excellent adhesion between the inorganic film and the flexible substrate, which is enabled by a mechanical "interlock" design. The enhanced adhesion along with the highly-textured morphology of the laser-printed films, result in flexible films of pure Bi_2Te_3 (i.e. without organic binders) that could bent to radii of curvature as low as 9 mm, without compromising their TE performance. This innovative fabrication method is further evolving towards multi-layer printing, which will enable 3D-printed TEGs as well.

Silicone Oil Emulsions as Oxygen-Enriched Flow Battery Catholytes for Multifunctional Energy Storage AlissaJohnson, AliceS. Fontaine, EmilyBeeman and JamesH. Pikul; University

of Pennsylvania, United States

In biology, multifunctional interconnected systems provide increased system-level efficiency. Animal circulatory systems, for example, transport oxygen and nutrients while simultaneously regulating temperature and maintaining homeostasis. Inspired by biology, recent work has shown how multifunctional fluids can increase the total energy density of a robotic fish by both storing electrochemical energy and transmitting mechanical work to hydraulic actuators[1]. Despite the low energy density of the zinc-iodide electrolytes, this multifunctional approach increased the robot energy density by 4 times compared to the same robot with just a lithium-ion battery.
Gas transport in aqueous environments is important for many biological and chemical processes; however, the low solubility of gases in water is often performance limiting. When animals require more energy in the form of oxygen, they can breathe in air to extract oxygen from their surroundings. Animal blood contains hemoglobin which allows for high concentrations of oxygen to be dissolved into the bloodstream and then distributed throughout the body to provide power locally to various cells. Combining multifunctional fluidic energy storage with the high energy density of air-rechargeable oxygen reduction chemistry will unlock the potential for ultra-high energy density soft robotic systems.
We present a fluid capable of storing twice as much oxygen as water and demonstrate its use as a catholyte for oxygen reduction in a metal air flow battery. Our catholyte is an emulsion with silicone oil droplets suspended in 0.5M potassium hydroxide (KOH) (1:4 v/v), stabilized by a surfactant (Span-60, 1.0 % w/v). The silicone oil acts like hemoglobin to increase the oxygen solubility of the entire emulsion. The silicone oil droplets have an average diameter of 280 nm and are uniformly dispersed within the aqueous phase. While droplet agglomeration is observed over time, this can be reversed with a simple re-homogenization process. Emulsions can maintain a uniformly dispersed oil phase and remain saturated with oxygen (15 mg/L) for several months.
We can extract energy directly from the oxygen in this fluid with a fully submerged electrode that is not exposed to surrounding air. Our emulsion-based electrolyte shows fast oxygen reduction reaction (ORR) kinetics, demonstrating twice as much diffusion limiting current as a control 0.5M KOH electrolyte in a rotation disk electrode study. Kinetics studies with stationary electrodes showed well-defined oxygen-reduction peaks with five times as much ORR peak current density for an emulsion electrolyte compared to KOH. Once the oxygen in the emulsion has been depleted, emulsions can be re-saturated and thus recharged with an influx of surrounding air.
We demonstrate the electrochemical performance of emulsion air-catholytes in two electrochemical cell configurations, a stationary flow cell and a multifunctional actuator flow cell (MAFC). Both configurations use a zinc anode and an emulsion electrolyte with a platinum carbon cloth catalyst for oxygen reduction. In the flow cell configuration, we achieve 4.6 mW/cm^2 peak instantaneous power density at 5.6 mA/cm^2 discharge current density. The MAFC demonstrates the ability for emulsion catholytes to enable multifunctional, flexible power sources for soft robotic systems. This cell uses the emulsion catholyte as a hydraulic working fluid for a McKibben actuator. The MAFC expands and contracts (~20% maximum strain) while energy is being extracted as the cell discharges. Our emulsion catholyte is a fundamental first step toward integrating soft robotic systems with multifunctional, high-energy, air-rechargeable energy storage.

Mechanically Rupturing Liquid Metal Oxide Induces Electrochemical Energy XingYe and JohnW. Boley; Boston University, United States

Liquid metals, such as alloys of gallium, have unique mechanical and electrical properties because they behave like liquid at room temperature. These properties make liquid metals an ideal candidate for soft electronics and stretchable conductors. In addition, these metals spontaneously form a thin oxide layer on its surface. Applications that are made possible by this delicate oxide skin include shape reconfigurable electronics, microfluidic devices, and unconventional actuators. This presentation introduces another class of applications of liquid metals as an electrochemical energy source. By mechanically rupturing their surface oxide, liquid metals can form a galvanic cell and convert its chemical energy to electrical energy. When dispersing liquid metals into an ionically-conductive liquid to form emulsions, this hybrid material can provide ~500 mV of open-circuit voltage and ~10 μA of short-circuit current. This approach is further used to make a strain-activated stretchable electrochemical device that can supply up to ~4 μW of power. Protected by the oxide skin naturally, this passivating layer of the liquid metal shields it from self-discharge over time or changes in operating environment. Future applications of this device are demonstrated by supplying energy to a LED or a capacitor during repeated stretches. Strategies to further improve the output power of these devices are also discussed. These findings may unlock new soft battery designs due to the special surface oxide of liquid metals and offer new pathways to harness their inherent energy for self-powered devices.

Energy Storage in Stiff Hydrostatic Skeletons DuhanZhang; Massachusetts Institute of Technology, United States

The multifunctionality of energy components allows versatility and compactness in biology. For example, fat, as energy storage in many animals, doubles as insulation and as a structural element. Multifunctional energy storage can also improve the operating time of robots. In this work, we demonstrate that a liquid energy source can be used to create a controllably stiff “hydroskeleton” type structure for use in robots. This hydroskeleton type structure can be combined with tendon actuation for fast, efficient motion. We characterize this method of stiffening for a generalizable structure, and use it in a demonstration soft marine creature inpired robot’s motion. We adopt a flow battery with this scheme, where the battery electrolyte is used as the fluid in the hydroskeleton, optimizing materials and methods for incorporating a flow battery into a soft robot, and improving lifetime and performance. The power system and actuation would interact symbiotically: the motors would be powered by the flow battery to make the electrolyte flow inside the robot, which provides controllable stiffness to help the robot swim. Simultaneously, the electrolytic hydraulic fluid increases energy density and reduces system resistance. We show why flow battery soft robots are most competitive in swimming applications and discuss more possibilities for multifunctional fluid energy storage in soft robots.

