[Results and Discussion] Agarose gel electrophoresis showed that the more mRNA formed polyplex with PMR synthesized by free radical polymerization (Mw ≈ 100,000) with an increase in the ArgMA composition, while the polymer without ArgMA failed to form polyplex. This suggests that ArgMA is the major mRNA binding domain of PMR. Next, in the mRNA protection assay, the PMR with an increasing composition of ArgMA inhibited mRNA degradation. However, naked mRNA was completely degraded. Similar results were observed using PMR synthesized by RAFT polymerization (Mw ranged from 7,400 to 27,000) in the agarose gel electrophoresis and the mRNA protection assay. Finally, transfection experiments were performed using iRFP fluorescence expression as an indicator. HEK293 cells expressed the highest iRFP expression by culturing in the medium containing the polyplex composed of RAFT-PMR containing 30 mol% ArgMA. ArgMA will be a promising motif for designing cationic moiety-free mRNA delivery carriers.

Lyophilized Porous Gelatin Microgels ZiqiangGuan; University of New Hampshire, United States

Injectable hydrogels are useful for wound healing and tissue engineering due to their ability to conform to the topography of target tissues and provide a natural hydrated 3D environment for cells. However, most injectable hydrogels are nonporous, resulting in a delayed cellular response. Previously, our group developed an injectable microporous hydrogel made of gelatin microgels, which are cured to form a bulk hydrogel using microbial transglutaminase (mTG). This novel hydrogel allowed efficient migration of surrounding cells into the hydrogel phase as well as rapid spreading and proliferation of encapsulated cells. These characteristics indicate its potential use in wound healing and stem cell delivery. In this research, we demonstrate the development of porous gelatin microgels and their assembly for cell encapsulation. The porous microgels are produced by swelling and lyophilization of nonporous gelatin microgels. The micropore structure of the microgels was confirmed using scanning electron microscopy (SEM). The pores in the microgels enabled more rapid diffusion of a model protein (bovine serum albumin) into the microgels, demonstrating that these porous microgels will facilitate the transfer of nutrients and gas molecules in and out of the hydrogel. When these porous microgels were used for the encapsulation of human dermal fibroblasts (hDFs), hDFs were found to exhibit more widespread morphologies. Taken together, these novel microgels will prove useful for stem cell delivery for tissue repair.

Novel Nanoscale 3D Mapping of Mechanical Heterogeneities in Hydrogels for Tissue Engineering FeiWang, KevinGrassie, FayekahAssanah, YusufKhan and BryanD. Huey; University of Connecticut, United States

We are developing a platform to investigate the forces experienced by cells in tissue engineering hydrogels when exposed to external loading by ultrasound, mimicking clinical procedures for bone tissue regeneration. A high density of embedded fluorescent microbeads, which serve as fiduciary markers for deformation tracking, is dispersed within the hydrogel. A series of optical images are first acquired over a range of focal planes, spanning thicknesses of tens of micrometers, to map the bead positions in 3D. Such optical stacks are then repeatedly collected as a function of time before, during, and after uniform acoustic loading. Post processing identifies the displacements of the several thousand beads in the field of view. This allows local distortions within the hydrogel, and even incorporated cells, to be volumetrically mapped. Variations in the magnitude and direction imply mechanical heterogeneities due to local differences in hydrogel cross-linking, density, hydration, and/or cellular mechanical structures and active adhesion.
This approach will help to investigate the cellular response to clinically applied, but still not well understood, low-intensity pulsed ultrasound (LIPUS) which has been demonstrated to enhance bone formation and healing. Ultimately this approach may enable 3D Traction Force Microscopy, with broader applications to other 3-dimensionally heterogenous systems including individual cells, tissue, and block copolymers, and nanocomposites.

Comparing Hydrodynamic Sizes of Solid and Mesoporous Silica Nanoparticles in De-Ionized Water and Cell Culture Media TrentGabriel, YuweiFan, LaishengChou and RussellGiordano II; Boston University, United States

Objective: To determine the hydrodynamic-size (HS) of 100nm spherical solid-silica-nanoparticles (SiNPs) and mesoporous-silica-nanoparticles (MSNs) in both de-ionized water (DI water) and cell-culture-media (CM). To confirm the stability of both nanoparticle (NP) dispersions in CM for at least 3 days.

Methods: Nanocomposix SiNPs and MSNs of MCM-41 type were used. Size distribution and shape of the NPs was confirmed with SEM, mesopores for MSNs were visualized with TEM. NPs were sonicated for 5min in an ice-ethanol-salt bath and then filtered with 1.2um sterile filters. HS was measured using Dynamic-light-scattering (DLS) with an average of 5 readings for intensity per sample. The HS for NPs in DI water and CM was compared. To assess stability of the dispersion in CM, samples were kept in an incubator at 37C and measured for 3 days using DLS.

The diameter of dried NPs measured with SEM and HS of sonicated NPs in DI water and CM was determined. The diameter was taken as an average of 50 NPs, the results for the DI water and CM were completed with one sample measured 5 times. Two way ANOVA with replication with alpha 0.05 analysis showed: H1: There is a difference in means between NP groups. H2: There is a difference in means between dispersion solution. H3: There is an interaction.

The HS of both NPs over 3 days in CM was also determined. Triplicate samples were prepared and each same was measured 5 times. Two way ANOVA with replication with alpha 0.05 analysis showed: H1: There is a difference in means between NP groups. H2: There is a difference in means between days. H3: There is no interaction.

Conclusions: The HS for both NPs increased in CM compared to DI water. The HS was larger for MSNs than SiNPs when the solution was the same, most likely due to the increased surface area allowing for more intermolecular interactions. The stability of both NPs in CM was confirmed up to 3 days. The decrease in size from day 0 to day 3 suggests that the NPs are dissolving in solution.

8:00 PM SB09.03.20
Biomimetic Scaffolds from Biopolymer Ionogels: Elucidating Processing Parameter Dependence on Cell Proliferation EvanMcDowell, LibertyYoder and LettiFrenadez; North Carolina A&T, United States

Novel tissue engineering approaches are imperative to address the increasing prevalence of replacing damaged or lost organs due to congenital defects, traumas, or disease. Reliance on traditional transplantation techniques as the primary step of intervention has been hindered, as it is constrained by the scarcity of available organs. Advancements in tissue engineering techniques have interested scientists and clinicians as it holds the potential to create safe and reliable methods for developing functional tissue providing the possibilities to improve patient outcomes, alleviate healthcare burdens, and improve quality of life globally. Recently, research developments in stem cells, biomimetics, biochemistry, and material science have begun to pioneer these new paths for researchers, in some cases allowing them to circumvent traditional methods altogether. Most regenerative medicines/techniques that have emerged are centered around infusing a cell's natural mechanisms with manufactured processes, but realizing a functional biomimetic synthetic tissue is an intricate process. Synthetic tissue must aim to mimic the heterogeneity, complexity, structural integrity, mechanical function, and biocompatibility of indigenous tissue. Additive manufacturing, hydrogel cell cultures, and electrospinning have been used to produce tissue that equates to or enhances the regenerative properties of the human body. Here in this study, we follow established ionic liquid protocols, synthesizing BmimCl from conventional precursors to be used in various dissolutions, forming ionogels. These ionogels are composed of cellulose, silk, or a blend of both, and in combination with our regenerating solution, served as the material for 3D printing the scaffolds. Here we show that via standard additive manufacturing processes, we were able to design and manufacture biomimetic ionogel scaffolds with tailored nanosized features that facilitated enhanced cellular activity and proliferation. Each scaffold was done in triplicate and seeded with MDA-MB-231 cells into individual T-75 flasks. They were cultured in 2 variable conditions in addition to the control: ambient dried ionogel, freshly regenerated ionogel, and no ionogel(control). Each condition was seeded without mixing and after 3 days in standard culture conditions, they were removed for counting. MTT analysis uncovered the viability of the cells increased in the freshly regenerated culture and decreased in the ambient dried condition in comparison to the control. This data supports that these scaffolds, when intact, can provide an advantageous nanostructured milieu, that

enhances cell proliferation. Polymer matrix density, porosity, and level of regeneration were tailored to improve cell viability, showing up to a 40% increase, outvying standard biocompatible plastics used in industry. While this work is in its nascent stages, the early indicators are pointing toward a possible pathway for producing rapid, and reliable tissue cultures that could be used for drug testing, medical research, or eventually in-vitro human models. Although it does not replace traditional transplantation, this approach offers researchers the potential to quickly prototype and test tissue models. It holds the potential to accelerate advancements in tissue engineering, providing valuable tools for scientific investigation and potentially transforming the field.

8:00 PM SB09.03.21
Actuating Extracellular Matrices Mechanically Program Anisotropy in Engineered Muscle Tissues BrandonRios, AngelBu and RituRaman; Massachusetts Institute of Technology, United States

Introduction: Multicellularity is the key to the dynamic functionality of biological tissues. Cells embedded in an extracellular matrix communicate with each other, and with their surrounding scaffold, through a combination of chemical, electrical, and mechanical signaling. A soft actuating substrate that is capable of controlling cell-cell mechanical interaction with high spatiotemporal precision, while also allowing for the generation of forces in the biologically relevant range, would enable probing the impact of external forces on intercellular communication and measuring downstream impact on morphology and function. We have developed a magnetically actuated extracellular matrix capable of modular, programmable, and tunable deformation. We test this platform as a mechanically active substrate for skeletal muscle and show that we can control the directional fusion of myoblasts into aligned fibers. By leveraging computational tools to track substrate deformation in response to muscle contraction, we further demonstrate that mechanically programmed anisotropy in muscle improves synchrony of tissue-wide coordinated twitch. This study sets the stage for deploying actuating extracellular matrices to map and modulate mechanical signaling and control a variety of complex biological processes.
Materials and Methods: We manufactured magnetic silicone microparticles by mixing iron nanoparticles within poly (dimethyl siloxane) and embedded these microparticles within a fibrin hydrogel. A custom-built linear actuator enabled moving a magnet under the hydrogel with precisely controllable direction and speed. We seeded optogenetic mouse myoblasts on magnetic fibrin gels and differentiated them to form mature muscle in the presence or absence of mechanical stimulation (30 minutes/day, 10 days). The resultant mechanical motion was recorded with a stereoscope and custom automated tracking software was used to map deformation of the hydrogel in response to magnetic (daily) and optical (only on day 10) stimulation. Tissues were fixed and stained for cell nuclei and myosin expression to quantify muscle fusion index and other indicators of mature tissue formation.
Results and Discussion: Global fiber alignment is critical to native muscle architecture, as global actuation can only be achieved by independent fibers twitching simultaneously and in the same direction and is thus of relevance for applications ranging from regenerative medicine to biorobotics. Morphological analysis revealed that both control and stimulated fibers grow significantly in length over time, but no significant difference in fiber length or width was observed between experimental groups. We used Fast Fourier Transform image analysis to assess differences in muscle fiber directionality and showed that mechanically stimulated tissues were more likely to align parallel to the direction of magnet movement (0°). By contrast, fibers in control groups did not demonstrate statistically significant global alignment. Optical stimulation of engineered muscle generated globally coordinated twitch deformation in the mechanically stimulated group, while the control group displayed asynchronous and arrhythmic contraction, indicating improved global fiber alignment had an observable downstream impact on function. These quantitative assays, which showed that enhanced x-direction alignment corresponds to increased synchrony of x-direction twitch, corroborate the observation that actuating extracellular matrices can mechanically program anisotropy of form and function in engineered muscle.
Conclusion: Our proof-of-concept study demonstrates how modulating intercellular forces in skeletal muscle during growth and maturation can dynamically program tissue anisotropy. Our platform can be readily adapted to a variety of natural and synthetic soft substrates, as well as a range of cell types, and anticipate that this platform will enable a broad range of fundamental studies of mechanobiology.

8:00 PM SB09.03.22
Laminin-Decorated Gelatin Microporous Injectable Hydrogel for the Encapsulation and Differentiation of Neural Progenitor Cells SethEdwards; University of New Hampshire, United States

Nervous tissues have limited capacity to regenerate, and damage to these tissues, due to neural injuries or neurological disorders, is often debilitating to the affected patients. The delivery of neural progenitor cells (NPCs), with biomaterials as a delivery vehicle is a promising strategy to promote neural tissue repair. Neural differentiation of NPCs is facilitated by cell spreading and morphological changes, as well as cell-cell interactions. An effective delivery vehicle for the nervous tissue regeneration should promote such cell-matrix and cell-cell interactions. In this report, we investigated the potential for a microporous injectable hydrogel, formed by annealing of gelatin microgels to promote the differentiation of encapsulated NPCs. In addition, we demonstrate a novel method of improving NPC adhesion in the microgel matrix by a facile covalent incorporation of laminin by microbial transglutaminase (mTG) during the microgel annealing process. We found that cell organization, morphology, and differentiation were dependent on the 3D environment, as examined through live/dead assay, immunofluorescence staining for neural markers, mitochondrial activity, and by investigating functional neuronal network formation through monitoring calcium flux of encapsulated cells in response to neurotransmitter. In summary, our results investigate and demonstrate the potential for microporous injectable hydrogels to serve as a vehicle for the encapsulation and differentiation of NPCs.

8:00 PM SB09.03.23
Guanidine-Based Hydrophilic Antimicrobial Polymer as a Textile Coating UrmiV. Mody and MichaelWolf; University of British Columbia, Canada

With the increase in infection transmission and resistance to antibiotics, using clothing as the first of defense can reduce transmission rates and contain disease spread. We report a guanidine-based cationic hydrophilic antimicrobial polymer (GAMS) that can selectively lyse bacterial cells. Antibacterial activity, hydrophilicity, haemolytic and thermal properties of the crosslinked siloxane-based cationic polymer are tested post-functionalization with guanidine groups at 10%, 30%, 50%, and 70% loading relative to the amine groups on the polymer. It is concluded that guanidine functionalized polymer is selective for bacterial cell lysis with complete elimination of class 2 pathogens (E. coli and MRSA) using a contact killing mechanism. GAMS polymers show high thermal stability. Structural characterization of GAMS polymers is performed using NMR (1H, 13C, COSY, HMBC), FTIR, elemental analysis, TGA, (E. Coli/MRSA). Bacterial colony counting assays are performed to evaluate the efficiency of GAMS compared to hydrophobic antibacterial polymers that have been previously reported.

8:00 PM SB09.03.24
Synthesis of Curcumin-Loaded LNP-Based Sarcopenia Treatment using Microfluidic Reaction System Jun-WonKook; Ajou University Medical Center, Korea (the Republic of)

Sarcopenia, characterized by progressive loss of skeletal muscle mass and function, is a prevalent condition associated with aging. Currently, there is a growing interest in developing effective therapeutic strategies to combat sarcopenia and improve the quality of life for affected individuals. In this study, we propose a novel approach for the synthesis of curcumin-loaded lipid nanoparticle (LNP)-based sarcopenia treatment using a microfluidic reaction system.

The microfluidic reaction system offers several advantages over traditional bulk synthesis methods, including precise control over reaction conditions, enhanced mass transfer, and reduced reaction times. These characteristics make it a promising tool for the synthesis of drug-loaded nanoparticles with improved physicochemical properties and therapeutic efficacy.

Curcumin, a naturally occurring polyphenol found in turmeric, has demonstrated potential as a therapeutic agent for sarcopenia due to its anti-inflammatory and antioxidant properties. However, its poor aqueous solubility and low bioavailability limit its clinical application. By encapsulating curcumin within LNPs, we aim to enhance its stability, solubility, and targeted delivery to skeletal muscle tissues.

The microfluidic reaction system enables the efficient production of curcumin-loaded LNPs by facilitating the rapid mixing of lipid precursors and curcumin in a continuous flow. This allows for the formation of uniform nanoparticles with controlled size and composition. Furthermore, the microscale dimensions of the system enable the precise tuning of reaction parameters, such as temperature, flow rates, and residence times, to optimize the encapsulation efficiency and loading capacity of curcumin within the LNPs.

To evaluate the potential of the synthesized curcumin-loaded LNPs as a sarcopenia treatment, in vitro and in vivo studies will be conducted. The nanoparticles will be characterized for their physicochemical properties, including size, zeta potential, and drug release kinetics. In vitro assays will assess the cellular uptake and cytotoxicity of the LNPs using skeletal muscle cells. In vivo studies will involve the administration of the curcumin-loaded LNPs to animal models of sarcopenia, followed by the evaluation of muscle mass, strength, and markers of inflammation and oxidative stress.

In conclusion, this study proposes a microfluidic-based approach for the synthesis of curcumin-loaded LNPs as a potential sarcopenia treatment. The use of a microfluidic reaction system offers unique advantages in terms of control, scalability, and reproducibility. If successful, this approach could provide a promising therapeutic strategy for the management of sarcopenia, addressing the unmet need for effective treatments for this age-related condition.

8:00 PM SB09.03.25
Noninvasive and Longitudinal Study of Multi-Contrast 3D Bioprinted Tissue Constructs via Photon Counting Computed Tomography CarmenJ. Gil[1,2], ConnorEvans[3], LanLi[3],

AlexanderAllphin[4], MartinTomov[1], LiqunNing[2], MingShen[1], JarredM. Kaiser[1], LuzRestrepo[5], VictorPutaturo[2], GabriellaKabboul[1], AnjumAlam[2], TravisFulton[1], RemiVeneziano[5], NickWillet[1], HichamDrissi[1], CristianBadea[4], HollyBauser-Heaton[1], RyanRoeder[3] and VahidSerpooshan[1,2]; [1]Emory University, United States; [2]Georgia Institute of Technology, United States; [3]University of Notre Dame, United States; [4]Duke University, United States; [5]George Mason University, United States

3D bioprinting has revolutionized the fields of personalized and precision medicine by offering the unique possibility of designing patient-specific tissue engineered constructs and therapies. For cardiovascular disease, patient-specific bioprinted cardiac patch devices have emerged as novel therapeutics, demonstrating promising results in restoring and/or improving cardiac function, reducing the infarct size, and enhanced angiogenesis in animal models of myocardial infarction (MI). However, current 3D bioprinted cardiac patch designs primarily lack the ability of noninvasive, longitudinal, and quantitative monitoring of their function following the implantation *in vivo*. Computed tomography (CT) is widely used in clinical settings to monitor cardiac function and anatomy. A recent advancement in CT imaging, i.e., photon-counting CT (PCCT), has enabled simultaneous imaging of multiple contrast agents at higher spatial resolution while potentially reducing the radiation dose. Through integrating advanced multi-material bioprinting and PCCT imaging, this research aimed at design and creation of novel 3D cardiac patch structures, incorporated with multiple CT imaging probes, which can be monitored noninvasively and longitudinally in both *in vitro* and *in vivo* applications.

In this study, distinct k-edge CT imaging probes were incorporated in different bioinks and used to print patch structures. To determine the feasibility of our approach, release profiles of various imaging probes from the constructs were investigated to optimize the production of bioinks with adequate and stable concentrations of imaging probes. Subsequently, imaging properties of bioprinted contrast agent-laden constructs were evaluated by CT/PCCT both *in vitro* and *in vivo*, in a subcutaneous mouse model. Imaging probes added to distinct bioink formulations included gadolinium (Gd) chelate, iodine (Iod), Gd_2O_3, gold nanoparticles (Au NPs), and methacrylated Au (AuMA) NPs. Printed patches with single and multiple imaging probes were able to be discriminated and quantified by PCCT, offering the ability to perform longitudinal and noninvasive monitoring of the implanted patch. In the final path design, AuMA and Gd_2O_3 NPs were used to label different components of the patch structure, and Iod was used to visualize and quantify perfusion through the printed vasculature in the patch. Future studies aim to further control the stability and release behavior of imaging probes, incorporate advanced drug delivery tools within the patch (e.g., co-encapsulation of therapeutic molecules and imagine probes), and development of novel imaging probes (e.g., via chemical conjugation of probes to the polymer matrix). In addition, we work on improving the functionality of cardiac patch by incorporating various molecular therapeutics and cardiovascular cells, together with the CT imaging probes. In summary, this study demonstrates the feasibility of designing a novel theranostic platform to treat cardiovascular disease using a new generation of bioprinted patch devices.

8:00 PM SB09.03.26

Compressive Modulus and Charge Dictate Surface Protein Adsorption on Injectable Cellulosic Hydrogels *In Vitro*AdamWeisel and StevenNicoll; The City College of New York, United States

Cellulose is a natural polysaccharide that can be modified to meet many physical, biological, and chemical requirements, making it an attractive candidate for tissue engineering[1]. Specifically, its inherent sustainability and the potential for *in-situ* gelling by functionalization with methacrylate groups, makes this system appealing for stable, minimally invasive implants[2]. Water-soluble cellulosic derivatives, such as methylcellulose (MC), which contains hydrophobic methoxy groups that afford thermogelation properties at body temperature, and carboxymethylcellulose (CMC), which provides polyanionic character analogous to native tissue glycosaminoglycans, allow for further tuning of the hydrogel features. The biological response to these materials is dependent on serum protein adsorption, which has not been examined for such cellulosic hydrogels. Thus, this study investigated the effect of hydrogel compressive modulus and charge on surface protein adsorption *in vitro* by varying MC and CMC fractional composition, macromer concentration, and molecular weight.

MC and CMC were functionalized by esterification of hydroxyl groups with methacrylic anhydride and gels were fabricated via free radical polymerization using ammonium persulfate and ascorbic acid redox initiators[2]. Hydrogel hydrophobicity/charge was varied by mixing combinations of MC and CMC, while the modulus was altered by changing the macromer concentration (3% & 6%, w/v) and molecular weight (90, 250 kDa CMC). Generally, concentration was the largest driver of gel stiffness as indicated by compressive moduli ranging from 5.8±1 kPa to 19.9±3 kPa for the 3% group and 59.3±3 kPa to 90.6±32 kPa for the 6%. Relatedly, stiffer gels exhibited less swelling as measured by the equilibrium weight swelling ratio (W_{wet}/W_{dry}), with the 6% gels yielding lower values on average. Within a concentration group, charge played a clear role on swelling. For the 3% gels, the CMC only (negatively charged) gels yielded the highest ratio of 41±9, the MC only (hydrophobic) gels the lowest at 22±0.7, and a 1:1 mix of the two polymers was in between (ratio of 36±7). Interestingly, there was an inverse relationship between serum protein adsorption and gel modulus where every 3% gel formulation promoted more adsorption than its 6% macromer counterpart. Adsorption was also affected by charge, as no more than 63±11 µg/mL of protein was measured on MC gels, whereas the CMC only gel values ranged from 138±24 to 568±155 µg/mL.

Tailoring an injectable device is crucial for successful tissue incorporation. Long-term implants often suffer from sustained foreign body responses that may result in dense fibrous tissue encapsulation, and surface protein adsorption is a precursor to this adverse outcome[3]. Thus, the effects of biomaterial stiffness and charge on adsorption are often investigated and are material specific[4,5]. These findings represent an improved understanding of cellulosic materials and are currently being investigated for correlations to *in vivo* foreign body reaction and potential fibrous encapsulation.

8:00 PM SB09.03.27

A Fillable Scaffold Mimicking Extracellular Matrix for Chronic Tunnelling Wound Healing XiaoyuWang[1], SigenA[2], HongyunTai[3] and WenxinWang[1]; [1]Charles Institution of Dermatology, School of Medicine, University College Dublin, Ireland; [2]School of Medicine, Anhui University of Science and Technology, China; [3]Blafar Ltd, Ireland

Chronic wounds impose significant social and financial costs for patients and healthcare systems. Pathogenic abnormalities and hostile wound environments, such as inflammation, and augmented levels of Matrix metalloproteinases (MMPs) render the healing of chronic wounds a major and long-term challenge. Most commercial wound dressings are aimed to target a single non-healing factor, only a few are tailored to the multiple pathological abnormalities of chronic wounds and even fewer are suitable for tunnelling chronic wounds due to the difficulty in making adequate contact with wound beds. Herein, a novel fillable wound matrix mimicking extracellular matrix was fabricated by crosslinking gelatin and glycosaminoglycan *via* Schiff's base reaction to inhibit the inflammatory response, and inactivate excessive MMPs, ultimately promoting chronic wound healing. The degradation rates, pore size, swelling profile, cytotoxicity, cell proliferation and migration were investigated. Highly promoted cell adhesion and proliferation, and significantly improved migration of fibroblasts demonstrated that this fillable scaffold could provide a scaffold for cellular invasion and promote wound healing. It is easy to apply in difficult-to-access tunnelling wounds, indicating the promising potential in treating chronic tunnelling wounds. Moreover, the validation of sterilisation and virus inactivation laid the foundations for the commercialization of this fillable wound matrix.

8:00 PM SB09.03.28

Synthesis and Characterisation of Photocurable Poly(glycerol sebacate)-Co-Poly(ethylene glycol) Methacrylates MinaAleemardani, MichaelZivojin Trikić, Nicola HelenGreen and FrederikClaeyssens; University of Sheffield, United Kingdom

Introduction

Poly(glycerol sebacate)-co-poly(ethylene glycol) (PGS-co-PEG) copolymers have multifunctional and tuneable properties and great potential as high-performance biomaterials. However, the application of these materials is currently limited by harsh crosslinking conditions that include high temperatures and long reaction times. In this study, in order to overcome these limitations, the methacrylation process was conducted on PGS-co-PEG, resulting in photocurable (PGS-co-PEG)-M copolymers. Methacrylation of PGS-co-PEG, formulated respectively from polyethylene glycol (PEG2) or glycerol ethoxylate (PEG3), was investigated for the first time. (PGS-co-PEG2)-M and (PGS-co-PEG3)-M were found to be biodegradable, biocompatible, bioadhesive, pH-responsive and photocurable. Multifunctional characteristics remained after methacrylation, they were, however, drastically altered.

Methods

Polyethylene glycol 1000 g/mol (PEG2) and glycerol ethoxylate 1000 g/mol (PEG3) as two different types of PEG were used. A two-step polycondensation reaction was then used to produce PGS-co-PEG copolymers. Further, the methacrylation was carried out to develop photocurable, (PGS-co-PEG)-M, copolymers. Solid samples were made by adding 2% wt of photoinitiator to the (PGS-co-PEG)-M solutions, mixing, and UV curing.

Results

We have shown that the properties of these copolymers can be controlled by altering the type and amount of PEG and degree of crosslinking. Mechanical strength was enhanced significantly for (PGS-co-PEG)-M copolymers. Tensile Young's moduli of (PGS-co-PEG2)-M samples ranged from 0.08 to 0.48 MPa, while those of (PGS-co-PEG3)-M ranged from 2.67 to 35.47 MPa,

indicating the mechanical properties of the materials can be tuned via crosslinking density. In contrast, bioadhesive properties, such as lap-shear and adhesion strengths, were almost halved due to methacrylation. The degradation and swelling rates were slightly reduced, but pH-responsive behaviours at pH = 5.0, 7.4 and 9.1 were still observed. Cell metabolic activity and double-stranded DNA content, investigated by resazurin and PicoGreen® assays, demonstrated that the (PGS-co-PEG)-M copolymers were biocompatible.
Discussion and Conclusions
Photocurable (PGS-co-PEG)-M copolymers facilitate a simple and user-friendly curing process (photocrosslinking) that could be used for biomedical applications. Moreover, these photocurable copolymers are beneficial for various biofabrication methods, including emulsion techniques and additive manufacturing, either directly or indirectly.

Enhancing Bioactivity of MgO-SiO_2-P_2O_5-CaO-CaF_2 Glass Compositions for Biomedical Applications AndualemB. Workie; National Taiwan University of Science and Technology, Taiwan

In 1982, Kokubo introduced the pioneering concept of glass-ceramics (GC) incorporating apatite and wollastonite (AW). This study delves into the sintering feasibility of glass compositions based on MgO-SiO_2-P_2O_5-CaO-CaF_2 via spray pyrolysis (SP). Furthermore, it explores the intricate interplay between the resulting microstructures and bioactivity, specifically the development of a Fluorapatite layer, following various immersion durations in a simulated bodily fluid (SBF) environment at 37°C. The assessment of this material's bioactivity involved immersing samples for distinct intervals of 3, 5, 7, 14, and 21 days within the SBF solution. A direct correlation was revealed between bioactivity, sintering temperature, and soaking time; notably, the pH level generated in the SBF environment remained in the range of 7.4 to 8.2, well below the critical threshold of 8.5. This pH range augments the material's biocompatibility for potential biological applications while minimizing toxicity concerns. In order to investigate phase compositions and morphologies of the material, X-ray diffraction and scanning electron microscopy were used. Degradation rates were meticulously calculated, revealing an average weight loss of 2.59% ± 1.6. Remarkably, among all the samples, the one sintered at 1100°C demonstrated the highest bioactivity following immersion in SBF. Within the glass matrix of this sample, Fluorapatite crystals, Wollastonite crystals, and Whitlockite crystals were present in a dominant manner. By increasing crystallinity percentage, AWGC becomes more suitable for pharmaceutical applications by promoting apatite formation. Wollastonite also has unique properties, such as spheroid particle shape, whiteness, and lack of volatile components, that elevate ceramic production standards. In summary, this material amalgamates the advantages of a resorbable P-Ca-rich glass with the intrinsic bioactivity of wollastonite and apatite phases. The heat treatment process, performed at varying temperatures between 700°C and 1100°C, precipitates minuscule crystals of apatite, wollastonite, and whitlockite, thus augmenting bioactivity and yielding an average bulk density of 2.49 ± 0.32 g/cm^3. Further, soaking leads to continuous dissolution of both amorphous and wollastonite phases due to the release of P and Ca ions into the SBF medium.

Silicone Cryogel Skeletons for Enhanced Survival and Mechanics of Hydrogel-Based Implantable Cell Therapies WilliamJ. Jeang[1,2], MatthewA. Bochenek[1,2], SumanBose[1,2], YichaoZhao[1], BryanM. Wong[1], JiaweiYang[1,2], AlexisL. Jiang[3], RobertLanger[1,2] and DanielG. Anderson[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Boston Children's Hospital, United States; [3]Wellesley College, United States

The transplantation of cells engineered to secrete therapeutic proteins presents a promising method to address a range of chronic diseases including diabetes, cancer, and blood disorders. However, clinical translation faces several challenges regarding immune rejection, adequate nutrient supply to therapeutic cells, and the mechanical integrity of delivery constructs. Typically, non-degradable hydrogels are used to encase and protect therapeutic cells from immune rejection while still permitting the exchange of nutrients and therapeutics. However, a critical tradeoff exists wherein improving hydrogel mechanics (e.g., by increased crosslinking or molecular weight) often compromises biocompatibility and diffusion. Consequently, the design of macroscale, retrievable hydrogel devices often must balance the risks of mechanical failure and poor viability of encapsulated cells.

We address this challenge through a composite materials system centered around an oxygen-permeable silicone cryogel, which acts as an internal skeletal support for conventional hydrogel matrices coated by an anti-inflammatory polyelectrolyte for alleviating immunological responses towards foreign objects. We show that integration of the skeletal structure dramatically improves mechanical properties and effectively mitigates fracturing of implanted devices. Notably, our approach forgoes the use of commonly employed external housings, which can impede both the transport of nutrients to cells and the release of therapeutics to the host. By contrast, the skeleton leverages the superior oxygen diffusivity of silicone elastomers and a judiciously designed microstructure to improve the oxygenation of encapsulated cells. Fluorescence microscopy reveals that the skeleton acts as an internal scaffold that guides cellular proliferation and results in favorable changes in cell morphology. Pre-clinical studies demonstrate that these functionalities translate to significantly enhanced protein secretion from genetically engineered, xenogeneic cells in immunocompetent animals over 4 weeks, without the need for immunosuppression.

The resulting technology drives important improvements in the efficacy and practicality of implantable cell therapies. Namely, superior materials mechanics translates to easier device handling and reduces risk of mechanical failure, while the ability to sustain denser cell populations enables miniaturization of therapeutic implants. With the capability to modify encapsulated transgenic cells to secrete different biologics, the presented platform promises to support a broad spectrum of protein replacement therapies.

8:00 PM SB09.03.31
Voxelated Bioprinting of Double-Network Hydrogel Scaffolds LihengCai; University of Virginia, United States

Analogous of pixels to two-dimensional pictures, voxels — in the form of either small cubes or spheres — are the basic building blocks of three-dimensional (3D) objects. Here, we present a voxelated bioprinting technology that enables the digital assembly of interpenetrating alginate and polyacrylamide (PAM) double-network (DN) hydrogel droplets. The hydrogel is crosslinked via additive-free bioorthogonal chemistry involving a pair of stoichiometrically matched polymers. We develop theoretical frameworks to describe the crosslinking kinetics and stiffness of the hydrogels, and construct a diagram-of-state to delineate their mechanical properties. Multi-channel print nozzles are developed to allow on-demand mixing of highly viscoelastic bio-inks without significantly impairing cell viability. Further, we showcase the distinctive capability of voxelated bioprinting by creating highly complex 3D structures such as a hollow sphere composed of interconnected yet distinguishable hydrogel particles. Finally, we validate the cytocompatibility and *in vivo* stability of the printed DN scaffolds through cell encapsulation and animal transplantation.

8:00 PM SB09.03.32
Conductive Biodegradable Elastomeric Scaffolds for Bladder Regeneration RebeccaKeate[1], MatthewBury[2], JonathanRivnay[1], ArunSharma[2] and GuillermoAmeer[1]; [1]Northwestern University, United States; [2]Lurie Children's Hospital of Chicago, United States

Electrically conductive polymers are a unique class of materials that have demonstrated promising potential to enhance regeneration in several systems including muscle, skin, and neural tissue. The capability to bolster repair in a variety of tissue systems makes conductive polymers a promising material for advanced tissue engineering applications, such as organ regeneration, that require synergistic repair with various cell lineages. One such organ that could benefit from advanced repair solutions is the bladder, the function of which is impaired in cases such as neurodegenerative disorders, cancer or injury. Conductive polymers have not been used for bladder regeneration, in part due to the difficulties of incorporating conductive polymers in a mechanically robust tissue engineering solution. One reason for this loss of material integrity is the inherent phase mismatch between hydrophobic conductive polymers and the primarily hydrophilic biomatrices they are integrated within. Furthermore, we sought to mitigate these shortcomings by adopting a phase-compatible functionalization approach wherein the hydrophobic conductive polymer is embedded within a similarly hydrophobic biomaterial. Citrate-based materials are one such class of hydrophobic biomaterials with excellent bioactivity, morphological versatility, and degradability. By utilizing an in situ polymerization of the conductive polymer poly(3,4-ethylenedioxythiophene) in conjunction with citrate-based elastomers, we are able to preserve the intrinsic benefits of the base material including its powerful antioxidant activity, biocompatibility, and mechanical durability. We further demonstrate the applicability of this material in a bladder augmentation model, comparing our PEDOT-citrate based films to cell-seeded citrate-based counterparts. Analyzing regenerated bladder function through urodynamics studies, we find that PEDOT-incorporated films facilitate repair significantly compared to the cell-seeded films and significantly better than the pristine citrate-based film. Furthermore, this work demonstrates (1) advantages of a phase-compatible functionalization approach from a materials-perspective, (2) application of conductive polymer-based materials in a novel regenerative system, and (3) the capabilities for conductive polymers to promote regeneration as effectively as a cell-seeded material.

SESSION SB09.04: Biomaterials for Regeneration of Tissues

Panthenol Citrate Biomaterials Accelerate Wound Healing and Restore Tissue Integrity HuifengWang, ChongwenDuan, RebeccaKeate and GuillermoAmeer; Northwestern University, United States

The global surge in diabetes has led to diabetic foot ulcers (DFU) becoming a predominant diabetes-related complication, resulting in hospitalizations and, in severe cases, lower limb amputations. A staggering 34% of individuals with diabetes will encounter a DFU during their lifetime, with 15-20% becoming chronic or non-healing wounds. These wounds differ significantly from normal wounds, plagued by persistent oxidative stress, abnormal inflammatory responses, impaired vascularization, and innervation, among other patient-specific challenges. Furthermore, suboptimal physical properties of regenerated tissue often lead to recurrent or reopened wounds, with alarming statistics indicating recurring DFUs may result in amputation in 71-85% of cases. Meeting the pressing need for wound treatments that not only expedite wound closure but also enhance the quality of regenerated tissue is paramount in improving diabetic wound care outcomes. In this study, we present the synthesis and characterization of panthenol citrate (PC), a versatile compound with potential applications in soluble form as a cleansing solution and as a regenerative dressing to address impaired wound healing in diabetes. PC is derived by reacting citric acid with panthenol, offering intriguing optical, chemical, and biological properties conducive to protecting and regenerating skin tissue. With citric acid's established safety record and panthenol's known skin benefits, PC represents a promising candidate. PC demonstrates antioxidant, antibacterial, anti-inflammatory, and proangiogenic properties, facilitating wound closure in diabetes while restoring skin's mechanical and electrophysiological properties. In both solution and hydrogel forms, PC stimulates keratinocyte and dermal fibroblast migration and proliferation, resulting in improved re-epithelialization, granulation tissue formation, and accelerated wound closure. Remarkably, PC significantly enhances the mechanical strength and electrophysiological properties of regenerated skin. To our knowledge, this is the first study to demonstrate such comprehensive improvements in the histological and physical properties of regenerated skin following treatment with both monomeric and polymeric forms of a compound. Our approach encompasses the utilization of PC as a wound cleansing solution or as a component of a thermoresponsive biomacromolecule for use as a regenerative dressing. In conclusion, PC emerges as a pivotal building block for advanced tissue regeneration therapies, holding the promise of markedly improving wound care management for diabetic patients.