11:45 AM EN01.08.06
Synchronous Generations of Electrical and Cellular Energies without Battery, Wiring even Generators: Inevitable Electrical Stimulation via Body-Mediated Energy Transfer HyungseokYong[1], SangminLee[2] and JinkeeHong[1]; [1]Department of Chemical & Biomolecular Engineering, Korea (the Republic of); [2]School of Mechanical Engineering, Korea (the Republic of)

Wearable technologies have become increasingly prevalent in various fields, ranging from smart devices and IoT to health monitoring and bioelectronics. However, finding a sustainable power source remains a challenge. Despite advancements in battery energy density, the need for frequent charging, heavy weight, and inconvenience continue to hinder the adoption of wearable technologies. Recent proposals for energy generation methods aim to harvest energy from the human body, but they often face limitations, such as being restricted to specific body parts or requiring large area devices like light exposure or physical motion. To address these constraints and eliminate the need for additional devices, researchers have explored utilizing the human body itself as a medium for transmitting energy and signals (nanogenerator-based ultrasound receivers, human body communication). However, the effectiveness of these methods is affected by the location of the energy source on the body, and the energy magnitude diminishes significantly with distance. On the other hand, low-frequency electric fields generated by electronic devices or physical activities can be converted into usable energy through the human body. Given the body's high relative permittivity at low frequencies, the transfer of low-frequency electric fields can be highly efficient regardless of the transmission distance. Nevertheless, existing body-mediated energy harvesting methods often neglect the physiological effects on biological tissue, such as cellular vitalization or necrosis. Although these electromagnetic waves inevitably affect biological tissues, conventional body-mediated technologies have not considered such physiological effects at all. In the end, ignorance of the correlation between physiological effects and body-mediated energy transfer undermines the latent ripple effect of this technology.
In this study, we aim to validate through various pre-clinical and clinical trials that body-mediated energy harvesting leads to local electric field concentration in the body, resulting in positive physiological effects. By focusing on the design factors and employing a trade-off approach between usability and energy strength, we propose a method for designing electrode grounds that can be implemented in practical applications. The waveform (AC and DC) and intensity (10 - 3000 mV/mm) of these electric fields can be adjusted by controlling several variables (grounding method, external resistance, charging capacitor) depending on the purpose (usefulness, energy strength) without using any additional battery or wiring. Practical body-mediated wearable devices were implemented using conductive threads and fabrics, and body-mediated bioelectronics for zero-powered ion release and electrical stimulation was also implemented through stimuli-responsive ion-diffusive hydrogel. Complex mechanisms for the body-mediated energy transfer and electric field concentration have been demonstrated in various environments through in human body, ex-vivo setup and simulations. In in-vivo setup we confirmed the positive effects of 1) wound healing and 2) hair regeneration of mice. Eventually, through clinical protocols, we have observed a 3) reduction in muscle fatigue of up to 6.4% using such electrical stimulation designs. Particularly outstanding is that when cellular energy is generated by electrical stimulation under the skin, electrical energy is generated outside the skin, allowing 4) small electronics (1.5 mW) to be operated synchronously. These findings underscore the potential of the human body to harvest low-frequency electrical energy from physical activities or electronic devices while offering positive physiological effects. Overall, this research will contribute to the advancement of wearable technologies by providing insights into the relationship between body-mediated energy generation and physiological effects, paving the way for comfortable and sustainable power sources.

1:30 PM *EN01.09.01
Zn Batteries—Stable Anode and High Energy Cathodes ChunyiZhi; City University of Hong Kong, Hong Kong

Our research focuses on a stable aqueous Zn-based battery with long cycling stability, decent energy density, and ultimate safety performance for large-scale energy storage. To achieve this purpose, we did systematic studies on the Zn metal anode, electrolytes, and new cathode development.

For the anode side, we developed a few strategies, including pH value manipulation, ion redistribution coating, gradient coating, etc to induce stable stripping and plating of Zn. Moreover, we also found that a Zn initially plated can be much more stable than the one initially stripped during the subsequent deposition. We further utilize this observation to develop a pre-deposited Zn for Zn batteries with improved stability.

For the electrolyte, we develop a reverse micelle electrolyte, with it, the Zn anode exhibits balanced merits including strong H_2 coevolution suppression, prevention of dendritic and dead Zn, inhibition of corrosion, as well as relatively fast reaction kinetics. In a more extensive context, the new reverse micelle structure of electrolytes is expected to benefit other emerging battery chemistries, where a balance between fast ion transport and sufficient stabilization against side reactions is required.

For the cathode with high energy density, we studied the critical research concerns and further potential developments of chalcogen/halogen-based batteries, primarily focusing on the electrochemically active chalcogen/halogen sources, reaction modes, soluble products, and electrolyte adaptability.

For the cathode, we use iodine as the fixing agents working in highly concentrated electrolytes to successfully enable reversible Cl-based redox electrode. The interhalogen coordinating chemistry fixes Cl in a configuration of ICl_3^-. Furthermore, we simultaneously exploit two redox centers of Cl and I to realize a novel three-electrons transfer electrode, in which the Cl-I electrode can deliver remarkably high capacity up to 612.5 mAh g_I^{-1} and energy density as 905 Wh kg_I^{-1}. The as-obtained energy density is 387% higher compared to the traditional one-electrons transfer of Zn‖I_2 battery system and superior cycling stability with capacity retention as 95.7% after 2,000 cycles.

2:00 PM EN01.09.02
Reversible Zn Powder Electrodes for Aqueous Batteries and Supercapacitors ZhixiaoXu and XiaoleiWang; University of Alberta, Canada

Aqueous energy storage devices require highly reversible Zn electrodes, but this has been impeded by challenges including dendrite growth, low efficiency, hydrogen evolution, and metal corrosion. Here, we report reversible Zn powder electrodes for aqueous batteries and supercapacitors. In the first part, through thermal reduction of spent anode in alkaline batteries, Zn powder anode was regenerated, which shows super-zincophilicity and low overpotentials even under fast rates (8 mA cm^{-2}) and high depth-of-discharge (50 %), resulting from coating of hydroxyl-rich organic layer with abundant nucleation sites as well as high orientation of favorable (002) plane and induced horizontal plating behavior. On the other hand, through thermal oxidation, spent MnO_2-based cathode was also regenerated to pair with the regenerated Zn powder anode. Under a low negative-to-positive (N/P) ratio of 3.8 and high loading of ~10 mg cm^{-2}, the regenerated full cell demonstrates high energy and power densities (94 Wh kg^{-1}, 1349 W kg^{-1}), holding potential for practical applications. In the second part, guided by theoretical calculation, we further fabricated Zn powder anodes *via* engineering the growth of zinc crystals in different solvents. Theoretical calculations demonstrate that the adsorption energy gap of different solvents on the (002) or (100) facet of Zn metal varies and that a larger energy gap favors a higher orientation of Zn (002) plane. Highly oriented Zn (002) powder exhibits horizontal deposition, corrosion resistance, faster kinetics and longer life under deep discharge (60%) in symmetric cells compared with less oriented Zn. Under practical conditions including low N/P ratios (1-3), high-loading cathodes (10-18 mg cm^{-2}), and lean electrolyte (5-9 μL mg^{-1}), highly (002)-oriented Zn powder-based batteries and supercapacitors demonstrate large capacity (~3 mAh cm^{-2}) and energy/power density (108 Wh kg^{-1}/2317 W kg^{-1}), showing promise for practical use.

2:15 PM EN01.09.03
High-Performance Aqueous Zinc-Ion Batteries with Synergistic Stabilized Zinc Anodes Through Molybdenum Dioxide Coating and Tween 80 Electrolyte Additive Nhat AnhT. Thieu[1], WeiLi[1], XiujuanChen[1], QingyuanLi[1], QingsongWang[2], MurugesanVelayutham[1], KhramtsovV. Valery[1], DavidReed[3], XiaolinLi[3] and XingboLiu[1]; [1]West Virginia University, United States; [2]University of Bayreuth, Germany; [3]Pacific Northwest National Laboratory, United States

Owing to their low cost, safety, environmental friendliness, and high energy density, aqueous zinc-ion batteries (AZIBs) have recently been considered a promising candidate for the new-generation energy storage systems. However, AZIBs usually suffer from poor cyclability due to various factors, including severe dendrite growth, self-corrosion, hydrogen evolution, and irreversible side reactions occurring at the Zn anodes. This work proposes a novel approach to develop a highly stable Zn anode by combining a surface coating layer with electrolyte additives. Molybdenum dioxide (MoO_2) is introduced as a coating layer, and Tween 80 acts as an electrolyte additive. As MoO_2 is structured in nanoplates, the coating layer facilitates the rapid diffusion of Zn^{2+} ions, which assists in inhibiting dendrite growth and by-products. Also, the MoO_2 coating layer shows a large redox capability due to the multivalent of Mo atoms in the nanostructure, which may be capable of homogenizing the concentration field of Zn^{2+} in the vicinity of the Zn anode. In addition, Tween 80, a surfactant additive, functions as an inhibitor of Zn metal corrosion as it is preferentially absorbed to the surface of the Zn anode to induce the deposition of Zn^{2+} ions. The MoO_2-coated Zn anode (MoO_2@Zn) then exhibits excellent electrochemical stability in a mildly acidic electrolyte due to the dual synergistic effects of the MoO_2 coating layer and Tw80 additive. With an optimal 1 mM Tw80, the symmetric cells of MoO_2@Zn achieve exceptional cyclability for 6000 h at 1 mA cm^{-2}. Even at a high current density of 5 mA cm^{-2}, the cells remained stable over 700 h. When assembled with the VO_2 cathode, the full cells exhibit a high capacity of 105.6 mAh g^{-1} after 1000 cycles with outstanding rate performance (171.4 mAh g^{-1} at 10 A g^{-1}). Hence, this study suggests an innovative strategy for stabilizing Zn anodes to develop long-life, cost-effective, and scalable AZIBs.

3:30 PM EN01.09.04
Simple Fabrication of Single Crystal Zinc Metal via Dislocation Motion for Zinc Ion Batteries ChihyunHwang[1], Myung-JunKwak[1], Ji-HyunJang[2] and Hyun-KonSong[2]; [1]Korea Electronics Technology Institute, Korea (the Republic of); [2]UNIST, Korea (the Republic of)

Despite being one of the most promising candidates for grid-level energy storage, practical aqueous zinc batteries encounter limitations that compromise their safety and cycling performance, primarily due to dendrite formation. However, this study introduces a novel approach by fabricating a single-crystal zinc metal, effectively preventing dendrite formation. The manufacturing method employed in this study is remarkably straightforward. By subjecting a zinc ingot to a pressing process at a high temperature for few hour pressing, single crystal zinc metal is successfully produced. Remarkably, the dendrite-free electrode retains its integrity even after prolonged cycling, surpassing 2000 cycles at 4 mA cm−2. This exceptional electrochemical performance is attributed to the use of single-crystal zinc metal, which effectively suppresses the primary sources of defect generation during electroplating and promotes planar deposition morphologies. By minimizing defect sites, including those typically found along grain boundaries or arising from lattice mismatch, the opportunity for dendritic structures to form is significantly reduced, even under extreme plating rates. Overall, this study demonstrates the potential of single-crystal zinc metal in achieving high-performance aqueous zinc batteries. By addressing the dendrite formation issue, we can enhance the safety and cycling stability of these batteries, making them even more suitable for large-scale energy storage applications.