8:45 AM SB09.04.02
Ultrasound-Responsive Engineered Tissue Constructs for Remote Manipulation of Cell Signaling KatherineT. Huynh, MaryK. Lowrey, SaraEvans-Dutson, KevinSchilling, DanielleS. Brasino, MithilaHandu, SeanSpeese and CarolynSchutt Ibsen; Oregon Health and Science University, United States

The controlled presentation of cell signaling proteins in time and space is critical for coordinating biological processes that regulate tissue regeneration. There is a need to recreate and harness these complex dynamic processes within 3D cell scaffolds to better understand their biological roles and provide new regenerative therapies. Manipulating gene expression of targeted cells at specific times and locations within these scaffolds enables controlled protein presentation within a 3D tissue construct. This is a critical tool to control cell behavior and influence cell interactions, including those involved in tissue vascularization and wound repair. These genetic manipulations are difficult to achieve in 3D using traditional transfection methods due to diffusional barriers created by the scaffold itself. To address this challenge, our team has pioneered the development of ultrasound-responsive cell culture platforms (SonoScaffolds) for noninvasive and spatiotemporally-controlled genetic manipulation of cells in 3D scaffolds. Here, focused ultrasound interacts with integrated echogenic particles within hydrogel matrices to locally deliver nucleic acids to cells to manipulate protein expression and secretion. Ultrasound has distinct advantages as a triggering stimulus as it can be focused to small volumes with multi-centimeter tissue penetration depth [1-2].

Using this approach, we have successfully demonstrated ultrasound-induced transfection of cells embedded in SonoScaffolds, including localized expression of vascular endothelial growth factor (VEGF). A dual expression VEGF-GFP fusion plasmid was coupled to lipid-based ultrasound-responsive microparticles and incorporated into a cell-seeded collagen hydrogel. Focused ultrasound (1 mm^3 focal zone) was applied noninvasively within the hydrogel matrix. Transfection of matrix-embedded cells was localized to the ultrasound-exposed region. The cells showed a punctate distribution of VEGF-GFP consistent with packaging of VEGF into secretory vesicles. Creating user-defined 3D spatiotemporal patterns of growth factor expression can be leveraged to elucidate how spatial presentation and timing of protein expression affect 3D cell migration and to inform therapeutic strategies for tissue repair.

Pushing the boundaries even further, we are creating ultrasound stimuli-responsive scaffolds with complex 3D architectures by integrating our echogenic gene delivery particles into 3D-bioprintable inks. Transfection was selectively activated by ultrasound within printed constructs, demonstrating the first cell-seeded bioprinted structure designed for ultrasound-controlled gene delivery. We are further extending this technique to 3D-printed spheroids and organoid cultures. Together, this work demonstrates a new class of 3D-programmable cell culture materials that enable remote, spatiotemporally-defined genetic perturbation of embedded cells and multicellular structures. These systems will provide new insights into coordinated cell processes and how growth factor presentation can be leveraged to direct healing in implantable biomaterials, with important applications in tissue construct maturation, vascularization, and tissue regeneration.

Shape Memory Polymer Bioglass Composite Scaffolds to Heal Complex Bone Defects BrandonM. Nitschke, AlexanderE. Konz, ElizabethA. Butchko, MaryGraceN. Wahby and MelissaGrunlan; Texas A&M University, United States

Craniomaxillofacial (CMF) defects are generally treated with autografts, but difficulty achieving a conformal fit with can lead to premature graft resorption. Thus, we have developed shape memory polymer (SMP) scaffolds that can “self-fit” into irregularly shaped CMF defects. These are formed from biodegradable *linear*-poly(e-caprolactone) diacrylate (*linear*-PCL-DA), with crystalline lamellae serving as switching segments (T_m = ~55 deg C) and crosslinks acting as netpoints. After exposure to warm saline (~55 deg C), the scaffold becomes malleable, allowing press-fitting into an irregular defect before cooling to body temperature restores its rigid state. Herein, SMP scaffold composition was systematically tailored to enhance thermal tissue safety, degradation rate, modulus, and bioactivity. *Star*-architectures of constituent polymers and inclusion of bioactive Bioglass (BG) were utilized to achieve these properties. To reduce the self-fitting temperature, SMP scaffolds were be formed from *star*-PCL-tetraacrylate (*star*-PCL-TA; T_m = ~45 deg C). Furthermore, to accelerate degradation and tune modulus, semi-interpenetrating networks (semi-IPNs) were formed by including *linear*- or *star*-poly(l-lactic acid) (PLLA). 45S5 BG is known to induce hydroxyapatite (HAp) mineralization that subsequently promotes osteogenic differentiation (i.e., osteoinductivity) as well as osseointegration. Scaffolds were prepared from *linear*-PCL-DA or *star*-PCL-DA, as well as each with *linear*- or *star*-PLLA (75:25 wt% ratio). BG was incorporated at varying levels into scaffolds (up to 30 wt%) during fabrication. The BG content was confirmed using thermal gravimetric analysis (TGA). The compressive mechanical properties of the scaffolds were evaluated, as well as the *in vitro* degradation behavior. Notably, composite scaffolds exhibited rapid formation (24 hours) of HAp when exposed to simulated body fluid (SBF) as confirmed by SEM/EDS. Overall, these composite SMP scaffolds are expected to provide enhanced healing of complex bone defects.

9:15 AM *SB09.04.04
***In Vitro* Engineered Tissue Screens for Cardiac Regeneration**NenadBursac; Duke University, United States

Cell and gene therapies for heart regeneration represent a promising approach to remuscularize the heart following myocardial injury. These regenerative therapies can benefit from *in vitro* chemical and genetic screens in engineered heart tissues to identify and study novel inducers of cardiomyocyte (CM) proliferation. Our recent screens in neonatal rat and human iPSC-derived CMs have identified activations of the mitogen activated protein kinase (MAPK) pathway and pentose phosphate pathway (PPP) as two promising strategies with pro-proliferative effects in engineered cardiac tissues (ECTs). Specifically, a doxycyclin-inducible, CM-specific expression of constitutively-active mutant of BRAF (BRAF-V600E), a major kinase in the MAPK pathway, was sufficient to induce CM cycling in ECTs, but resulted in functional decline and tissue stiffening. These adverse functional effects were associated with broad transcriptional changes, a shift to glycolytic metabolism, and induction of a pro-migratory CM phenotype. While ERK activation was required for the initial establishment of the caBRAF-induced phenotype, inhibition of ERK after the phenotype had been established was insufficient to restore the loss of tissue function. Transient caBRAF expression in ECTs rapidly induced CM cycling that preceded functional decline, which was reversible only if MAPK activation was brief (<3 days). Notably, the increase in ECT stiffness resulting from sustained caBRAF expression was dispensable for induction of CM cycling, as transient caBRAF expression yielded increased CM cycling without altered stiffness. Furthermore, in an independent in vitro CRISPR/Cas9 knockout screen, we identified adenosine deaminase knockout (ADA-KO) as the most effective inducer of CM cycle activity in neonatal rat ECTs and long-term cultured hiPSC-CMs. RNA sequencing of ADA-KO vs. control ECTs and measurements of metabolite abundance and enzyme activity suggested lactate generation and PPP upregulation as potential drivers of CM proliferation. Inhibition of the PPP rate-limiting enzyme glucose-6-phosphate dehydrogenase (G6PD) via the small molecule inhibitor 6-aminonicotinamide prevented ADA-KO

induced CM cycling, while increased PPP activity *via* doxycycline-inducible lentiviral G6PD overexpression yielded a significant increase in CM cycling. Overall, our studies demonstrate the utility of *in vitro* engineered cardiac tissues as a testbed for identification of novel CM mitogens with potential for use in cardiac regenerative therapies.

9:45 AM SB09.04.05
3D Bioprinting of Dense Cellular Structures within Functional Hydrogels with User-Defined Heterogeneity AlperenAbaci and MuratGuvendiren; New Jersey Institute of Technology, United States

3D bioprinting has a strong potential to address tissue and organ shortage for transplantation. Successful fabrication of a functional tissue requires bioprinting strategies that can replicate the biological and structural features of the native tissue including formation of dense cellular structures. Embedded 3D printing approaches advanced extrusion-based bioprinting technology for fabrication of architecturally and biologically complex structures, yet this technology requires the use of support baths which generally hinders the relevant bioactivity and heterogeneity. In this study, we developed a new method to create dense cellular structures where cell-only bioinks could be deposited into photocurable support hydrogels with tunable stiffness, degradation and bioactivity. Our approach can utilize multiple cell types or functional hydrogels to create highly heterogeneous and complex structures that could potentially be used to fabricate functional tissue models, as well as tissue interfaces, with relevant biochemical and physical complexities.

In this study, we demonstrate bioprinting of dense cellular structures using fibroblasts (NIH 3T3), human umbilical vein endothelial cells (HUVECs), and human mesenchymal stem cells (hMSCs) within support or functional hydrogels. To demonstrate the potential of our approach and importance of matrix functionalization, we investigate the osteogenic differentiation of hMSCs bioprinted within MeHA hydrogels with controlled stiffness and bioactivity. To control stem cell aspect ratio initial concentration of the MeHA hydrogel is varied (5-15%). Bioactivity is varied by tethering RGD and BMP-2. Dense hMSCs structures show great overall cell viability (>80%) and inclusion of RGD and then BMP-2 significantly enhanced osteogenic differentiation. This is confirmed with ALP assay, Alizarin Red staining and osteocalcin immunostaining. Finally, we fabricated dense cellular structures with spatially controlled cellular composition and matrix composition towards creating tissue interfaces.

Conflict of Interest: New Jersey Institute of Technology has a financial interest in the bioprinting approach reported in this manuscript and has already filed a patent application for the technology described in this paper (U.S. Application No. 17/588,998).

Materials for Engineering Cartilage Integration HelenLu; Columbia University, United States

Musculoskeletal joint motion is facilitated by synchronized interactions between multiple tissue types and the seamless integration of bone with soft tissues such as tendons, ligaments or cartilage. Many of these soft tissues transit into bone through a multi-region interface that minimizes the formation of stress concentrations while enabling load transfer between soft and hard tissues. Given its functional significance, re-establishment of multi-tissue interface is thus critical for promoting the integrative repair of biological as well as tissue engineering cartilage grafts. To this end, interface regeneration and formation of composite tissue units have become a design consideration in tissue engineering. Using the classic osteochondral interface as an example and inspired by current understandings of the native interface structure-function relationship, strategies for interface regeneration and homeostasis will be discussed, with the focus on strategic biomimicry and functional multi-tissue integration.

11:00 AM SB09.04.07
Development of a Biomimetic Multi-Layered Functionalised Antimicrobial Biomaterial Scaffold for Healing of Complex Wounds MatthewMcGrath[1,2], Juan CarlosPalomeque-Chávez[1,2], ShaneBrowne[1] and FergalJ. O'Brien[1,2,3]; [1]Royal College of Suregons in Ireland, Ireland; [2]Advanced Materials and Bioengineering Research Centre (AMBER), RCSI and TCD, Ireland; [3]Trinity Centre for Biomedical Engineering, TCD, Ireland

Diabetic foot ulcers (DFUs) are chronic non-healing wounds that constitute one of the most devastating complications of diabetes. Dysfunctional angiogenesis plays a key role in DFU, limiting tissue repair leaving wounds open and prone to infection[1]. Biomaterial approaches, and in particular the use of collagen-glycosaminoglycan (CG) scaffolds, have shown promise to promote tissue regeneration and burn wound healing[2]. These biomaterial scaffolds provide a platform for infiltrating cells into the wound environment but do not directly deal with the underlying pathology of diabetic wounds, so further functionalisation is needed for these complex wounds. The aim of this project was to engineer a biomimetic bi-layered biomaterial scaffold designed to replicate the anatomical structure of the native skin with an epidermal antimicrobial collagen/chitosan film to prevent wound infection and a pro-angiogenic, matrix molecule functionalised dermal porous CG scaffold layer to heal complex wounds.

A bi-layered scaffold was developed by combining an antimicrobial collagen/chitosan film (0.5%, 1% / 0.75%) with a type I collagen, chondroitin-6-sulfate slurry by lyophilisation. Mechanical properties, including interlayer adhesion, were optimised through the film's collagen content and crosslinking treatment (non-crosslinked (NXL)/dehydrothermal/carbodiimide EDAC crosslinking). The CG layer was then functionalised with either fibronectin, collagen IV, or laminin-1 to enhance its angiogenic and regenerative potential. The film's antimicrobial potential was tested versus *staphylococcus aureus*, and the ability of the film to support re-epithelialisation was verified through seeding of human epidermal keratinocytes (HaCaTs). The vascularisation potential of the scaffold was investigated through the culture of human umbilical vein endothelial cells (HUVECs), and human dermal fibroblasts (HDFs) on the functionalised CG scaffold layer.

The bi-layered scaffolds had enhanced mechanical properties suitable for implantation following EDAC crosslinking (compressive modulus = 1.83 ± 0.0035 kPa (EDAC), 0.72 ± 0.15 kPa (NXL)) adhesion strength between layers = 32.3 ± 4.5 kPa (EDAC), 22.5 ± 8.8 kPa (NXL)) Biological characterisation showed that all collagen/chitosan films had antimicrobial activity versus s*taphylococcus aureus* regardless of crosslinking regime and collagen composition and supported the metabolic activity of human epidermal keratinocytes. However, crosslinked scaffolds showed enhanced infiltration and growth of vascular cells[3]. Functionalisation, of the CG layer with laminin-1 significant increased production of vascular endothelial growth factor (VEGF) by HDFs over 7 days (1044 ± 112 pg/ml). In addition, HUVECs seeded on these scaffolds formed tubular structures.

This study has led to the development of a novel biomimetic multi-layered functionalised antimicrobial biomaterial scaffold for complex wound healing. The collagen/chitosan film layer demonstrated the ability to inhibit growth and infiltration of *staphylococcus aureus*, the most common bacterial isolate found in infected wounds[4] and supported metabolic activity of epidermal cells, demonstrating significant potential as a protective barrier to cover the wound and as a surface for re-epithelialisation. Functionalisation of the CG scaffold layer with laminin-1 enhanced the pro-angiogenic regenerative potential of the dermal CG scaffold layer, with increased growth factor production and vascular cell tube formation. Taken together, these results demonstrate the promise of this scaffold as a biomaterial-based solution to treat DFUs.

A Versatile, Bioengineered Skin Reconstruction Device Designed for Austere Environments JoachimG. Veit, MorganWeidow and MonicaSerban; University of Montana, United States

Austere environments in which access to medical facilities, medical personnel, or even water and electricity is limited or unavailable pose unique challenges for medical device product design. Currently existing skin substitutes are severely inadequate for the treatment of severe burns, chronic wounds, battlefield injuries, or work-related injuries in resource-limited settings. For such settings, an ideal device should be biocompatible, bioresorbable, promote tissue healing, not require trained medical personnel for deployment and use, and should enable topical drug delivery. As proof of concept for such a device, silk fibroin and an antioxidant hyaluronic acid derivative were chosen as primary constituents. The final formulation was selected to optimize tensile strength while retaining mechanical compliance and protection from reactive oxygen species (ROS). The ultimate tensile strength of the device was 438.0 KPa. Viability of dermal fibroblasts challenged with ROS-generating menadione decreased to 49.7% of control, which was rescued by pre-treatment with the hyaluronic acid derivative to 85.0% of control. The final device

formulation was also tested in a standardized, validated, *in vitro* skin irritation test which revealed no tissue damage or statistical difference from control. Improved topical drug delivery was achieved via an integrated silk fibroin microneedle array and selective device processing to generate crosslinked/through pores. The final device including these features showed a 223% increase in small molecule epidermal permeation relative to the control. Scaffold porosity and microneedle integrity before and after application were confirmed by electron microscopy. Next, the device was designed to be self-adherent to enable deployment without the need of traditional fixation methods. Device tissue adhesive strength (12.0 MPa) was evaluated and shown to be comparable to a commercial adhesive surgical drape (12.9 MPa) and superior to an over-the-counter liquid bandage (4.1 MPa). Finally, the device's wound healing potential was assessed in an *in vitro* full-thickness skin wound model which showed promising device integration into the tissue and cellular migration into and above the device. Overall, these results suggest that this prototype, specifically designed for use in austere environments, is mechanically robust, is cytocompatible, protects from ROS damage, is self-adherent without traditional fixation methods, and promotes tissue repair.

11:45 AM SB09.04.09

Development of Antibiotic-Free Antimicrobial Scaffolds for Effective Delivery of Osteogenic & Angiogenic MicroRNAs to Simultaneously Treat and Repair Infected Bone Tissue JoannaSadowska[1], KatelynGenoud[1], RachaelPower[1], AustynMatheson[1], ArlyngGonzález-Vázquez[1], LaraCostard[1], TanguyHallegouet[2], GangChen[1], BrentonCavanagh[1], HuijunZhang[3], AldoBoccaccini[3] and FergalO'Brien[1]; [1]Royal College of Surgeons in Ireland, Ireland; [2]University of Strasbourg, France; [3]Friedrich–Alexander University Erlangen– Nuremberg, Germany

INTRODUCTION: The treatment of bacterial infection of bone while regenerating bone at the same time is extraordinarily challenging in clinical settings (1). The escalating problem of antimicrobial resistance necessitates the development of novel antibiotic-free strategies to eradicate bacteria. One such approach is the use of metal-doped nanoparticles (2). To address bone regeneration, the approaches include the local delivery of gene therapies, such as microRNA in scaffold systems. A scaffold provides structural support while microRNA induces host cells to produce multiple angiogenic and osteogenic proteins essential for bone healing (3). The present study combines these two promising approaches to develop a multifunctional biomaterial-based platform with angiogenic, osteogenic and antimicrobial properties. The scaffold delivers osteogenic genes (by delivering antagomiR-138, a microRNA targeting ERK pathway) (4) and antibiotic-free antimicrobial nanoparticles (copper-doped bioactive glass, CuBG) (2), leading to a novel platform with superior therapeutic potential and angiogenic, osteogenic and antimicrobial features.

METHODS: Freeze-dried collagen-based scaffolds, previously optimized in our lab for bone regeneration (3), were enriched with antagomiR-138 and Cu-BG nanoparticles and assessed *in vitro* using human mesenchymal stem cells (transfection efficacy, osteogenic and angiogenic gene expression, metabolic activity, DNA content, alkaline phosphatase activity, calcium deposition). The antimicrobial properties of the scaffolds were assessed using gram-positive (*S.aureus*) and gram-negative (*E.coli*). The angiogenic and osteogenic properties of the scaffolds were assessed in two *in vivo* models: a load-bearing 5 mm femoral defect in female Sprague Dawley rats and a chick chorioallantoic membrane model (CAM).

RESULTS SECTION: The CuBG and antagomiR-138 particles were effectively incorporated into collagen scaffolds without affecting the mechanical and structural properties of the scaffolds. The CuBG scaffolds reduced the adhesion of *S.aureus* and *E.coli* 5-fold and 2-fold, respectively. The antagomiR138 and-CuBG functionalised scaffolds effectively transfected hMSCs *in vitro*, enhancing the osteogenic (COLL1A2, NOCH4, SMAD5) and angiogenic genes (VEGFA) and calcium production. The *in vivo* assessment showed that antagomiR-138 scaffolds promoted enhanced healing in the femoral defect model by producing endochondral ossification. The antagomiR138-CuBG scaffold promoted vasculogenesis, improving the number of branches and the length of blood vessels in *in vivo* CAM model.

DISCUSSION: The study demonstrated the therapeutic potential of a multifunctional, antagomiR138 antimicrobial scaffold system. The system delivered antagomiR138 to hMSCs *in vitro*, enhancing the osteogenic genes and mineralisation. The incorporation of CuBG nanoparticles enhanced antimicrobial mechanisms (production of ROS) in *S.aureus* and *E.coli*, inhibiting the attachment to the scaffold. The antagomiR138 scaffolds improved osteogenesis and vasculogenesis *in vivo* in a femoral defect model and a chick chorioallantoic membrane model, respectively. Our work demonstrates, for the first time, the feasibility of combining non-antibiotic biomaterial based-approaches with gene therapeutics for developing a platform which not only regenerates bone but also fights rising problems of antimicrobial resistance. This approach opens the door to new possibilities in a myriad of indications beyond bone repair.

A Decellularized Cartilage Biomaterials Approach to Pediatric Airway Reconstruction PaulGehret[1,2], SoheilaAli Akbari Ghavimi[2], AlexandraDumas[1,2], RyanBorek[2,1], IanJacobs[2,1] and RiccardoGottardi[1,2]; [1]University of Pennsylvania, United States; [2]Children's Hospital of Philadelphia, United States

Introduction: Severe subglottic stenosis (SGS), the narrowing of the airway just below the vocal folds, develops in 8.3% of ICU neonates and directly leads to debilitating comorbidities [1,2]. Pediatric SGS is the result of prolonged intubation and dramatically lowers the child's long-term quality of life, as they often suffer speech and cognitive delays. In the most severe cases, laryngotracheal reconstruction (LTR) surgery is required to expand the airway and restore airflow [1,2]. During LTR, autologous costal cartilage is harvested, shaped, and implanted into the child's airway. However, a major obstacle is that young children often lack sufficient costal cartilage to ensure a successful graft surgery, leading to donor site morbidity and high risk for restenosis, necessitating revision surgery3. Our objective is to utilize xenogeneic decellularized meniscal cartilage (MEND) to engineer a cartilage implant populated with patients' cells to circumvent the limitations of pediatric autologous cartilage.
Materials and Methods: *Meniscus decellularization and channel formation:* Meniscus cross-sections were devitalized with 4 freeze/thaw cycles then subjected to pepsin and acetic followed by treatment with elastase. 6 mm cylinders were created with a biopsy punch from the posterior half of the digested cross-sections to ensure the maximum number of channels. *Decellularized Meniscus Reinvasion:* Sterile decellularized, digested meniscus (MEND) cylinders were placed on top of the membrane insert of a transwell plate and cartilage progenitor cells (CPC) were seeded on top of the MEND cylinders. After 3 days, the MEND cylinders were fixed, sectioned, and stained. *In Vitro Differentiation:* CPC-invaded MEND were cultured in chondrogenic medium for 3 weeks and media was renewed twice/week. The differentiated construct were examined for gene expression, compression testing, and histology. *Rabbit Laryngotracheal Reconstructions:* Acellular, re-cellularized, or differentiated decellularized cartilage was implanted in an anterior cricoid split LTR. After 3 months, the rabbits were euthanized and the construct phenotype, airway expansion, and histomorphometry were assessed.
Results and Discussion: After enzymatic treatment, H&E images of circumferential sections showed that clearly aligned channels are visible post-treatment. Following a serum gradient (transwell) migration, cartilage progenitor cells (blue DAPI nuclei) penetrated in 3 days through the channels the entire depth of the construct (collagen red auto-fluorescence) reaching a density similar to that of native cartilage. After 3 weeks of differentiation, cells were arranged into lacunae with columnar structures resembling the organization of native cartilage and secreted a substantial amount of glycosaminoglycans (GAGs). Importantly, the constructs increased in both bulk mechanical strength and GAG content. Finally, a 38 rabbit study was conducted and MEND was implanted in a rabbit LTR. MEND successfully expanded the airway over the course of the 3 months and integrated with the existing cartilage as shown by the increase of GAGs within the construct and the neo-chondrification protruding from the cartilage rings. We established how decellularized meniscal cartilage reinvaded with progenitor cells can significantly improve outcomes for pediatric LTR.
Ethical Statement: All animal studies were conducted with IACUC approval.

Strategies and Tools for Next-Generation Cardiovascular Medical Device Materials AnnaWaterhouse[1,2,2]; [1]University of Sydney, Australia; [2]The University of Sydney, Australia

An increasing number of medical devices directly contact the blood, from temporary catheters and dialysis machines, to permanent stents and artificial hearts. However, blood-contacting medical devices remain problematic due to the body's recognition of the foreign materials they are made from, resulting in side effects such as blood clots (thrombosis), inflammatory based reactions or a lack of endothelialisation. Blood clots can cause the devices to fail, or they can break off (embolise) and lead to a stroke or pulmonary embolism. This is currently mitigated using anti-thrombotic drugs, however these cause bleeding risks in patients.

Biomimetic approaches to both create tools to evaluate materials, and to design next generation materials for medical devices are increasingly used and hold potential to improve blood-contacting medical devices. Recent years have seen the wide adoption of microfluidic and organ-on-a-chip technologies to mimic aspects of the host environment, providing physiologically relevant conditions allowing advances in biological knowledge of biointerfaces and material function. We have developed a range of microfluidic and organ-on-a-chip based tools to evaluate existing materials to better understand failure mechanisms of medical devices, pathophysiological processes, and mechanisms of actions of newly developed medical device materials aimed to improve function and reduce device complications.

We are also developing a range of biomimetic approaches to generate new materials including mimicking the local host environment to integrate implants, mimicking biological processes or structures to create new devices and mimicking nature to impart specific functions to devices. The ultimate aim of these biomimetic tools and novel materials is to promote integration of the device with the host to improve outcomes for patients receiving medical devices.

Magneto-Responsive Silk Microfibers for Neuroregeneration JeannineCoburn and MelissaWojnowski; Worcester Polytechnic Institute, United States

Magneto-responsive fiber-based architectures represent an exciting prospect in the development of hierarchically ordered tissue engineering scaffolds, facilitating non-invasive, in situ spatiotemporal manipulation and organization of regenerative cues via an externally applied magnetic field. [1] While magneto-responsive fiber architectures are typically fabricated from magnetic nanoparticle (MNP)-doped polymeric solutions, risks of MNP leaching and subsequent cytotoxic intracellular accumulation remain unaddressed. To this end, chelation of paramagnetic ferric iron ions (Fe^{3+}) is a promising alternative to MNP-doping. [2] Given its innately fibrous structure, notable capacity for heavy metal chelation, and FDA-approval as a biocompatible, biodegradable, naturally derived biomaterial [3, 4], silk fibroin extracted from *Bombyx mori* silkworm cocoons offers a unique, unexplored opportunity to fabricate MNP-free magneto-responsive fiber architectures. In this work, passive chelation of ferric iron is explored as an MNP-free alternative in the magnetic functionalization of silk-based biomaterials. Silk fibroin microfibers (mSF) treated with aqueous ferric chloride ($FeCl_3$) exhibit significantly increased iron content relative to the nascent protein as determined by x-ray photoelectron spectroscopy (XPS). Coupled with the absence of detectable chlorine traces and iron oxide species, the predominantly ferric oxidation state of iron within $FeCl_3$-treated mSF (Fe^{3+}-mSF) suggest incorporation of iron, without reduction, at innate oxygen-containing ligands of mSF. On exposure to an external magnetic field, Fe^{3+}-mSF displays paramagnetic magnetization behaviors that facilitate field-parallel alignment. Both magnetization and directional uniformity increased concomitantly with iron exposure during $FeCl_3$ treatment, suggesting the observed magnetic response of Fe^{3+}-mSF is derived from the chelated iron. In vitro biocompatibility of the Fe^{3+}-mSF has been confirmed using human dermal fibroblasts and neuroprogenitor cells (NPCs). This work is the first to investigate the magneto-responsive properties and biocompatibility of ferric iron chelated SF, demonstrating a novel, MNP-free alternative approach to magnetic functionalization of TE scaffolds. Ongoing work is underway to evaluate NPC alignment and axonal growth, differentiation, and function in response to the aligned guidance architecture.

Engineering Extracellular Vesicles as Therapeutics Agents for Atherosclerosis EunjiChung; University of Southern California, United States

Atherosclerosis is the primary contributor to cardiovascular disease which is the leading cause of death worldwide. Although vascular smooth muscle cells (VSMCs) undergo phenotypic switching and play a significant role in atherosclerosis progression, extracellular vesicles (EVs) secreted from healthy, contractile VSMCs have been reported to contain endogenous therapeutic cargo including calcification inhibitors and atheroprotective microRNAs (miR) that can inhibit disease progression. Thus, we hypothesized that EVs secreted from contractile VSMCs can be harnessed and further engineered to act as both safe and effective drug delivery vehicles for atherosclerosis. To test our hypothesis, we isolated, characterized, and modified the surface of EVs with CCR2 and hydroxyapatite (HA) binding peptides to actively target synthetic and osteoblast-like, atherogenic VSMCs. Additionally, we enriched EVs with therapeutic miR-145 and miR-133 through sonication as well as by overexpressing miR-145 and miR-133 in VSMCs and collecting the secreted, engineered EVs. We show engineered EVs can modulate phenotypic switching in VSMCs and present their potential in vivo in atherogenic mouse models.

Microvascular Imaging in Brain Tumors by Supramolecular MR Contrast Agents AtsushiMahara[1], SoniRaghav[1], ShigeyoshiSaito[2] and TetsujiYamaoka[1,3]; [1]National Cerebral and Cardiovascular Center, Japan; [2]Osaka University Graduate School of Medicine, Japan; [3]Komatsu University, Japan

[Introduction] Magnetic resonance angiography (MRA) is used clinically to diagnose brain diseases. Although the MRA visualizes the main cerebral artery such as Willis arterial circle and middle cerebral artery without any contrast agents, it is hard to imagine the microvasculature and entire vascular network due to low MR signals. In our previous study, we developed the fluorescein and Gd-chelate conjugated 8-arm PEGs (8-arm PEG-FGd_3) as the MRA contrast agents, and microvascular structure was enhanced on MRA scan by the administration of these contrast agents[1,2]. Here, we discuss the structural feature of the 8-arm PEG-FGd_3 and its blood circulating profile. Furthermore, the microvascular formation in the brain tumor would be presented.
[Methods] The 8-arm PEG conjugated with one fluorescein and three Gd-chelates (8-arm PEG-FGd_3) was synthesized by the reported procedure2. Briefly, fluorescein isothiocyanate and 1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA) mono-N-hydroxysuccinimide ester were added into the 8-arm PEG with 15 kDa of the molecular weight. The polymers were purified by a dialysis membrane. After the addition of gadolinium, 8-arm PEG-FGd3 was acquired. The products in each step were confirmed by 1H-NMR. As the control, 8-arm PEG conjugated with one fluorescein (8-arm PEG-F) was also prepared. Structural features were estimated by dynamic light scattering analysis (DLS) and atomic force microscopy (AFM), and the molecular environment of fluorescein was analyzed by fluorescence spectroscopy and 1H-NMR measurements. The brain tumor in the SD-rat was scanned by 7T-MRI with or without contrast agents.
[Results and Discussion] The hydrodynamic radius of the 8-arm PEG was 6 to 8 nm within the concentration range from 0.5 to 100 mg/mL. On the other hand, the hydrodynamic radius of 8-arm PEG-FGd_3 largely depended on the polymer concentration. When the concentration of the 8-arm PEG-FG_3 was 1 to 5 mg/mL, the radius was approximately 7 nm. At the concentration ranges higher than 100 mg/mL, the radius was increased to over 1000 nm. As the results of AFM observation, nanoparticles, and fiber structure were observed at the concentration ranges from more than 100 mg/mL. The fiber was formed by the stacking of the nanoparticles. Spectroscopic analysis revealed that fluorescein groups of 8-arm PEG-FGd_3 were in the center part of the particle and stacked with the π-stacking interactions. The brain microvessel and tumors in rats were scanned on MRI. Microvasculature with a minimum diameter of 45 μm was clearly visualized on MR images only when the 8-arm PEG-FGd_3 at the concentration of 200 mg/mL was administrated. The microvessel structure in the tumors was also visualized with the supra-high resolution, and these data provided information on vascular permeability.

8:00 PM SB09.06.02
Rapamycin-Loaded Boronic Acid-Based Hydrogel as Artificial Perivascular Tissue for Prevention of Vascular Graft Failure HueT. Le[1], AtsushiMahara[1], TakeshiNagasaki[2] and TetsujiYamaoka[1,3]; [1]The National Cerebral and Cardiovascular Center Research Institute, Japan; [2]The Osaka Metropolitan University, Japan; [3]The Komatsu University, Japan

Introduction: Excessive proliferation of subendothelial smooth muscle cells (SMC) leads to anastomotic stenosis, resulting in an increase in graft failure rate, a big issue of vascular graft

transplantation. Perivascular adipose tissue (PVAT), an adipose tissue adherent on the vessel's external surface, has been shown to inhibit the excessive proliferation of SMC via releasing biomolecules[1]. However, the PVAT is mostly absent in vascular grafts involving native and artificial ones. Phenylboronic acid (PBA)-based polymer has been reported to form a hydrogel with synthetic polyvinyl alcohol (PVA) and bind to cell membranes and tissue surfaces via PBA-sialic acid integration[2]. Rapamycin (RPM) has been clinically approved as an anti-stenosis drug because of its cell anti-proliferative ability[3]. Recently, we synthesized poly (3-acrylamidophenylboronic acid-co-acrylamide) (BAAm) polymer. In this study, we proposed RPM-loaded BAAm/PVA (BAVA) hydrogel serving as an artificial PVAT[4], thus its tissue adhesive and drug release characterization and anti-SMC proliferative function were investigated. Furthermore, we tested its effectiveness on graft patency in a porcine model.
Method: Two hydrogels with 25 and 50 mg/mL of BAAm (named BAVA25 and BAVA50, respectively) were prepared. A decellularized vascular graft with 2.5mm in inner diameter was selected as the graft model[5]. To examine the tissue adhesive ability, the lap-shear test was done after loading the hydrogel on the graft's external surface. To assess drug release ability, the RPM-loaded BAVA hydrogel was immersed in PBS solution, and the released RPM was measured every day of 6d after incubation. To test the anti-cell proliferative function, the BAVA hydrogel with or without RPM was co-cultured with porcine SMC cells, then the cell viability was examined at 1d and 3d. Finally, a porcine carotid artery interposition grafting was performed. The external surface of the transplanted graft was then coated with the RPM-loaded BAVA hydrogel, and its graft patency was followed for six months by computer tomography.
Result: The BAVA25 and BAVA50 hydrogels could adhere to the graft surface, and their adhesion was stable for 15d after immersion in PBS solution. In the lap shear adhesion test, initial loading slope (1.5) of the BAVA25 hydrogels was similar to that (1.3) of the BAVA50 hydrogels, and the displacement at fraction point of the BAVA25 hydrogels was approximately two-fold higher than that of the BAVA50 hydrogels. As incubated in PBS solution, the BAVA25 and BAVA50 hydrogels released 83 and 73% of the initial loaded RPM within the first day. As co-cultured with SMC cells, the RPM-loaded BAVA25 and RPM-loaded BAVA50 hydrogels significantly reduced cell proliferation after one day and three days of incubation, respectively. In porcine experiments, the graft without any treatment or with RPM-loaded BAVA50 hydrogel was occluded within three days after transplantation. However, in three cases treated with RPM-loaded BAVA25 hydrogel, two grafts were patent for 10 and 17d and one graft was patent for at least 180d.
Conclusion: The BAVA25 hydrogel had a higher tissue adhesive and more rapid drug release potential than the BAVA50 hydrogel. By loading with RPM, the BAVA25 and the BAVA50 hydrogel showed the in-vitro anti-SMC proliferative function. In the porcine model, the RPM-loaded BAVA25 hydrogel effectively maintained the patency of small-diameter decellularized vascular grafts. The RPM-loaded BAVA25 hydrogel, as an artificial PVAT, might be a therapeutic approach for preventing graft occlusion by suppressing SMC proliferation.

Design of High Throughput Techniques for Functional Medical Devices VictorM. Villapun Puzas, LukeN. Carter, DaisyRabbitt, XueCao, BillyPlant and SophieCox; University of Birmingham, United Kingdom

Since the early designs of medical devices, it has become apparent that implants should act as modulators of specific biological processes to ensure short- and long-term benefits[1]. Nevertheless, standard alloys used in orthopaedics have been repurposed from other industries (e.g. aerospace) as a consequence of their mechanical behaviour, corrosion resistance and biocompatibility. With increased life expectancy requiring longer service life of implantable devices and common alloying elements (e.g. aluminium or vanadium) demonstrated to negatively impact biological processes beyond cytotoxicity, it is clear that novel medical alloys should be developed to modulate clinical outcomes[2.] In this work, the difficulties of designing alloys for implantable devices will be contextualised, providing case studies focused on generating high throughput methods for their use in alloy development with especial attention on the advantages posed by metal additive manufacturing (AM) platforms.

When metallic elements are considered, there exist a plethora of materials with reported effects on biocompatibility, antimicrobial, angiogenic, osteogenic properties and/or their ability to modulate the innate and adaptive immune response[3.] Nevertheless, most effects been reported for single element compounds, reducing their direct correlation to complex alloys and calling for methods to rapidly evaluate biological properties. The first case study will showcase the development of high throughput techniques for both material processing and biological evaluation. The use of AM and novel Reduce Build Volume designs for Powder Bed fusion coupled with powder blending will be shown as a tool to enable the rapid evaluation of alloy systems for antimicrobial applications with conventional and AM Ti-Cu samples used to highlight their benefits over traditional casting. Microstructural variations were assessed through SEM imaging, X-ray diffraction and Vickers microhardness evaluation which were complemented with antimicrobial assays in model strains of *S. aureus* and *P. aeruginosa*. In addition, the power of powder compaction and HIP technologies will be harnessed to enable the rapid analysis of bacterial behaviour and antibiotic synergistic/antagonistic effects through the agar diffuse method and metabolic assays in model strains of Gram-positive and Gram-negative species to enable novel databases in the healthcare industry.

Besides combinations of different metallic elements, alloy design should consider the effect of microstructure and the manufacturing of complex alloys with significantly different processing parameters. Copper and Molybdenum are two elements that have shown promise to tackle antibiotic infection, nevertheless, their disparity in reflectivity or melting point has made their incorporation in titanium alloys a challenge from a manufacturing perspective. Herein, the use of AM, powder compaction and sintering will be used to demonstrate the possibility of providing novel alloys with highly different elemental properties and their use in multicomponent alloys. Through variations in composition and heat treatment, we successfully produced a blended powder of two dissimilar elements which can be used to manufacture SLM parts with reduced input energies (133J/m instead of 300J/m)[4]. Similarly, the effect of microstructural variations with antimicrobial properties and eukaryotic cell line responses will be shown for the rapid optimisation of novel alloys.

Therapeutic Mesoporous Cerium Oxide Nanoparticles for Modulating Excessive Oxidative Stress as a Treatment for Age-Related Macular Degeneration Seung WooChoi[1] and JaeyunKim[2,3,2]; [1]Seoul National University Bundang Hospital, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Samsung Advanced Institute for Health Sciences & Technology, Korea (the Republic of)

Age-related macular degeneration (AMD), the leading cause of vision loss in the elderly, is characterized by progressive visual impairment caused by destructive changes in the photoreceptor and retinal pigment epithelial cells (RPEs). Since reactive oxygen species (ROS) and chronic inflammation in the retina are believed to be essential contributors to AMD pathogenesis, the regulation of the ROS and inflammation levels may be effective therapeutic targets. As cerium oxide nanoparticles (CeNPs) have attracted attention due to good ROS scavenging activities mimicking the enzymatic activity of superoxide dismutase (SOD) and catalase, many researchers have studied to confirm the therapeutic efficacy of the CeNPs and apply these to treat clinical diseases in the biomedical fields. In addition, mesoporous materials have recently been spotlighted as versatile drug carriers and catalysts due to their high surface area and pore volume, therefore, some studies have been reported on the development of various forms of mesoporous CeNPs (mCeNPs). However, most of the previous reports have been derived from hydrothermal methods with harsh conditions, such as high pressure and temperature, and mainly focused on catalytic ability for industrial use, rather than biomedical applications. To combine the advantages of CeNPs and mesoporous materials, mCeNPs are simply synthesized by using the chemical reaction with 1,1′-carbonyldiimidazole and imidazole in acetone without the need for heating and pressurization. The mCeNPs exhibiting mesoporous structures with a pore size of 2.3 nm show good ROS scavenging properties, suitable biocompatibility for human RPEs and Raw264.7 cells (murine macrophage cells), and cytoprotective effect on RPEs against the harmful effect of high H_2O_2, as well as additional anti-inflammatory effects. In addition, the mCeNPs were intravitreally administrated to a $NaIO_3$-induced AMD mouse model, and the mCeNP-treated group showed a partial salvage effect of at least 14 % in outer nuclear layer (ONL) thickness, indicating that mCeNPs protected RPEs from $NaIO_3$ injury by exerting a disease-preventive effect. In addition, the drug-carrying capacity of mCeNPs was demonstrated by loading indomethacin (IDM) as a model drug, and IDM-loaded mCeNPs exhibited an additional 17.3% reduction in interleukin-6 levels in vitro compared to the group treated with mCeNPs alone, suggesting that a synergistic anti-inflammatory effect when an additional drug is loaded onto mCeNPs, thereby enhancing their therapeutic potential. These findings suggest that mCeNP can be a therapeutic alternative or adjuvant for the treatment of AMD.

8:00 PM SB09.06.05

Glycoprotein Hydrogel-Based Implantable Nerve Guidance Conduits for Peripheral Nerve Regeneration MelisOzkan[1,2], SujeetPawar[1], XavierNavarro[3,4,5], FrancescoStallacci[1,6] and SilvestroMicera[2,7]; [1]Institute of Materials, Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland; [2]Bertarelli Foundation Chair in Translational Neural Engineering, Center for Neuroprosthetics and Institute of Bioengineering, Ecole Polytechnique Federale de Lausanne, Switzerland; [3]Department of Cell Biology, Physiology and Immunology, Institute of Neurosciences, Universitat Autònoma de Barcelona (UAB), Spain; [4]Institute Guttmann Foundation, Hospital of Neurorehabilitation, Badalona, Spain, Spain; [5]Centro de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas (CIBERNED), Spain; [6]Institute of Materials, Department of Bioengineering and Global Health Institute, École Polytechnique Fédérale de Lausanne (EPFL), Station 12, CH-1015 Lausanne, Switzerland, Switzerland; [7]Department of Excellence in Robotics & AI, Scuola Superiore Sant'Anna, Piazza Martiri della Libertà, Italy

Peripheral nerve injuries (PNIs) beyond the critical gap length pose a serious problem in neural tissue engineering and regenerative medicine. Research on effective therapeutic strategies has centered primarily on implantable nerve guidance conduits (INGCs) over the past several decades.
A significant amount of progress has been made in INGC development. Still, the field has remained stagnant due to the lack of an optimal solution for ensuring target reinnervation accuracy,

which requires a delicate balance of biochemical cues, including growth factors that govern tissue formation and regeneration throughout the regeneration process. In recent years, researchers have utilized heparin-based materials for sustained growth factor delivery owing to the intrinsic characteristic of heparin to bind and stabilize the growth factors through electrostatic interactions to afford more efficient regenerative outcomes. However, several shortcomings of heparin, such as immunogenicity, could hinder the successful clinical translation of heparin-based INGCs. For this reason, structurally well-defined synthetic mimics fulfilling the same function without triggering immune response are in demand.
In this work, we introduce a silk fibroin-modified gelatin tyramine hydrogel matrix fabricated through enzymatic crosslinking. Both 2D-shaped (planar film) and 3D-shaped (tubular INGC) protein hydrogel scaffolds with the same composition were produced for *in vitro* and *in vivo* investigations, respectively. At the macroscale, silk fibroin modification facilitated enhanced mechanical strength to provide the native nerve tissue-like mechanical properties and prolonged the degradation time of the hydrogel implant. It acted as a biocompatible scaffold for Sprague Dawley rat Schwann cells (SCs).
Then, we directed our efforts toward creating a small library of synthetic small-molecule heparin glycomimetics to address the limitations of native heparin. We synthesized monosaccharides and disaccharides with different sulfation patterns to conjugate to the hydrogel matrix covalently via a PEG linker for cellular-level nerve regeneration. The binding affinities of these synthetic heparin glycomimetics to nerve regeneration-promoting biochemical cues, namely, brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), and fibroblast growth factor 2 (FGF2), were screened using isothermal titration calorimetry (ITC) and surface plasmon resonance (SPR) techniques and our findings showed sulfation pattern-dependent binding affinity. The best-performing molecule was able to bind to NGF and FGF2 with acceptable affinity. We covalently conjugated this compound to the hydrogel matrix. Fluorescence assays and gel permeation chromatography (GPC) confirmed small molecule sugar conjugation to the hydrogel. Hydrogel scaffold, which bears small molecule heparin glycomimetic complexed with NGF, referred to as glycoprotein-based hydrogel, accelerated the neurite growth of Sprague Dawley rat dorsal root ganglion (DRG) neurons and extended retention time of NGF.
Inspired by *in vitro* evaluations, we currently fabricated 3D tubular glycoprotein hydrogel-based INGCs (heavily grafted with our small molecule heparin glycomimetic and with native heparin having the same degree of grafting for comparison) to assess *in vivo* nerve regeneration in Sprague Dawley rat sciatic nerve defect model. Our final goal is long-term monitoring of INGC to unveil how heparin glycomimetics affect the cumulative release of NGF *in vivo* compared to native heparin and as well as to analyze the immunogenicity of both INGCs at the same degree of grafting.
To the best of our knowledge, it is the first report systematically investigating the structure-activity relationship of small molecule heparin glycomimetics for *in vivo* nerve regeneration applications. This approach could be further extended to related regenerative medicine and tissue engineering disciplines.

8:00 PM SB09.06.06
Direct Delivery of Nanobeads into Cells with Nanoinjector KazuhiroOyama, BowenZhang, BingfuLiu and TakeoMiyake; Waseda University, Japan

Delivering biomolecules into living cells has become an important challenge in medical and biological fields. Conventional techniques such as virus vector and electroporation are utilized commonly for small molecule delivery, but still remain several problems of low efficiency and low viability for large molecules such as biological proteins and organelles. To overcome this problem, we demonstrate the macromolecular delivery into adhesive cells with metallic nanotube ducts, which is called as nanoinjector. The metallic nanotubes were developed by an electroless plating of gold onto track-etched polycarbonate template and wet/dry etching [1-2]. To insert Au nanotubes into the cells (such as HeLa and NIH3T3), we have developed an autostamping system that can be integrated with the microscope. Here we demonstrated the delivery of macro molecules (a few hundred nanobeads) into the cells and compare it with the endocytosis delivery. The nanoinjector system provide the high efficient delivery of 200nm diameter beads for 10min injection, while the endocytosis was at low efficiency, which takes for 24h to deliver the nanobeads. Furthermore, our nanoinjector can deliver the nanobeads uniformly into the cells.

Fabrication and *In Vitro* Evaluation of Hydroxyapatite Based Biodegradable Nanocomposite Scaffolds for Osteochondral Defect RepairAneelaAnwar[1,2]; [1]University of Engineering and Technology, Lahore, Pakistan; [2]Stevens Institute of Technology, United States

Osteochondral defects, resulting from trauma or degenerative conditions, present a significant challenge in the field of orthopedics. Due to their limited regeneration ability, osteochondral defects (damage to both the articular cartilage and the underlying subchondral bone) offer a substantial difficulty in orthopedic treatment. Osteochondral regeneration may benefit from the development of novel biomaterials and production processes. The purpose of this research is to propose the electrospinning synthesis of a new nanocomposite for improved osteochondral regeneration. The nanocomposite is made up of bioactive nanoparticles that are embedded in a biocompatible polymer matrix. This creates an optimal setting for cell adhesion, proliferation, and differentiation. To simulate the native extracellular matrix (ECM) architecture, a fibrous scaffold with a large surface area and interconnected porosity is created using electrospinning, a flexible and cost-effective production approach. Bioactive nanoparticles of hydroxyapatite boost the nanocomposite's regeneration capacity by encouraging osteogenic and chondrogenic development. A biocompatible polymer, polycaprolactone (PCL), is used as the matrix material during synthesis. Because of its high biocompatibility, rapid biodegradability, and outstanding mechanical qualities, PCL is a promising material for use in tissue engineering. Optimizing the polymer concentration, solvent system, and applied voltage during electrospinning produces fibers with the appropriate shape and durability.
Multiple techniques are being used to characterize the synthesized nanocomposite. The fibrous shape and interconnected pore structure of the electrospun scaffold are being revealed using scanning electron microscopy (SEM). The effective integration of bioactive nanoparticles into the polymer matrix is being confirmed by Fourier-transform infrared spectroscopy (FTIR). The mechanical integrity of the nanocomposite and its appropriateness for load-bearing applications are being assessed by mechanical testing, which includes tensile strength and compressive modulus.
Using osteochondral cell cultures, the nanocomposite is being tested in vitro. Studies on cell viability and adhesion show that the nanocomposite is biocompatible and can encourage cell attachment and growth. Histological stains and biochemical tests are being used to gauge the nanocomposite's capacity to promote the formation of extracellular matrix. In vivo assessment of the nanocomposite is being performed using an osteochondral defect model in small animal subjects. Small animal test subjects are used in an osteochondral defect model to evaluate the nanocomposite in vivo. The implanted nanocomposite's ability to support tissue regeneration, integrate with adjacent tissues, and restore natural tissue architecture is being evaluated constantly. The structural and functional results of the regenerated tissue are being assessed using a variety of imaging methods, including micro-CT and histological analyses. This research will show that a new nanocomposite may be synthesized using electrospinning to improve osteochondral regeneration. Bioactive nanoparticles HA can increase tissue regeneration through promoting osteogenic and chondrogenic differentiation. HA nanoparticles induce osteogenic and chondrogenic differentiation, improving tissue regeneration. The electrospun fibrous scaffold will mimic cell attachment, proliferation, and extracellular matrix deposition. The nanocomposite will be biocompatible, mechanically integrity, and regenerative after in vitro and in vivo testing. This work will enhance osteochondral tissue engineering biomaterials and manufacturing methods for orthopedic medicine and regenerative therapies.

Light-Degradable Nanocomposite Hydrogels for Antibacterial Wound Dressing Applications ChanghaoFang, YingnanZhang, QimingShen and Michael J.Serpe; University of Alberta, Canada

Bacterial infections in skin injuries can lead to life-threatening human diseases if not treated appropriately. Wound dressings can function as a barrier that can cover the infected sites and inhibit further bacterial infection, thus promoting wound healing processes. In recent years, hydrogel-based materials have emerged as ideal candidates for wound dressing applications due to their biochemical and mechanical similarity to human tissues, high biocompatibility, ability to conform to irregular wound surfaces, and their capability to encapsulate a variety of antibacterial agents. Nanocomposite hydrogels, on the other hand, possess novel nanostructures and/or incorporate nanomaterials into the hydrogel matrix to afford interesting properties such as enhanced mechanical strength and unique drug release profiles.

However, there are still many limitations associated with current hydrogel-based wound dressings, such as the on-demand release of antibacterial agents and triggered degradation. Therefore, the focus of my research project is to address these limitations by developing a light-degradable nanocomposite hydrogel that can achieve both of these goals using light (365 nm) as the single stimulus.

The approach we are taking involves incorporating triclosan-loaded, poly(*N*-isopropylacrylamide)-based nanogels (TCS-NGs) into a light-degradable poly(ethylene glycol)-based hydrogel matrix via a simple physical entrapment method. Upon exposure to 365 nm light, the hydrogel matrix can rapidly degrade, which subsequently releases the entrapped TCS-NGs into the surrounding environment.

Our results have first demonstrated that TCS-NGs possessed potent antibacterial activities. Moreover, TCS-NGs could be entrapped in light-degradable hydrogel matrix with high encapsulation efficiency. Upon exposure to light (365 nm), TCS-NGs can be released from light-degradable nanocomposite hydrogels, which still possess remarkable antibacterial efficacy in terms of inhibiting the growth of *Staphylococcus aureus* both in solution and on bacteria-infected porcine skins. Next, based on Alamar Blue assay on human dermal fibroblasts, each component of the nanocomposite hydrogel exhibited excellent biocompatibility and would not cause significant cytotoxicity. Finally, we showed that the nanocomposite hydrogel can be rapidly degraded by exposure of light, and the extent of degradation was dependent on exposure time. The results here indicate that the fabricated light-degradable nanocomposite hydrogels

could serve as novel materials for antibacterial wound dressing applications.

The Role of Discoidin Domain Receptor 2 (DDR2) and Collagen on Neuroblastoma Cellular Mechanosensing TheadoraVessella, StevenXiang, MadelynStilwell, QiWen and SusanZhou; Worcester Polytechnic Institute, United States

Increased extracellular matrix (ECM) stiffness is a characteristic commonly observed in tumors. Cancer cells can sense changes in substrate stiffness and adjust their migration, proliferation, and differentiation accordingly. Cell-ECM adhesion is crucial for cells to sense substrate stiffness. Discoidin Domain Receptor 2 (DDR2) is a collagen receptor and has been shown to play a role cell-ECM adhesion. Elevated levels of DDR2 in tumor cells have been associated with unfavorable outcomes and metastatic disease. In this study, we aim to investigate the significance of DDR2-collagen interaction in substrate stiffness sensing by studying how DDR2 downregulation affects the responses of SHY5Y cells, a neuroblastoma cell line that expresses DDR2, to substrate stiffness changes. Cells were cultured on collagen-coated polyacrylamide gels with stiffness ranging from 800 Pa to 20 kPa. On stiffer substrates, we observed cells with larger spreading area, more polarized shape, stronger traction force, greater cytoskeletal stiffness, and upregulated neuroblastoma-associated gene expression. These suggest that SHY5Y cells are sensitive to sense ECM stiffness. In contrast, the sh-DDR2 SHY5Ycell line, in which DDR2 expression was downregulated by sh-RNA mediated depletion, did not demonstrate substrate stiffness sensitivity. Our results indicate that DDR2 plays an important role in cellular substrate stiffness sensing. This highlights the potential significance of DDR2 as a target for cancer treatment, as modulation of DDR2-collagen interactions could potentially impact cancer cell behavior and invasion.

8:00 PM SB09.06.10
Nanotopographical Regulation of Glucose-Induced Behaviour in Human MG63 Osteoblastic Cells by Titanium Nanotubular Architectures RyanR. Berthelot and FabioVariola; University of Ottawa, Canada

Titanium nanotubular surfaces have been extensively studied for use in biomedical implants due to their ability to promote osseointegration and bone formation. However, despite the large body of literature on the subject, the impact of the biochemical environment, in particular the glucose levels, and potential synergistic/antagonistic effects with surface physicochemical cueing remains poorly understood. In this study, we investigated the effects of cellular preconditioning in elevated glucose environments on the interaction of human MG63 osteoblast-like cells with nanotubes of 20 nm and 80 nm, as well as with a two-tier honeycomb (HC) structure composed of smaller 20 nm domains nested within larger tubes of approximately 90 nm in diameter. The design and production of these nanotubular surfaces saw significant improvement in this study over previous work, with surfaces demonstrating enhanced order, homogeneity, and reproducibility. Experiments utilizing standard TC-treated well plates were used to effectively separate environmental and surface effects. In determining preconditioning parameters, MG63 cells were cultured in low glucose (5mM) and high glucose (25mM) environments over a three-week period, and a portion of every passage was seeded on TC treated 48-well plates, monitoring differentiation through ALP assays and cell viability using the PrestoBlue viability assay. Normalization of these two markers was well established after two weeks of preconditioning. Preconditioned cells were successively seeded on 20nm, 80nm, and HC surfaces. Cell proliferation, morphology, and viability were assessed through Ki67 and actin staining (48 hrs), along with the PrestoBlue assay (Days 1, 3 and 7). Our results indicated that MG63 cells cultured in high glucose conditions on TC culture plates had significantly lower cell viability compared to those cultured in normal glucose conditions, as previously shown by relevant literature. This effect, however, was mitigated or reversed completely by interaction with the nanotubular surfaces. A parallel outcome was observed in wound healing assays, where migration rates, slowed by the high glucose, were restored or elevated upon exposure to the nanotubular surfaces. The 80 nm and HC surfaces demonstrated significantly higher cell viability (Day 7) and elevated ALP activity (Days 7 and 14) relative to the other surfaces. This trend in differentiation was further explored through the expression of osteogenic markers: osteocalcin (OCN) and osteopontin (OPN), analyzed using fluorescence microscopy and Western blot staining, as well as the degree of mineralization, quantified via the Alizarin Red absorbance assay. Our results demonstrate that high glucose preconditioning significantly influences cell surface dynamics, altering rates of proliferation, migration, mineralization and expression of differentiation markers. Prolonged exposure to high glucose media increases cell metabolic activity and total osteogenic marker expression relative to immediate transition from low to high glucose environments, effectively addressing a gap in the literature where information regarding prolonged exposure to high glucose prior to experimentation is missing or arbitrarily chosen. This normalization aids in distinguishing environmental effects of increased glucose concentration from the physicochemical cueing induced via cell-surface interactions. Although nanotubular surfaces largely outperformed, the multi-hierarchical HC surface's elevated levels of differentiation and proliferative markers in both high and low glucose conditions, as well as ease of production, shows promising signs of being an optimal surface, thereby highlighting the potential of the 2-tier structure for tissue engineering and regenerative medicine. Taken together, our study demonstrates the potential to counteract certain effects of negative environmental stimuli through careful control of nanotopographical surface features.

8:00 PM SB09.06.11
An Emerging and Cost Effective State-Of-The-Art for Biosensing on Paper Substrate Materials SupriyaYadav[1], KulwantSingh[1] and NitinipunSharma[2]; [1]Manipal University Jaipur, India; [2]Manipal Academy of Higher Education, Manipal,, India

Fast diagnosis and proper prevention of infectious diseases are essential and important factors in therapeutic upshots for curing such diseases and low mortality rates in the global public health picture. Lack of sanitation and resources, these diseases extremely impact remote and rural areas, and peoples living in these areas face outstanding challenges so they require cost-effective technology-based reliable solutions for the diagnosis. Current diagnostic assays require sophisticated laboratory infrastructure with expensive reagents. Therefore, such assays are not suitable for resource-limited settings where trained technicians are not present in hospitals to test basic health diagnoses. A point-of-care (POC) test is performed at or near the patient's site where a person initially meets the health care system that has provided accurate rapid results.. Thus, an ideal point-of-care diagnostic platform is something on which a drop of the sample of interest will be put and thereafter the results will be analyzed with a smartphone. Considering the current high-cost standard scenario of diagnosis it is essential to implement point-of-care (POC) testing as an alternative diagnostic tool to fill the gap between the need and affordability. In consequence, the microfluidic system is an attractive platform and has been predicted to provide a boon in health care, especially in the diagnosis and detection of diseases through point-of-care diagnostic devices. In past decades' various microfluidic materials like silicon, and glass technologies have been developed for the diagnosis of these infectious diseases. In the current era, among all the materials used in microfluidics, the paper substrate has attracted the attention of the research community to demonstrate cost-effective and portable devices to meet the challenges in the least developed countries or at remote locations. The competency of the paper substrate for building the proposed microfluidic device is assessed by placing the functional (hydrophobic) components on the surface of the paper substrate. The functional materials that are placed on the paper surface determine its appropriateness for fabricating the suggested device. There isn't a single property or concept that can be defined as a specific paper for microfluidics applications. Undeniably, several characteristics of the paper substrate such as pore size, porosity, texture, color, etc. either are necessary for a printed device design to function or enhance its print characterization, hydrophobic barrier qualities, and surface smoothness in microfluidics. The paper manufacturing process plays an important role in the selection of paper for multiple applications. A suitable selection of paper used for microfluidics applications seems to be critical. Analysis of paper structure is very difficult because of intra and inters hydroxyl groups of cellulose molecules to make voids or spaces on the surface and across the surface. Surface structure creates a vital significance to use the paper in multiple applications in paper manufacturing and printing process. Based on experimental investigation carried out on various test cases of paper substrate, it is concluded that the internal structure of cellulose fiber works as a micro/nanofiber channel for fluid flow via the capillary mechanism. The work predicts making a stable paper substrate that has large internal (Intra and inter-fiber) pores, and small void spaces (external pores) with high capillary pressure to have the tendency to wrench the fluid in an onward direction. Therefore, it can be concluded safely that the paper substrates properties such as pores, porosity, surface energy, and entropy need to optimize to manufacture suitable paper substrates for different microfluidic applications.

8:00 PM SB09.06.12
Milk Exosome for Oral Delivery of Tumor Necrosis Factor-α siRNA to Ameliorate Inflammatory Bowel Disease Sun HwaKim; Korea Institute of Science and Technology, Korea (the Republic of)

Oral administration facilitates the direct delivery of drugs to lesions within the small intestine and colon, making it an ideal approach for treating patients with colitis. However, multiple physical barriers impede the delivery of oral RNA drugs through the gastrointestinal tract. Herein, we developed a novel oral siRNA delivery system that protects nucleic acids in extreme environments by employing exosomes derived from milk to completely encapsulate tumour necrosis factor-alpha (TNF-α) siRNA. Results show that milk exosomes loaded with TNF-α siRNA (M-Exo/siR) can efficiently inhibit the expression of TNF-α-related inflammatory cytokines. Moreover, given that milk exosomes are composed of unique lipids with high bioavailability, orally administered M-Exo/siR can effectively reach colonic tissues, leading to decreased TNF-α expression and successful alleviation of colitis symptoms in an ulcerative colitis murine model. In conclusion, we highlight the specific use of milk-derived exosomes for the treatment of inflammatory bowel disease with TNF-α siRNA. Using exosomes naturally derived from milk may shift the current paradigm of oral gene delivery, including that of siRNA.

8:00 PM SB09.06.13
Elucidating the Mechanism of Gelation for Decellularized Extracellular Matrix Hydrogels AlexanderChen and KarenChristman; UCSD, United States

Naturally derived, decellularized extracellular matrix-based hydrogels (ECM hydrogels) have been increasingly investigated as biomaterial scaffolds for tissue repair and regeneration in a variety of disease models due to their injectability through minimally invasive methods, tunable properties, ability to assemble and form a hydrogel *in situ*, and intrinsic regenerative properties. Most commonly, their rheological, mechanical, optical properties, and protein composition have been studied to understand the gel's stability, gel formation kinetics and the extracellular matrix protein component type and distribution. Natively within mammals, type I collagen is the most abundant structural fibrillar protein and forms a hydrogel through fibril

self-assembly and crosslinking when it is pure and has been assumed to be the main driver for hydrogel formation within heterogeneous ECM hydrogels. The goal of this study was to provide more fundamental materials characterization of ECM hydrogels and determine whether type I collagen is in fact the driver for ECM hydrogel formation.

Using three batches of a porcine derived decellularized myocardial ECM hydrogel, we first ensured batch consistency by quantifying residual dsDNA, quantifying sGAG concentration and rheological measurements. We also employ Fourier transform infrared spectroscopy (FTIR) to analyze the bonds within our ECM hydrogels, thermal gravimetric analysis (TGA) from 30 to 700°C to analyze degradation temperatures, and turbidimetry analysis to observe gelation kinetics. Finally, using cryogenic transmission electron microscopy and two photon microscopy, we analyze the fibril structures within our ECM hydrogel and quantify the differences in fibril diameters before and after incubation at 37°C.

All batches contained less than 1 ng DNA per mg of ECM showing adequate decellularization and 10 µg of sGAGs per mg of ECM. We observed consistent complex viscosity across all samples that had not been incubated, and similar storage and loss moduli values for gels after 24 hours of incubation. The FTIR revealed the same peptide-related peaks (amides I, II and III) at similar peak intensity ratios also seen in a pure type I collagen control. TGA of our ECM hydrogel revealed degradation onset temperatures around 304.6±1.7°C and 624.9±16.8°[KC1] C, consistent with literature reported values for collagen. Turbidimetry analysis revealed similar kinetics of gelation evidenced through similar times to achieve 50% of maximum equilibrium absorbance at around 15 minutes. ECM hydrogel batches were imaged before and after incubation at 37°C for 24 hours using two photon microscopy through second harmonics generation and two photon fluorescence, which leveraged the intrinsic property that only fibrillar, helical collagens produce signal. Incubated samples revealed distributed linear fibers in a grid-like conformation signifying the formation of a hydrogel network. Using cryogenic transmission electron microscopy, we analyzed fiber diameters within our samples for fresh, unincubated samples and samples incubated at 37°C for 24 hours. Fibers in fresh samples averaged 45.6 ± 21.7 nm, 48.7 ± 10.8 nm, and 43.7±15.5 nm in diameter across batches showing consistency. Incubated samples averaged significantly higher fiber diameters when compared to their fresh counterparts at 113.1±48.2 nm, 156.1±79.3 nm and 128.9±56.8 nm, respectively, where all measured fibers within the incubated group revealed a distinct 67 nm D-periodicity unique to fibrillar collagens. Combined, these data reveal batch to batch consistency using more sensitive materials characterization techniques for the ECM hydrogel while also providing visual evidence, through two microscopy techniques, that type I collagen self-assembly occurs during incubation at 37°C and is one of the main drivers of ECM hydrogel formation.

8:00 PM SB09.06.14
A High-Throughput Micropatterning Platform for Screening of Nanoparticles in Regenerative Engineering CherylKoh, Liu YingChen, LingyanGong, Shao JieTan, Han WeiHou and Chor YongTay; Nanyang Technological University, Singapore

Engineered nanoparticles (ENPs) have been gaining traction in the field of regenerative engineering due to their unique physical, chemical and biological properties that are able to modulate cellular behaviour by influencing cell adhesion, migration, and proliferation. These nanomaterial-cellular interactions are important in directing tissue regeneration processes at the cellular level. However, the usage of nanoparticles brings about safety concerns with regards to impairment of cellular dynamics. In this context, micropatterning platform has emerged as a high-throughput tool for assessing stress response of ENPs. This platform not only allow the analysis of biological responses to nanoparticles in a controlled and reproducible environment, but also provides the identification of subtle effects that may not be discernible using traditional methods. This abstract discusses how two commonly incorporated engineered nanoparticles in regenerative engineering, specifically zinc oxide (ZnO) and titanium dioxide (TiO2) have an influence on collective epithelial rotation via the use of micropatterned platform. The confinement of cells in geometrical constraints were achievable through the precise control over the geometry and size of the adhesive fibronectin islands which aids in cell attachment. Collective rotation is essential in tissue morphogenesis and wound healing, and disruption to this collective behaviour could lead to a wide range of biological dysregulations. Through this approach, it was observed that the micropatterned human keratinocytes clusters exhibited spontaneous rotation without external stimulus, at relatively constant uniform speeds of 10 µm/h. However, acute (6 h) exposure to non-cytotoxic doses of ZnO and TiO2 NPs (≤100 nm) resulted in a loss of directionality and slowing down of cell rotation, respectively. The loss in collective cell rotation (CCR) was determined to be attributed to reactive oxygen species (ROS)-induced proliferation by ZnO. While cell proliferation is desired in regenerative engineering, the generation of new, heterogeneous localised velocity fields by the increased cell density led to cell jamming within the epithelial units. On the other hand, the retardation of the velocity of TiO2-treated units was most likely as a result of degradation of membrane recycling integrins that are necessary for continued cell migration. This is because TiO2-treated units were found to induce autophagy, which has been reported to compete with endocytosis-driven recycling. Taken together, our findings offer nano-biological insights into the distinct signalling pathways exerted by different nanoparticles - ZnO NPs promoting cell proliferation, yet disrupting cell migration, and TiO2 NPs decreasing cell migration. This suggests that when it comes to the usage of ENPs in regenerative engineering, further studies have to be done to ensure that cellular dynamics are not compromised.

8:00 PM SB09.06.15
Directing Phase Separation to Harness Biomaterial Microstructures for Controlled Cellular Behavior Saniya YesminBubli, JeniferSidhwa and LinqingLi; University of New Hampshire, United States

The compositional heterogeneity and structural diversity of native extracellular matrix are essential in regulating cell behavior and promoting tissue regeneration. Thermoresponsive polysaccharide-based materials with tunable transition temperatures and phase-separated microstructure offer substantial opportunities in tissue engineering, drug delivery, and wound healing applications. To develop novel synthetic thermoresponsive polysaccharides, we employed versatile chemical routes to attach intrinsically hydrophobic adducts to the backbone of hydrophilic dextran and developed protocols to form hydrogels with defined microstructures. Systematically conjugating methacrylate moieties to the dextran backbone yielded a continuous increase in macromolecular hydrophobicity that induced a reversible phase transition whose lower critical solution temperature can be systematically modulated *via* variations in polysaccharides concentration, molecular weight, degree of methacrylation, ionic strengths, and Hofmeister salts. Photo-initiated radical polymerization permits facile chemical crosslinking and kinetic capture of phase separation, enabling the formation of hydrogels with defined microdomains. The resulting heterogeneous hydrogels feature tunable microstructures and exhibited both microspheres and continuous phases that promoted enhanced cell adhesion in 2D and interfacial-driven cell migration in 3D. Engineering macromolecular hydrophobicity with temperature-triggered phase separation of conventional hydrophilic, non-phase separating polysaccharides to generate heterogeneous hydrogels with controlled microstructures will find potential applications in chronic wound healing.

8:00 PM SB09.06.16
Study of The Senescence Progress of Human Skin Fibroblast on Silica Nanobeads Array YerinChoi, SoojinRoh and Jin SeokLee; Hanyang University, Korea (the Republic of)

Senescence is a physiological process that progresses with age. Cellular senescence is induced by stimuli such as telomere shortening and oxidative stress. In particular, it refers to the cell cycle arrest state. Senescence cells are characterized by reduced cell proliferation, migration, and speed. In addition, aging proteins p16, p21, and p53 are expressed.
We study the adhesion changes of senescence cells on silica nanobeads (SiNBs) of various sizes. In particular, it analyzes how senescence changes due to different adhesion. We induced aging by adding Paclitaxel (PTX) to WS1 cells, which are human skin fibroblasts. PTX causes cellular senescence due to damage from ROS. The optimal PTX concentration was fixed, and the cell survival rate was confirmed by MTT assay. In particular, we have identified different adhesion on SiNB arrays of various sizes. In addition, changes in cell proliferation, migration, speed, and aging proteins were analyzed. As a result, we observed the correlation between the topographic factors of SiNB arrays and cellular senescence.

8:00 PM SB09.06.17
Microhardness and Electrochemical Behavior of Binary Ti-Zr Alloy for Dental Implants AncaFratila[1], SantiagoBrito-Garcia[2], JuliaC. Mirza[2,3], IoanAron[3] and AdrianaSaceleanu[1]; [1]LB University of Sibiu, Romania; [2]Universidad de Las Palmas de Gran Canaria, Spain; [3]Transilvania University of Brasov, Romania

Introduction: In response to the pressing concerns surrounding potential cytotoxicity and adverse tissue reactions arising from the presence of vanadium and aluminum in the widely employed biomaterial Ti-6Al-4V, a compelling alternative has emerged in the form of the Ti–20Zr alloy.
Material and methods: This alloy, Ti-20Zr, generously provided by R&D CS in Bucharest, Romania, underwent a rigorous evaluation process, positioning itself as a possible contender for use in human body implant materials. The journey of Ti–20Zr's evaluation commenced with the meticulous process of alloy creation through vacuum melting. Cylindrical electrodes, crafted with precision, were seamlessly embedded in a resin matrix. Subsequently, the specimens underwent thorough ultrasonic cleaning using deionized water, followed by etching in the renowned Kroll's reagent, comprising 10 ml of HF, 5 ml of HNO3, and 85 ml of water, all in preparation for microscopic observation using the Olympus PME 3 – ADL microscope. The microstructure and microhardness were tested. The electrochemical behavior has been evaluated in simulated body fluid (SBF) using Electrochemical Impedance Spectroscopy technique (EIS).
Discussion: From metallographic images can be observed that the sample has an alpha-beta structure. From microhardness measurements can be concluded that the alloy formed a hard layer on its surface, which greatly improves the wear resistance. The electrochemical behavior demonstrates that Ti-20Zr alloy exhibits excellent corrosion resistance due to the stable oxide layer formed on the surface, an attribute that promises long-term implant stability. Zirconium (Zr), a key component of the alloy, has been recognized for its superior resistance to corrosion, setting it apart from the majority of other metals.
Conclusion: In light of these remarkable findings, it becomes evident that the Ti-20Zr alloy surpasses even commercially pure titanium (cpTi) in terms of corrosion resistance. Furthermore, the consensus in the scientific community regarding the absence of local or systemic toxic effects associated with Zr compounds reinforces the notion that Ti-20Zr has the potential to serve as a safe and efficacious biomaterial for artificial surgical implants.

Tensile Testing of Two Amniotic Membrane Products: Artacent Wound® and Artacent AC®AbbigailPoland, OliviaLogan, MoraMelican and IsabellaSledge; Tides Medical, United States

Amniotic membrane is a promising biomaterial for regenerative medicine and a plethora of placental membrane products products exist in the market today and are used for varying applications. When assessing and characterizing the multitude of amniotic products on the market, it is important to ensure that each product meets user need for handling capabilities so that the membrane can be properly applied to the wound. One way this characterization can be achieved is via tensile testing using an Instron 5544. The process of tensile testing amniotic products with the Instron 5544 has not previously been well-standardized or optimized for this material. With this study, a standardized test method for tensile testing of dehydrated amniotic membrane has been established. In this study, the established tensile testing procedure is used to distinguish differences in the handling capabilities of Artacent Wound, a dual layer amniotic scaffold, and Artacent AC, a tri-layer amniotic scaffold composed of a layer of chorion between two layers of amnion. In addition, this repeatable test method is also used to assess a modified version of Artacent AC where one of the tissue processing steps has been altered.

Methods:

Tensile Testing
1. Nonslip material is cut to size and applied to Instron Jaw Faces.
2. ASTM D1708 dog bone die cutter is used to cut samples to the proper size and shape.
3. Width and thickness measurements of the sample are taken in triplicate and averaged.
3.The force sensor is calibrated.
4.Tare load of 0.5N is applied to the sample prior to test start.
5. Length measurements of the product are taken.
6. Length, width, and thickness measurements are entered into Bluehill Software.
7. Strain Rate of 0.40mm/min. is entered into software.
8. "Zero displacement" is selected.
8. Test is started until full sample break is achieved.
9. Test is stopped and data is collected.

Data Analysis:
One – Way ANOVA Multicomparison Tukey Tests were used to compare each test group.

Results:
Comparative graphs summarize the failure stress (MPa), failure strain (%) and Young's Modulus (Mpa) of the following test groups:
- Artacent Wound
- Artacent AC
- Modified Artacent AC

Discussion:
There are no significant differences between the measured biomechanical properties of Artacent Wound and Artacent AC, although Artacent Wound has slightly increased strength when compared to Artacent AC.
The modified version of Artacent AC did not show any significant difference when compared to original Artacent AC. However, the modified Artacent AC is shown to have higher Young’s Modulus and failure stress when compared to original Artacent AC. This demonstrates that modifying certain tissue processing steps could be advantageous for improving material handling properties.