3:45 PM *EN01.09.06
Wear and Wash: Stretchable Zn-MnO_2 Rechargeable Cells JohnD. Madden[1], TanN. Nguyen[1], BaharIranpour[1], EvanCheng[1], CliffL. Ng[2] and ZiqiangChen[1]; [1]University of British Columbia, Canada; [2]Simon Fraser University, Canada

Wearable devices require power. There are opportunities to store energy in watch straps, belts, waistbands, suspenders, bra straps, shoes, hats, jackets and in custom fabrics. Typically, however, batteries have a hard metal shell, and are not suited for washing. Here we present a cell that is entirely stretchable and washable. It need not be removed from a garment prior to washing, and it conforms to its surroundings. The approach makes use of one of the lowest permeability elastomers– poly(styrene – isobutylene – styrene) block co-polymer or SIBS – as the encapsulation layer. This allows it to operate over the course of more than a year and a half without drying out. The active materials are zinc and manganese dioxide, both in powder form, combined with a near neutral aqueous electrolyte, making for safe operation, low cost, and possible recycling. The current collectors, active layers, and separator all contain SIBS, which helps to bind the device together, and allows the device to stretch to more than double its length. Carbon black provides electrical conduction, combined with carbon nanofibers to reduce resistance (27 ohms per square) and keep resistance stable over time. The cell has a reversible capacity of 160 mAh/g based on cathode active mass, shows 75% capacity retention after 500 cycles, and underwent 39 washing cycles before it began to leak. The cell is shown to operate effectively after mechanical cycling, runs a low power digital watch from a custom strap, and can briefly drive low energy Bluetooth.
In the process of applying the cell we have found that it is relatively stiff. The stiffness can be reduced by making the cell thinner or combining SIBS with a softer polymer. The separator is

created using evaporation induced phase separation to create pores in SIBS. The hydrophobicity of the bare SIBS separator could be improved by incorporating surfactant into the electrolyte or embedding hydrophilic groups onto the separator surface.. The cell would also benefit from lower resistance current collectors, as these appear to be limiting power output. Applications such as wireless communications are difficult to run continuously as a result of the relatively high resistance. Finally, the chemistry can be improved – and in particular cycle life and stability in the discharged state. Some approaches to further improving the cell are discussed, along with prospects for application.

SESSION EN01.10: Electrolyte and Binder Materials for Improved Li-ion Battery Performance
Session Chair: Mihai Duduta

8:30 AM EN01.10.01
End-Group Assisted Electrodeposition of Ultrathin Solid Polymer Electrolyte Films on 3D-Micro Architected Electrodes ZhaoyiZheng, JoergG. Werner, AntonResing and WenluWang; Boston University, United States

Solid state batteries with three-dimensional micro-architected cell geometry are promising candidates for next-generation batteries with high power density, high energy density, and low safety risks because they take advantage of short ion diffusion distance and high active material loading in 3D interdigitated thin-film structures.
A major challenge in producing 3D micro-architected batteries is the fabrication of a thin and uniform solid electrolyte layer that separates the two interdigitated electrodes. Electrodeposition as a non-line-of-sight fabrication method is readily adapted to modify conductive 3D substrates such as architected electrodes with a polymer film as a thin electrolyte layer. While previous studies reported the electrodeposition of polymer electrolytes on micro structured materials, the resulting thin films exhibited limited functionality, heterogeneous topography, or were only applicable to a single substrate material. To address those issues, we developed the electrodeposition of a polymer electrolyte utilizing a two-component electrocoupling reaction to form a step-growth polymer network instead of the conventional electrochemically initiated chain-growth polymerization that causes uncontrolled polymer formation and precipitation in solution. Specifically, poly(ethylene oxide) (PEO), known for high dielectric constant and Li-ion conductivity, is selected as the backbone of the polymer electrolyte network. The PEO chain ends are functionalized with electrochemically labile groups that undergo direct coupling reactions with a small molecule crosslinker. This electrochemically mediated coupling reaction of polymeric extender and polyfunctional crosslinker generates a polymer network close to the 3D electrode surface that leads to film deposition. This method is applied to coat a layer of solid polymer electrolyte on a low-tortuosity 3D Carbon electrode. As a result, the entire surface of the 3D Carbon electrode is effectively enveloped by a sub-micron polymer film. The deposited polymer film exhibits high electronic resistance and is able to serve as solid electrolytes. Our approach decouples the polymer functionality from its electrodeposition chemistry with electrochemically active end groups that make up only a small fraction of the resulting polymer thin film and can be combined with arbitrary functional polymer chains. Therefore, this method can be a universal method to coat various conductive micro-architected 3D substrates with tailorable functional polymers.

8:45 AM EN01.10.02
Demixing the Miscible Liquids: Toward Biphasic Battery Electrolytes Based on the Kosmotropic Effect Won-YeongKim[1], Hong-IKim[1], Kyung MinLee[2], EunhyeShin[2], XuLiu[3], HyunseokMoon[1], HenryAdenusi[4], StefanoPasserini[3], Sang KyuKwak[2] and Sang-YoungLee[1]; [1]Yonsei University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Karlsruhe Institute of Technology, Germany; [4]Hong Kong Quantum AI Lab, China

Exploring new electrolyte chemistry beyond conventional single-phase battery electrolytes is needed to fulfill the heterogeneous requirements of anodes and cathodes. Here, we report a biphasic liquid electrolyte (BLE) based on the kosmotropic effect. The key underlying technology for the BLE is phase separation of its electrolyte couples using a principle of ‘‘demixing the miscible liquids’’. Kosmotropic/chaotropic anions affect the ion coordination structures and the intermolecular interactions of electrolyte couples, enabling on-demand control of their immiscibility/miscibility. Despite the intrinsic miscibility of water (in aqueous electrolytes) and acetonitrile (in nonaqueous electrolytes), the structural change of the aqueous electrolyte induced by kosmotropic anions allows demixing with the nonaqueous electrolyte. The resultant BLE facilitates redox kinetics at cathodes and Zn plating/stripping cyclability at anodes. Consequently, the BLE enables Zn-metal full cells to exhibit a long cyclability (86.6% retention after 3500 cycles). Moreover, Zn anode-free full cells with the BLE exhibit a higher energy density (183 W h kg^{-1}) than previously reported Zn batteries.

9:00 AM EN01.10.03
Regulating Electrostatic Phenomena by Cationic Polymer Binder: Toward Scalable High-Areal-Capacity Li Battery Electrodes Jung HuiKim[1,2], Kyung MinLee[1,3], Sang KyuKwak[3] and Sang-YoungLee[2]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Korea University, Korea (the Republic of)

The promising potential of forthcoming smart electronics, electric vehicles, and grid-scale energy storage systems has spurred the unremitting pursuit of high-energy-density Li batteries. Accordingly, in addition to the ever-continuing search for advanced electrode active materials, designing high-areal-capacity (C/A) electrodes has garnered attention as a facile and scalable approach to achieve this goal. High-C/A electrodes increase the energy density of a cell without requiring the synthesis of new electrode active materials.

To achieve high-C/A electrodes (= areal-mass-loading (M/A) × specific capacity of electrode active materials (C_{sp})), the M/A should be maximized while stably maintaining the C_{sp}. However, owing to the use of thick electrodes (physical issue) and non-uniform charge transfer throughout the electrodes (electrochemical issue), conventional electrodes cannot achieve this requirement. Particularly, the drying of processing solvents, such as N-methyl pyrrolidone (NMP) and water, during the fabrication of thick electrodes often induces crack formation and delamination from metallic current collectors, thus limiting the increase in the M/A values. Additionally, with an increase in the electrode thickness, charge transfer in electrode active materials tends to demonstrate uneven and sluggish reaction kinetics in the through-thickness direction of the electrodes, resulting in the loss of the Csp values.

Herein, we present a cationic semi-interpenetrating polymer network (c-IPN) binder strategy, with a focus on the regulation of electrostatic phenomena in electrodes. Compared to conventional neutral linear binders, the c-IPN suppresses solvent-drying-induced crack evolution of electrodes and improves dispersion state of electrode components owing to its surface charge-driven electrostatic repulsion and mechanical toughness. The c-IPN immobilizes anions of electrolytes inside the electrodes via electrostatic attraction, thereby facilitating Li^+ conduction and forming stable cathode–electrolyte interphases. Consequently, the c-IPN enables high-C/A (20 mAh cm^{-2}) cathodes with decent cyclability using commercial slurry-cast electrode fabrication, while fully utilizing the theoretical C_{sp} of $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$. Further, coupling of the c-IPN cathodes with Li-metal anodes yields double-stacked pouch-type cells with high-energy-density (376 Wh kg_{cell}^{-1}/1043 Wh L_{cell}^{-1}), demonstrating practical viability of the c-IPN binder for scalable high-C/A electrodes.

9:15 AM EN01.10.04
Tuning the Electronic and Ionic Thermoelectric Transport Properties in Lithium-and Sodium-Based Polymer Electrolytes by Carbon Based Additive MaximilianFrank, Julian-StevenSchilling, PhilippKessler, TheresaZorn, Ann-ChristinPöppler and JensPflaum; Julius-Maximilians-Universität Würzburg, Germany

Hybrid-organic energy storage media utilize the electrochemical transport of ionic species, at present, preferentially originating from lithium compounds. As such, much work on the device performance is devoted to cyclability, energy density and conductivity. Vice versa, the ionic transport characteristics offer also intriguing possibilities for the implementation of this material class in thermoelectrics (TE), the latter considered essential for recovering waste heat into electrical power. At the same time, the electrolytes’ sustainability and alternatives to lithium are becoming increasingly important.
In this work, we present a comparative study on the electrical and thermoelectrical properties of a methacrylate-based solution processable solid polymer electrolyte containing lithium bis(trifluoromethanesulfonyl)imide salt (LiTFSI) [1] and sodium bis(trifluoromethanesulfonyl)imide salt (NaTFSI), respectively. By means of impedance spectroscopy over a frequency range from 10^{-1} Hz up to 5×10^{5} Hz and in a technologically relevant temperature range between 263 K and 363 K, we investigate the transport and dynamics of charge carriers in the solidified electrolytes. The observed high ionic conductivity of about 10^{-3} S m^{-1} at room temperature distinguishes this material for polymer battery applications [2]. In combination with highly sensitive thermovoltage measurements, we demonstrate that the electronic and ionic transport properties can be efficiently tuned by the content of lithium- and sodium-salt, respectively. Complementary multinuclear solid-state NMR studies further indicate interactions between ions and the polymer backbone. Additionally, a significant influence of the cations on the crosslinking of the resulting polymer network can be observed. These results showcase the potential for sustainable sodium-based ionic thermoelectric applications.
By further varying the concentration of suspended carbon-based additives, we investigate the influence of the respective dimensionality on the charge carrier transport. Different transport regimes merge and can be related to a Vogel-Fulcher-Tammann and Arrhenius activated conductivity. For these composite materials, we were able to increase the power factor by several orders of magnitude. Even more, we can reversibly switch the sign of the occurring thermovoltage and thus the respective operational mode by tuning the ambient temperature, which promises new applications in autonomous TE units.

Together with the high electrical conductivity achieved on macroscopic length scales, thermovoltages of about 2 mV K^{-1} allow for high output powers while the polymeric matrix maintains the temperature gradient which in turn is a prerequisite for application in thermoelectric generators (TEG). As a proof-of-concept, an all organic TEG verifies the functionality of our approach and, thereby, substantiates the potential of mixed ionic and electronic materials for future TE applications.

High-Performance Polymeric Electrode Materials for Organic Lithium-Ion Batteries FebriBaskoro, Hui QiWong and Hung-JuYen; Academia Sinica, Taiwan

This talk covers our recent works on high performance aromatic polymers as electrode materials for Li-ion batteries. Polymers with high thermal stability and thermo-oxidative stability complemented by excellent solvent resistance, good electrical and mechanical properties and chemical resistance make them as great candidate as electrode materials. Electrochemical performance tests reveal that these electrode materials delivered a reversible specific capacity and stability over thousand cycles. The long cycle lifetime and excellent battery performance further suggest that the reported polymers are promising electrode materials for next generation Li-ion batteries.