Conclusion:
Artacent Wound has increased failure stress and Young’s Modulus when compared to Artacent AC.
Modifying certain steps of the Artacent AC tissue processing procedure is shown to be beneficial for improving handling properties of the scaffold, as it demonstrates increased Young’s Modulus and failure stress when compared to that of original Artacent AC.

8:00 PM SB09.06.19
Balancing Charge Density and Hydrophobicity in Polysaccharide Biomaterials to Regulate Cell Behavior TranTruong, LinqingLi and NathanJ. Oldenhuis; University of New Hampshire, United States

Hydrogel surface properties play an important role in regulating cellular behavior for tissue engineering and biomedical device design application. Alterations in the biointerface can activate specific cellular signals, resulting in different physiological outcomes. Developing a hydrogel system where surface physiochemical characteristics such as stiffness, charge density, and hydrophobicity can be independently tuned would provide significant insights to tailor material-cell interactions at tissue interface for various therapeutic applications. In this study, we synthesized methacrylate and carboxylate dual-functionalized dextran derivatives, and investigated the impact of the intricate balance between hydrogel surface charge density and hydrophobicity on cell behavior. We are leveraging the defined chemical moieties and tunable surface properties of modified dextran hydrogels to probe the impact of our materials on regulating cell adhesion and spreading. By synthetically tuning these two parameters in dextran-based substrates, we revealed that increased surface charge density and decreased hydrophobicity enhance hydrogel surface wettability and prevent cell adhesion. On the contrary, increasing surface hydrophobicity facilitates the adsorption of fibronectin that supports cell adhesion. Our findings suggest an optimized balance between charge density and hydrophobicity that can be engineered to promote desired cell behavior. Imbalances between these two parameters resulted in an inhibition of cell attachment, emphasizing the importance of fine-tuning charge density and hydrophobicity in biomaterial design. This project will differentiate and identify critical chemical characteristics of hydrogel surface properties responsible for cell behaviors and develop a new class of synthetic polysaccharide biomaterials.

8:00 PM SB09.06.20
Crimping Process Investigation to Enable Informed Design of 3D Printed Bioresorbable Vascular Scaffolds CaralynCollins[1], JunqingLeng[1], RaoFu[2], YonghuiDing[2], GuillermoAmeer[1] and ChengSun[1]; [1]Northwestern University, United States; [2]Worcester Polytechnic Institute, United States

With cases of coronary and peripheral artery disease on the rise, vascular stenting has become a popular procedure which is crucial to the health of millions of patients across the United States and more across the globe. In the past several decades, the field has seen a shift from bare metal and metal drug eluting stents to bioresorbable vascular scaffolds (BVS) with the goal of addressing restenosis, thrombosis, and stent migration concerns. These BVS utilize polymeric materials to degrade over time *in vivo*, and as a result, have drastically different mechanical responses to deformation than the preceding metal stents. As such, additional consideration of the BVS mechanical deformation response both prior to and post-deployment is important to enhancing the performance of these polymeric scaffolds *in vivo*. The crimping process, or diameter reduction of the stent or BVS prior to deployment, marks the first time after manufacturing that the scaffold must undergo a significant amount of mechanical deformation. As it is also an easy deformation step to monitor, crimping serves as a good baseline for understanding the mechanical response of BVS. Simulation of this step can not only provide information on BVS radial force as a function of diameter to mimic results from experimental testing, but can also give additional information on the response of the BVS as it undergoes this deformation in a fraction of the time required in experiment. This allows for a time-effective solution to enable understanding of both the deformation of different scaffold designs and the deformation of scaffolds with different material additives incorporated, like those utilized to enable visibility of the BVS when imaged *in vivo*. Here, we utilize a finite element crimping simulation in ABAQUS to rapidly reproduce experimentally validated qualitative design comparisons between several designs of 3D printed bioresorbable vascular scaffolds made of a previously developed citrate-based polymer, taking into consideration both the properties of the base polymeric material and the properties of the polymeric material with a radiopaque additive. By doing so, it is possible to harness the advantages of additive manufacturing to allow for more optimal bioresorbable vascular scaffold design and production, simultaneously elucidating the relationship between material, structure, and mechanical response of scaffolds.

8:00 PM SB09.06.21
***In-Vitro* Human Cell Behavior: Using Cell Culture to Assess Biocompatibility and Cell Proliferation on Artacent Products**OliviaLogan, SadhanaJoshi, BabakSafavieh, MoraMelican and IsabellaSledge; Tides Medical, United States

Introduction:
Cell culture is a useful method of determining cell interactions and assessing product safety in-vitro before completing in-vivo testing, such as animal models. In this study, cell culture is utilized to assess the proliferation and attachment of various cell types on amniotic scaffolds. The selected cell types represent cells that are known to play a part in the wound healing process and include Human Umbilical Vein Endothelial Cells (HUVEC), Neonatal Human Dermal Fibroblasts (NHDF), Normal Human Epidermal Keratinocytes (NHEK) and L929 cells (an adherent type of mouse fibroblast cell line).

Methods:

Cell Culture

All cell lines are maintained in appropriate culture media supplemented with necessary growth factors, antibiotics, and serum per manufacturer's protocol. These cells were incubated at optimal conditions in a humidified cell culture incubator.

Cell Treatment

Optimal seeding density for each cell type was determined from preliminary testing. Determined seeding densities were then used to seed each cell type on circular 6mm diameter samples from each test group. Cells were seeded for 2,3,7 and 9 days in 96 well Low cluster microplates.

Alamer Blue Assay

After the treatment period, the culture medium was removed from each well or plate and Alamar blue was added to the wells. The cells were treated with the Alamar Blue reagent for 6 hours and under appropriate conditions. The absorbance of these wells was measured using a microplate reader at 570nm and 600nm.

Microscopy

To validate the Alamer Blue Assay results, the cells seeded on Artacent product were labelled with DAPI and Vimentin 647 and observed under Zeiss LSM 800 with Airyscan.

Results:
Graphs summarize the Alamer Blue reduction (%) for the following test groups at the following time points. Chosen time points reflect when the most Alamer Blue reduction was observed for each cell type.
- HDF at 7 day time point
- NHEK at 7 day time point
- HUVEC at 9 day time point

Discussion:
HDF cells showed improved proliferation and attachment on Artacent AC compared to other test groups.
NHEK cells showed improved proliferation and attachment on Artacent Wound compared to other test groups.
NHEK cells showed improved proliferation and attachment on Artacent Wound compared to other test groups.

Conclusion:
Different types of amniotic scaffolds are shown to be optimal for the proliferation and attachment of different cell types.
- HDF cells showed improved proliferation and attachment on Artacent AC.
- NHEK cells showed improved proliferation and attachment on Artacent Wound.
- NHEK cells showed improved proliferation and attachment on Artacent Wound.

8:00 PM SB09.06.22
Comparison of Amniotic Products in Full Thickness Rat Wound Model: Artacent Wound and Artacent AC OliviaLogan, IsabellaSledge and MoraMelican; Tides Medical, United States

Introduction:
It is well understood that human placental tissue contains a multitude of factors that play a part in the healing process [1]. Placental membrane is an attractive biomaterial for regenerative medicine applications due to its natural factors that aid in wound healing. angiogenetic and regenerative remodeling, as well as immunomodulation. However, the processing methods used to create final product have an impact on the growth factors that are retained [2]. A plethora of placental tissue processing methods has led to the creation of an array of placental product compositions and applications. Two products currently being used in the field are Artacent Wound®, a dehydrated dual layer amniotic graft and Artacent AC®, a tri-layer graft composed of a chorion sandwiched between two layers of amnion. In this study, we assessed these wound coverings in Sprague Dawley rats to elucidate the influence these scaffolds have on a healing wound. Additionally, this test is used to assess a modified version of Artacent AC to see if modifying certain tissue processing steps has implications on wound healing.

Methods:
Two full thickness wounds were created on the dorsal side of each rat using a 2 cm x 2 cm square stencil and scalpel. Implant dimensions were approximately 2.5 x 2.5 cm. Samples were randomized into implantation sites across the animals. Implants were harvested at 7 days and grossly assessed for healed wound geometry, remodeling and re-epithelization. Implants were fixed in neutral buffered solution (NBS). Samples were stained with H&E and stained cross sections were evaluated for surface re-epithelialization, cellular infiltration, and remodeling. A numerical scoring system was utilized to quantify re-epithelialization and granulation tissue formation based on histological images.

Results:
Initial and final wound measurements were used to calculate the percentage of wound closure for each test group. Re-epithelialization and granulation tissue formation ratings are used to calculate average values for each test group.

Discussion:
No adverse effects were noted during this 7 day study. Partial wound healing is observed during the 7 day study, and healing is accelerated by the addition of a placental scaffold. Modified Artacent AC shows increased wound closure, equivalent re-epithelialization, and increased granulation tissue formation when compared to positive control (original Artacent AC).

Conclusion:
No adverse effects were noted.
The 2x2 Challenge Full Thickness Wound model in the rat shows partial healing at 7 days that is accelerated by the addition of a human placental membrane product to the wound bed.
Modified version of Artacent AC shows improved wound healing when compared to original Artacent AC.
- Increased wound closure
- Equivalent re-epithelialization
- Increased granulation tissue formation

Protein Characterization of Placental Membrane Products: Artacent Wound and Artacent AC OliviaLogan, BabakSafavieh, IsabellaSledge and MoraMelican; Tides Medical, United States

Introduction:

Placental membrane is a highly biocompatible natural scaffold and is a source of several native factors that may aid in wound healing. Some of the many factors that make placental membrane such an attractive material are the natural anti-inflammatory, angiogenic, and antibacterial properties of the membrane. These properties are mostly dictated by released growth factors and cytokines. The angiogenic properties are attributed mostly to its capacity to produce VEGF and platelet-derived growth factor (PDGF), both of which mediate wound healing. The anti-inflammatory and immune-modulatory effects are largely attributed to the secretion of IL-10 and IL-6 [1].
Here, we characterize the protein content in Artacent Wound (a dual layer amniotic product) and Artacent AC (a tri-layer composed of a layer of chorion in between layers of amnion) using a Microarray assay. In addition, immunohistochemistry (IHC) was used to quantify protein composition of extracellular matrix (ECM), growth factors, and immune modulating cytokines. This analysis provides further insight into the protein composition and cell interactions of hAM scaffolds currently on the market.

Methods:
The chosen assay for testing is Quantibody® Human Cytokine Antibody Array 1000 assay from RayBiotech Inc., a multiplexed ELISA that enables the detection and quantification of up to 1000 human cytokines in a single experiment. To prepare samples for testing, they were first incubated on captured antibody for 2 hours. The biotinylated antibody cocktail was then added, followed by another 2 hour incubation. After the final incubation, streptavidin labeled dye was added. The results were then analyzed using fluorescent microarray reader.

Results:
The various cytokines and growth factors observed in each test group were categorized based on Angiogenetic cues, immune modulating cytokines and Regenerative growth factors.

Discussion:
Protein microarray analysis reveals that Artacent AC and Artacent Wound have various factors that are attributed to angiogenetic and regenerative remodeling as well as immunomodulation. The Artacent Wound protein distribution shows that factors are uniformly distributed amongst the angiogenetic (28%), regenerative (34.1%), and immunomodulatory (37.8%) categories. In contrast, the protein distribution for Artacent AC shows that a large portion of the observed factors are regenerative growth factors (78.4%), with a smaller portion of results falling into the angiogenetic (8.3%) and immunomodulatory (13.2%) categories.

Conclusion:
The varying products are each shown to contain a unique profile of proteins that play a role in angiogenetic and regenerative remodeling as well as immunomodulation.
- Artacent Wound proteins are evenly distributed amongst the angiogenetic, regenerative, and immunomodulatory categories.
- Artacent AC protein distribution largely falls in the regenerative category, with smaller percentages of proteins falling into angiogenetic and immunomodulatory categories.

8:00 PM SB09.06.24
Subcutaneous Implantation of Amniotic Products in Sprague Dawley Rats: Artacent Wound and Artacent AC OliviaLogan, IsabellaSledge and MoraMelican; Tides Medical, United States

Introduction:
Although there are numerous placental membrane products currently being used in wound healing applications, it is not yet well-understood how these products interract with the wound bed as the wound heals. In this study, we assess subcutaneous implantation of varying amniotic membranes to better understand how these products support the wound healing process.

Methods:
Four incisions were made on the back of each rat—two incisions left of the spine and two incisions to the right with each incision measuring approximately 2 cm. Four individual pouches were created by bluntly dissecting laterally at each incision site with scissors. A 1 x 1 cm implant was placed in each implantation site and samples were randomized in location. Implants were fixed in neutral buffered solution (NBS). Samples were stained with H&E and stained cross sections were evaluated for surface re-epithelialization, cellular infiltration, and remodeling.

Results:
Representative histological images from each test group.

Discussion:
In both Artacent Wound and Artacent AC, tissue ingrowth within the placental membrane product can be observed. Results support that the biological membranes provide an extracellular matrix that provides a natural scaffolding which supports the wound healing process.

Conclusion:
In both Artacent Wound and Artacent AC, tissue ingrowth within the placental membrane product can be observed. Results support that the biological membranes provide an extracellular matrix that provides a natural scaffolding which supports the wound healing process.

Stimulus-Responsive Double Network Hydrogels with MoS_2 Nanosheets for High Toughness and Self-Healing Smart Biomaterials for Tissue Engineering FrancescaA. Sepúlveda[1,2], HumbertoPalza[1,2], FelipeOlate-Moya[1,2] and Juan PabloAcevedo[2,3]; [1]Universidad de Chile, Chile; [2]IMPACT, Chile; [3]Universidad de los Andes, Chile

The design of stimulus-responsive smart hydrogel actuators for tissue engineering holds great promise, as they enable the creation of 3D structures mimicking the functionality of natural tissues, responding in a controlled manner to changes in temperature, light, or pH. To achieve near-infrared (NIR) light-induced responses in smart hydrogels, molybdenum disulfide (MoS_2) nanosheets have gained recent attention due to their layered structures and strong NIR absorbance, making them promising photothermal agents. Among various hydrogels, we focus on double-network hydrogels (DN) composed of chitosan (C) and polyvinyl alcohol (P), known for providing a robust and flexible matrix for cell growth and tissue regeneration. In this study, we developed C-P DN hydrogels with MoS_2 nanoparticles to create 3D printed scaffolds (3D C-P) and evaluated their mechanical properties, water content, NIR light irradiation response, and cell viability.
By adjusting manufacturing parameters like freezing temperature, chitosan cross-linking time, and lyophilization, we tailored the mechanical properties of C-P DN hydrogels. These inks were successfully extruded using a fourth-generation 3D BioplotterTM (Envisiontec, Germany), enabling precise scaffold production. After 2 hours of crosslinking, the 3D C-P scaffold exhibited high toughness and mechanical stiffness resembling native heart tissue, with a stiffness value of 0.78 MPa. Interestingly, DN C-P_MoS_2 hydrogels with 0.5% w/w MoS_2 incorporation did not show improved mechanical stiffness compared to pure DN, maintaining material structural stability. Furthermore, MoS_2 incorporation led to a slight decrease in water content, attributed to its hydrophobic nature.
The material's responsiveness was evident through rapid contraction and bending upon NIR light irradiation due to dehydration, and this response was 40% faster than that of DN C-P hydrogels. This confirmed their potential as candidates for generating light-stimulated smart DN hydrogels. Additionally, MoS_2-incorporated hydrogels exhibited mechanical self-healing under NIR light exposure, enhancing their tissue engineering applications. These multifunctional behaviors arise from MoS_2's ability to convert light energy into thermal energy, triggering NIR light-induced contraction. Furthermore, NIR-induced heat facilitates polymer chain diffusion, enabling a self-healing process through hydrogen bond reformation in MoS_2-incorporated hydrogels. MoS_2 absorbs NIR light, releasing heat, and leading to hydrogel contraction, while reconstituted hydrogen bonds allow the material to 'heal,' restoring structural integrity and functionality.
Viability studies on umbilical cord-derived mesenchymal stem cells (UC-MSCs) cultured on MoS_2 hydrogels showed improvement from day 1 to day 7, suggesting that DN and DN C-P MoS_2 hydrogels offer a conducive environment for UC-MSC growth and survival, serving as a three-dimensional support and suitable substrate matrix.
The results demonstrate that the incorporation of MoS_2 nanosheets into C-P DN hydrogels achieves a rapid actuation response to NIR light irradiation and a mechanical self-healing behavior, making them ideal for light-stimulated flexible hydrogels. Additionally, cell viability studies indicate MoS_2-containing hydrogels' suitability as three-dimensional support in regenerative medicine and tissue engineering.

8:00 PM SB09.06.26
Development of Bio-Hybrid Nanoparticles based *In Situ* Raman Imaging for Intracellular miRNA DetectionYeochanYun[1], Hyeon-YeolCho[1], Won-JunLee[2], Kyeong-JunKim[2], Md. KhaledHossain[2] and Jeong-WooChoi[2]; [1]Kookmin University, Korea (the Republic of); [2]Sogang University, Korea (the Republic of)

Currently, microRNAs (miRNAs) were widely recognized as valuable biomarkers to identify in typical cancer characteristics. These small RNA molecules frequently exhibited dysregulation in various cancers, leading them to serve as either oncogenic or tumor-suppressor miRNAs, depending on their specific target genes. Moreover, miRNAs can modulate cancer cells to chemotherapy. Real time polymerase chain reaction (RT-PCR) was currently used as a method to detect intracellular miRNA. However, it required cell lysis, miRNA isolation, purification that makes hard to use in live cells. Therefore, several fluorescence-based analysis techniques (e.g., fluorescence resonance energy transfer (FRET)) were used for live cell detection, but they had limitation in detecting miRNA with low expression levels. We aimed to overcome these limitations by using surface-enhanced Raman spectroscopy (SERS), a technique widely used as a

tool for sensing application, which analyzed based on the distances between molecules, to detect intracellular miRNA in live cells.
In this study, we developed highly sensitive Raman activating gold nanoparticles (HS-RGNs) which were containing gold nanoparticles, Raman reporter, and single strand DNAs (ssDNAs) complementary to target miRNA. When HS-RGNs hybridized with target miRNA, these particles amplified the Raman signal. We selected microRNA 200c (miR-200c) as a model biomaterial which was related to the chemoresistance of cancer cells. After treatment of HS-RGNs to SK-BR-3 and MCF-7 which are cancer cells, the ssDNAs of HS-RGN were hybridized with miR-200c, bringing two HS-RGNs closer, thereby enhancing the Raman signal. The higher expression level of miR-200c in SK-BR-3 compared to MCF-7 led to the observation of a higher Raman signal in SK-BR-3 cells. When treated with HS-RGNs, increased expression levels of Zinc finger E-box binding homeobox 1 (Zeb1) and Tropomyosin receptor kinase B (TrkB), which were inhibited by miR-200c, indicated the effective binding of HS-RGNs to miR-200c. Additionally, when assessing the cytotoxicity of doxorubicin, SK-BR-3, which exhibited higher miR-200c expression, showed a lower survival rate compared to MCF-7. However, when treated with HS-RGNs, miR-200c was effectively consumed, resulting in a higher survival rate in both SK-BR-3 and MCF-7 cells. This result suggested that HS-RGNs can hybridize with miR-200c, impact of miRNA on cell behavior.
Our study showed that HS-RGNs effectively amplified the Raman signal, indicating their potential applicability for in situ intracellular analysis. Additionally, they can be applied as a platform technology to investigate the impact of miRNA on cell behavior by consuming miRNA within cells.

8:00 PM SB09.06.27
Bioprinting Hydrogels for Dentin Pulp Regeneration and Disinfection SaranyaAnantapantula[1], AbdelMahmoud[2], AaronSloutski[2], Kuan-CheFang[2] and MiriamRafailovich[2]; [1]Spring Ford Area High School, United States; [2]Stony Brook University, The State University of New York, United States

Oral and maxillofacial complications pose challenges due to issues like lack of material biocompatibility and invasive treatments. One common example is the endodontic treatment, where the infected pulp is removed. Bacteria and their byproducts that interact with host tissues in the dental pulpal and periradicular regions are the primary cause of endodontic pathosis. The elimination of microorganisms from the root canal system (RCS) is essential for effective endodontic therapy. This process can leave the tooth brittle in the long-term. Because they can promote, in a biologically based framework, the continuation of root development and apical closure, regenerative endodontic therapies (RETs) in necrotic immature teeth have drawn a lot of interest recently. Getting a sufficient disinfection of the root canal system is a must for success in RETs since bacterial persistence in root canals in such instances considerably impede healing and root maturation. Moreover, additive manufacturing can facilitate the development of hydrogels that can regenerate lost dentin pulp, restoring tooth strength and longevity and achieve sustainable drug release. This research aimed to identify a scaffold, which possesses optimal degradability, chemical, mechanical, cytocompatible features, that can deliver antibiotics or induce stem cell differentiation for regenerative endodontic treatment while maintaining durability. For this purpose, methacrylated Pluronic polymers were chosen due to their well researched drug releasing capabilities, as well as their potential injectability, stemming from their reverse thermo-responsive nature.
Initially, the studies focused on F127-DMA and F88-DMA hydrogels and their crosslinking efficiency with two photoinitiators (Irgacure- 651 and 2959). Different assays, such as mechanical properties characterization by rheology, swelling ratio, crosslinking efficiency and drug release analysis, were conducted. Crosslinking was mediated by UV lamp and by 3D printer (BioX 3D Bioprinter) where the durability of the constructs was researched. Irgacure 2959 showed superiority both in terms of crosslinking efficiency (~16% difference) and mechanical stiffness. Comparing both Pluronics, the data collected showed that F88 had a higher swelling ratio than F127. Elastic modulus measurements confirmed that F127 was inherently stronger, and its cross-linking efficiency was superior due to its lower swelling ratio. Aiming at imparting degradability, the Pluronic were end capped with L-Lactide prior to methacrylation and similar studies were conducted throughout prolonged time incubated in aqueous medium at 37 degrees. The lactide-containing matrixed exhibited elevated swelling until full degradation after several weeks, demonstrating the rapid degradability. Furthermore, aiming at exploring drug release capabilities, release profiles of Clindamycin, Metronidazole and Ciprofloxacine (Triple paste antibiotic) were researched.
In conclusion, while F127's stiffness and effective crosslinking make it a promising candidate in terms of mechanical features and F88's hydrophilic properties and favorable degradation profile also make it a favorable option in regards to hydrophilic affinity and mass loss, further research is required to assess the biocompatibility of photoinitiators and their concentrations in terms of cell viability. Thus, further studies will be conducted on the hydrogels' bio-printability, cell viability, cytotoxicity, antibacterial efficiency of drugs added and osteogenic differentiation or the ability of stem cells to differentiate into bone cells. The gels developed will present multiple potential endodontic applications: it could be placed on the top of the pulp cavity to induce dentin regeneration or disinfect the canal area. Thus, these hydrogels will ultimately pave the way for more potent dental treatment approaches.

The Influence of Donor Age and Cholesterol Inhibition on Fibroblast Mechanical Properties and Susceptibility to Bacterial Infection SharisHsu[1], PiaV. Sodhi[2], AviTalsania[3], SamuelD. Coopersmith[4], RichardA. Wong[5], Sai PranavKota[6], AdamHansen[7] and MiriamRafailovich[7]; [1]Valley Christian High School, United States; [2]The Brearley School, United States; [3]Sachem High School North, United States; [4]Casa Grande High School, United States; [5]Plainview-Old Bethpage John F. Kennedy High School, United States; [6]Cedar Falls High School, United States; [7]Stony Brook University, The State University of New York, United States

Cell mechanics depend upon cell membrane mechanics (which, in part, depends upon cholesterol content) and the rigidity and organization of the cytoskeleton. The latter was shown to depend on the properties of the substrate upon which cells are cultured, where tensegrity models were used to explain reorientation of the scaffold. With aging, measurements of the viscoelastic properties of cells were shown to stiffen, but these measurements were performed on individual cells without mechanical cues from surrounding tissue or the substrate. We report on experiments performed on dermal fibroblasts, which were obtained from female donors: "young" (ages 28 and 29 years) and "old" (ages 69 and 71 years), where we applied the technique of scanning force modulation microscopy (SFMM) which allows for measurements of cell modulus that account for the underlying substrate mechanics. The results represent an average of n=9 measurements.

Cells were cultured on polybutadiene thin films whose moduli were varied (ratio of 3:1) by adjusting the film thickness without additional chemical additives. On both substrates the moduli of the cells became significantly harder with age, consistently 40±1.6%, in agreement with previous work. For both young and old cells the cell modulus responded to changes in the substrate, where the moduli between cells plated on the hard and soft substrates differed significantly, 50±2% and 60±2.4% for the old and young cells, respectively. These results indicate that even though cells become harder as they age their ability to adjust to mechanical changes in their environment is not diminished. We were also able to image the actin filaments and we found that the moduli of the filaments in the older cells were consistently 20±0.8% higher than those of the younger cells independent of substrate.

Cholesterol is the most dominant sterol found in mammalian tissue and is a major structural component of the cell membrane. We investigated the impact of cholesterol on the moduli of dermal fibroblasts. To prevent uptake of cholesterol, we cultured cells in lipid-free media. We then added AY9944, a known disruptor of cholesterol synthesis, which has been shown to cause a shift to 7-dehydrocholesterol (7DHC), a precursor to cholesterol, as the major sterol. In the lipid-free media, we observed that while the proliferation of the cells was reduced, the moduli of the cells increased significantly by 100±4% and 66±2.64% for the young and old cells, respectively, relative to the cultures in standard media. Introduction of AY9944 at a concentration of 50nM decreased the modulus in the lipid-free media by 25±1% for both ages, which represented an overall increase relative to the control media of only 20±0.8% for young and 60±2.4% for old. This confirmed prior observation of increased membrane ductility.

Finally, it has been shown that cholesterol increases the susceptibility of cells to infection by Staphylococcus aureus bacteria. Therefore, we exposed cells to S. aureus at an MOI of 1000 for 90 minutes. The infection rate of old cells appeared to be approximately ⅓ that of younger cells, and the infection rate overall was nearly zero when AY9944 was added. These results illustrate that changes in the sterol composition of the membrane can have a significant impact on dermal fibroblasts. Hence, further studies are in progress to quantify the cholesterol to 7DHC quantities, as well as the impact on fibroblast functions, which are affected by aging such as collagen contraction, deposition, and turnover.

8:00 PM SB09.06.29
Osteogenic Differentiation of Dental Pulp Stem Cells via Titanium Deposition in a Static Magnetic Field EthanLai[1], MichaelWang[2], AmanYarlagadda[3], DvitaBhattacharya[4], CatherineChun[5], AnitaA. Gaenko[6], AlexanderC. Wang[7], AdamZaidi[8], Kuan-CheFang[9] and MiriamRafailovich[9]; [1]Phillips Academy, United States; [2]Mounds View High School, United States; [3]Newman Smith High School, United States; [4]Kent Place School, United States; [5]Ardsley High School, United States; [6]Huron High School, United States; [7]Sewickley Academy, United States; [8]San Francisco University High School, United States; [9]Stony Brook University, The State University of New York, United States

Osteogenic differentiation of dental pulp stem cells (DPSCs) offers potential treatments for bone-related diseases such as osteoporosis. DPSCs are preferred over other stem cells due to their ease of preservation and relative ease to obtain. Previous literature has shown that continuous exposure to a static magnetic field (SMF) induces osteogenic differentiation in rat DPSCs [1]. Past studies also suggest titanium-treated surfaces improve the rate of differentiation of DPSCs. [2] We report the degree of osteogenic differentiation with the combined effects of titanium deposition and an SMF, and compare each treatment individually. Investigating these factors will provide crucial insight to the differentiation of DPSCs and the discovery of a stem cell-based

treatment for endemic bone diseases.
DPSCs of strain 13 were isolated from third molar teeth and prepared via trypsinization every 4 days for 16 days. 4x104 cells were plated on each sample with agarose, along with MEM-α, 10% fetal bovine serum, and 1% glutaMAX. After 1 day, the media was changed to ascorbic acid and β-glycerophosphate, which has been shown to induce cell biomineralization. [2] 4 groups contained 2-inch x 2-inch silicon wafers while 2 others were in tissue culture plastic (TCP). All wafers were coated with Polylactic Acid (PLA). Half the wafers were further treated with titanium via atomic layer deposition (ALD). Half of all groups were placed in an SMF parallel to the surface for the duration of their incubation period of 28 days.
Images produced by atomic force microscopy for ALD and PLA groups were analyzed via NanoScope Analysis to quantify the roughness of the wafers. Roughness did not play a role in differentiation, as it was in the nanometer scale for all groups. Cells were also counted via alamarBlue staining on days 1 and 5 to ensure similar proliferation rates.
RT-PCR was performed after incubation to measure the expression of the following genetic markers: osteocalcin (OCN), dentin sialophosphoprotein (DSPP), and bone sialoprotein (BSP). RNA lysed from DPSCs on day 0 was used as a baseline to compare the relative expression levels of each gene for each treatment group after the 28 days. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) served as the housekeeping gene. Our results show an upregulation of BSP expression for the ALD/SMF group compared to PLA/SMF and TCP/SMF groups, confirming titanium deposition's inductive effect on osteogenic differentiation. ALD/SMF produces the greatest osteogenic differentiation with respect to BSP expression. OCN expression was also upregulated by a factor of two for ALD groups compared to PLA, and by a factor of four when compared to TCP. DSPP expression was downregulated for ALD groups in comparison to PLA and TCP, and further downregulated for ALD/SMF. Addition of other magnetic materials, such as iron oxide, may further induce osteogenic differentiation.
Collagen triple helices are abundant in osteoblasts. Scanning electron microscopy will be used to further analyze collagen triple helix formation, allowing us to understand the role of an SMF on the rate of collagen triple helix formation and thus osteogenic differentiation. Raman spectroscopy will be used to determine the nature of mineralization.

8:00 PM SB09.06.30
Mechanical Characterization of Poly(vinyl alcohol) and Resorcinol Diphenyl Phosphate Clay Blend Vascular Grafts HannahOh, LeoraStochel, HaoyuXu, MeghaGopal, RobertWong, AaronSloutski, AdamHansen, RezaDashti, ChanderSadasivan and MiriamRafailovich; Stony Brook University, The State University of New York, United States

Poly(vinyl alcohol) is suitable for vascular grafts in patients due to its biocompatibility and tunable mechanical properties, but its documented bioinert nature limits cell-adhesiveness, which is critical for the long-term patency of grafts in vivo [1]. We have previously found that Resorcinol Diphenyl Phosphate (RDP)-clay, a phosphate ester flame retardant, can enhance mechanical and cell-adhesive properties when blended with other polymers[2]. Here, we report on the effect of RDP-clay on the mechanical properties of PVA hydrogels towards manufacture of small-diameter vascular grafts.
PVA/RDP-clay blend solutions were synthesized by combining 10% PVA (w/w) solution with RDP-clay at 0%, 1%, 5%, and 10% (w/w), respectively. These solutions were crosslinked with 15% (w/w) sodium trimetaphosphate (STMP) and 30% (w/w) sodium hydroxide (NaOH). This solution was poured into 26mm diameter molds and allowed to dry overnight, after which the resulting discs were rehydrated in Dulbecco's Phosphate Buffered Saline (DPBS) for about 24 hours. Rheology of these discs was characterized using a Kinexus Pro+ rheometer (Netzsch), with oscillatory amplitude sweeps with parameters 0.1 to 100 Pa range, 1 Hz frequency, and 25 C temperature.
To create small-diameter grafts from this polymer blend, we devised a 3-step process. Melted wax was injected into a metal tube and allowed to harden, creating a 2 mm diameter wax rod. For all RDP-clay concentrations, these rods were affixed to a single-axis spinner and dipped 10 times in PVA blend, with 15 minutes of spin-drying between dips. After the final dip, rods were allowed to spin-dry overnight, rehydrated the next day, and the wax rods were removed to obtain patent vascular grafts. These grafts were orthogonally cut into thin rings, allowing wall thickness measurements to be found using a Keyence VHX-7000 microscope. 2 cm lengths of vascular graft tubes were also orthogonally cut, then attached to a PG-5 Digital Pressure Gauge and pressurized until rupture to determine vessel burst pressure.
Blend characterization through rheology indicated an average modulus of 35 kPa, with a slight increase as RDP-clay concentration increased. The described manufacture method for these small-diameter grafts was successful at creating patent vessels at all RDP-clay concentrations tested. Vessel thickness was significantly larger in 10% RDP-clay vessels than in 0%, 1% and 5%. 10% RDP-clay vessels were also visibly less smooth and homogenous than lower RDP-clay concentration vessels. Burst pressures were greater than physiological values for all RDP-clay concentrations (200-700 mmHg), but 10% RDP-clay vessels were more prone to pin-prick bursts. As such, we posit that 10% RDP-clay may be an upper limit for organoclay additive concentration to maintain mechanical integrity of the PVA hydrogel.
The mechanical properties of the PVA/RDP-clay blends under these manufacture and processing techniques show great promise for use as vascular grafts in patients. Future steps include characterizing endothelial cell adhesion and proliferation within these manufactured vessels as well as better controlling drying time between dips during manufacture to attain consistent wall thickness.

8:00 PM SB09.06.31
Characterizing Thrombogenic and Cell-Adhesive Properties of Poly(vinyl alcohol) Blended with Resorcinol Diphenyl Phosphate-Clay towards Vascular Graft Manufacture HannahOh, LeoraStochel, HaoyuXu, MeghaGopal, RobertWong, AaronSloutski, AdamHansen, RezaDashti, ChanderSadasivan and MiriamRafailovich; Stony Brook University, The State University of New York, United States

Poly(vinyl alcohol) (PVA) is an excellent candidate for manufactured vascular grafts to replace occluded arteries due to its mechanical and biocompatibility properties, but its lack of cell-adhesion prevents it from being used in humans [1]. Previously, we found that resorcinol diphenyl phosphate (RDP)-clay can improve cell adhesion within polymer blends [3]. We aim here to characterize the thrombogenic and cell-adhesive properties of PVA/RDP-clay blends on both thin films and hydrogels.
2% PVA (w/w) solutions with each of 0%, 0.1%, 0.5%, 1%, 2%, 3%, 5%, 7% and 10% (w/w) RDP-clay added were spun cast onto silicon wafers. Human umbilical vein endothelial cells expressing green fluorescent protein (HUVEC-EGFP) were plated on the spun-cast wafers at a concentration of 20,000 cells/cm2, then imaged on an EVOS M7000 fluorescent microscope. Good HUVEC cell adhesion with notable elongated cell morphology and cell-to-cell connections were observed on all spun cast films regardless of RDP-Clay concentration, indicating that in the absence of cross linker, PVA polymer was biocompatible, supporting cell adhesion and proliferation.
Potential thrombogeneity of the spun cast films was assayed by placing the substrate in a 4mg/ml solution of human fibrinogen. When fibrinogen contacts a hydrophobic surface, protein unfolding has been reported [3], which frees the alpha-C domains and exposes interior of the molecule in the absence of thrombin. Soluble fibrin is then recruited, forming large fibers which have been shown [3] to initiate clots in the presence of plasma. While multiple large fibers were observed here on the unfilled PVA films via Atomic Force Microscopy, the number of fibers and their diameters decreased with increasing RDP clay concentration, disappearing completely at a maximum loading of 5% RDP clay. This correlated with a continuous decrease in water contact angle with increasing RDP-Clay concentration, with a critical value between 1 and 2% RDP-clay.
Formation of the PVA hydrogels for the grafts, though, require cross linking with NaOH followed by rehydration of the PVA. In this case, samples with different clay concentrations were produced by dissolving 10% PVA with 0% and 10% RDP-clay, then crosslinking the solution with 15% sodium trimetaphosphate (STMP) and 30% sodium hydroxide (NaOH). The crosslinked solution was poured into 35 mm diameter molds and dried, creating hydrogel discs for cell plating. Discs were sterilized in isopropyl alcohol for 5 minutes, then rehydrated in media. Fibroblasts expressing Green Fluorescent Protein were plated atop the discs at a concentration of 2000 cells/cm^2, then imaged after 12 hours with the EVOS microscope. Without extensive washing of the discs, cells were unable to adhere to the hydrogel due to leaching NaOH from the polymer matrix. However, after hydrogel discs were subjected to daily DI exchanges for 5 days and placed under constant agitation from a magnetic stirrer, high fibroblast adhesion to both 0% and 10% RDP-clay gels was observed. This finding contradicts previous studies that show little endothelial cell adhesion to pure PVA [1], which we believe can be attributed to a lack of extensive hydrogel washing.
Our novel processing method of PVA hydrogels as well as the hemocompatibility of PVA/RDP-clay blend thin films show great promise towards using this material for long-term, implanted vascular grafts in humans.

8:00 PM SB09.06.32
Developing a Skin Construct for Wound Healing Associated with Endothelial Cell Network CaitlynLimbert[1], SahanaDhama[2], MichaelLotwin[3], JacquelineHan[4], GraceWang[5], ChunuoChu[6], AnnikaJoshi[7], RachelNa[8], ShiFu[9] and MiriamRafailovich[9]; [1]British School Jakarta, Indonesia; [2]The Wheatley School, United States; [3]Rambam Mesivta, United States; [4]Great Neck South High School, United States; [5]Detroit Country Day School, United States; [6]Shenzhen Middle School, China; [7]Johns Creek High School, United States; [8]Washington University in St. Louis, United States; [9]Stony Brook University, The State University of New York, United States

Researchers have recently engineered skin constructs incorporating epidermal and dermal layers from the collagen matrix. A significant disadvantage in designing this organotypic culture for

wound healing applications is the lack of a vascular network that promotes anastomosis of the graft-host vasculature. Meanwhile, relying on the additive growth factor to promote vascularization and angiogenesis is not sustainable and could be costly. Mesenchymal cells like fibroblasts and dental pulp stem cells are known to secrete several pro-angiogenic growth factors. Hence, our objective in this research is to (a) establish a microvascular network by co-culturing human umbilical vein endothelial cells (HUVECs) with mesenchymal cells in vitro without additional growth factors, (b) develop a series of altered mediums where both the endothelial and the epithelial cells can be co-cultured, (c) determine the role of an endothelial cell network in predicting vascularization and anastomosis response in vivo and (d) evaluating the impact of these constructs on wound healing.

Living skin equivalents were prepared for 17 days according to the procedures from our previous work [1], modified with the HUVECs-EGFP and mesenchymal cells co-culture layer on the bottom of skin constructs, cultured in the altered mediums to enhance both vascularization and epithelial differentiations. The non-vascularized skin equivalents with the same bottom layer without HUVECs were prepared similarly for comparison. Three SCID Hairless Outbred mice were used as hosts for wound healing experiments. 8mm diameter wound beds were created on the back of the mice. The harvested skin equivalents were then placed on the wound beds and bandaged with silicone film to prevent dehydration during healing.

Following a 7-day period of postoperative recovery, skin tissue samples were collected for histological analysis. Hematoxylin and eosin (H&E) staining revealed a seamless integration between the graft and the surrounding epithelium and dermis. Additionally, lumens were scattered throughout the grafted tissue, identified as human using anti-EGFP staining, and filled with blood cells. The luminal diameters of the human blood vessels ranged from approximately 10um to 40um without observable leakage, confirming successful anastomosis. The joining of blood vessels between graft and host is a necessary milestone for successful tissue regeneration and long-term engraftment.

In conclusion, we have designed a highly effective scaffold that enables the simultaneous culture of HUVEC networks with skin organotypics, promoting anastomosis and accelerating wound healing.

We acknowledge the Morin Charitable Trust for funding.

Promoting Angiogenesis via HGF Upregulation using Titanium Dioxide Nanoparticles GraceWang[1], MichaelLotwin[2], CaitlynLimbert[3], JacquelineHan[4], AnnikaJoshi[5], ChunuoChu[6], SahanaDhama[7], RachelNa[8], ShiFu[9] and MiriamRafailovich[9]; [1]Detroit Country Day School, United States; [2]Rambam Mesivta, United States; [3]British School Jakarta, Indonesia; [4]Great Neck South High School, United States; [5]Johns Creek High School, United States; [6]Shenzhen Middle School, China; [7]The Wheatley School, United States; [8]Washington University in St. Louis, United States; [9]Stony Brook University, The State University of New York, United States

Titanium dioxide (TiO2) nanoparticles (NPs) have high biocompatibility, antimicrobial properties, and light-scattering abilities, making them a valuable tool across various industries. As such, TiO2 NPs have become strong points of interest in the modern biomedical field. Previous research has demonstrated that TiO2 NPs induce the activation of human umbilical vein endothelial cells (HUVECs) due to increased expression of adhesion and other molecules associated with inflammatory response [1]. Such NPs may be linked to promoting angiogenesis, the process by which new capillaries are formed from existing vascular structures in the human body. Hence, this study examines the effects of TiO2 NPs on HUVECs angiogenesis through flow cytometry and cell sorting based on TiO2 uptake, imaging time lapses of vascular development using EVOS microscopy, network quantification with Celleste Image Analysis software, scanning electron microscopy (SEM), and Reverse Transcription Polymerase Chain Reaction (RT-PCR).

HUVECs were cultured with and without 0.1mg/ml Rutile TiO2 particles for 24 hours. The cultures were then sorted using FACS, where cells were sorted by a low and high scattering angle window, and it was assumed that the high scattering fraction would increase with TiO2 uptake. The results showed that 91% of the treated cells contained TiO2 particles.

The high scattering fraction and the control untreated cells were then plated on a 10mg/ml matrigel substrate, and the progress of angiogenesis was recorded using an EVOS microscope with a CO2 onstage incubator. Images of triplicate cell cultures were captured every 20 minutes over 18 hours. The images were then analyzed using Celleste Image Analysis software. From the images, it was found that the culture with TiO2 nanoparticles nucleated a network, and the network was more robust and persisted longer than the control. SEM analysis of the networks indicated that TiO2 particles were present in the cells, which constituted the nodes, splines, and all aspects of the network.

RT-PCR was performed on the cultures, and the results of the treated cultures were compared to those of the control. The data showed that while the housekeeping gene, GAPDH, was significantly upregulated by the particles, no difference with the control group was observed for the other housekeeping gene, Actin Beta. Hence, only the latter was used for normalization.

The data demonstrated that TiO2 exposure upregulated the hepatocyte growth factor (HGF) expression by more than an order of magnitude. In contrast, Vascular endothelial growth factor A (VEGFA) expression, which was previously observed to be upregulated in tumors with HGF, did not occur. These results indicate that despite no evidence of TiO2 nanoparticle penetration into the nucleus, exposure to TiO2 can result in upregulation of multiple genes. Further research into the precise mechanism is underway to determine whether the findings can serve as a beneficial factor in promoting wound healing.

We acknowledge the Morin Charitable Trust for funding.

Thrombosis: An Analysis of Pseudo-Thrombi to Understand Collagen-Fibrin Interaction SripradhaManikantan[1], HuitingLuo[2], ShiFu[2], RobertWong[2], ShiffoniSukhlal[2] and MiriamRafailovich[2]; [1]James Logan High School, United States; [2]Stony Brook University, The State University of New York, United States

When vascular injury occurs, the exposed tissue factor initiates thrombosis through a cascade of events including the aggregation of platelets and their coagulation, which in turn triggers the formation of fibrin and collagen to wrap around the coagulated platelets. Clinical treatment of thrombosis in patients with deep vein thrombosis or pulmonary embolism uses fibrinolytics in order to break down the fibrin and cause thrombolysis [1]. However, for arterial thrombi, fibrinolytics do not often respond well. Research shows that collagen plays a dual role in thrombosis [2] by stimulating glycoprotein VI to promote platelet accumulation and by activating factor XII to promote blood coagulation. In this research, we intend to understand the disparity between venous and arterial thrombosis by studying the interaction between collagen and fibrin in thrombi which prevent lysis. A model scaffold was produced where fibrinogen and collagen were mixed at low temperature and then allowed to crosslink at 37 C. The scaffold was submerged in osteogenic media for 21 days and biomineralization was assayed using XRF and Raman spectroscopy.
Results show that in-vitro XRF of scaffold revealed that biomineralization is significant in collagen when compared to fibrin. The calcium to phosphate ratio for the mixture of collagen and fibrin samples is 1.67, consistent with the formation of hydroxyapatite in the sample. Raman spectroscopy confirmed the formation of crystalline HA in the matrix . The spectra showed a greater peak for collagen when compared to fibrin or the collagen/fibrin scaffold mix, consistent with the XRF results. This means that fibrin has very little biomineralization. Also, unique peaks identified in the fibrin-collagen mix graph suggest the possible formation of a new biomaterial.
Venous thrombi were analyzed histologically and it was shown that they were predominantly composed of fibrin, while arterial thrombi were shown to contain collagen. XRF confirmed the absence of biomineralization in the venous thrombus, consistent with the in-vitro model. Results on the arterial thrombus will be presented, where the presence of mineral deposits will be investigated, as a function of collagen content and the hypothesis that they interfere with lysis will be investigated.

8:00 PM SB09.06.35

Neurogenic Differentiation of Micro-Spheric Dental Pulp Stem Cells via Poly-Lactic Acid, Poly(4-vinylpyridine) and Resorcinol Diphosphate Clay Polymer Scaffoldings DvitaBhattacharya[1], CatherineChun[2], AnitaA. Gaenko[3], AlexanderC. Wang[4], AdamZaidi[5], EthanLai[6], MichaelWang[7], AmanYarlagadda[8], Kuan-CheFang[9] and MiriamRafailovich[9]; [1]Kent Place School, United States; [2]Ardsley High School, United States; [3]Huron High School, United States; [4]Sewickley Academy Senior School, United States; [5]San Francisco University High School, United States; [6]Phillips Academy, United States; [7]Mounds View High School, United States; [8]Newman Smith High School, United States; [9]Stony Brook University, The State University of New York, United States

Neurodegenerative diseases such as Alzheimer's pose a major risk to the central nervous system due to the intrinsic non-dividing nature of neurons. Therefore, it is imperative to find methods of generating functionally and morphologically neuronal-like cells from non-neuronal cells under biomimetic conditions. Previously, dental pulp stem cells (DPSCs) have been shown to differentiate into neurons via plating on Polylactic Acid (PLA), Poly(4-vinylpyridine) (P4VP), and Polylactic Acid with Resorcinol Diphosphate (RDP) Clay. A concentration of 20% RDP-

Clay was found to provide the highest extent of differentiation into neurons on rough PLA surfaces [1]. Also, the usage of micro-sphere forming U-bottomed StemFit 3D suspension well plates increased the differentiability of DPSCs [2]. Therefore, in this experiment, we are investigating the effects of PLA, P4VP, and RDP Clay scaffolding on neuronal differentiation of DPSCs plated on 3D micro-sphere forming plates.
DPSC micro-spheres (created using suspension well plates) were plated onto silicon wafers spin-casted with pure PLA, PLA with 20% RDP-Clay, PLA with 30% RDP Clay, pure P4VP, P4VP with 20% RDP-Clay, and P4VP with 30% RDP-Clay. These spin-coated surfaces were analyzed with Atomic Force Microscopy (AFM) to ensure homogeneous roughness across the samples so that roughness wouldn't be a confounding factor in the growth and differentiation of the DPSCs. The RDP-Clay particles dispersed throughout the PLA with 20% RDP-Clay sample became nuclei for PLA crystals. Conversely, P4VP does not crystallize around the RDP-Clay.
The plated cells were incubated for 28 days with regular media changes. EVOS images of the DPSCs were taken on Day 1, 6 days after the cells were cultured in TCP and 1 day after plating on polymer scaffolds, confirming microsphere formation following suspension well culturing.
On Day 4, the elastic modulus of the DPSCs was measured for each group of polymer scaffolding via AFM. Cells plated on TCP served as a baseline for modulus. Lower modulus values indicate neuronal differentiation, as neurons are softer cells compared to DPSCs. P4VP had lower modulus (half that of TCP), which indicates that cells plated on pure P4VP had the highest elasticity and were therefore likely differentiating into neurons at a higher rate. Adding RDP-Clay concentration corresponded to a significant difference in modulus for cells plated on PV4P, but an increasing concentration of RDP-Clay was not consistent with a significant change in modulus for PLA scaffolds.
On Day 28, the expression of early-stage neuronal development markers TUBB3 and NES and late-stage marker NEFM was measured using RT-PCR and compared to expression in undifferentiated DPSCs. In differentiated neuronal cells, expression of TUBB3 and NES is expected to be downregulated, and NEFM is expected to be upregulated. Corresponding to our modulus data's implications, adding RDP-Clay to PLA did not lead to significant downregulation of TUBB3, NES, or upregulation of NEFM. However, an increasing concentration of RDP-Clay in P4VP correlated with significant downregulation of TUBB4, NES, and upregulation of NEFM in comparison to undifferentiated DPSCs, indicating that the cells likely underwent neuronal differentiation. Further data will be collected to analyze the effects of these polymer scaffoldings on the neuronal functionality of these morphologically and genetically differentiated cells.

ECM Based Hydrogel Delivery Vehicles and 3D In Vitro Injection Model for Human Retinal Progenitor Cells Transplantation RebeccaCarrier[1], PengZhao[1], SidiA. Bencherif[1] and Michael J.Young[2]; [1]Northeastern University, United States; [2]Schepens Eye Research Institute, an affiliate of Harvard Medical School, United States

Retinal degenerative diseases caused by photoreceptor cell loss and damage are the leading cause of blindness worldwide1. Treatments, including gene therapy, drug, and neuroprotective approach, mainly focus on slowing down the degeneration process rather than reversing it. Retinal cells implanted into the subretinal space have been shown to integrate within host retina, improving visual function in models of retinal degeneration1. One barrier to clinical success is the loss, through efflux and death, of the majority (>99%) of implanted cells2. A factor likely contributing to cell death is the host microenvironment of the subretinal space after a high cell density (~105 cells/ul) bolus injection (e.g., lacking oxygen/nutrients, missing physical support, and chemical cues). Recent studies have demonstrated that the delivery of retinal progenitor cells (RPCs) using polymer scaffolds results in improved cell survival and differentiation with associated increases in RPC integration3-4. However, current polymer scaffolds still result in minimal overall integration (<2%). We have established an in vitro bolus injection model mimicking clinical subretinal injection to explore the impact of bolus injection on human RPCs viability. Studies using this model have revealed that indeed RPCs are damaged during the injection process, leading to cell death. To better understand what cues may improve survival of RPCs in the post-injection bolus microenvironment, inert hydrogel systems (oxidized low viscosity alginate) were employed in conjunction with retinal ECM cues including glycosaminoglycans (GAGs): hyaluronic acid (HA) and chondroitin sulfate (CS), laminin (important component of basement membrane), and RGDS (adhesive peptides). The effects of the stiffness and chemical modifications of the delivery vehicles on cell survival/death mechanisms in the bolus injection environment were investigated using fractional factorial design, revealing advantages of stiffer substrates and laminin in promoting RPC survival. Ultimately, this information can be used to guide design of cell delivery vehicles for human RPCs transplantation with improved post-injection survival.

Biomimetic Crosslinking of Collagen Gels by Energetic Electrons for Advanced Scaffolds NilsWilharm[1,2] and StefanG. Mayr[1,2]; [1]Leibniz-Institute of Surface Engineering (IOM), Germany; [2]University of Leipzig, Germany

Design of advanced scaffolds on a biopolymer basis frequently require functionalization and crosslinking for optimum matching biomedial needs. Energetic electrons have recently evolved as a powerful tool for crosslinking bio-derived hydrogels without the need for adding potentially hazardous reagents. Application of this approach allows for synthesis of biomimetic collagen-derived networks of highly tunable properties and functionalization. Yet, the underlying reaction kinetics has been not sufficiently established at this point. While hydroxyl radicals are generated by energetic electron-induced hydrolysis of water and play a key role in introducing covalent bonds between network fibers, a detailed mechanistic understanding would significantly increase applicability. We present a comprehensive analysis of central aspects of the reactivity between the hydroxyl radical (OH) and collagen, elastin, glycine (Gly) and l-lysine (Lys). Overall, energetic electron based crosslinking opens the venue for customized hybrid gels of outstanding biomimicry and –compatibility.

Poly 1,8-Octanediol Citrate Breast Biopsy Scaffold and Deployment System DarnellR. Campbell, MarcosBenavides, JordanForte, CliffordHoward and NicoleLevi; Wake Forest University School of Medicine, United States

During a breast biopsy, it is crucial to accurately identify regions of concern and deliver markers accurately for subsequent imaging and surgical procedures. If surgical removal is not required, it is essential for the marker to be biocompatible, as it will remain in the tissue for the remainder of the patient's lifetime. Current breast biopsy systems employ a forceful deployment during marker administration leaving a void within the tissue that contributes to marker migration. Furthermore, current marker-encapsulating-meshes are not robust and lack compliance to breast tissue which further contributes to rapid mesh disintegration and marker migration.

To address the aforementioned problems present in the current standard of care, our group developed a three-pronged approach consisting of the creation of an elastic biodegradable scaffold to encapsulate the marker, a deployment device for *in vivo* testing on rats that does not utilize forces during administration, and a transparent breast tissue phantom to determine real-time expansion of the scaffold.

First, a biodegradable Poly 1,8-Octanediol co-citrate (POC) elastic scaffold capable of securing both metallic and non-metallic markers was developed and characterized. Our initial results indicate that POC's properties can be tuned to user-preference by changing crosslinking time, porogen size and leaching time during fabrication; to ensure elasticity of the scaffold, we optimized the pore size by using 400µm NaCl as a porogen. Next, we optimized POC compression and expansion by testing tensile forces at different crosslinking and porogen leaching times. Interestingly, we encountered that during subsequent crosslinking after leaching, POC develops limited self-healing capabilities which allowed for previously embedded markers to be repositioned within a completed scaffold.

Secondly, we developed a 3D-printed deployment device which releases the encapsulated breast biopsy marker passively in a retractable motion, eliminating the forces that cause an increase in void size within the biopsy incision. The device was subsequently employed during *in vivo* testing in rats, from which initial results demonstrate little to no marker migration when compared to current standard of care.

Finally, an optically transparent breast phantom was made from Dermasol. This reusable, insensitive to temperature or dehydration phantom allows for POC scaffold deployment and expansion in real time.

Here we presented our solutions to address the challenges associated with breast biopsy marker placement. We achieved this by developing a biodegradable POC scaffold capable of encapsulating markers and expanding to fill the biopsy void, a retractable deployment device to release the scaffold passively, a breast tissue phantom for visualization of sponge expansion, and tested of our approach *in vivo*. We are currently determining POC's degradation profile as well as continuing to evaluate our prototype scaffold and deployment system *in vivo* to measure the reduction in metallic marker migration compared to commercially available devices.

Responsive Antimicrobial Biomaterials for Treatment of Wound Infections AnitaShukla; Brown University, United States

The wound repair and regeneration process is greatly complicated by the presence of infections. Chronic wounds in particular are highly prone to infection. As a prominent example, nearly 60% of individuals with diabetic foot ulcers develop infections. Preventing and treating wound infections is a critical challenge in promoting successful tissue repair. The existence of biofilms and antimicrobial-resistant microorganisms within wound environments further complicates the effective treatment of these infections. In this talk, I will describe recent approaches we have taken to treat wound infections using hydrogel biomaterials and nanoparticle therapeutic formulations. I will discuss the development of a bacteria-responsive hydrogel drug delivery platform that can provide on-demand treatment of wound infections, while facilitating tissue repair. These hydrogels respond to the presence of beta-lactamases, which are bacteria-produced enzymes that are a common cause of antibiotic resistance. Upon exposure to beta-lactamases, the hydrogel backbone undergoes degradation, leading to the release of encapsulated antibacterial liposomes. Our findings using a *Pseudomonas aeruginosa*-infected murine skin abrasion wound model indicate complete clearance of infection within one day of treatment. Importantly, there were no instances of infection recurrence during the four-day wound monitoring period. Furthermore, timely eradication of the infection helped promote wound healing, as evidenced by histological analysis revealing rapid regeneration of the epidermis. Notably, the hydrogel itself exhibited no signs of toxicity. I will also describe our work on the development of bacteria-responsive gelatin nanoparticles that have demonstrated promising antibiofilm efficacy against prevalent wound infection-causing bacteria, including *Vibrio vulnificus* and *P. aeruginosa*. Overall, the technologies described in this talk are biocompatible and effective at eliminating wound infections, thus holding immense potential for promoting effective wound healing.

9:30 AM SB09.07.05
Biomimetic Semi-Flexible Hydrogel with Reduced Inflammation for Bone Defects JaeseoLee[1,2,3] and Il KeunKwon[3]; [1]Harvard Medical School, United States; [2]Brigham and Women's Hospital, United States; [3]Kyung Hee University, Korea (the Republic of)

Engineered 3D scaffolds must be biomechanically capable to substitute injured tissues, and have typically been made of tissue-mimicking stiffness. However, this paradigm is shifting towards the understanding that the stiffness of scaffolds can be directly responded to by cells. Herein, we have designed a soft hydrogel to meet two criteria that can shift from soft to progressively hard tissue, similar to tissue development in nature. First, inspired by clotting of blood at the wound site, the goal is to achieve strong bonding with adjacent tissues through physical crosslinking of fibrinogen (FBG). Second, the hydrogel is needed mattress to dissipate energy such as existing collagen (COL) in the body. This scaffold promotes energy dissipation by strengthening the elastic and soft fibers of the FBG through COL to form a dense structure. As a crucial fundamental substrate, soft hydrogels initially induce rapid cell adhesion due to their soft surface. Sequentially, the cells increase to penetration inner part and make rigid themselves, and leading to bone formation. Furthermore, this hydrogel was composed of ECM-like tissue, which could reduce inflammation in the early stage. Therefore, our dual-function system provides a promising strategy for natural tissue-mimicking bone regeneration by reducing inflammation, and concurrently bridging defect area through harmonizing the newly assemble cells and ECMs.

9:45 AM SB09.07.06
Neuron Viability and Maturation on Electroactive Materials and Effect of Electroactive Stimulation on Neural Cell Response TeresaMarques-Almeida[1], ClarisseRibeiro[1], IgorIrastorza[2,3], PatriciaMiranda[4], IgnacioTorres-Alemán[4], UnaiSilvan[2] and SenentxuLanceros-Mendez[2,1,5]; [1]University of Minho, Portugal; [2]BCMaterials, Basque Center for Materials, Applications and Nanostructures, Spain; [3]University of the Basque Country, Spain; [4]Achucarro Basque Center for Neuroscience, Spain; [5]Ikerbasque, Basque Foundation for Science, Spain

Electric cues are intimately related connected to physiological functions of cells and tissues. The ability to control and direct electric signals within tissue-engineered constructs is therefore increasingly important for proper tissue engineering strategies, as they influence cell behaviour and guide tissue development towards more functional and biomimetic outcomes. IN this context, smart materials, able to react in a controllable and reversible way to external stimuli by varying a specific physical or chemical quantity, show great potential for the development of advanced biomedical strategies, including biosensing, tissue regeneration and repair, immuno- and cancer therapy. Among the different types of smart materials, piezoelectric ones, that convert mechanical solicitations into electrical potential variations and vice versa, represent as suitable candidates to induce specific cell behaviors through electric cues, mainly by improving biomimicry of the cell microenvironment.
The presence of piezoelectric properties in different tissues is known and the effect of surface charge and piezoelectric stimulation has been proven to be beneficial in a variety of cells, including mesenchymal stem cells, myoblast and osteoblasts, among others, has been evaluated,
Since neurons were first cultured outside a living organism more than a century ago, a number of experimental techniques for their *in vitro* maintenance have been developed. These methods have been further adapted and refined to study specific neurobiological processes under controlled experimental conditions. Nevertheless, the impact of fundamental properties of the surfaces to which neurons adhere when cultured *in vitro* has not been sufficiently considered.

In the present work we have analyzed the response of primary neurons when cultured on piezoelectric poly(vinylidene fluoride), PVDF, surfaces with different surface electric charge and electric charge type, allowing to stablish the effect of the net charge on neuron behavior. It is shown that PVDF films promote the attachment, viability and maturation of primary neurons. More cells per unit area and longer neurites were already present in neurons cultured for one day on PVDF surfaces. Early neurite outgrowth was induced using poled PVDF as culture substrates, since by day 4 of culture neurons already show significantly increased neural process development, and by day 7, this development is even more obvious in neurons cultured on PVDF–. Negative surface charges particularly increased cell metabolism, being about 3 times higher than in control and around 1.7 times higher than in the absence of charge (PVDF NP). When adhering to PVDF–, neurons undergo maturation at a faster rate, as revealed by the higher expression levels of MAP2 and NeuN.
Further, the effect of surface charged PVDF films (positive, negative, and non-poled (average neutral surface charge)) on adhesion, proliferation and differentiation of neural-derived cell line, under static and dynamic mechanoelectrical stimulation was assessed.
Upon mechanoelectrical stimulation, PVDF with average positive surface charge allows to significantly improve cellular adhesion compared to PVDF with negative or without average surface charges. Independently of the PVDF surface charge type, the applied electrical stimulus throughout the assay improved neurite extension and differentiation.
The obtained results highlight the importance of considering the electric charge of the culture surface for the in vitro maintenance of neurons, demonstrating the suitability of the use of 2D PVDF based surface-charged substrates. Further, these findings highlight the possibility of novel therapeutic strategies for the regeneration of neural tissues based on the dynamically surface charge variation that can be induced in the electroactive films.

Curcumin and Polydopamine Loaded 3D-Printed Calcium Phosphate Bone Scaffolds for Orthopedic and Dental Implants ArjakBhattacharjee and SusmitaBose; Washington State University, United States

Musculoskeletal disorders, including bone cancer, birth defects, war injuries, and osteoporosis, affect a significant portion of the global population. The aging population and active lifestyles of younger individuals are expected to increase the prevalence of these disorders in younger patients. To address this concerning trend, research is focused on developing bio-implants and scaffolds with extended durability. This study aims to explore the impact of naturally occurring biomolecules such as curcumin from turmeric and biomimetic polymers such as polydopamine on the osteogenic, antibacterial, and *in vitro* chemo-preventive properties when directly integrated into 3D printed bioceramic scaffolds tailored for specific defects. Chemical modification of curcumin through polymer-metal-drug complexation results in approximately 2.5 times greater drug release in biological media at pH 5.0 and 7.4 compared to unmodified curcumin. The presence of curcumin reduces osteosarcoma viability by up to approximately 9 times compared to control after 11 days of cell culture. Antibacterial tests show that scaffolds containing curcumin or gingerol exhibit up to around 90% antibacterial efficacy and rupture bacterial cell walls.
Implantation of the drug-loaded scaffolds in rat distal femur model and histological assessment with H&E, vWF, and Movat pentachrome staining results indicate that the presence of MgO and curcumin leads to up to ~ 2.5 times higher early-stage bone formation than the control. These 3D-printed scaffolds result in up to ~ 75% antibacterial potential against gram-positive and gram-negative bacteria. The designed scaffolds with osteogenic and chemopreventive scaffolds can be utilized in patient-specific low load-bearing defect repair sites.

10:45 AM SB09.07.08

Magnetic Hyperthermia Enhances *In Vivo* Tissue Regeneration Through Intracellular Ros ProductionGiuseppinaTommasini[1], SuselDel Sol-Fernández[1], AngelaTino[2], ClaudiaTortiglione[2] and MariaMoros[1,3]; [1]Institute of Nanoscience and Materials of Aragon (INMA-CSIC), Spain; [2]Institute of Applied Science and Intelligent System (ISASI-CNR), Italy; [3]Centro de Investigación Biomédica en red en Bioingenieria, Biomateriales y Nanomedicina (CIBER-BBN), Spain

Regenerative medicine is a pioneering field aimed at restoring and regenerating damaged tissues and organs through numerous strategies, including the use of new materials and de novo generated cells[1-2]. As a dynamic biological process, tissue regeneration requires a variety of intracellular and extracellular molecular mechanisms to facilitate cell division and regeneration. In recent years, multiple studies have demonstrated a central role of reactive oxygen species (ROS) in tissue regeneration, acting as signaling molecules that trigger the activation of molecular pathways involved with cell proliferation and differentiation[3]. Recently, regenerative medicine has found a surge of interest in magnetic nanoparticles, using their magnetomechanical and heating potential to activate different pathways. In this optics, a promising therapeutic approach could be the possibility of manipulating the ROS production to enhance tissue repair using mild magnetic hyperthermia (MH).
Here, we present a novel approach for enhancing tissue regeneration in vivo through mild magnetothermal stimulation using manganese iron oxide nanoparticles (MnxFe3-xO4) with improved heating performance. We evaluated the biological effect of internalized MNPs subjected to an alternating magnetic field on the regeneration process that physiologically occurs in the freshwater invertebrate polyps Hydra vulgaris. To decipher the molecular mechanism underlying this process, we performed gene expression analysis of molecular markers normally modulated in ROS homeostasis in regenerated polyps after the MH stimulation. This innovative approach has not been applied before to improve tissue regeneration and thus could represent a breakthrough in tissue engineering.

The Effects of Varying Ratios of PEGDA:PDMS on the Mechanical Properties of Hydrogels with Differring PEGDA Concentrations for Bone Tissue Engineering SamLloyd-Harry[1], OzgulYasar-Inceoglu[1] and OzlemYasar[2]; [1]California State University Chico, United States; [2]The City College of New York, United States

The mechanical properties of hydrogels play a crucial role in determining their suitability as scaffolds for cell growth. Properties such as biocompatibility, porosity, and mechanical properties dictate the success of a candidate scaffold material. The effects on the mechanical properties of varying ratios of Poly (ethylene glycol) diacrylate (PEGDA) to polydimethylsiloxane (PDMS) have been reported; however, the effects of differing PEGDA:PDMS ratios in varying amounts of water have not been studied. In this work, the effects of varying ratios of PEGDA:PDMS (90:10, 85:15, 80:20) on the mechanical properties of PEGDA concentrations (20%, 40%, 60%, 80%, 100%) were investigated and compared with the embedment of SiO_2 nanoparticles (NPs). PEGDA, PDMS, water, and photoinitiator were mixed and cured under a 365 nm UV light for 10-30 minutes (increasing by 5 minutes with increasing PEGDA concentrations). Compressive testing was performed on all samples using a QT/50 Universal Testing Machine at a 5mm/min rate until breaking. Results indicate that introducing silicon and increasing oxygen strengthens PEGDA hydrogels significantly, regardless of concentration. The comparison of SiO_2 embedded samples to varying PEGDA:PDMS samples reflects the tunability that makes PEGDA hydrogels ideal candidates for tissue engineering.

11:15 AM SB09.07.10

Building Cardiac Valves with Focused Rotary Jet Spinning MichaelPeters[1,1], SarahMotta[1,1,2], ChristopheChantre[1,1], HuibinChang[1,1], LucaCera[1,1], QihanLiu[1,1], ElizabethCordoves[1], EmanuelaFioretta[2], PolinaZaytseva[2], NikolaCesarovic[3,4], MaximilianEmmert[2,3,5], SimonHoerstrup[1,2,5] and KevinK. Parker[1,1]; [1]Harvard University, United States; [2]University of Zurich, Switzerland; [3]Deutsches Herzzentrum der Charite, Germany; [4]ETH Zürich, Switzerland; [5]University of Zurich and ETH Zurich, Switzerland

Pediatric patients suffering from heart valve disease often require multiple highly invasive valve replacement surgeries throughout their childhood. Building heart valve replacements that remodel and grow alongside the patient could provide a potential solution to avoid these repeat interventions. Here, we present FibraValves as heart valve replacements that mimic the multiscale structure of the native valve, ranging from the nanoscale of the extracellular matrix (ECM) to the macroscale of the native leaflet geometries. Current valve manufacturing processes struggle to recreate these hierarchical structures. With Focused Rotary Jet Spinning (FRJS), we fabricated these valve scaffolds in less than ten minutes. Utilizing centrifugal forces to extrude synthetic polymer fibers and a focused air stream to direct them, FRJS prints micro- and nanofibers onto customizable trileaflet valve shaped collection mandrels. Fiber production and valve formation occur simultaneously. The micro- and nanofibers serve as ECM analogs, interacting with the native tissue at the cellular level, while the macroscale shape of the valve leaflets control unidirectional cardiac flow. We manufactured FibraValves using Poly(L-Lactide-co-ε-Caprolactone) fibers, due to their elastic mechanical properties and ability to facilitate rapid cellular infiltration. To evaluate clinical translatability, FibraValves were implanted in sheep using a minimally invasive transcatheter approach. The stented valves were deployed successfully and provided one-way cardiac flow control in initial acute studies. This work indicates the potential viability for FRJS to be used for future heart valve manufacturing as well as other medical implants.

11:30 AM SB09.07.11

Cell-Seeding Promotion of Phages Functionalized Surfaces GraziaM. Messina[1], GiovannaCalabrese[2], SalvatoreGuglielmino[2] and GiovanniMarletta[1]; [1]University of Catania, Italy; [2]University of Messina, Italy

Regenerative medicine is a developing field of interdisciplinary research that includes a combination of *in vitro/ex vivo* and *in vivo* techniques, including the transplantation of stem/progenitor, differentiated, or modified cells, either alone or in biomaterial scaffolds. Many strategies have been developed based on the stimulation of body's endogenous process to grow and repair. Phage display represent a powerful, high-throughput method for discovering peptide ligands for a specific target. The method uses a library of phage particles containing a wide range of peptides or proteins to identify those that bind to a specific target. This technique has evolved and now it contributes to a variety of different areas of medicine and technology, i.e., targeted drugs, imaging diagnosis, gene delivery and nanomaterials. It is a low-cost technique for screening peptide ligands on cells or tissues, distinguishing between small changes in cell surface phenotypes and between normal and sick tissues. In particular, phage-derived peptides can be used to functionalize synthetic scaffolds to drive stem cell proliferation and differentiation in vitro.
In this communication we will show how self-organization processes of phages on model substrates, at the liquid/solid interface, promotes anisotropic nanometric alignments of these macromolecular systems, characterized by peculiar nanosized diameters, with lengths of the order of micrometre. The further goal, however, is to correlate the capability of organized phage assemblies to efficiently promote specific processes of "cell seeding" and, in turn, developing suitable control strategies of the phage organization, based on the tuning of pH and surface free energy, as a preliminary step in the development of efficient scaffold functionalization strategies for tissue regeneration. The efficiency of the adopted surface functionalization technique was evaluated by using AFM, while the cell-response has been assessed by optical microscopy and by Force Spectroscopy, focusing the attention on the effect of phages on the mechanical properties of the extracellular matrix. We think that these studies may pave the way to a tailored use of surfaces functionalized with phages, as a smart scaffold able to increase the beneficial cell response.

11:45 AM SB09.07.12

3D Printed High-Strength, Void-Free, Heterogeneous Microneedle Flexible Patch for Multi-Drug Delivery JaehoKim[1], SangH. Ahn[1], SeungHyunPark[2] and WonHyoungRyu[1]; [1]Yonsei University, Korea (the Republic of); [2]Pukyong National University, Korea (the Republic of)

Microneedle (MN) has been extensively studied for drug delivery with the rapid development of various designs and fabrication methods. Dissolving MN made of fast-dissolving biomaterial such as hyaluronic acid (HA) has shown great potential and has been the most popular MN type. However, dissolving MNs have several unsolved issues: less reliable tissue insertion and inconsistent drug delivery to the tissue. Dissolving MNs are usually fabricated with an aqueous polymer solution, which requires a solvent evaporation step for solidification. However, evaporation deforms MN's shape and results in air voids trapped in MN. This inevitably affects each MN's stiffness, insertion ability, and dose distribution. Nevertheless, most of the studies on dissolving MNs have focused on studying their clinical effects and neglected the reliability of MN insertion and drug delivery to the tissue. Multi-drug delivery from MNs have been introduced as an advanced form of MNs when more than one drug needs to be administered for cancer treatment. They are mostly fabricated by micro-molding two drugs together or dip-coating the second drug formulation on dissolving MNs containing the first drug. However, these MNs can have unwanted interactions between drug compounds and can have difficulty with accurate dose control at the MN insertion site. A heterogeneous MN (h-MN) device which contains different drugs in different MNs in a single patch can be a great alternative since it can avoid drug interaction. Nevertheless, the fabrication process of the h-MN array is challenging since the traditional micro-molding process produces an array of MNs with a single material.

This study established a vacuum-assisted extrusion 3D printing process for high-strength, void-free h-MN flexible patch fabrication. We confirmed reliable tissue penetration and accurate drug delivery to a target tissue. Negative pressure was applied beneath a PDMS mold to remove the air void remaining after molding the polymer solution. For efficient removal, the mold was fabricated with a thickness of less than 1 mm. The mold was located on the customized vacuum jig which was connected to a vacuum pump to apply negative pressure beneath the mold. An array of poly (lactic-co-glycolic acid) (PLGA) and HA MNs were fabricated in a single flexible patch for long-term and short-term drug delivery. For PLGA MN fabrication, PLGA5050 57.14 wt.% solution was prepared using dimethyl sulfoxide (DMSO) with rhodamine b (0.1 w/v %) at 60 °C for 1 h. The solution was extruded single time by an extrusion 3D printer (Nordson Pro4L EFD) with 20 kPa of pneumatic pressure into the cavity. DMSO was evaporated after the extrusion at 130 °C for 60 min. For HA MN fabrication, HA 9.09 wt.% solution was prepared using 0.2 w/v % fluorescein isothiocyanate–dextran (FITC-Dextran) aqueous solution. The solution was extruded 9 times with 90 kPa of pneumatic pressure and a humidifier was applied to maintain relative humidity over 50 %. After the MNs fabrication, the mechanical properties of each MNs were analyzed by the penetration test conducted on porcine skin. The penetration force of each MNs was up to 30 g on the porcine skin which was inserted into tissue to a depth of about 550 μm. Afterward, the drug release rate of h-MNs was estimated by measuring the fluorescence intensity using a plate reader. Drug release test showed that PLGA MN released rhodamine b for 98 h and HA MN released FITC-Dextran for 3 h. Finally, HA solution (13.04 wt.%) was extruded in a mesh pattern over a fabricated 3 x 3 h-MN array to form an h-MN flexible patch. After preparing the h-MN patch, it was again inserted into the porcine skin to identify the penetration ability by confirming the cross-sectional view using a cryo-sectioning machine. Through the development of the fabrication process and analysis result, vacuum-assisted extrusion 3D printed h-MN patch has demonstrated its mechanical, and clinical feasibility.