9:45 AM EN01.10.06
A Highly Reversible Electroconductive Liquid–Solid Electrolyte System for Na Metal Plating/Stripping with High Areal Capacity YoungjaeJung, YoungsikKim and Wang-GeunLee; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Anode-free sodium metal batteries (AFSMB) are promising candidates for maximizing energy density and minimizing cost and safety hazards in the absence of metallic sodium during cell assembly. The practical implementation of AFSMBs is hindered by the low cycling stability of Na metal plating and stripping, particularly under high areal capacities. Despite the high energy density of AFSMBs, most of their reported areal capacities are less than 5 mAh/cm^2, which is a similar level to those of conventional lithium-ion batteries, owing to the irreversibility of Na metal plating and stripping. The main causes of irreversible metal plating/stripping can be classified into two categories: 1) electrolyte decomposition and the formation of a solid electrolyte interphase (SEI) layer, and 2) the formation of an electronically inactive dead metal.
Here, we proposed an electroconductive liquid/solid dual electrolyte system that simultaneously suppresses the side reactions of electrolytes and confers electronic conductivity to connect the inactive dead Na. The electroconductive liquid electrolyte accepts electrons at a certain energy level and forms electronic conductivity, and the solid electrolyte can prevent internal short-circuit through a low electronic conductivity. Each function is verified using sodium biphenyl (NaBP) liquid electrolyte and NASICON (Na Super Ionic CONductor, $Na_{1+x}Zr_2Si_xP_{3-x}O_{12}$) solid electrolyte through a seawater battery (SWB) system, which consists of an infinite seawater sodium source at the cathode. Compared with conventional 1 M $NaPF_6$ in dimethoxyethane (DME) electrolyte, the NaBP electrolyte suppresses side reactions such as gas evolution according to the redox-active properties. In addition, the electronic conductivity of NaBP enables the full stripping of dead Na in the absence of direct contact with the current collector, and the stripping efficiency is quantitatively confirmed through the designed experiments. Finally, the anode-free SWB cells have achieved a high coulombic efficiency of >99.9% for over 60 cycles at a high areal capacity of ~24 mAh/cm^2. This study provides insight into the Na plating/stripping properties in anode-free systems and proposes a significant strategy for improving the reversibility of metal anodes for various battery systems with solid electrolytes.

Deicing with Bubbles SaurabhNath, Henri-LouisGirard, Ha Eun DavidKang, SrinivasB. Subramanyam, YangShao-Horn and KripaVaranasi; MIT, United States

Ice accretion is ubiquitous and destructive: from car windshields to powerlines, wind turbines to airplanes, ice-induced damages comprise a multibillion-dollar problem in the United States alone. Traditional deicing methods rely on mechanical scrubbing, heating, or chemical melting that are crude, inefficient, and even environmentally toxic. Here we propose a fundamentally different approach to the classical problem of deicing using bubbles generated via in situ electrolysis of the liquid water – before it freezes. We show with experiments how a progressing ice front can trap the electrolytically generated bubbles at the interface that subsequently act as stress concentrators to diminish the energy required to fracture ice. Our proposed mechanism constitutes a self-starting, self-limiting means to reduce ice adhesion – a feature hitherto non-existent.

Photoresponsive Electrospun PVDF-TiO_2 Meshes with Switchable Wettability for Fog Water Harvesting and Energy Harvesting GregoryParisi[1,2], PiotrSzewczyk[2], ShankarNarayan[1] and UrszulaStachewicz[2]; [1]Rensselaer Polytechnic Institute, United States; [2]AGH University of Krakow, Poland

Water scarcity is a global issue that effects the lives of billions of people. Fog water harvesters can catch water droplets out of humid air and provide water to arid areas. An efficient fog harvester catches majority of liquid from a fog stream and quickly evacuates it to storage. A fiber mesh is an efficient way to collect water due to its larger surface area, permeability, and tunable material properties. This study will take advantage of electrospinning to produce water harvesting polymer fibrous mats with specific surface characteristics. The efficiency and particular usages of fog harvesters depends heavily on surface wettability, which is the liquids' ability to form interfaces with solid surfaces. Hydrophilic surfaces can easily catch water and hydrophobic surfaces minimize the pinning effect of water on the mat surface improving the water collection rate.
To create meshes for water harvesting, polyvinylidene fluoride-titanium dioxide (PVDF-TiO_2) core-shell fibers were produced by electrospinning and additional TiO_2 nanoparticles were electrosprayed on the electrospun membrane. Due to the presence of TiO_2 particles, the wettability of the PVDF-TiO_2 mats can reversibly switch between hydrophilic and hydrophobic with the exposure of UV light and heat, respectively. Since the surface properties of meshes are tunable, the dynamic switch of their wettability increases the potential application of PVDF water collectors. Additionally, PVDF exhibits piezoelectric behavior, meaning it generates electric charges when subjected to mechanical stress, such as the wind from foggy conditions. This provides multifunctional technology that is more efficient and sustainable, as it doubles as an energy harvesting device. Energy generation offers the potential of operating necessary devices without external power sources, such as fog and wind sensors. This switchable fog water collector can be utilized in arid or humid environments and adds additional advantages of energy harvesting and sensing.

Modeling and Optimizing Temperature-Dependent Elastocaloric Effects in Elastic Olefin Block Copolymer Fibers YouLyu[1,2], BuxuanLi[1], VolodymyrKorolovych[1], DuoXu[1], YuanZhu[2] and SvetlanaV. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]Southern University of Science and Technology, China

Solid-state cooling technology based on elastocaloric effects [1–3] provides a competitive alternative to vapor-compression refrigeration technology by demonstrating higher energy efficiency, compactness, noise-free operation, and environmental friendliness. Well-studied metal alloy-based elastocaloric materials such as Ni-Ti and Cu-Al-Ni fail to reach industrial adoption due to their high cost of fabrication and operation, despite exhibiting high temperature spans (Tspan) of 12~30 K and coefficients of performance (COP) of 6~18 [4]. Polymers, on the other hand, are the largest product synthesized by volume nowadays, and have low tensile stress, chemical inertness, light weight, and low cost. Recent progress in elastocaloric polymer experiments shows performances comparable with those of metal alloys. E.g., Tspan around 15 K and COP over 10 in natural rubber [5] and other elastomers [6] have been demonstrated, opening new opportunities for polymer-based elastocaloric materials.

Different from the well-known cross-linked elastomers like natural rubber, we present an experimental study on an entanglement-enabled-elastic olefin block copolymer(OBC) fibers, whose elastocaloric performances feature a high cooling COP exceeding 10 and stable performance for at least 1000 cyclic loadings. We observed a Tspan over 22 K for the first loading, exceeding all existing polymer-based materials. After over 100 cyclic loadings, the stabilized Tspan at room temperature is 5 K. For stabilized Tspan, we noticed a non-linear temperature dependence on cooling Tspan with peaks at 6 K at -20 ºC and 60 ºC, while 2 K at room temperature. We explained such a nonlinear trend quantitatively by modeling the configurational entropy change upon

deformations and predicted different temperature dependences for different deformation trajectories. Such temperature and deformation dependencies suggest a new direction for optimizing and designing polymer-based elastocaloric cooling devices. Finally, a conceptual device for heating and cooling is designed and analyzed with practical working cycles.