SESSION SB09.08: Scaffolds for Regenerative Engineering II
Session Chairs: Gulden Camci-Unal and Carolyn Schutt Ibsen
Thursday Afternoon, November30, 2023
Hynes, Level 1, Room 104

1:30 PM SB09.08.01
Bioinspired Flexible Helical Electrospun Mat for Cardiac Patch Application AlexiSwitz, DarrylA. Dickerson and AnamikaPrasad; Florida International University, United States

Overview: Fiber orientation dictates mechanical properties such as mechanical flexibility and porosity. Controlling these properties allows for increased and improved growth of cardiomyocytes for cardiac patch applications. Our work focused on developing helically coiled fiber mats made of polycaprolactone produced via electrospinning, then testing the biocompatibility and function of these fibers in a cardiac patch application and comparing these results to patches reinforced with aligned fibers and patches without fibers.
Background: Helically coiled structures are found in nature from animal to the plant world and provide mechanical support, higher porosity, and increased flexibility. Replicating these structures via electrospinning as a manufacturing method, helically coiled nanofibers promote elasticity and flexibility and have a large surface area for biomolecular interactions, which is suitable for cardiovascular applications due to the demanding dynamic environment of cardiovascular tissue.
Methods and Results: Two types of polycaprolactone fibers were produced via electrospinning; aligned fibers and helically coiled fibers. Fiber formation was dictated by the electrospinning parameters, specifically the flow rate of the polymer solution through the syringe. The biocompatibility and function of these fiber scaffolds were tested by encasing the fiber scaffolds in a hydrogel comprised of gelatin glycidyl methacrylate. Fibronectin was added to this hydrogel to increase biocompatibility and aid in cardiomyocyte attachment and spreading. This hydrogel was seeded with cardiomyocytes differentiated from human-induced pluripotent stem cells to form a preliminary cardiac patch. In total three types of patches were produced: a cardiac patch containing aligned fibers, a cardiac patch containing helically coiled fibers and a third cardiac patch containing no fibers. The cardiac patches were then placed on a holder made of PDMS that provided a passive mechanical stimulus to the cardiomyocytes. These holders were placed in a 12-well plate, and the cardiomyocytes seeded in the cardiac patch scaffold were incubated for 28 days. Cell media was regularly changed to provide the cells with nutrients. Cell growth, cell viability, and cardiomyocyte function were monitored and compared within the three patches. Additionally, the cardiac patch mechanics were examined using nanoindentation, tensile testing, and Raman spectroscopy to discuss the overall suitability of the fibrous mat in cardiac tissue engineering applications.

1:45 PM SB09.08.02
Cancer Testbeds for Bone Metastasis Therapeutics KalpanaKatti[1], PreethamRavi[1], QuyenHoang[1], JihaKim[1], AnuGaba[2], ParthVyas[2] and DineshR. Katti[1]; [1]North Dakota State University, United States; [2]Sanford Health, United States

Worldwide over a million deaths occur each year from breast and prostate cancer bone metastasis. Majority of the deaths due to breast and prostate cancer are attributed to metastasis, the process of migration of cancers from the primary site to a remote location which happens to be bone for breast and prostate cancer. Bone metastasis of cancer often causes skeletal failures that become the cause of death in patients. The anticancer drugs available are ineffective for bone metastasis treatment. The inefficacy of anticancer drugs and failure of animal models necessitates the need for reliable in vitro models. We have developed a novel nanoclay tissue engineering scaffold that enables development of a remodeling stage fetal bone, a preferred niche for breast and prostate cancer metastasis. The bone mimetic scaffold utilizes modification of the clay galleries with amino acids to allow biomimetic mineralization of hydroxyapatite inside clay galleries. The bone scaffold is further sequentially seeded with commercial and patient derived cell lines of prostate and breast cancer to generate invitro models of bone metastasis in breast and prostate cancer. A specially designed horizontal flow bioreactor enables physiologically relavant fluid flow through the scaffolds thus creating a realistic testbed of bone metastasis. The cancer testbed servs as a useful platform to investigate new biomarkers using FTIR spectroscopy, RAMAN imaging and nanomechanical investigations. We have developed unique mechanics-based biomarkers that use direct nanoindentation to evaluate thew change in elastic modulus, mechanical plasticity and viscoelasticity of cancer cells as a measure of metastasis progression. We have developed unique FTIR based spectroscopic biomarkers with the help of the testbed that also demonstrate the use of FTIR in developing markers for progression of metastasis[9]. Since clinical observations indicate extensive skeletal problems and failures in bone metastasis patients, we use the testbed to evaluate the mechanisms of influence of cancer cells on the Wnt b catenin pathway an important osteogenesis pathways. We observe the specific role of cancer cell factors DKK and ET-1 on influence osteogenesis at the bone site. Lastly we demonstrate the use of testbed for screening new drugs and plant-based compounds for efficacy in treatment of bone metastasis. Overall the cancer testbed presented here is a useful in vitro system for development of new metastasis therapies and personized medicine.

2:00 PM SB09.08.03
Lacunar Bone-Inspired Biodegradable Constructs: Towards Mini-Invasive Bone Repair FedericaBuccino[1], GiulianaTromba[2], SandraHofmann[3] and Laura MariaVergani[1]; [1]Polytechnic University of Milan, Italy; [2]Elettra Synchrotron, Italy; [3]Technische Universiteit Eindhoven, Netherlands

Advancements in the field of medicine have resulted in increased life expectancy but have also led to a rise in age-related illnesses, with osteoporosis being one of the most prevalent and widespread diseases. Each year, approximately 9 million fragility fractures occur globally, imposing a significant economic and psychosocial burden for disease management. While accidents and bone tumors directly cause pain and deformity, bone fragility often remains undetected, gradually deteriorating quality of life and creating a pressing need for effective regenerative strategies.
Despite notable progress in microsurgical techniques in recent decades, achieving satisfactory functional and structural repair of damaged bone tissue remains challenging. Although bone tissue possesses intrinsic regrowth and self-restoration capabilities to some extent, the injured bones frequently fail to regain their load-bearing function, resulting in fracture nonunion. Current approaches for treating large bone injuries involve the use of autografts, allografts, and scaffolds, but none of these methods are entirely satisfactory due to specific limitations. These limitations include reduced bioactivity, potential spread of pathogens, inflammation, the need for additional surgery, limited availability, inappropriate shape and size, and a lack of monitoring for newly formed bone. In particular, difficulties in detecting bone-scaffold interactions and understanding the complex relationships between bone formation and local scaffold geometry are currently impeding the clinical applicability of minimally invasive constructs for bone healing.
To overcome these challenges, we propose the design of a novel construct for bone healing that has the potential for scalability, while addressing the current geometric, biological, and monitoring issues. The geometry of the construct is inspired by the natural lacunar micro-porosity and interconnectivity found in human bones, facilitating an improved cell seeding process. The constructs are fabricated using silk fibroin and seeded with mesenchymal stem cells. Two different culture media are considered: the state-of-the-art fetal bovine serum (FBS) and the human platelet lysate (hPL). To assess the mechanical response of cellularized constructs, we employ image-guided failure assessment within a synchrotron using a newly developed X-ray and human eye testing equipment, performing micro-compression tests on the seeded constructs. Scans are acquired at various time frames, corresponding to increasing levels of applied displacement to the construct.
To evaluate the interplay between bone regeneration and the architecture of the silk fibroin scaffold, we utilize neural networks (NN). With a NN accuracy of 0.92, our findings demonstrate the following: i) there is a statistically significant correlation ($p<0.05$) between pore density and bone formation; ii) constructs seeded with hPL exhibit enhanced bone regeneration (+26%) compared to those seeded with FBS; iii) pore shape may play a crucial role in modulating bone remodeling.
The unprecedented resolution of synchrotron imaging, coupled with the ability to gain novel insights into the mechanical response of constructs for bone healing, enables us to elucidate the intricate connections between scaffold geometry, woven bone formation, and the restoration of mechanical function. Future endeavors will focus on the utilization of shape-responsive materials in construct design, allowing the shape of the construct to be adapted according to specific requirements and needs.

2:15 PM SB09.08.04
Nanotube Scaffolds: Versatile and Customizable Long-Term Culture Platform for Primary Cells and Adult Tissues AstridKupferer[1,2], SabrinaFriebe[1,2], PhilineJauch[1,2], SonjaKallendrusch[3], IvonneNel[4], BahriyeAktas[4] and StefanG. Mayr[1,2]; [1]Leibniz Institute for Surface Engineering, Germany; [2]University of Leipzig, Faculty of Physics and Earth Sciences, Division of Surface Physics, Germany; [3]HMU Health and Medical University Potsdam, Germany; [4]University of Leipzig, Medical Center, Germany

A personalized therapy for each patient is one of the milestones in medicine. Associated with this is the organotypic culture of endogenous tissue. In this context, the extracellular matrix plays a major role, because it is unique for every part of the body. Hence, each tissue requires a specific microenvironment when cultured or grown *ex vivo*. For instance, topography and prominent chemical characteristics of the surface are crucial for protein adsorption, cell and tissue adhesion. Usually, the discrepancy between tissue demands and culture conditions results in a loss of physiological properties such as structural integrity, function, or viability of healthy tissues and tumors when the culture period exceeds seven days. This indicates that a one-size-fits-all approach of commonly used Teflon membranes is not effective for an organotypic culture. In contrast, the systematic tailoring of titania nanotube scaffolds aims to enable enhanced culture of adult human tissues *ex vivo* and preserves its structure and viability.
As an example, we present long-term cultured human mamma carcinomas that are highly responsive to the underlying nanostructures. Characteristic structural features as blood vessels, glands and connective tissues that contain for instance adipocytes, fibrocytes, immune cells (like macrophages) and tumor cells show an surface-mediated preservation. In order to maintain a normal degree of proliferation, migration and apoptosis that corresponds to the endogenous state, to preserve the extracellular matrix overall, glands and bloods vessels in specific, and to observe active immune cells, we designed advanced titania nanotube scaffolds with the desired functionality.
Altogether, we aim to realize a platform for organotypic tissue culture of up to several weeks, where primary cells and adult tissues are maintained in physiologic condition *ex vivo*. In particular, we aim to maintain an intact histomorphology, proper function, infiltration with immune cells and preserved physiological niches. Chemical and physical characteristics of the titania nanotube scaffolds are tunable with regard to e.g. surface morphology and topography, surface functionalization and overall conductivity. In this way, the scaffolds can also serve as a tailorable basis for primary cells and 3D bioprinted organ structures. Hence, we pave the way for reliable drug testing and personalized medicine.

We acknowledge the Heinrich-Böll-Stiftung and the German Federal Ministry of Education and Research, project EYECULTURE, as well as the Saxon State Ministry for Economic Affairs, Labor and Traffic (SMWA), project NanotubeUpscaling, for funding.

2:30 PM SB09.08.05
Advances in Cell Coculture Porous Membranes to Mimic *In Vivo* MicroenvironmentsJinYoo; Korea Institute of Science and Technology, Korea (the Republic of)

In this presentation, we will discuss the advancements in cell coculture platforms that integrate engineered porous membranes to recapitulate *in vivo* microenvironments and facilitate diverse cell-cell signaling. The utilization of a porous membrane-based coculture platform holds great importance in cell research as it enables the creation of modular interfaces for cells and tissues, while also establishing barrier models for tissue-on-a-chip applications. *In vitro* coculture systems that incorporate porous membranes are commonly employed to mimic *in vivo* microenvironments, such as inducing differentiation of stem cells by recapitulating naturally occurring cell-cell communications. Using porous membrane-based coculture to Induce stem cell differentiation proves to be a more cost-effective approach compared to relying on growth factors or specific mediums. A widely used commercial coculture membrane, typically a Transwell®, has played a significant role in fundamental and practical studies involving heterogeneous cell coculture systems. However, due to its relatively thick membrane thickness (~10 µm) and low porosity, it has limitations in facilitating sufficient interactions between cocultured cells. To address these limitations, we have developed advanced coculture membranes using polymers. These new membranes have a thinner thickness and higher porosity, resulting in improved cell-cell interactions that more closely mimic native tissue microenvironments. We have successfully applied these newly developed porous coculture membranes to enhance stem cell differentiation efficiency and establish endothelial barrier function.

3:15 PM SB09.08.06
The Dynamic Interplay Between Tumor Stromal Discoidin Domain Receptor 2 (DDR2) and Collagen on Neuroblastoma Cellular Mechanics TheadoraVessella[1], EstebanRozen[2], JasonShohet[2], QiWen[1] and SusanZhou[1]; [1]Worcester Polytechnic Institute, United States; [2]UMass Chan Medical School, United States

Cancer development, progression, invasion, metastasis, and responses to therapy rely on a permissive tumor microenvironment. The migration invasion of cancer cells through 3D confined extracellular matrices is coupled with cellular mechanics. Abnormal or dysregulated receptor tyrosine kinase (RTK) signalizing is common within neuroblastoma. Fibrillar collagen RTK discoidin domain receptor 2 (DDR2) is studied in this project as it is presented in both tumor cells and tumor stromal cells, with high DDR2 levels correlated with poor outcomes and metastatic disease. Because DDR2 is upregulated in various cancer cells, we hypothesized that DDR2 binds to collagen within the extracellular matrix (ECM) to promote cellular mechanics during cancer migration. In this work, a comparative study between neuroblastoma cells with normal and down-regulated DDR2 levels is conducted. Downregulated DDR2 cell areas and aspect ratios were significantly decreased when plated on collagen coated substrates. Protrusive speeds were found to be comparable among all cell lines. However, contractile speeds were significantly slower in DDR2 downregulated cells, resulting in decreased detachment of cell edges to participate in migration. Additionally, the depletion of DDR2 was shown to reduce cellular traction forces on collagen coated soft substrates (2kPa), when compared to the control cells. Together, our findings suggests that DDR2 is vital to the role of collagen binding in mediating cellular mechanics and cellular migration in neuroblastoma cells.

3:30 PM SB09.08.07
3D Printed Nanofibrous Multidomain Peptide Hydrogels for Regenerative Medicine AdamFarsheed and JeffreyHartgerink; Rice University, United States

Tissues vary in their biological, mechanical, and structural properties. In the field of regenerative medicine, 3D printing has emerged as a powerful technique for producing hydrogel scaffolds that replicate the geometric complexity of tissues. Biologically derived polymers are commonly used as hydrogel inks in 3D printing due to their inherent bioactivity. However, these polymers lack the mechanical flexibility offered by synthetic counterparts. In addition, many biologically derived polymers lack the fibrous composition that naturally exists at the nano and micro scale within the body. This necessitates the development of hydrogel inks that are both bioactive and fibrous in structure to better replicate tissues. Here, we present the use of Multidomain Peptides (MDPs), a class of self-assembling peptides that form a nanofibrous hydrogel, as a novel ink for 3D printing [1]. After optimizing MDPs for 3D printing, we show that they can be used to create complex, overhanging structures, and multi material prints. In addition, we demonstrate how cationic and anionic MDPs can be strategically patterned to influence cell behavior. Building upon this work, we have developed a novel fabrication method for producing MDP hydrogels with aligned nanofibers, resembling the alignment present in tissues such as skeletal muscle and peripheral nerve. We show that these anisotropic MDP scaffolds can guide cell growth and spreading. Further, by fabricating hydrogel scaffolds with controlled degrees of alignment, we observe that cells exhibit distinct growth patterns in response to nanoscale differences. Leveraging 3D printing, we have scaled this fabrication method to create multilayer hydrogel scaffolds with precise control over the direction of fibrous alignment. The ability to generate aligned hydrogel scaffolds in a scalable manner sets this fabrication technology apart from other techniques. This work highlights the unique potential of using self-assembling multidomain peptides as 3D printable inks, enabling the creation of improved scaffolds for regenerative medicine.

Nature-Inspired Functional Biomaterials to Reduce Biofouling for Medical Implants and Devices Woo KyungCho; Chungnam National University, Korea (the Republic of)

The formation of bacterial biofilms on medical implants and devices has been recognized as a major cause of healthcare-acquired infections. These infections not only affect the quality of patient care but can also result in implant or device failure. To address healthcare-acquired infections, we have developed anti-biofouling materials that can suppress bacterial adhesion and biofilm formation. Drawing inspiration from mussel's adhesive foot proteins, we synthesized a zwitterionic derivative of 3-(3,4-dihydroxyphenyl)-L-alanine (L-DOPA) and catechol-conjugated fucoidan. Robust antibacterial coatings were achieved through oxidative polymerization and the complexation between catechol groups and Fe(III) ions. These synthesized biomaterials can be applied to silicone implants for plastic surgery and various medical-grade substrates. Additionally, we have recently explored polyphenol chemistry to prevent thrombus formation on blood-contacting medical devices in a substrate-independent manner. In this presentation, I will discuss the development of these biomaterials and surface modification methods. The antibacterial and antiplatelet properties will be discussed in terms of non-specific protein adsorption, bacterial and platelet adhesion, as well as relevant infections and side effects associated with biomedical implants and tools.

4:00 PM SB09.08.09
Increasing Aqueous Drug Solubility by Solvent Electrospinning of Poly(2-Ethyl-2-Oxazoline) Based Stable Amorphous Solid Dispersions with High Drug Loading OlmoFrateur,

JanaBecelaere, ChrisVervaet, RichardHoogenboom and KarenDe Clerck; Ghent University, Belgium

Unfortunately, approximately 40% of all marketed drugs and over 90% of medicines in development suffer from poor aqueous solubility and hence limited bioavailability upon oral administration. This critical, current challenge in pharmaceutics has led to an increased interest in advanced aqueous solubility-enhancing strategies, with the formulation of amorphous solid dispersions (ASDs) as one of the most promising routes. Here, the active pharmaceutical ingredient is ideally molecularly dispersed in a polymeric carrier, hence increasing its chemical potential with respect to its highly stable crystalline counterpart and improving the thermodynamic driving force for dissolution in the gastrointestinal fluids. Nonetheless, the amount of marketed ASDs is still limited, as many ASDs lack physical stability due to their amorphous nature, and recrystallization to their less soluble state during production, downstream processing, storage, and dissolution often limits the applicability. In this research, an important step is taken towards the bioavailability improvement of poorly water-soluble drugs through the formulation of stable ASDs, with flubendazole (FBZ), itraconazole (ITC), mebendazole (MBZ), and celecoxib (CCX) as known Biopharmaceutics Classification System (BCS) class II model compounds. Solvent electrospinning of a working solution of the drug and poly(2-ethyl-2-oxazoline) is put forward, because of the extremely fast solvent evaporation, which freezes the API in the polymeric carrier in a highly homogeneous manner. This work demonstrates the viability and broad applicability of this strategy to produce stable nanofibrous ASDs with ultrahigh drug loadings (up to 55, 60, 70, and 80 wt% for FBZ, ITC, MBZ, and CCX, respectively) and long-term stability (at least one year). Importantly, at such high drug loadings, lowering the concentration of the polymer in the electrospinning solution below the concentration where it can be spun in the absence of the drug is essential, as the interactions between the polymer and the drug result in an increased solution viscosity. A combination of experimental analysis and molecular dynamics simulations revealed that this formulation strategy provides strong, dominant, and highly stable hydrogen bonds between the polymer and the drug, which is crucial to obtain the high drug loadings and to preserve the long-term amorphous character of the ASDs upon storage. *In vitro* drug release studies confirm the remarkable potential of this electrospinning formulation strategy by significantly increasing drug solubility values (*e.g.* up to 50 times for ITC after 5 hours) and dissolution rates, even after one-year storage of the formulations (as tested for FBZ).

Shear-Responsive Boundary-Lubricated Hydrogels Attenuate Osteoarthritis YitingLei; The First Affiliated Hospital of Chongqing Medical University, China

Lipid-based boundary layers formed on liposome-containing hydrogels can facilitate lubrication. However, these boundary layers can be damaged by shear, resulting in decreased lubrication. Here, a shear-responsive boundary-lubricated drug-loaded hydrogel is created by incorporating celecoxib (CLX)-loaded liposomes within dynamic covalent bond-based hyaluronic acid (HA) hydrogels (CLX@Lipo@HA-gel). The dynamic cross-linked network enables the hydrogel to get restructured in response to shear, and the HA matrix allows the accumulation of internal liposome microreservoirs on the sliding surfaces, which results in the formation of boundary layers to provide stable lubrication. Moreover, hydration shells formed surrounding the hydrogel can retard the degradation process, thus helping in sustaining lubrication. Furthermore, in vitro and in vivo experiments found that CLX@Lipo@HA-gels can maintain anabolic-catabolic balance, alleviate cartilage wear, and attenuate osteoarthritis progression by releasing CLX and shear-responsive boundary lubrication. Overall, CLX@Lipo@HA-gels can serve as shear-responsive boundary lubricants and drug-delivery vehicles to alleviate friction-related diseases like osteoarthritis.

10:45 AM SB09.09.02
Application of Degradable Porous Scaffold for Bone Regeneration BenZhang; SINOPEC Bejing Research Institute of Chemical Industry, China

Bone defects caused by trauma and disease present severe threat to human health. At present, allografts and autografts are the most utilized methods to repair bone defects. However, these treatments have inherent shortcomings such as high failure rates due to poor graft fixation/tissue integration, potential disease transmission and limited supplies, as well as additional surgical hurt. Synthetic bone grafts, if properly engineered with physical properties enabling stable graft fixation, robust osteoconductive and osteoinductive properties encouraging new bone growth, and safe degradation, could help address these challenges.
We report here degradable scaffolds based on poly(lactic acid) derivatives modified with poly(ethylene glycol), which exhibit high-efficiency shape recovery around body temperature and hydration induced stiffening and swelling effects. Composites of these polymers mixed with nanosized hydroxyapatite were electrospun to fabricate meshes composed of nano/micro fibers with size range from 150 nm to 10 μm. With the help of hydroxyapatite, the morphology of electrospun meshes improved wherein bulk nodules in the fibers reduced and nano/micro fibers become more smooth. As the content of hydroxyapatite increased, the average size of nano/micro fibers decreased and mechanical strength of electrospun mesh lowered. These electrospun meshes showed to support the attachment, proliferation and osteogenesis of osteoprogenitor cells *in vitro*. However, mouse bone marrow stromal cells (BMSCs) cultured on electrospun meshes exhibited suppressed activity with high hydroxyapatite content of 30 wt% indicated by CCK-8 result. Gene expressions of RUNX2, ALPL, COL1A1 and OCN increased at 14th day shown with q-PCR data, demonstrated potential osteogenic differentiation.

11:00 AM SB09.09.03
3D Printing using Oxygen-Generating Filaments for Bone Scaffold Tissue Engineering AdnanMemic; King AbdulAziz University, Saudi Arabia

The latest advancements in bone scaffold technology have introduced novel biomaterials that have the ability to generate oxygen when implanted, improving cell viability and tissue maturation. We developed a new oxygen-generating nanocomposite filament that can be used in FDM based 3D printing of bone tissue scaffolds. Initially, the polymer nanocomposites were characterised using an X-ray diffraction analysis, surface morphology assessment, evaluation of filament extrudability, microstructural analysis, and examination of their rheological and mechanical properties in order to optimized filament production. Next, the filaments were optimized in terms of nanocomposite content to control oxygen release, porosity, and antibacterial activities.Our results indicate that an optimized oxygen releasing filament with a holds great promise for improving bone generation through supporting bone cell oxygenation and resistance to bacterial infections.

11:15 AM SB09.09.04
Multifunctional Patch Systems for Breast Cancer Treatment JalalKarimzadehkhoei[1], EdaGüney[1], BerilUstunkaya[1], BuğraSenel[2], OzlemKutlu[3] and GozdeO. Ince[1,3]; [1]Faculty of Engineering and Natural Sciences, Materials Science and Nano-Engineering Program, Sabanci University, Turkey; [2]Faculty of Engineering and Natural Sciences, Molecular biology, Genetics and Bioengineering Program, Sabanci University, Turkey; [3]Nanotechnology Research and Application Center (SUNUM), Sabanci University, Turkey

Breast cancer, although treatable in its early stages with available chemotherapy drugs, remains a significant challenge in the field of oncology due to treatment difficulties, high risk of recurrence, and increased metastasis development, particularly in advanced stages. There is a pressing need in oncology for efficient therapies that provide long-term protection against cancer recurrence. However, the clinical application of chemotherapy drugs is hindered by the lack of efficient drug delivery systems, resulting in diminished treatment success and severe side effects that negatively impact patients' quality of life. In this study, we present the development of a multi-functional patch system for both short-term and long-term treatment of breast cancer. The patch system comprises two components: drug-loaded nanoparticles dedicated to the therapy and antigen epitope-loaded polymer patches designed to enhance the immune response against potential recurrence. These patches are fabricated using Solution Blow Spinning (SBS), a technique that utilizes a biodegradable polymer for the controlled release of growth factors alongside the drug-loaded nanoparticles. To evaluate the patch's degradation properties, degradation tests are performed by incubating the fabricated patch in phosphate buffered saline (PBS) solution and a lysosome-mimicking solution (LMS). The morphology of the fibers is assessed using scanning electron microscopy (SEM) before and after the spinning process, as well as after the degradation process. Fourier transform infrared spectroscopy (FTIR) is employed to analyze changes in the chemical composition of the fibers. To monitor the release of antigen epitopes from the patches and drugs from the nanoparticles, enzyme-linked immunosorbent assay (ELISA) is employed. Furthermore, in vitro studies are conducted to assess the effectiveness of the patches in stimulating the immune system. Overall, this study presents a promising approach to address the challenges associated with breast cancer treatment. The development of a multi-functional patch system that combines drug delivery and immune response enhancement may pave the way for more efficient therapies and improved outcomes for patients with breast cancer.

Synthesis and Characterization of Carbon-Based Nano-Adsorbent for Dyes Removal from Wastewater AngelesI. Licona Aguilar[1], Aidé MinervaTorres Huerta[2], MiguelA. Domínguez Crespo[2], María de la LuzX. Negrete Rodríguez[1], EloyConde Barajas[1], Silvia BeatrizBrachetti Sibaja[3] and IssisC. Romero Ibarra[4]; [1]TecNM/ Instituto Tecnológico de Celaya, Mexico; [2]UPIIH - Instituto Politecnico Nacional, Mexico; [3]TecNM/ Instituto Tecnológico de Ciudad Madero, Mexico; [4]UPIITA- Instituto Politecnico Nacional, Mexico

Water pollution is the main part of environmental pollution and it has been increased due to factors such as urbanization and rapid industrialization, considering to human activities in various

industrial fields *e.g.* textile industry, metallurgical, and others. In particular, dyes are hazardous and toxic components, present in trace amounts in wastewater effluents, for its treatment the adsorption method has been the most promising and widely used treatment technique due to its efficient and its flexible operation compared to other methods. Currently, in the nanotechnology field, there are substantial studies researching the potential application of nano- adsorbents for dye removal such as carbon nanotubes (CNTs) and activated carbon (AC) due their physical-chemical properties *e.g*., large surface area associated with the availability of active binding sites, chemical and thermal properties. These materials can be modified chemically with metallic nanoparticles to increase the surface area and their adsorption capacities through high selectivity and active centers generation. In the present work, multiwalled carbon nanotubes (MWCNTs) and activated carbon from orange peel (AC) were modified to obtain adsorbent materials. Firstly, a functionalization using a mixing acid (HNO_3 and H_2SO_4) was proposed, to improve groups such as oxygen, nitrogen and sulfur on carbon surface materials. Furthermore, MWCNTs and AC surface were modified with nanoparticles with oxide zinc (ZnO) at different concentration (15 and 30 wt%) by precipitation method. The carbon materials were tests to removal methylene blue (MB) and the optimum adsorption conditions were evaluated. The carbon materials (CM) were analyzed by X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FT-IR), thermogravimetric analysis (TGA), scanning electron microscopy (SEM), Nitrogen (N_2) adsorption-desorption, zeta potential and UV-VIS technique were used to quantify the concentration of MB. Results revealed that CM developed a large surface area from 200 to 1100 m^2g^{-1} and chemical groups such as OH, C=O and C-O were conserved; adsorption studies reveal that materials with nanoparticles at 30 wt% can removal until 89.5 % of MB considering conditions such as pH 10, time 24 h, adsorbent dose 20 mg, concentration 80 ppm. The overall all results indicated that CM are promising candidates for dye removals.
Keywords: carbon nanotubes, activated carbon, nanoparticles, dyes, adsorption.

Poly(β-Amino ester) Nanoparticle for Lung Capillary Endothelium Specific Gene Delivery ZichengDeng[1], DongluShi[2] and VladimirKalinichenko[1,3]; [1]The University of Arizona, United States; [2]University of Cincinnati, United States; [3]Phoenix Children's Hospital, United States

Introduction and Background: Endothelial cell dysfunction occurs in a variety of acute and chronic pulmonary diseases including pulmonary hypertension, viral and bacterial pneumonia, bronchopulmonary dysplasia, and congenital lung diseases such as alveolar capillary dysplasia with misalignment of pulmonary veins (ACDMPV). To correct endothelial dysfunction, there is a critical need for the development of nanoparticle systems that can deliver drugs and nucleic acids to endothelial cells with high efficiency and precision. While several nanoparticle delivery systems targeting endothelial cells have been recently developed, none of them are specific to lung endothelial cells without targeting other organs in the body. **Methods/Experimental Approach:** Poly(β-amino) ester (PBAE) nanoparticles with specific structure and fluorination was designed, screened, and injected into WT mice intravenously. Typical nanoparticle and transfection detection methods like whole body imaging, flowcytometry and microscopy were used to evaluate the pulmonary endothelial cell targeting efficiency. **Results**: After intravenous administration, the PBAE nanoparticles with specific structure and NP:DNA ratio can deliver non-integrating DNA plasmids to lung microvascular endothelial cells but not to other lung cell types. IVIS whole body imaging and flow cytometry demonstrated that plasmids were functional in the lung endothelial cells but not in endothelial cells of other organs. Toxicity study showed that the PBAE nanoparticles were non-toxic. **Conclusions:** This specifically designed PBAE nanoparticles have promise for new pulmonary vascular diseases therapies development.

11:50 AM +SB09.09.07
Development of Metabonegenic Citrate Biomaterials for Orthopedic Engineering JianYang; Westlake University, China

Background: Although significant progress has been made in the development of orthopedic biomaterials, the currently available materials are limited by their inabilities to mimic the native tissue composition, weak mechanical strength, minimal osteoinductivity, significant inflammatory responses, poor bone integration, and slow bone regeneration. Metabolic factors such as glucose were shown to regulate the energy needs of stem cells during osteoblast differentiation. However, a full picture of the metabolic processes guiding or supporting osteogenic differentiation is far from complete. Citrate is a small molecule participating as the starting metabolite in the TCA cycle, is also a key component of bone. However, very limited information is available on what role the citrate plays in bone development and bone biomaterial design despite of its well-known unusual high abundance in bone.

Methods: In this study, a new class of highly versatile and functional citrate-based biomaterials has been developed by reacting citric acid with various carefully selected compounds including amino acids, diols and other functional molecules. We seek to answer several unexplored questions: 1) Can exogenous soluble citrate be uptaken by MSCs? 2) What is the role of extracellular citrate on the energy metabolism of bone forming cells? 3) Can the citrate-regulated cell energy metabolism crosstalk with MSCs signaling pathways involved in osteogenic differentiation? 4) Can the citrate-presenting materials mediate MSCs differentiation through the same mechanism as the soluble citrate? We also explore how these understandings can be applied to novel citrate-presenting biomaterial design and validate if the use of citrate-presenting anatomically similar and mechanically compliant scaffolds can enhance tissue integration and bone regeneration in a critically sized bone defect model.

Results: Our studies showed that extracellular citrate uptake through solute carrier family 13, member 5 (SLC13a5) supported osteogenic differentiation via regulation of energy-producing metabolic pathways, which led to elevated cell energy status to fuel osteo-differentiation of hMSCs with high metabolic demands. We next identified citrate and phosphoserine (PSer) as a synergistic pair in polymeric design, exhibiting concerted action not only in metabonegenic potential for orthopedic regeneration, but also in facile reactivity into a fluorescent system for materials tracking and imaging. We herein designed a novel, citrate/phosphoserine-based photoluminescent biodegradable polymer (BPLP-PSer), which was lastly fabricated into BPLP-PSer/hydroxyapatite composite microparticulate scaffolds, demonstrating significant improvements in bone regeneration and tissue response in rat femoral condyle and cranial defect models.

Discussion and Conclusion: We have revealed a previously unexplored expression pattern of SLC13a5 citrate transporter along osteo-differentiation, and a mechanism focusing on the metabolic regulation of citrate to elevate cell energy status for bone formation, referred to as citrate metabonegenic regulation. These findings not only identify citrate as a new metabolic factor in the stem cell micro-environment favorable for osteo-differentiation, but also suggest that citrate should be considered in bone biomaterials design, providing guidance to develop biomimetic BPLP-PSer/HA for prolonged citrate metabonegenic effect well into late stage of differentiation, which demonstrated therapeutic potential for bone injuries [1-3]. The unprecedented knowledge on the citrate mechanism enables us to design the next generation of biomimetic dynamic orthopedic implants that may present citrate signals in demand during cellular and tissue development.

Development and Translation of New Biomaterial Platforms for Biofabrication RamilleShah; Dimension Inx, United States

Over the past 10 years my research lab and start up, Dimension Inx, has been working to develop and commercialize new advanced regenerative biomaterials that are compatible with 3D-printing. We have developed an extensive range of tunable 3D-printable material platforms that greatly expand the biomaterial palette for complex soft and hard tissue biofabrication. Examples of these new advanced materials include a synthetic *Hyperelastic "Bone"*® material with unique properties that allow for scalable, surgically friendly bone-defect repair, a *Fluffy-X*™ material that has ideal properties for soft tissue and organ biofabrication, and electrically conductive *3D-Graphene* for nerve and muscle regeneration. In this talk I will describe these new advanced biomaterials, their promise in medicine, and how we are taking them from development through to scale up production for commercial and clinical translation.

Advanced Soft Hydrogel Materials: New Theoretical Frameworks for Their Chemical and Physical Structure NicholasA. Peppas; The University of Texas at Austin, United States

Soft hydrogel materials are water-swollen polymer networks that can be tuned to mimic the physical and biochemical properties of their surrounding environment. The signaling mechanisms between the hydrogel properties and their environmental behavior are not always clear, especially because hydrogels and exterior matrix serve the dual functions of mechanically supporting other materials (including tissues or cells) and regulating how chemical signals travel between. In hydrogels, stiffness and solute diffusivity are closely associated with the hydrogel's polymer network structure. The structure-property relationships of hydrogels are summarized by numerous mathematical modeling systems. We present robust, well-tested predictive models that describe how structural changes affect hydrogel properties to make hydrogels into the precise, nuanced tools needed to solve modern engineering problems. We have coordinated swollen polymer network models based on four structural parameters and demonstrate how those four parameters work together to decouple stiffness and other parameters in hydrogels without changing the chemical properties of the network. The resulting decoupling and associated fundamental models facilitate more nuanced investigations of polymer-environment interactions.

Interfacial Reinforcement of a 3D-Printable Double Network Granular Hydrogel TianyuYuan, ChenzhuoLi, JohnKolinski and EstherAmstad; École Polytechnique Fédérale de Lausanne, Switzerland

Load-bearing soft materials that can be processed into 3D shapes gain increasing importance in the biomedical field. Granular hydrogels have the potential to be used as 3D-printable artificial tissues and their local composition can be tuned over micrometer-length scales. However, the development of mechanically strong granular hydrogels that can be used for load-bearing applications remains challenging. To overcome this challenge, a secondary hydrogel network that covalently crosslinks adjacent microgels can be introduced.[1] However, the resulting double network granular hydrogel is relatively brittle because of the weak interparticle interactions and the lack of energy dissipation mechanisms.
In this work, two types of oppositely charged polyelectrolyte microgels, one made of the negatively charged polyacrylic acid (PAA), the other made of the positively charged poly(3-Acrylamidopropyl)trimethylammonium chloride (PATC) are used to produce a double network granular hydrogel (DNGH). Due to the electrostatic interactions between the oppositely charged PAA and PATC microgels, the hydrogel exhibits values for the Young's modulus and fracture energy that are similar to those of cartilage[2,3] and skeletal muscles.[4] We experimentally investigate the contribution of the interparticle reinforcement to the overall fracture energy of the hydrogel. Based on these studies, we propose an empirical model that takes into account the damage zone size, contact area, and adhesion energy. We demonstrate that this model, albeit being simple, can predict the mechanical properties of DNGHs with a reasonably high accuracy. Thanks to the interfacial reinforcement between PAA and PATC microgels, free-standing structures can be 3D-printed with high printing resolutions, providing new possibilities for designing strong and tough soft materials with versatile processability.

1:30 PM *SB10.02.01
Influence of Solvent Quality on the Swelling and Deswelling and the Shear Modulus of Semi-Dilute Solution Cross-Linked Poly(vinyl acetate) Gels JackF. Douglas[1] and FerencHorkay[2]; [1]National Institute of Standards and Technology, United States; [2]National Institutes of Health, United States

We systematically examine the influence of varying temperature (T) over a large range in model poly(vinyl acetate) gels swollen in isopropyl alcohol. The theta tempearture Θ of our gels, at which the second virial coefficient A_2 vanishes, is found to be equal to within numerical uncertainty to the corresponding high molecular mass polymer solution value without cross-links, and

we quantify the swelling and deswelling of our model gels relative to their size at $T = \Theta$, as customary for individual flexible polymer chains in solution. We also quantify the "solvent quality" dependence of the shear modulus G relative to $G(T = \Theta)$ and compare to the hydrogel swelling factor, α. We find that all our network swelling and deswelling data can be reduced to a scaling equation of the same general form as derived from renormalization group theory for flexible linear polymer chains in solutions so that it is not necessary to invoke either the Flory-Huggins mean field theory or the Flory-Rehner hypothesis that the elastic and mixing contributions to the free energy of network swelling are separable to describe our data. We also find that changes of G relative to $G(T = \Theta)$ are directly related to α. At the same time, we find that classical rubber elasticity theory describes many aspects of these semi-dilute solution cross-linked networks, regardless of the solvent quality, although the perfector clearly reflects the existence of network defects whose concentration depends on the initial polymer concentration of the polymer solution from which the networks were synthesized.

Tunable Surfaces and Interfaces from Responsive Polymers for Biomedical Applications NamitaChoudhury, NisalWanasingha, RajkamalBalu and NabaK. Dutta; RMIT University, Australia

Design of responsive surfaces, interfaces and nanostructures, whose characteristics can be modulated on demand is an important challenge in diverse applications. In this presentation, we discuss the responsive behaviour of soft surfaces, interfaces and solid-liquid interfaces derived from biomimetic polymers. The unique structural features of such polymers and the changes in their characteristics properties and conformation induced by a change in the environment have been evaluated in detail using highly sensitive tools such as quartz crystal microbalance (QCM-D), surface plasmon resonance (SPR), dynamic light scattering, small angle neutron scattering, UV-Vis, and spectroscopy. The talk will illustrate how this responsiveness could be used towards the construction of novel hydrogels, hybrids, conjugates and functional nanoparticles such as high surface area nanoparticles for specific applications. It will also highlight the new classes of multifunctional biomimetic polypeptide synthesis, 3D fabrication of hydrogel and the nano-bioconjugates, that we are developing for biomedical and injury applications, including effective therapeutic, adhesion and repair.

2:30 PM SB10.02.03
Textile Electronics for Long-Term Electrophysiological Signal Recording Application ChansooKim, JunyiZhao and ChuanWang; Washington University in St. Louis, United States

Long-term electrophysiologic signal collecting is important since it provides a prior warning to people by detecting diseases such as heart failure or arrhythmia before the diseases progress to a more dangerous stage. It also provides fundamental data for training to improve performance by identifying the accurate amount of exercise and muscle usage for athletes. For this purpose, flexible and stretchable sensors have shown great potential for wearable and ambulatory electrocardiography signal monitoring applications. These soft sensors are comfortable, conform to human skin, and daily wearable in contradistinction to rigid metal-based conventional electronic devices. Nevertheless, most of long-term electrophysiologic sensors have focused on sticky dry electrodes for long-term signal collection because conformal contact of electrodes on the human skin can decrease contact impedance.
Here, we propose an interesting approach for long-term electrophysiologic signal collecting electrode in dry condition by E-textile system. This system consists of textile and microfiber electrode that were coated by Poly(3,4-ethylenedioxythiophene) polystyrenesulfonate (PEDOT:PSS). For the textile electrode, PEDOT:PSS was simply printed on the nylon-based textile through screen printing manner and the stretchability of electrode was enhanced via polyethylene oxide (PEO) crosslinking process. In addition, hydrophobic treatment through 1H,1H,2H,2H-Perfluorooctyl-trichlorosilane (FTOS) effectively prevent water permeation that can cause erosion and dissolving of the electrode. Consequently, the textile electrode shows high durability in water. Moreover, the microfiber electrode offers greatly reduced contact impedance between skin and electrode, and improved signal-to-noise ratio (SNR) through dramatically increasing contact area. These electrodes combined via electrolyte conductive gel pad and build E-Textile system. Therefore, we achieve 1.1×10^5 $\Omega\times cm^2$ contact impedance. In addition, the SNR of the electrocardiogram (ECG) and electromyography (EMG) SNR were 27 dB and 29 dB in dry atmosphere.

2:45 PM SB10.02.04
Understanding Hydrodynamic Wear in Self-Similar Superhydrophobic Coatings Subjected to Rapid Droplet Impacts DanielBraconnier[1], TerenceDavidovits[2] and RandallM. Erb[1]; [1]Northeastern University, United States; [2]Thermobionics LLC, United States

Superhydrophobic materials rely on both chemical apolarity and surface roughness to achieve the high contact angles and the low roll-off angles that lead to self-cleaning and antibacterial properties. Current superhydrophobic coatings tend to be delicate and lose their properties easily when subjected to droplet impact. Such impact quickly deteriorates these coatings through hydrodynamic wear; changing structure, eroding hydrophobic chemistry, and quickly leading to full wet out of the substrate. In fact, hydrodynamic wear is more detrimental to coatings than seemingly more aggressive mechanical wear including scratching with sandpaper - a common approach used to claim both self-similarity of a material and extreme robustness against wear. What makes certain coatings more robust against hydrodynamic wear? To understand this answer, we systematically study ten disparate self-similar superhydrophobic coating approaches from academia to industry by subjecting them to hydrodynamic wear with rapid droplet impacts. We find rapid droplet impact that simulates a medium rain can deteriorate most coatings within seconds or minutes. Meanwhile, the more resilient coatings share common attributes including robust apolar chemistry, hierarchal topography, and a slow loss of sacrificial material. In addition, we offer an analytical model that nicely characterizes the hydrophobic lifetimes of these systems.

3:30 PM *SB10.02.05
Characterization of the Network Structures of PEGDA and Dextran Hydrogels by Complementary Methods JosephM. Scalet and StevinH. Gehrke; University of Kansas, United States

The physical properties of hydrogels are directly affected by their network structure; thus, characterization of that structure is a key part of their development for specific applications. There are generally several different characteristic length scales from the molecular to macroscopic dimensions. Additive manufacturing of hydrogel components introduces additional levels of network structures, depending on the manufacturing methods. Thus, many different methods of characterizing network structures have been developed and used to characterize gels. In this presentation, two fundamentally different but complementary methods will be examined for their potential to evaluate the network structure. The first is the most widely used method – mechanical testing –, but the data is examined in terms of multi-parameter models. The second is the use of time domain low-field NMR (LF NMR), a method that has not been widely used but has the potential for rapid screening of hydrogel formulations. Two hydrogels with quite different network structures widely used in a variety of applications, including 3D printing, are examined: poly(ethylene glycol diacrylate) (PEGDA) and thiol-ene crosslinked dextran.

PEGDA hydrogels were synthesized from monomers of molecular weight from 575 to 8000 Da by photopolymerization at polymer concentrations ranging from 7% to 50 wt.% in water. Dextran gels were made by functionalization of dextran with pentanoate groups which makes it possible to crosslink them by a photopolymerized thiol-ene reaction with dithiothreitol.

Generally, hydrogels are assumed to follow the classic neo-Hookean elastic model under compression or tension, from which network mesh size is estimated. However, not all gels fit this model well, often with deviation increasing with strain. Multiple parameter models can accurately fit data over a broader range of strains and provide further structural information than the standard model. For PEGDA, molecular weights, and concentrations were varied. As the polymer concentration at hydrogel formation increases, the covalent and the entanglement contributions of the modulus both increase. For dextran, a range of molecular weights and polymer concentrations were tested, as well as pentanoate functionalization and thiol:ene ratio. As the thiol:ene ratio was varied, the covalent contributions increased, but the entanglement contributions were less strongly affected. When the polymer concentration at formation was increased, however, both contributions increased.

LF-NMR is an experimentally simple, quick, and non-destructive technique that has the potential to determine a distribution of characteristic length scales in hydrogels. Its speed and experimental simplicity suggest a potential use for the rapid characterization of hydrogel formulations in application development. Proton relaxation times in the time domain (T_2) are related to surface-solvent interactions, and theory can be used to convert the T_2 distributions into network mesh sizes. PEGDA gels were characterized in solution before polymerization, after polymerization, and after equilibration with water. A noticeable reduction in T_2 was observed for PEGDA gels upon cross-linking, indicative of the mobility constraint caused by the formation of the hydrogel network.

4:00 PM SB10.02.06

Effects of Zig-Zag Hydrogen Bonding and Movable Cross-Linking on the Physical Properties of Poly(ether-thioureas)-Based Elastomer SojungSeo and Ji-HunSeo; Korea University, Korea (the Republic of)

It is important but challenging to overcome the trade-off in mechanical properties by simultaneously increasing the tensile strength and elongation of elastomers for many applications requiring diverse mechanical properties of polymeric materials. Here, we fabricated an elastomer that forms two types of physical bonds (hydrogen bond and host-guest interaction). The combination of poly(ether-thiourea) (TUEG) with zig-zag array of hydrogen bonds and polyrotaxane (PRX) with movable cross-linking junctions simultaneously increased the mechanical strength (tensile stress of 15 MPa) and elongation (tensile strain of 600%) of the elastomer. It was investigated that degradation of mechanical properties of polymer network against repeated deformation (10 times, tensile strain of 150%) was prevented owing to movable cross-linking junction of PRX. Therefore, this work presents a dual physically cross-linked elastomer having a short main chain (3k) with high tensile strength, tensile strain, and resilience.

4:15 PM SB10.02.07
Nonlocal Intrinsic Fracture Energy of Polymer-Like Networks BoleiDeng, ShuWang, ChaseHartquist and XuanheZhao; Massachusetts Institute of Technology, United States

Connecting the molecular level details of chain scission to the macroscopic fracture of polymer networks remains a long-standing problem. The Lake-Thomas model predicts the intrinsic fracture energy of a polymer network is the energy to scission a layer of polymer chains. However, recent experiments showed that the Lake-Thomas model underestimated the intrinsic fracture energy by about one to two orders of magnitude. We show that the intrinsic fracture energy of polymer-like networks mainly results from nonlocal energy dissipation by relaxing polymer chains far away from the crack tip. Experiments and simulations show that increasing nonlinearity in single chain mechanics amplifies the intrinsic fracture energy in 2D and 3D polymer-like networks and sustains despite varying defects, dispersity, topologies, and length scales. Our findings not only provide new physical insights into the fracture of polymer networks but also offer design guidelines for tough architected materials.

4:30 PM SB10.02.08
Network Materials with Soft Matrix with Extreme Properties CatalinR. Picu and MithunDey; Rensselaer Polytechnic Institute, United States

Most biological materials and many engineering materials, including those used in sports equipment, are network materials with matrix. Their mechanical function is conditioned by the presence of a stochastic network of crosslinked fibers. The embedding matrix is typically a hard thermoset (e.g. epoxy) or a soft hydrogel. The interplay of the two constituents is pronounced when the stiffness of the network tested independently is equal to the stiffness of the matrix. We explore the design principles of this type of composite to determine the parametric space in which special properties can be obtained. Matrices with extreme properties, i.e. incompressible and auxetic, lead to the most pronounced effects. Of special interest is the response to indentation/impact, case in which the interplay of the network and matrix is enhanced. The results are relevant for the design of hybrid materials with exceptional properties and with applications in multiple areas, including in sports equipment design.

4:45 PM SB10.02.09
Reducing Weight of Additively Manufactured Recycled Polymer Sandwich Panels Through Core Topology Exploration MelanieEdmund[1], AndrewNeils[1], MikeBallin[2], LukeDiehl[2] and JackLesko[1]; [1]The Roux Institute at Northeastern University, United States; [2]Blueprint Surf Co., United States

The development of new topologies has the potential to overcome mechanical performance shortcomings seen by structures 3D printed with recycled polymer materials. We investigated the lightweighting of polymer fused deposition modeling (FDM) additively manufactured sandwich panels through the use of high performing closed cell lattice topologies. This study was inspired by Blueprint Surf (Portland, ME), a company that uses FDM additive to make surfboards from recycled polymer feedstocks, with triangular honeycomb cores. For this study, sandwich panels were chosen as the model system for lab-based investigation of surfboard structural properties. Analytical models were used to identify sandwich panel core topologies, like the octet lattice, which should outperform current state-of-the-art (triangular honeycomb). These weight optimization models were validated experimentally through three-point bend testing. Further, the relevance of the lab based three-point bend test of sandwich panels to surfboard structural performance was also considered. The applications for this study extends past surfboards and open the door for more applications of recycled polymers in additive manufacturing. By determining the topologies and densities that yield performance results similar if not better than virgin materials, recycled polymers can be utilized instead of virgin materials in the production of other sports, medical, and general safety equipment.

SESSION SB10.03: Poster Session: Hydrogels

8:00 PM SB10.03.01
The Role of Hyaluronic Acid in the Organization of Aggrecan in the Extracellular Matrix FerencHorkay, EmiliosK. Dimitriadis, IrenHorkayne-Szakaly and PeterBasser; National Institutes of Health, United States

Aggrecan is a negatively charged bottlebrush shaped biopolymer molecule. Bottlebrush structures provide excellent lubrication in living systems. Inspired by the lubrication properties of biological systems (e.g., synovial fluid), synthetic bottlebrush polymers have been designed and synthesized. In the extracellular matrix (ECM) aggrecan exists as an aggregate where aggrecan molecules are noncovalently attached to long hyaluronic acid (HA) chains. Aggrecan-HA complexes are important for the mechanical response of cartilage. They exhibit high osmotic modulus, which defines the resistance of the tissue to compressive stress. We studied the hierarchical organization and the scattering properties of hyaluronic acid solutions and aggrecan-hyaluronic acid complexes. Small angle neutron scattering (SANS) and static and dynamic light scatting (SLS and DLS) measurements reveal a domain structure of size greater than several hundred nanometers. At higher values of wave vector, the SANS response corresponds to rod-like structures, of length consistent with the hydrodynamic correlation length associated with the fast diffusion coefficient. Calcium ions do not affect the geometric properties of these domains. DLS is used to investigate the effect of charge valence on the relaxation rates of the concentration fluctuations. The fast diffusive mode in the autocorrelation function becomes slower in the presence of calcium ions relative to sodium counter-ions. The slow mode, however, becomes faster with calcium ions. Reasonable agreement is found between the scattering intensity of the osmotic concentration fluctuations obtained from DLS and from the SANS response. Atomic Force Microscopy is used to determine the morphology of the aggrecan-HA complexes.

8:00 PM SB10.03.02
Surface Function Transformation Through Deformation of 3D Structure using Soft Materials YejinOh, HyeminLee and HyunsikYoon; Seoul National University of Science and Technology, Korea (the Republic of)

Recently, the study of surface morphology alterations has been extensively studied due to their ability to control material properties by changing surface morphology. As for materials, hydrogels are gaining attention due to structural changes through water penetration into the hydrogel network in a wet environment. And as for technology, there are various processes to fabricate three-dimensional (3D) structures but issues of low throughput or low resolution remain. Therefore, we propose a novel approach that 2D structures, made of conventional lithography, transform into complicated 3D structures using hydrogels. By swelling hydrogels under constrained conditions, we achieved the desired shape transformations. We replicated the swollen pattern because of its moisture transport behavior. To optimize material for replication, we investigated about affinity for water of prepolymer and indentified that the lower the affinity for water compared to hydrogels the better the swollen pattern retained its shape. In this way, we manufactured molds for buckling and inversely tapered structures and noted that replication from complicated 3D shapes was possible due to the softness of swollen hydrogel. In this method, buckling structures made of polydimethylsiloxane (PDMS) can be utilized as protective films due to their ability to disperse forces laterally. Also, the inverse tapered patterns made of perfluoropolyether (PFPE) exhibit oleophobic surfaces, enabling self-cleaning properties for oil. We also identified that as swelling ratio increased, dispersion capability in buckling film and oleophobicity in inversely tapered film were improved. Therefore, this research demonstrated the potential of utilizing surface shape modifications to achieve various properties using desired materials. It is expected that function transformation can be a platform to create unprecedented functions arising from unique shapes morphed from conventional straight shapes.

Measuring the Flex in Surfboard Fins during Surfing PawelKryzanowski and MarcIn het Panhuis; University of Wollongong, Australia

In this paper we describe the fitting out of a surfboard with inbuilt measurement system and a set of fins instrumented with commercial obtained Wheatstone bridge sensors. The inbuilt

measurement system consisted of GPS, accelerometers, and gyroscope. Telemetry data was collected during characteristic surfing maneuvers on ocean waves at a sampling rate of up to 80 Hz. Our results indicated that our surfboard with instrumented fins can be used to measure the flex in fins during surfing. Our data showed that both fins flex while on waves (surfing speed), but not during paddling (low speed). The commercial sensors recorded fin flex values of up to 10% as the fins are loading and unloading at surfing speeds of up to 6 m/s (from GPS data).

8:00 PM SB10.03.04
Blood Oxygen and Heart Rate Monitoring by a Flexible Hybrid Electronics Device Fabricated by Multilayer Screen-PrintingGáborMéhes[1,2], AyakoYoshida[2] and ShizuoTokito[2]; [1]Waseda University, Japan; [2]Yamagata University, Japan

Finger-based pulse oximetry (SpO_2) and heart rate monitoring are widely used in medical settings and are penetrating the everyday life. However, SpO_2 response measured on the peripheral parts of the body (such as fingers and wrists) has a time lag and is less accurate compared to measuring on forehead. In addition, current devices are centimeter-thick, making seamless integration with the body difficult, hindering continuous monitoring and wide adoption. We designed, fabricated, and evaluated an SpO_2 and heart rate sensing device based on flexible hybrid electronics (FHE) technology. The marriage of flexible electronics with high performance commercially available IC chips makes it possible to have advanced sensing, data processing and wireless data transmission functionalities on a thin (1.5 mm) and flexible form that can be attached to various parts of the body. Differently from most devices using FHE technology, here we describe a cost-efficient and mass production compatible multilayer screen-printing process based on conducting Ag-based and non-conducting inks for making the flexible interconnection circuitry in detail, including advanced topographic analysis. By optimizing the printing steps, we could fabricate interconnecting lines vertically traversing up to five printed layers over several tens of micrometers, increasing the spatial density of functional units. By this, we widen the possibilities to utilize screen-printing for advanced wearable devices. Indeed, our FHE device reliably detects induced hypoxemia, and when applied on forehead, detects changes in SpO_2 more than 10 seconds earlier compared to a finger-based medical grade reference device.

8:00 PM SB10.03.05
Highly Entanglement Hydrogel-Coated Sticker for Diverse Surface Applications via Copolymerization Method Joon HyungAn[1], JunsooKim[2] and SeongminKang[1]; [1]Chungnam National University, Korea (the Republic of); [2]Harvard University, United States

High entanglement hydrogel has advantages such as low friction and high stiffness. However, its applicability is limited by its tendency to easily delaminate when adhering to a surface, which is caused by its high swelling property. In this study, we propose a simple method for surface coating highly entangled hydrogels. By utilizing the designed copolymerization of polymers with hydrogel, we enable high entanglement hydrogels to adhere strongly to various surfaces, even under high swelling conditions. The copolymerized polymers are fabricated into a bilayer film of hydrogel and hydrophobic polymer, creating a freestanding sticker that can be used. The hydrophobic polymer layer prevents moisture transfer, thereby preventing the delamination of the hydrogel caused by swelling. Through this study, we have expanded the potential applications in various fields by enabling the application of high entanglement hydrogel regardless of the surface material.

8:00 PM SB10.03.06
A Fully Self-Healable, Temperature Tolerant and Stretchable Supercapacitor for Operating Integrated Self-Healing Strain Sensor Yeon JiChoi and Jeong SookHa; Korea University, Korea (the Republic of)

With the rapid advancement in wearable technology, there has been extensive effort on the development of high performance flexible/stretchable energy storage devices. Among various energy storage devices, supercapacitors are considered to be one of the most promising devices as integrated power supply of wearable electronics owing to many advantages of high power density, high cyclic stability and simple structures. Since the wearable devices are frequently exposed to extreme conditions of enviroments and/or physical damage, however, durability issue has evolved to be a serious challenge for their practical applications. Thus, addition of novel functionality such as self-healing from mechanical damage and tolerance over dramatic changes in temperature to stretchable supercapacitors can be a solution for that. Up-to now, most of the reports showed the self-healing of electrolyte only instead of fully self-healing supercapacitors. Even though many temperature tolerant supercapacitors were reported, there is a few supercapacitors with both self-healing and stability over wide temperature ranges which requires a deliberate design of device structure and materials.
In this work, we report on the fabrication of a fully self-healing, temperature tolerant, and stretchable supercapacitor and its application as a powering device for integrated strain sensor. Organohydrogel with a self-healing via the diol-borate bonding as well as the hydrogen bonding, and the stability over wide temperature range via hydrogen bonding between water and ethylene glycol, could be obtained, respectively. As a self-healing encapsulating film as well as a substrate, a polyurethane film based on oxime-carbamate bonding and hydrogen bonding was synthesized. As a self-healing strectchable electrode, CNT/polyaniline spray-coated on Au nanosheets functionalized with a poly(ether-thioureas) triethylene glycol was used.
By sandwiching the self-healing and temperature tolerant electrolytes with self-healing electrodes on both sides, the fully self-healing supercapacitor stable over temperature changes from -20 to 100 °C was completed. Such fabricated supercapacitor showed the fully self-healing efficiency of 83% even after 5 repetitive cycles of bisection and thermal healing at 65 °C for 6 hr. Also, the supercapacitor was mechaically stable over stretching by 40%, with a capacitance rention of 99%. Furthermore, the whole supercapacitor recovered the electrochemical performance even after bisection and self-healing. The capacitance of the supercapacitor at room temperature was retained over 85% with the temperature changes between -20 and 100 °C. After attachement of the vertically integrated device of the supercapacitor and the strain sensor, bio-signals such as finger-bending and wrist bending could be detected by using the supercapacitor as a self-healing energy storage device. This work suggests that our fabricated fully self-healing, temperature-tolerant, and stretchable supercapacitor should be widely applied to future wearable electronics with a longevity.

8:00 PM SB10.03.07
Overprinted Osmotically Actuated Joint via Computed Axial Lithography CameronDarkes-Burkey and RobertShepherd; Cornell University, United States

Computed Axial Lithography (CAL) forms complete 3D objects all at once by exposing a rotating volume of photopolymer resin with a series of projections at each angular step. This method decouples the formation of complex geometries with the need for a layer by layer build approach historically integral to the Additive Manufacturing (AM) process. This enables another unique advantage of CAL called overprinting where a 3D geometry is printed around a prepositioned insert. Overprinting opens the door for novel apllications within AM. Here we demonstrate onesuch application with a hydrogel osmotic actuator. By tuning the material, the geometry, and the post-processing, swelling-induced actuation is achieved.

8:00 PM SB10.03.08
Vapor-Responsive Impact Energy Absorbing and Dissipating Eutectogel YounaKim and JinkeeHong; Yonsei University, Korea (the Republic of)

Every year 2 million people have experienced sports injuries. Especially, in ball games such as basketball, baseball, and golf, serious injury could be caused by a high-speed ball. To prevent sports injuries, players should wear sports protective equipment. For example, in a baseball game, catchers wear protective equipment such as chest protectors, protective helmets, and shin guards. However, as the total weight of the protective equipment approaches 5 kg, the catchers suffer from extreme physical fatigue during the game. Therefore, it is necessary to develop materials for protective equipment that are lightweight and block impact.
As shock-preventing materials, there are representative viscoelastic hydrogels and organogels. These materials are effective in blocking impact due to their viscosity properties that absorb impact and elastic properties that dissipate impact. However, hydrogels have limited ability to withstand the impact energy of spherical projectiles due to their weak mechanical properties. In addition, it is difficult to apply to sports games due to shrinkage and weakening of physical properties due to water evaporation. Organogels overcome the limitations of hydrogels but use harmful solvents. It is necessary to develop viscoelastic protective materials that are lightweight, non-harmful, and can block impact.
In this study, a shock-preventing viscoelastomer (SPV) is designed by using non-toxic deep eutectic solvents (DES) and polyvinyl alcohol (PVA). Shock-preventing materials should absorb all impact energy and convert it into kinetic energy, preventing the energy from being transferred to the wearer. SPV could regulate the dissipation and absorption of impact energy through hydrophobic vapor treatment.
The entangled polymer chains within the amorphous phase could dissipate impact energy. PVA is a hydrophilic semi-crystalline polymer. DES is an azeotropic mixture composed of hydrogen bond donors and hydrogen bond acceptors, which hinder hydrogen bonds between PVA chains. For the increment in the amorphous phase, DES is used as an additive. As the amorphous phase increases in SPV, SPV shows viscoelasticity and could dissipate impact energy. Moreover, SPV is tougher than conventional hydrogels.
Hydrophilic SPV has a different chemical affinity with hydrophobic methyl salicylate (MeS), an analgesic and mint flavoring agent. Due to the different affinity, the solvation effect of MeS within SPV increases the chain entanglement density by H-bonding PVA chains. However, as the MeS treatment does not affect the crystallinity of SPV, MeS-treated SPV still maintains the rubbery phase at a high amplitude sweep. That is, MeS-treated SPV could absorb the impact energy to break the H-bonding and dissipate impact energy.
The MeS-treated SPV is restored to its original state after 50 min. It can be used as protective equipment for baseball and hockey within 1 h per inning. In addition, SPV can be applied to sports protective equipment in various forms such as thin film, fiber, and spray coating. We expect that SPV is suitable as an impact protection material to prevent sports injuries.

8:00 PM SB10.03.09
Auxetic Metamaterials with Structurally Programmed Reconfigurability JosefJancar, JanZidek and JakubPeroutka; Brno University of Technology, Czechia

Low density engineering materials capable of reacting to mechanical stimuli in a manner programmed by their structural architecture can improve design of shock and impact resistant or

tunable acoustic damping structures, robust actuators, and adaptable heat insulators.Similarly to computers, structural programming translates the human developed algorithm into a string of structural commands obeying syntax enabling to perform the desired task. The structural coding of commands converts the materials programming language (MPL) into a low-level language understandable by the executing architected structure. While constitutive materials capable of carrying the basic structural information already exist, designing the source code, commands compiler, assembler, and linker for the MPL remains a foundational challenge. Here, we outline the strategy for developing the source code for simple MPL commands using functional polymer nanocomposites as the units of structural information (USIs). USIs are spatially organized within simple geometrical elements of the re-entrant auxetic unit cell constituting the basic storage units of structural information (SUSIs). SUSIs are combined in a library of bending eigenmodes and rotations forming the structural source code enabling to program simple MPL commands. Primitive algorithms are developed, and simple commands are structurally coded at the auxetic unit cell array and lattice levels to achieve desired stimuli induced reconfigurations of the auxetic structure. Finally, multi-port FDM fabrication process is employed for physically compiling, assembling, and linking the structural commands into the auxetic structure with structurally pre-programmed system level response.

8:00 PM SB10.03.10
Multi-Responsive 3D Printed Nanocellulose-Based Hydrogels Programmable in Space and Time BeatrizArsuffi[1,2], GilbertoSiqueira[3], SilviaTitotto[2], TommasoMagrini[1] and ChiaraDaraio[1]; [1]California Institute of Technology, United States; [2]Federal University of ABC, Brazil; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Stimuli-responsive materials are desirable for a variety of functional applications, that range from biomedical devices, sensors and actuators to adaptive surfaces and deployable structures. However, as the natural environment offers multiple stimuli at the same time, current solutions often lack multi-responsiveness and display poor control over their properties over time. Here, I will introduce a new multi-stimuli-responsive material platform, realized via additive manufacturing, that can be precisely programmable to morph both in space and time. In my talk, I will highlight the fabrication steps that led to the development of composite inks for Direct Ink Writing (DIW), formed by double-network hydrogel matrices, reinforced by a high content of cellulose nanofibers and nanocrystals. Thus, I will display how the alignment of the reinforcing particles, induced by intense shear forces during DIW, provides composites with a highly anisotropic microstructure, key to tune the stiffness as well as the swelling/shrinking behavior of printed actuators [1, 2]. Additionally, I will highlight how the reversible shape-morphing capability of bilayer systems, as well as their activity in time, as a fourth dimension, can be tailored through processing parameters and geometrical design [3], in response to multiple stimuli scenarios, such as simultaneous variations in humidity, temperature, pH, and ion concentration. Finally, I will show how the performance of multi-responsive hydrogels can be leveraged to design and fabricate, by additive manufacturing, mechanically versatile architectures and mechanical sensors with outputs structured through the Boolean logic and logic gates, paving the way to multi-logic stimuli-responsive materials.

Establishing a reliable bidirectional communication interface between the nervous system and electronic devices is crucial for exploiting the full potential of neurotechnology. Despite recent advancements, current technologies evidence important shortcomings, e.g. lack of focal stimulation, low signal-to-noise ratio, etc. Thus, efforts to explore novel materials are essential for the development of next-generation neural interfaces. Graphene and graphene-based materials possess a very attractive set of physicochemical properties holding great potential for biomedical applications, in particular for implantable neural interfaces. This presentation provides an overview on fundamentals and applications of several graphene-based technologies and devices aiming at developing an efficient bidirectional communication with the nervous system. The main goal of this talk is to discuss opportunities of graphene-based neurotechnologies in neuroscience and implantable medical applications, and at the same time to identify the main challenges ahead.

Collagen/Pristine Graphene as an Electroconductive Interface Material for Neuronal Medical Device Applications JackMaughan[1,2,3], PedroJ. Gouveia[2,3], JonathanN. Coleman[1,3] and FergalO'Brien[2,3]; [1]Trinity College Dublin, Ireland; [2]Royal College of Surgeons in Ireland, Ireland; [3]Advanced Materials and BioEngineering Research (AMBER) Centre, Ireland

INTRODUCTION
The growing clinical demand for electrical stimulation-based therapies for spinal cord and peripheral nerve injury repair, cardiac devices, and other tissue engineering challenges requires the development of conductive biomaterials that balance conductivity, biocompatibility, and mechanical performance. Traditional conductive materials often induce scarring, due to their stiffness and poor biocompatibility, presenting challenges to their clinical translation. To address these issues, we report the development of a pristine graphene-based (pG) composite material for central nervous system applications, consisting of type I collagen loaded with 60 wt% pG, yielding conductivities (~1 S/m) necessary for efficient electrical stimulation, and with versatile processability.

METHODS
Pristine graphene (60 wt%) and collagen films (CpG) were synthesised and characterised. Neural cell lines and induced pluripotent stem cell derived neurons were seeded on the surface of the composites, and the metabolic activity, DNA content, cell morphology and release of inflammatory cytokines were assessed. Electrical stimulation was applied to mouse primary cortical neuron isolates to enhance neurite outgrowth and viability. Finally, the CpG composites were fabricated into porous 3D scaffolds, microneedle arrays, and bioelectronics circuits, using freeze drying, dry casting, and 3D printing approaches respectively.

RESULTS
Of all composites tested, CpG 60% exhibited physiologically relevant conductivities (~1 S/m), and robust mechanical properties (~17.8 MPa). To test biocompatibility, four neuronal and glial cell types were grown on composite films, and exhibited robust growth, and glial cells exhibited no change in inflammatory markers IL-6, IL-10, or IL-1β, indicating no significant neuro-inflammatory response. iPSC-derived neurons exhibited typical cellular morphology after 15 days growth on the films, indicating the potential of the material for supporting long-term growth. The achieved conductivity enabled the efficient delivery of electrical stimulation, which was delivered to mouse primary cortical neurons on the composite (200 mV/mm, 12 Hz, 4h/day, 5 days), enhancing neurite outgrowth, cellular viability and morphology compared to collagen controls. Finally, we demonstrate the versatility and potential applications of the composite using a range of conductive, neural-interfacing structures, including porous scaffolds with aligned internal pores visible under SEM, microneedle arrays (5×5 conical needles, height - 2.5 mm, 625 μm base diameter, tip diameter - 40-80 μm), and 3D-printed working LED circuits for bioelectronics.

DISCUSSION
These results demonstrate that CpG 60% composites form a versatile neurotrophic platform that balances the need for physiologically relevant conductivity, robust mechanical properties, and excellent biocompatibility. The mechanical properties of the composite give it an advantage over stiffer traditional electrode materials, which can cause scarring due to extreme mechanical mismatch. The composite supported robust neuronal and glial cell growth, with an absence of neuro-inflammatory responses in microglia and astrocytes. In addition, it efficiently delivered electrical stimulation to primary neurons without loss of viability, enhancing neurite outgrowth. Finally, the versatile processing capabilities of CpG were used to fabricate several neural device types, allowing for a range of applications and treatment approaches.

CONCLUSION
These results show that CpG composites are versatile, neurotrophic materials, which balance the requirement for physiologically relevant conductivity, robust mechanical properties, and strong biocompatibility, demonstrating the potential for these collagen/pristine graphene composites to be fabricated into next-generation electroconductive medical devices.

Insights into Biocompatible and Bioorthogonal Fluorous-Phase Neural Probe for *In Vivo* Detection of AcetylcholineMaralMousavi, FarbodAmirghasemi and AbdulrahmanAl-Shami; University of Southern California, United States

Acetylcholine (ACh) is one of the least understood neurotransmitters, mainly due to difficulty in its selective detection in biological matrices. ACh appears in the brain and body of mammalians, and is released as a messenger by the nerve cells to communicate with other nerve cells, muscle cells, and gland cells. In the brain, ACh functions both as a neuromuscular transmitter and neuromodulator, and thus plays key roles in learning and memory, motivation, and muscle control. Alterations in ACh concentration in the cerebral cortex was correlated to dementia and Alzheimer's disease, psychiatric disorders such as schizophrenia and major depressive disorder, as well as anxiety and depression. Tools for selective sensing of ACh are crucial for better understanding the role of this neurotransmitter in disease progression, as well as rational design and testing of therapeutics that interact with the cholinergic receptors.
For successful in-vivo recording of ACh levels, the neural probe (1) should have high selectivity to enable detection of ACh in the large background of other species in the complex brain environment, (2) should be flexible to minimize tissue scaring during probe insertion, (3) should be resistant to biofouling and remain functional after implantation, and (4) should be non-toxic and safe. This talk will discuss the strategies we have take to address these requirements for an ACh in-vivo probe through development of new materials for sensing and for electrode fabrication. We detect ACh using its permanent positive charge and a potentiometric sensing membrane. This membrane is made of a unique fluorous-phase material that provides outstanding selectivity and biocompatibility to the electrode. Fluorous compounds (not to be mistaken with fluorescent compounds) are molecules with high content of fluorine atoms. They are extremely non-polar to the extent that they are NOT miscible with oil and water. In fact, mixing water, hexanes, and perfluorohexane results in formation of three distinct phases. That is, fluorinated compounds are both hydrophobic and lipophobic. This sets apart fluorocarbons for novel biomedical applications. As a matter of fact, living systems are made of water and lipophilic compounds, making fluorocarbons bio-orthogonal, meaning that they do not interfere with biology. This work will show how the low polarity of the fluorous phase can enhance the selectivity and biocompatibility of our ACh sensor by orders of magnitude. We integrate this fluorous sensing membrane with a porous graphene electrode that is engraved on a flexible polyimide film using a CO_2 laser. This talk will discuss integration of laser-induced graphene electrodes (LIGs) with fluorous-phase sensing membranes to produce a new generation of highly selective, biocompatible, and resilient neural probes.

9:30 AM *SB11.01.04
Implantable Graphene Electrode for Diagnosis and Treatment of Brain Diseases Jong-HyunAhn; Yonsei University, Korea (the Republic of)

Various electrophysiological and imaging techniques have been studied for the diagnosis and treatment of brain diseases such as epilepsy. In particular, electrocorticography (ECoG) provides valuable information that can guide clinical treatment in patients with brain diseases. In this talk, we report a highly flexible graphene electrode that stably wraps onto the cortex surface of the brain, exhibiting a remarkable signal-to-noise ratio and providing enhanced data quality. The graphene multichannel electrode successfully detects brain signals with high-throughput spatiotemporal resolution. Furthermore, the exceptional flexibility of graphene electrodes enables the fabrication of injectable electrodes that can be introduced through tiny skull openings. These injectable electrodes allow precise measurement of ECoG signals without the need for extensive surgical procedures. The results highlight the immense potential of flexible graphene electrode array in improving both diagnostic capabilities and therapeutic interventions for brain diseases. This technology holds promise for revolutionizing current treatment strategies and opening new avenues for effectively managing various medically significant brain diseases.

Monolayer Semimetal and Semiconductor Materials for Label-Free Hybrid Biosensing and Neural Voltage Sensing ErtugrulCubukcu, YundongRen, ChawinaDe-Eknamkul and

WenzhuoHuang; University of California, San Diego, United States

A general, overarching theme in nanotechnology is the integration of multiple disparate fields to realize novel or expanded functionalities. At this extreme limit, emerging atomically thin semimetals like graphene and molecularly thick semiconductor such as transition metal dichalcogenides provide a unique opportunity with their non-ubiquitous optical and electrical properties. To this end, we will discuss our work on utilizing these exciting materials for various modalities in biosensing applications with hybrid integration schemes and unique capabilities in all optical recording of neural activity. First, we will discuss our work on a graphene based multimodal biosensor with optical, electrical, and mechanical sensing modes integrated on the same sensor footprint providing simultaneous transduction signals with unprecedented dynamic sensing range and while maintaining sub-picomolar detection limit. Second, we will talk about a MoS2 based hybrid sensor with an array of optical nanoantenna integrated on a field effect transistor to provide both optical and electrical sensing of a water-soluble variant of the μ-opioid receptor (MOR), via a nickel ion-mediated linker chemistry. Last but not least, we will introduce some of our recent results on all-optical electrophysiology that can achieve high spatio-temporal resolution for potential mapping of biological neural networks as a non-genetic complimentary approach to genetically encoded voltage indicators (GEVIs).