The entanglement-enabled reversible deformation of flexible polymer segments in the melt-spun OBC fibers makes them elastic at room temperature without cross-linking. We built a twisting-stretching coupled stage with an IR camera and force/torque sensors to measure in-situ temperature responses and force/torque during the fiber adiabatic deformation process. Experiments revealed that our fibers achieve greater than 10 cooling COP under stretching at room temperature and twisting at higher (60 ^{o}C) and lower (-20 ^{o}C) temperatures. We also characterized fiber structural changes by X-ray and Raman spectroscopy to understand the mechanisms underlying the elastocaloric fiber performance. Significant drops in both orthorhombic crystalline (6%) and amorphous domains by (13%) were observed upon stretching, while the interfacial oriented amorphous domains grew by 19%, accompanied by Herman's orientation factor increase from 0.02 to 0.17. These observations suggest the entropic change due to chain alignment, rather than strain-induced crystallinity, is revealed to be a dominant factor that explains the elastocaloric effects and its temperature dependence. Finally, the new elastomer fibers are extremely inert and suitable for operation in harsh corrosive environments, as well as fully mechanically recyclable at the end of their lifespan.

Thermoelectric Materials in Membrane Distillation: Improving Performance Metric OlawaleMakanjuola[1,2] and RaedHashaikeh[2]; [1]New York University, United States; [2]New York University Abu Dhabi, United Arab Emirates

The commercial deployment of membrane distillation (MD) as an alternative to reverse osmosis (RO) and multistage flash (MSF) or multi-effect distillation (MED) for desalination has been largely hindered by the high specific energy consumption (SEC) in MD systems. Many studies have succeeded in reducing the SEC in MD to a threshold value of around 1,000 kWh/m^3 by using energy recovery devices (ERD) and other techniques. While this is a significant improvement for MD, RO and thermal desalination present much lower SEC values (7 – 150 kWh/m^3), and the ERD incorporated in MD systems will increase the complexity, equipment cost, and required real estate for MD operations.

Our previous works have indicated that using thermoelectric devices as a direct thermal source inside the MD module can reduce the SEC by more than 35% below the 1,000 kWh/m^3 threshold (i.e. < 650 kWh/m^3) whilst greatly simplifying the MD system by eliminating the support subsystems generally required for heating and cooling in MD. The thermoelectric device doubles as both a direct thermal source to drive the process and as an ERD reducing heat exchange losses to near zero. By combining high-fidelity computational fluid dynamics simulation and mathematical modeling of the thermoelectric device with experimental validation, we developed a fairly good model for predicting the performance of a thermoelectric MD system.

We are currently investigating the possibility of embedding column-type p and n thermoelectric pellets inside the MD membrane itself. This thermoelectric membrane is expected to provide a more localized thermal source and sink for driving the MD process. This in turn is likely to lower the SEC when used in an MD system. A theoretical model developed from the constitutive relations under isotropic conditions while assuming steady-state conditions, one-dimensional heat flow, and constant properties for both the membrane and thermoelectric material allows us to predict the SEC (in kWh/m^3) in an MD process driven by a thermoelectric membrane. The result indicates that while a thermoelectric membrane can potentially reduce the SEC by over 90% below the 1000 kWh/m^3 threshold for conventional MD equipped with ERD, the SEC cannot go below around 15 kWh/ m^3 even for the best permeable thermoelectric membrane.
Our current efforts are geared towards realizing a physical thermoelectric membrane. Several avenues are being explored to successfully embed thermoelectric bismuth telluride pellets inside electrospun membrane. Concurrently, we are also working to improve the current theoretical model by accounting for all pertinent thermal and electrical resistances. Contact resistance and small-scale effects are some of the phenomena that the improved model will account for.

Enhancing Thermoelectric Performance with Electrically Aligned Single-Walled Carbon Nanotubes in Polymer Matrix HyunjinJoh[1], GopinathanAnoop[1], SeunghyunJo[1], KwangSupEom[1], Hyeon JunLee[2] and Ji YoungJo[1]; [1]GIST, Korea (the Republic of); [2]Kangwon National University, Korea (the Republic of)

Polymer-based thermoelectrics are a promising material to generate energy for wearable devices due to their flexibility and ability to directly convert thermal energy into electrical energy in low temperature. However, the fundamental limit of thermoelectric performance arising from interdependent parameters(electrical/thermal conductivity, Seebeck coefficient) is the main obstacles in preexisting homogeneous thermoelectric materials based on conducting polymers [1]. In the pursuit of enhancing the thermoelectric ZT of flexible thermoelectric generators, a composite consisting of an insulating polymer and conducting nanoparticles is proposed. This study explores the use of single-walled carbon nanotubes (SWCNTs) in a poly(vinylidene fluoride-trifluoroethylene) P(VDF-TrFE) polymer matrix. In polymer-CNT composites, the CNTs form networks within the polymer matrix that are electrically conductive but less thermally conductive due to phonon scattering at the polymer-nanotube interfaces, thereby enhancing the ZT of the composite [2]. The unique approach of electrical alignment of SWCNTs in the polymer matrix is employed to optimize their orientation and distribution. This method involves applying an external electric field during the drying process of the composites, causing the SWCNTs to align along the field lines through in-plane direction. The alignment of SWCNTs facilitates direct paths for charge carriers, thereby reducing scattering events and increasing carrier mobility. This enhancement in carrier mobility, coupled with a reduction in thermal conductivity, leads to a significant improvement in thermoelectric properties.
Here, we have successfully fabricated freestanding composite films that exhibit excellent flexibility. Dispersion-drying method is used for the fabrication of the composite film, and electrical field is induced before the drying process to align the SWCNTs in the matrix. The alignment of CNTs are observed in the cross-sectional SEM image, and the resistance change according to the in-plane measurement direction. By incorporating 11.3 wt% of CNTs into the composite, the initial thermoelectric power factor (PF) was measured to be 1.25 μW/mK^2. To further enhance the PF, an alternating electric field (150 V, 1 kHz) was applied during the solution process to align the SWCNTs within the P(VDF-TrFE) matrix. CNT alignment resulted in a significant increase in electrical conductivity and a slight decrease in Seebeck coefficient, leading to an overall increase in PF up to 1.79 μW/mK^2. Even when highly bent (with a bending radius of less than 5 mm), the PF remained over 95%, and it also remained stable after undergoing 10^3 cycles of bending tests. The results demonstrate a substantial increase in the thermoelectric ZT from 1.54×10^{-3} to 5.67×10^{-3}, paving the way for the development of highly efficient, flexible thermoelectric generators. This research provides a promising direction for future advancements in flexible electronics and energy harvesting technologies.

Chemical Additive-Regulated Thermocells with High Thermopower for Low-Grade Heat Harvesting YijieMu[1], WendiLi[1] and Shien-PingFeng[2]; [1]The University of Hong Kong, Hong Kong; [2]City University of Hong Kong, Hong Kong

Low-grade heat (below 373 K) is ubiquitous in the human body, environment, and industry, but is usually wasted without proper recovery. Thermogalvanic cells (TGCs) are one of the most investigated technologies that can directly convert such waste heat into electricity, which present satisfactory thermopower in the magnitude of mV K-1. A typical method to improve the thermopower of aqueous TGCs is to introduce additives to change the solvation entropy or establish a concentration ratio difference between two electrodes at different temperatures. However, the introduction of additives may lead to the lower ionic conductivity of electrolyte, thus the current density of TGCs is not promising for powering electronics. From this point of view, further modification towards electrodes is required, making it complicated to optimize the performance of TGCs as a whole. Here, we first introduced a small amount of guanidine hydrochloride (GdnHCl) into 0.4 M potassium ferri/ferrocyanide (K3Fe(CN)6/K4Fe(CN)6) aqueous electrolyte. With the thermosensitive crystallization and redissolution effect between GdnHCl and Fe(CN)64-, a low local concentration of Fe(CN)64- due to the crystallization induced by GdnHCl at the cold electrode and a high local concentration of Fe(CN)64- via the redissolution process at the hot electrode were established, corresponding to a low concentration ratio of Fe(CN)64-/Fe(CN)63- at the cold side ([Fe(CN)64-/Fe(CN)63-]cold) and a high concentration ratio of Fe(CN)64-/Fe(CN)63- at the hot side ([Fe(CN)64-/Fe(CN)63-]hot), respectively. A thermopower of 1.91 mV K-1 was achieved by solely adding 0.75 M GdnHCl to the electrolyte. On the basis of thermopower being enhanced by regulating the concentration profile of Fe(CN)64- via GdnHCl, in this work, we proposed to further improve the thermopower from the perspective of Fe(CN)63-. We added the second chemical, cysteamine hydrochloride (CysHCl), into the K3Fe(CN)6/K4Fe(CN)6 aqueous electrolyte with 0.75 M GdnHCl to trigger

a high temperature-favored chemical reaction with Fe(CN)63-. CysHCl was featured with temperature selectivity, the kinetic reaction rate of which was relatively slow at lower temperatures, making little contribution to the thermopower enhancement. But at temperatures above 323 K, which were within our designed temperature range for low-grade heat recovery application, the chemical interaction between CysHCl and Fe(CN)63- played a prominent part in the thermopower improvement, leading to a high ([Fe(CN)64-/Fe(CN)63-]hot ratio. As a result, a large concentration ratio difference between the cold and hot electrodes was established by GdnHCl via inducing the crystallization and redissolution of Fe(CN)64-, and was further enlarged by CysHCl via chemically regulating the concentration of Fe(CN)63-. A high thermopower of 4.32 mV K-1 and a short-circuit current density of 133.33 A m-2 were generated using planar graphite sheets as electrodes, compared with the performance of 1.0 mV K-1 and 56.44 A m-2 of pristine electrolyte in the same cell configuration. Furthermore, a maximum thermopower of 9.06 mV K-1 and a short-circuit current density of 129.24 A m-2 were achieved by optimizing the concentrations of both GdnHCl and CysHCl simultaneously. The results elucidate that the introduction of GdnHCl enables a high thermopower and current density via the thermosensitive crystallization effect, and more importantly, by interacting with Fe(CN)64-, it allows more free Fe(CN)63- to react with CysHCl, which enables the thermopower and current density being boosted to a higher level via chemical regulation effect. This work develops a new design route for TGCs to achieve high thermopower and current density, while no complex modification towards both electrolyte and electrodes is needed, which is highly important for extending the possible application fields of TGCs.

Electro-Spun Polymer Fibres Derived Carbon-Supported 1D Hierarchical WO_3/SnO_2 Nanocomposites with Enriched Surface Defects for High-Performance Supercapacitor Devices VaishaliTanwar, Saurabh KumarPathak and PravinP. Ingole; Indian Institute of Technology Delhi, India

Pseudocapacitive metal oxides are considered promising energy storage systems; however, their overall performance suffers from low intrinsic conductivity. [1] Herein, we report the design of 1D hierarchical architecture, carbon-supported WO_3/SnO_2 nanocomposite-based fibers, via efficient and scalable strategies of single-spinneret electrospinning followed by controlled annealing for high-performance supercapacitor devices. As evident from the XPS and Raman analyses, the composite surface is enriched with surface defects such as oxygen vacancies (O_{vac}), which improves surface chemical structure, aids in efficient diffusion of the charge carriers, and enhances the conductivity.[2] The significant contribution of the two distinctive charge storage mechanisms accounts for the synergistic contribution of WO_3 and SnO_2 to the overall electrochemical behavior of the electrode.[3] Moreover, an interfacial charge build-up between WO_3 and SnO_2 due to nanoscale integration eradicates the charging and discharging processes, leading to better performance. Overall the unique combination of 1D hierarchical nanostructures, abundant electrochemically active sites (O_{vac}), and unique heterointerfacial properties have boosted the performance.[4] The half-cell measurements demonstrated a specific capacitance of 589 F g^{-1} at 6 A g^{-1} and enhanced columbic efficiency with a capacity retention of ~80% after 5000 charging-discharging cycles, indicating longer durability. Importantly, a flexible all-solid-state symmetric device (full-cell configuration) was assembled having energy density (E_d) of 2000 mW h kg^{-1}, power density (P_d) of 1200 W kg^{-1}, 100% durability (1,000 cycles), and the gravimetric capacitance of 10 F g^{-1} at 0.5 A g^{-1} for an extended working voltage window of 1.2 V. This work provides insight into the synthesis of hierarchical 1D nanocomposites of bimetallic metal oxides for high-performance, portable, and flexible supercapacitor device applications.