11:00 AM SB11.02.02
Conformable Ultrasound Breast Patch for Deep Tissue Scanning and Imaging CananDagdeviren; Massachusetts Institute of Technology, United States

Ultrasound is widely used for tissue imaging such as breast cancer diagnosis; however, fundamental challenges limit its integration with wearable technologies, namely imaging over large-area curvilinear organs. We introduced a wearable, conformable ultrasound breast patch (cUSBr-Patch) that enables standardized and reproducible image acquisition over the entire breast with less reliance on operator training and applied transducer compression. A nature-inspired honeycomb-shaped patch combined with a phased array is guided by an easy-to-operate tracker that provides for large-area, deep scanning and multi-angle breast imaging capability. The clinical trials reveal that the array using a piezoelectric crystal (Yb/Bi-PIN-PMN-PT) exhibits a sufficient contrast resolution (~3 dB) and axial/lateral resolutions of 0.25/1.0 mm at 30 mm depth, allowing the observation of small cysts (~ 0.3 cm) in the breast. This research develops a first-of-its-kind ultrasound technology for breast tissue scanning and imaging which offers a non-invasive method for tracking real-time dynamic changes of soft tissue.

11:15 AM SB11.02.03
Heavy-to-Light Electron Transition in Quasi-2D Organic Semiconductor Enabling Real-Time Spectra Detection of Charged Particles DouZhao[1,2], TomoyukiYokota[1], TakaoSomeya[1], WanqiJie[2] and YadongXu[2]; [1]The University of Tokyo, Japan; [2]Northwestern Polytechnical University, China

Wearable/implantable personal dosimeter achieving real-time and in-vivo radiation safety monitoring are significant for aerospace, medical diagnosis, and radiotherapy, while the current challenge is the lack of suitable detector materials possessing both excellent biocompatibility and high detection performance.
Here, we report a novel biocompatible organic single crystalline semiconductor (OSCS) with 2D anisotropic crystallographic structure, achieving excellent electron's transport and real-time spectral detection for charged particles. For the first time, the charge-transport mechanism responsible for such superior performance is clarified in this quasi-2D OSCS from the viewpoint of high-energy physics. Radiation-excited electrons occupy the high-energy L1 level with smaller effective mass than LUMO level, leading to a high electron drift velocity of 5×10^5 cm s^{-1} under the electric field of 4000 V cm^{-1} at "radiation-detection mode". In addition, nanoscale surface layer edges on the OSCS, originating from its 2D crystallographic structure induced molecular self-assembly during the solution growth process, also promote the excitons dissociation along the in-plane direction of this OSCS.
As a result, the OSCS detector exhibit the record spectra detection for ^{241}Am α particles among their organic counterparts, with the energy resolution of 36%, the electron's μt product of $(4.91\pm0.07)\times10^{-5}$ cm^2 V^{-1}, and the spectra detection time down to 3 ms. In addition, the OSCS shows good biocompatibility that the cell viability still overs 90% after 24-hour incubation with 2 mg ml^{-1} OSCS. This work reports a quasi-2D organic semiconductor with superior electron transport property and biocompatibility towards to real-time and in-vivo personal radiation dosimeters.

11:30 AM SB11.02.04
Transparent Flexible Strain Gauges for Wearable Devices based on Tiled Graphene Films JosephNeilson[1] and BrianDerby[2]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]University of Manchester, United Kingdom

Here we present a novel transparent strain gauge, with a large gauge factor (GF) and usable strain range, based on 2D materials confined to the surface of an elastomeric substrate. These have good optical transmittance and demonstrate repeatability, under cyclic straining at frequencies > 1 kHz, Gauges have also been mounted on a thin polymer glove to demonstrate its capability as a transparent e-skin strain sensor.
During manufacture, closely packed films of graphene oxide are confined to a 2D plane, through assembly at an immiscible H_2O/hexane interface. These films have predominantly edge-to-edge nanosheet contact and show little overlap after deposition onto a polydimethylsiloxane (PDMS) substrate. The films are treated in a hydroiodic acid (HI) reducing atmosphere to introduce electrical conductivity, with the consequent reduced graphene oxide (rGO) films showing < 900 Ω/sq sheet resistance, and > 88% optical transmittance. Piezoresistivity is generated through a pre-straining process that introduces a population of cracks, normal to the straining direction, into the conducting film. After relaxation the cracked films show a repeatable change in resistance when strained to values smaller than the initial pre-strain. Through careful control of the HI chemical reduction phase, it is possible to generate strain gauging devices with different operating ranges and sensitivity. Films pre-strained after reduction for 30 s form an array of parallel cracks that do not individually span the membrane. Subsequent straining of the cracked membrane does not further extend these cracks and the sheet extends in a kirigami manner as the cracks open. This cracking behaviour results in a strain gauge with a usable strain range > 0.2 and GF of 20 - 100 at low strains, however, this GF increases with increasing pre-strain. In all cases, GF decreases with increasing applied strain and asymptotes to a value of about 3 as it approaches the pre-strain value. However, If the rGO film is reduced for a longer time of 60 s, the cracks extend during pre-straining to fully span the width of the PDMS membrane, leading to a much more sensitive strain gauge with GF ranging from 1000 - 16000. However, in this case, the usable strain range reduces to < 0.01. We present a simplified, equivalent resistor model, that can be used to interpret the behaviour of both gauge cracking configurations.

11:45 AM SB11.02.05
High Performance Bismuth Cobaltite Nanoparticles-PDMS based Self-Powered Temperature Nanosensor for Biomedical Applications DhirajDhiraj and J. P.Singh; Indian Institute of Technology Delhi, India

A multifunction nanogenerator is an advanced nanoscale device designed to harvest various forms of unused energy from the environment and convert them into meaning electrical energy. In this work, we have synthesized the $BiCoO_3$nanoparticles using thermal decomposition technique. X-ray diffraction confirms the cubic oxides (space group I23) structure with the rhombohedral shape of $BiCoO_3$ nanoparticles with high crystallinity. The rhombohedral shape type morphology of nanoparticles was confirmed using High Resolution Transmission Electron Microscope with the average length of 20 nm. Piezoelectric Force Microscope studied of $BiCoO_3$ nanoparticles was also performed and piezoelectric charge coefficient of 330.42 pm/V was recorded. $BiCoO_3$-PDMS based flexible piezoelectric nanogenerator was fabricated using the device design of using low-cost hydrothermal technique. PENG generates the high output voltage of 40V and output current of 0.9 mA/cm^2 that can charge various capacitors and also can light up to 20 LEDs mountainously or even more. PENG have very long durability as it can work continuously for 60,000 cycles. Nanogenerator was utilized as the self-powered temperature sensor that can detect human body temperature by attaching on a wrist and also able to detect high temperature up to 310 C. This type of pressure-driven PENG has potential application in biomedical applications that can do monitor human wrist pulse and body temperature in real time.

SESSION SB11.03: 2D Bioelectronics II
Session Chairs: Linda Giro and Dmitry Kireev

Input/Output (I/O) Bioelectronics using Two-Dimensional Nanocarbons TzahiCohen-Karni; Carnegie Mellon University, United States

My team’s efforts are focused on the development and engineering of nanocarbons-based flexible platforms to interrogate and affect the properties of cells and tissue, with a specific goal to understand signal transduction (chemical or electrical) in tissue or complex three-dimensional (3D) cellular assemblies. Our highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials that can be used in various input/output bioelectrical interfaces, i.e., bioelectrical platforms for chemical and physical sensing and actuation. In this talk I will review our current efforts for monitoring (and affecting) the complex signal transduction in 3D in vitro systems toward disease progression investigations. Utilizing graphene, a two-dimensional (2D) atomically thin carbon allotrope, we can simultaneously record the intracellular electrical activity of multiple excitable cells with ultra-microelectrodes that can be as small as an axon (ca. 2μm). The outstanding electrochemical properties of the synthesized hybrid-nanomaterials allow us to develop highly efficient catalysts, that can be deployed as electrical

sensors and (chemical) actuators. We demonstrated sensors capable of exploring brain chemistry and sensors/actuators that are deployed in a large volumetric muscle loss animal model. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and potentially seamlessly merge nanomaterials-based platforms with cells, fusing nonliving and living systems together.

2:00 PM SB11.03.02
3D Printed Electronic Skin for Strain, Pressure and Temperature Sensing AkhileshK. Gaharwar; Texas A&M University, United States

Electronic skin, or e-skin, is an innovative material designed to emulate human skin's flexibility and stretchability. With its capability to detect environmental changes like pressure, temperature, and humidity, it has the potential to revolutionize fields such as robotics, wearable technology, and healthcare. Nevertheless, developing e-skin poses significant challenges: creating durable materials with skin-like flexibility, integrating biosensing abilities, and using advanced fabrication techniques like 3D printing for wearable or implantable applications. To overcome these hurdles, we have fabricated a 3D-printed electronic skin utilizing a novel class of nanoengineered hydrogels with tunable electronic and thermal biosensing capabilities. Our methodology takes advantage of shear-thinning behaviour in hydrogel precursors, allowing us to construct intricate 2D and 3D electronic structures. We simulate the elasticity of skin using triple crosslinking in a robust fungal exopolysaccharide, pullulan, while defect-rich 2D molybdenum disulfide (MoS_2) nanoassemblies ensure high electrical conductivity. The addition of polydopamine (PDA) nanoparticles enhances adhesion to wet tissue. Our nanoengineered hydrogel exhibits outstanding flexibility, stretchability, adhesion, mouldability, and electrical conductivity. A distinctive feature of this technology is the precise detection of dynamic changes in strain, pressure, and temperature enabled by the combination of triple crosslinking and defect-rich MoS_2. As a human motion tracker, phonatory-recognition platform, flexible touchpad, and thermometer, this technology represents a breakthrough in flexible wearable skins and holds transformative potential for the future of robotics and human-machine interfaces.

2:15 PM SB11.03.03
Interaction Of Graphene And WS_2 With Neural Cells, Neutrophils And Mesenchymal Stem Cells: Implications For Peripheral Nerve Regeneration DomenicaConvertino[1], LauraMarchetti[1,2] and CamillaColetti[1,1]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of Pisa, Italy

The employment of graphene and 2D materials in tissue engineering has been recently exploited for the repair and regeneration of nerve tissue. Among the possible applications, these relatively new materials display a great potential as peripheral neural interfaces, especially for their unique combination of electrical, optical and tribological properties[1-4].

In this work we present recent results on graphene (G) and tungsten disulfide (WS_2) interaction with some of the key players involved in nerve regeneration, namely peripheral neurons, neutrophils and mesenchymal stem cells (MSCs).

Firstly, we will discuss the effect of G on primary peripheral neurons, i.e. neonatal dorsal root ganglions (DRG) neurons. Graphene obtained via chemical vapor deposition (CVD), a promising candidate to realize functional nerve conduits, was used as a culture substrate. There, axons were found to be significantly longer (up to >70%) with respect to controls during the early developmental phase (up to 2 days), confirming the trend previously reported by our group for embryonic DRG neurons on G on silicon carbide (SiC)[5]. Notably, with the same time-dependent fashion, we found a significative modification of the axonal transport of nerve growth factor (NGF), the neurotrophin involved in the development of peripheral neurons. The amount of retrogradely moving vesicles was strongly reduced in favor of a locally stalled population in the first two days of culture[6]. In addition, electrophysiological and ultrastructural analysis concurred to show the rearrangements that occur in axons developing on G[6]. Our results provide a broad structural and functional understanding of the impact of G on DRG neurons, key information toward the development of G-based devices for neural regeneration. Similarly, we tested WS_2, another 2D material with promising biomedical applications. CVD-grown WS_2, known for its optoelectronic properties, was used to culture neuronal-like cells (SH-SY5Y) displaying neurite length and viability comparable to the controls[4].

However, the use of these innovative materials has raised questions about their interaction with the other players involved in nerve regeneration, including neutrophils, whose immune response affects the regenerative outcome[7], and MSCs, a novel therapeutic avenue for peripheral nerve regeneration[8].

Therefore, in the third part of the study we tested WS_2 on sapphire and different graphene, namely G on sapphire, G on SiC, both as-grown and H-intercalated, G-CVD transferred on glass, to assess the effect of the production method on neutrophils and MSCs[9].
We first characterized neutrophil activation and discussed how material properties influenced the NETs production and adhesion to the substrates. Furthermore, G resistance to NETs-induced degradation was carefully investigated and compared with the results reported for graphene oxide[10]. Ultimately, 2D materials cytocompatibility for MSCs are tested to estimate cell viability, morphology and mitochondrial health.

Overall, our results aimed at understanding the interface between 2D material and some of the key players involved in nerve injury, with special attention to the molecular mechanisms that govern axon outgrowth in neurons, a critical point for regenerative medicine.

2:30 PMBREAK

3:30 PM *SB11.03.04
Wearable Graphene Biosensors for Microfluidic Sweat Analysis WeiGao; California Institute of Technology, United States

Wearable sweat biosensors have the potential to provide non-invasive molecular analysis toward predictive analytics and treatment. However, it is highly challenging to accurately detect low-concentration analytes in situ and manufacture high-performance flexible biosensors at large scale and low cost. In this talk, I will introduce our efforts in developing microfluidic wearable sweat biosensors based on laser-engraved graphene. Through materials and sensor design innovations, such wireless wearables can autonomously access human sweat via iontophoresis across activities and seamlessly measure a broad spectrum of analytes including metabolites, nutrients, hormones, proteins, and drugs. The clinical value of our wearable systems is evaluated through various human trials involving healthy and patient populations toward precision nutrition, mental health assessment, gout management, and systemic inflammation monitoring. I will also discuss our research progress on energy harvesting from the human body and the environment to realize battery-free wireless wearable biosensing. These wearable technologies could open the door to a wide range of personalized monitoring and diagnostic applications.

4:00 PM SB11.03.05
Wearable and Implantable Bioelectronics Enabled by 2D Materials-Based Layer Transfer JihoShin[1], YeonginKim[2], Jun MinSuh[1], HyunseokKim[1], SureshSundaram[3], Young JoonHong[4], AbdallahOugazzaden[3] and JeehwanKim[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Cincinnati, United States; [3]Georgia Tech Lorraine, France; [4]Sejong University, Korea (the Republic of)

2D materials-based layer transfer (2DLT) is an emerging lift-off technique for producing large-area freestanding single-crystalline epitaxial films, which offer high electronic/optoelectronic performance and ultrathin form factor that are essential for wearable and implantable bioelectronic device applications. Single-crystalline III-V/III-N compound semiconductor membranes can be epitaxially grown on substrates coated with 2D materials such as graphene or boron nitride, which results in weak van der Waals interface that facilitates mechanical exfoliation of the device layer from wafer [1]. In this talk, I will discuss our recent efforts that utilize 2DLT to build: (i) chipless wireless electronic skins based on gallium nitride surface acoustic wave sensors capable of low-power and high-sensitivity detection of a broad range of external stimuli [2], and (ii) 3D-integrated micro-LED heterostructures that achieve extremely high device densities

and suggest potential applications in optoelectronic-based neural interfaces [3].

4:15 PM *SB11.03.06
Biointegrated Interfaces with Carbon Nanostructures MaurizioPrato[1,2]; [1]Universitá Degli Studi di Trieste, Italy; [2]CIC biomaGUNE, Spain

Nanostructured interfaces can be shaped for the molecular control of physical/chemical adsorption, with enhanced surface area to promote interfacial chemistry, nano-catalysis, and bio-inspired interfaces. For instance, connecting nanostructured materials to biological compartments is a crucial step in prosthetic applications, where the interfacing surfaces should provide minimal undesired perturbation to the target tissue. Ultimately, the (nano)material of choice has to be biocompatible and promote cellular growth and adhesion with minimal cytotoxicity or dis-regulation of, for example, cellular activity and proliferation. In this context, carbon nanomaterials, including nanotubes and graphene, are particularly well suited for the design and construction of functional interfaces. This is mainly due to the extraordinary properties of these novel materials, which combine mechanical strength, thermal and electrical conductivity. Our group has been involved in the organic functionalization of various types of nanocarbons, including carbon nanotubes, and graphene. The organic functionalization offers the great advantage of producing soluble and easy-to-handle materials. As a consequence, since biocompatibility is expected to improve upon functionalization, many modified carbon nanomaterials may be useful in the field of nanomedicine. In particular, we have recently shown that carbon nanotubes and graphene can act as active substrates for neuronal growth, a field that has given so far very exciting results. Nanotubes and graphene are compatible with neurons, but, especially, they play a very interesting role in interneuronal communication. Improved synaptic communication is just one example. During this talk, we will discuss the latest and most exciting results obtained in our laboratories in these fast developing fields.

4:45 PM *SB11.03.07
Heterogeneous Integration of 2D Sensors for Wearable and Healthcare Applications ChristianLopez Angeles, YiyueLuo, DavidMorales Loro, JiadiZhu, MantianXue, WojciechMatusik, JingKong and TomasPalacios; MIT, United States

The next wave of innovation and business opportunities related to electronics will probably be about enabling “edge intelligence”. These are new microsystems with unprecedented levels of autonomy in terms of energy harvesting, sensing and information processing. Heterogeneous integration of new materials will be necessary to provide these microsystems with functionality not possible today in Si chips alone. This talk will discuss a few examples of how edge intelligence enabled by the use of two-dimensional (2D) materials will impact wearable devices for healthcare applications. The first example uses metallic fibers coated with a graphitic material to embed hundreds of pressure sensors on fabrics and garments. These sensors are then coupled to an RF harvesting chip based on a MoS2 rectifier to enable autonomous sensing of people’s movements. A second example uses arrays of hundreds of graphene-based chemical sensors inside a breathalyzer chamber to analyze the volatile organic compounds in patients’ breath. Finally, the low temperature synthesis of MoS2 allows for the integration of high performance devices based on this material on flexible polymer substrates for the development of flexible and active electrodes for electrophysiology.

8:00 PM SB11.04.01
Two-Dimensional $Cs_2AgBiBr_6$-Based Biosensor for the Sensitive Detection of Cardiac Biomarkers Yin-ChengLu[1], EvanDarius[1], Mei-ChinLien[1], I-HsiuYeh[1], Hung-WenChen[1], Ching YuanSu[2], Ru-YinHsu[3] and Keng-KuLiu[1]; [1]National Tsing Hua University, Taiwan; [2]National Central University, Taiwan; [3]National Taiwan University Hospital Hsinchu Branch, Taiwan

Inspired by graphene and transition metal dichalcogenides, 2D layered materials that possess excellent electronic, optical, physical, and chemical properties have been actively investigated and explored to further expand their applications. In particular, 2D lead-free double perovskite with strong quantum confinement and excellent electronic performance are promising for optoelectronic applications. Owing to its nontoxicity, inherent stability, and high optical and electrical sensitivity, 2D lead-free double perovskite has attracted significant research interests. Cardiac troponin I (cTnI), a protein with molecular weight of 23.8 kDa, plays an important role as the regulator that is involved in the process of skeletal and cardiac muscle contraction. Owing to its superior cardiac specificity and selectivity, cTnI has been widely employed as the biomarker for the detection of myocardial damage and risk stratification in acute myocardial infarction (AMI) patients. In this study, we report the synthesis of 2D layered $Cs_2AgBiBr_6$ and the fabrication of biological sensors based on plasmonic nanomaterials-decorated 2D $Cs_2AgBiBr_6$ for the sensitive detection of cardiac biomarker, cTnI.

8:00 PM SB11.04.02
Enhancing Mechanical Strength of Wearable Microneedles using Silica Nanoparticle Coatings HyewonChoi, SohyunKim and HyunsikYoon; Seoul National University of Science and Technology, Korea (the Republic of)

Wearable medical devices are currently being developed for a wide range of healthcare systems, and microneedles (MNs) have emerged as promising transdermal delivery systems due to their painless and non-invasive characteristics. Polymers are commonly used as MN materials because of their simple, low-cost fabrication, and biocompatibility. However, their mechanical strength may be insufficient compared to metals and ceramics, resulting in potential penetration failures that can leave fractured MNs under the skin, leading to unsuccessful delivery. Therefore, enhancing the mechanical strength of polymeric MNs is essential. In this study, we employed silica (SiO2) nanoparticles (NPs) and poly(diallyldimethylammonium chloride) (PDADMAC) through a Layer-by-Layer (LbL) assembly on MNs. Subsequently, we applied hydrothermal (HT) treatment to sinter the coated silica NPs, thereby increasing the mechanical stability of the thin film. Initially, we conducted dye loading and release tests using fluorescent dyes, which demonstrated that MNs coated with the LbL thin film and LbL/HT-treated MNs exhibited significantly higher loading and release efficiency compared to unmodified MNs. This improvement was attributed to the increased surface area facilitated by the silica NPs coating. Additionally, we assessed the mechanical properties of MNs through abrasion and penetration tests, revealing that silica NPs-coated MNs showed higher mechanical stability, which was further enhanced after the HT treatment. The LbL system described in this study holds great potential for application in various three-dimensional structures, including MNs, which will contribute to the advancement of wearable drug delivery systems.

8:00 PM SB11.04.03
Folic Acid-Gold Nanoparticle@$MoSe_2$ for Targeted Photothermal Cancer Therapy Chang HyeonHa, Han BeenLee, Se HwaCheon, Su JeongLee, Do HyeonKim and Gi hunSeong; Hanyang University, Korea (the Republic of)

Transition Metal Dichalcogenides (TMDs) have recently emerged as novel 2D materials, possessing significant electrical, mechanical, and optical properties. These materials consist of a single metal combined with two chalcogens (known as dichalcogenides), and their unique characteristics are determined by the specific elements comprising them. Moreover, TMDs exhibit gifted potential for clinical applications, thanks to their remarkable photothermal capabilities. Photothermal and photodynamic therapies (PTT and PDT) represent notable light-based treatment modalities. PTT involves generating heat through light-to-heat conversion, while PDT involves inducing the production of Reactive Oxygen Species (ROS) using light-sensitive agents. These therapies have gained significant attention in the field of cancer therapy due to their sensitivity and usefulness. Among these approaches, PTT has garnered interest due to the high light-to-heat conversion capability of TMDs. However, relying solely on TMDs may not be sufficient for effective therapy. Therefore, we have incorporated gold nanoparticles (AuNPs) to enhance the PTT potential of TMDs through spontaneous reduction.
AuNPs possess biocompatible properties, exhibit photothermal capabilities through Localized Surface Plasmon Resonance, and can be easily modified. As a result, they can be effectively utilized as clinical materials in conjunction with TMDs. To specifically target cancer cells, we have additionally introduced Folic acid (FA). FA is an artificial molecule that closely mimics natural folate, enabling it to bind with folate receptors present in the cellular membrane. This targeted approach allows for precise cancer cell localization, particularly in cases of folate receptor-overexpressed cancer, such as Triple Negative Breast Cancer (TNBC). TNBC, which lacks the widely utilized targeting receptor and carries a high risk of metastasis, exhibits significant potential for successful cancer targeting utilizing FA.
In this study, we synthesized complex materials for PTT by coating $MoSe_2$ with AuNPs and FA (FA-Au@$MoSe_2$, FAM). Glycyrrhizic acid was utilized to exfoliate bulk $MoSe_2$ into 2D monolayers. This exfoliation process induced a transition from an indirect to a direct-band gap, enhancing the PTT capabilities of the TMDs. $MoSe_2$ was selected as the primary TMD due to its well-known high light-to-heat transfer properties in PTT applications. AuNPs were employed as enhanced photothermal agents. To modify the gold surface, cysteine was used and FA was linked to the gold surface through EDC/NHS coupling. Lastly, MDA-MB-231 breast cancer cells, known for their folate receptor overexpression, were used as the target cells since MDA-

MB-231 cells are representative of TNBC.
The deposition of AuNPs and FA led to an increase in both size and surface charge. This was confirmed by the UV-visible spectra, which exhibited peaks corresponding to AuNPs and FA. SEM and TEM images demonstrated the presence of AuNPs on the surfaces of TMDs. Consequently, the successful synthesis of FAM was achieved. Regarding biocompatibility and PTT, the temperature elevation reached a level sufficient for PTT within biocompatible concentrations. Furthermore, FAM exhibited a significantly greater effect compared to $MoSe_2$, indicating that AuNPs effectively enhanced the PTT capability of $MoSe_2$. Specifically, FAM demonstrated non-toxicity to cells at a concentration of 30 μg/mL, similar to $MoSe_2$, but displayed a higher therapeutic effect when exposed to a NIR laser (808 nm, 0.8 W cm^{-2}). These findings, confirmed by WST-1 assay and calcein-AM staining, highlight the biocompatibility and photothermal ability of FAM. As a result, this easily synthesized 2D material, achieved through simple sonication and stirring processes, has exhibited remarkable biocompatibility, photothermal activity, and targeting capability. These findings position it as a promising candidate for utilization in cancer therapy.

8:00 PM SB11.04.04
Biocompatible Molybdenum Diselenide Nanosheets: A Two-Dimensional Nanomaterial for Near-Infrared Photothermal Cancer Therapy Su JeongLee, Se HwaCheon, Han BeenLee, Chang HyeonHa, Do HyeonKim and Gi hunSeong; Hanyang University, Korea (the Republic of)

Transition metal dichalcogenide (TMD) nanosheets are two-dimensional (2D) nanomaterials composed of layered structures. In the 2D TMD structure, denoted as 'X-M-X', two layers of X chalcogen atoms (such as S or Se) are sandwiched between a layer of M transition metal atoms (such as Mo or W). The interaction between adjacent layers in the nanosheet structure is driven by van der Waals forces. These forces play a crucial role in holding the layers together and are essential for the development of the band structure. 2D TMD possesses outstanding optical, electronic, mechanical, and thermal properties due to its adjustable band gap and interaction with light. Consequently, they have gained significant attention in recent years for applications in electronic devices, energy storage, and photothermal therapy.
Among various TMDs, molybdenum diselenide ($MoSe_2$) has emerged as a prominent focus of research due to its remarkable chemical and physical properties. Notably, when $MoSe_2$ transitions from multiple layers to a single layer, its electronic bandgap undergoes a significant change from an original indirect bandgap of 1.1 eV to a direct bandgap of 1.55 eV. As a result, single-layer $MoSe_2$ represents a novel semiconductor material that exhibits strong light absorption in the proximity of the band-gap energy.
In this study, we employed an inexpensive liquid exfoliation method to fabricate $MoSe_2$ nanosheets. This approach enables high-yield production and renders the nanosheets suitable for application in photothermal cancer therapy. To disperse $MoSe_2$ in water, we utilized glycyrrhizic acid (GA), an amphiphilic natural surfactant from licorice root, as the exfoliating agent. Notably, this study marks the first instance of GA being used as an exfoliating agent for preparing nanosheets. Additionally, we enhanced biocompatibility and intracellular uptake by conjugating polyethylene glycol (PEG), resulting in PEG-modified GA-$MoSe_2$ (PGM) nanosheets.
The successful exfoliation utilizing GA was confirmed by SEM and TEM analysis, revealing the presence of monolayer nanosheets. The PEGylation of the nanosheets was validated through an observed increase in size and zeta potential. Thermogravimetric analysis (TGA) results demonstrated the thermal stability of PGM as a material. Furthermore, UV-visible spectra of PGM exhibited an absorption peak at 808 nm, and when PGM was subjected to NIR laser irradiation (808 nm, 0.8 W cm2), they demonstrated the highest photothermal effect. Based on these findings, PGM was identified as a promising agent for photothermal cancer therapy, offering a minimally invasive treatment option with reduced side effects.
To assess the cytotoxicity and anticancer potential of PGM in MDA-MB-231 human breast cancer cells, we conducted a WST-1 assay and a live-dead cell staining assay. The PGM group without laser irradiation displayed remarkably high cell viability at 98.6%, whereas the group subjected to laser irradiation exhibited viability of 22.7%, indicating a substantial inhibitory effect on cancer cells. Additionally, PGM demonstrated significantly higher intracellular uptake. Subsequently, we directly administered PGM to a breast cancer-bearing mouse model to evaluate its in vivo anticancer effect. Tumors exposed to Near Infrared (NIR) laser exhibited a notable decrease in size or complete disappearance, and no significant weight loss was observed during the treatment period.
The findings obtained from experiments strongly indicate that PGM possesses minimal cytotoxicity and holds great promise as a valuable biomaterial for cancer therapy, particularly in harnessing the photothermal effect of PGM through hyperthermia. Building upon these results, our future objectives include incorporating anti-cancer drugs into PGM to develop drug delivery platforms, as well as directly fabricating PGM scaffolds for transplantation at the target site, thereby enabling effective implementation of photothermal cancer therapy.

8:00 PM SB11.04.05
Synthesis of Transition Metal Dichalcogenides Nanosheets and its Application to Photothermal Immunoassays Do HyeonKim, Chang HyeonHa, Han BeenLee, Su JeongLee, Se HwaCheon and Gi hunSeong; Hanyang University, Korea (the Republic of)

Two-dimensional nanomaterials, including graphene, transition metal oxides, and carbon nitrides, have gained significant attention due to their large surface area, mechanical properties, and unique electro-optical characteristics. Among these materials, transition metal dichalcogenides (TMDs) have emerged as particularly promising in biosensing, electronics, and photothermal therapy, due to their distinctive properties. Most TMDs feature an MX_2-type structure, where M represents transition metals like Mo and W, and X represents chalcogenides such as S, and Se. TMDs exhibit a sandwich-like structure, with hexagonal planes of transition metal atoms separating the chalcogen atoms.
TMD, a two-dimensional semiconductor material, exhibits unique electrical, mechanical, and optical properties. One of its most notable characteristics is the photothermal effect. TMD demonstrates the ability to absorb light in the near-infrared region and convert it into heat. Monolayer TMD, in particular, possesses enhanced photothermal capabilities compared to multi-layered TMD, thanks to its altered band gap. The transition from an indirect to a direct band gap occurs when TMD forms monolayers. This transition facilitates more efficient electron transfer and shifts the band gap position from the infrared to the near-infrared region. Consequently, the change in the band gap enables higher photothermal efficiency at near-infrared wavelengths.
To obtain a monolayer of TMD, various methods including mechanical separation and chemical vapor deposition have been employed. However, these methods suffer from drawbacks such as high costs and time consumption. In contrast, the liquid exfoliation method offers a simple and cost-effective approach for producing monolayers. Traditionally, organic solvents have been used in the liquid exfoliation. However, by utilizing glycyrrhizic acid (GA), a natural compound, deionized water can be employed as a solvent. The inclusion of GA in the liquid exfoliation weakens the van der Waals forces between the TMD layers, simultaneously serving as a stabilizer and enhancing the colloidal stability of the resulting TMD monolayer.
Lateral Flow Immunoassay (LFIA) is a powerful method used for the analysis of target molecules. It offers several advantages, including simplicity and short assay times. In general, LFIA utilizing gold nanoparticles (AuNPs) as a colorimetric indicator demonstrates high sensitivity in detecting target molecules. However, there remains a challenge in further enhancing the sensitivity of LFIA. Therefore, novel approaches are necessary to overcome this challenge and achieve increased sensitivity.
In this study, we synthesized monolayer $MoSe_2$ and investigated its application in a photothermal-based LFIA. The $MoSe_2$ nanosheets were successfully obtained through GA-mediated liquid exfoliation, as confirmed by TEM images showing well-dispersed monolayers. UV-vis spectra of GA-$MoSe_2$ exhibited an absorption peak at 808 nm, within the near-infrared region. Subsequently, we irradiated GA- $MoSe_2$ with a NIR laser at 808 nm and observed an increase in temperature, validating its role as a photothermal agent.
To develop a detection probe for the LFIA, we conjugated GA-$MoSe_2$ with goat-anti mouse immunoglobulin G (IgG) antibodies, resulting in GA-$MoSe_2$/mAb. In the immunoassay, as GA-$MoSe_2$/mAb interacted with IgG and reached the test line, the capture antibody on the test line bound to the conjugate, producing a distinct color line. The intensity of the test line's color increased with the IgG concentration. Additionally, the temperature change associated with laser irradiation also increased with increasing IgG concentration. These results suggest that GA-$MoSe_2$ holds the potential to serve as a platform for high-sensitivity photothermal LFIA. Looking ahead, the utilization of TMDs as photothermal agents is expected to open up various applications, including biosensors for diagnosing virus infections and wearable sensors.

8:00 PM SB11.04.06
Structural Deformation using Metal Deposition for Bio-Adhesive Patch ChorongKim, JaekyuongKim and HyunsikYoon; Seoul National University of Science and Technology, Korea (the Republic of)

Recently, adhesive patches have been studied for medical treatment. Depending on their characteristics, these can be applied in various situations such as wound healing, drug delivery, and biosensor attachment. Given that the body is a moist environment, current research focuses on incorporating chemical adhesives or utilizing structural properties for surface attachment such as suction effects. Additionally, liquid-repellency is essential to prevent the risk of detachment caused by wetting. We adopted structural adhesives to avoid allergic reaction due to toxicity of chemical adhesives. This research presents a method of structural deformation through different metal deposition on hyperbola structure to achieve new properties such as wet adhesion (Au) or liquid-repellency (Al). Hyperbola structures were fabricated by wrapping liquid prepolymer around micropillars driven by capillary force. Due to its flexible edges, the metal, deposited on top surface, caused structural deformation depending on its residual stress. In the case of Au, tensile stress of Au thin film made edges shrink inward, created an empty space inside for adhesive behavior. Conversely, in the case of Al, edges expanded outward because of compressive stress of Al thin film caused by oxidation. So, this structure had more liquid-repellency characteristics. These novel structures can be easily replicated and mass-produced using soft lithography, offering the advantage of non-allergic reactions as no additional adhesives are required. Furthermore, deformation can be easily controlled by adjusting the deposition thickness and Young's modulus of the structure's material. This technology is expected to contribute to the medical industry as for skin/organ-attachable patches.

8:00 PM SB11.04.07
Improving Stability of Nickel Hydroxide/Oxyhydroxide Visible Light-Induced Actuators by Aluminum Doping NanHe; University of Hong Kong, Hong Kong

Material-based actuation systems have been an emerging field of interest because of their direct and simple mechanism without the need to use bulky and complicated hydraulic, electric or magnetic motors. Material-based actuators utilize external stimuli such as light, temperature or humidity to drive mechanical movements. In recent research studies, transition metal

oxides/hydroxides (TMOs) were introduced and studied for light-induced actuation based on their simple and effective photothermal mechanism for water de-intercalation from the turbostratic crystal structures of these materials. Turbostratic phases of nickel hydroxide/oxyhydroxide (NHO) have been found to be high-performing multi-stimuli driven actuating materials. However, these material phases are known to be unstable, and over time they become crystallized and lose their actuating properties. In this work, aluminium doping is used to stabilize the turbostraticity and actuation performance. Visible-light actuation experiments are conducted on NHO samples with and without aluminium doping to characterize their actuation performance over time. Turbostraticity is examined and quantified by techniques including XRD, Raman spectroscopy and high resolution TEM, via information such as d-spacings, intensity ratio and band peak changing. The turbostraticity difference between aluminium-doped and pure NHO actuators is correlated with their actuation performances.

8:00 PM SB11.04.08
Injectable Neural Sensor Array for Post-Surgery Brain Monitoring KyungtaiPark, JuyeongHong, JejungKim and Jong-HyunAhn; Yonsei University, Korea (the Republic of)

Brain diseases, such as epilepsy and traumatic brain injury, affect millions of people worldwide, causing severe side effects. Monitoring postoperative seizures and the recovery of brain function after surgery is crucial for diagnosing and treating these conditions, providing vital information. However, conventional neural implants involve a large-area craniotomy and rely on bulky sensors, which restrict the natural movement of patients. In this study, we present an injectable neural sensor array for monitoring the brain after surgery. The device utilizes a thin and flexible mesh-structured substrate that can be injected onto the cortical surface through a small hole, minimizing the invasiveness. This approach allows the 12mm diameter device to spread out from a 2mm diameter syringe and achieve conformal contact with the surface of the cortex. The device performs neural recording and micro-stimulation for seizure alleviation using multichannel electrocorticography (ECoG) electrodes and a stimulation pad. Additionally, it integrates a sensor array for multimodal sensing of intracranial pressure (ICP) and intracranial temperature (ICT). This technology provides a convenient healthcare solution for the comprehensive assessment of the patient's post-surgery brain condition.

8:00 PM SB11.04.09
The Development of Choline, Calcium and pH Sensors based on Laser-Inscribed Graphene Electrodes AbdulrahmanAl-Shami, AliSoleimani, FarbodAmirghasemi, VictorOng, SinaGharahtekan and MaralMousavi; University of Southern California, United States

Introduction: Graphene, a two-dimensional layer of carbon atoms arranged in a hexagonal lattice, has gained significant attraction in electrochemical biomedical sensors. Graphene exhibits high electrical conductivity, flexibility, and a high surface-to-volume ratio. That makes graphene ideal for developing sensitive, selective, reliable, precise, and accurate sensing platforms for detecting biomarkers and other substances. Another interesting feature of graphene is its high hydrophobicity. This property is important for developing solid contact potentiometric sensors for quantifying biologically important ions. This is because the hydrophilic electrodes allow the formation of a water layer between the electrode surface and the ion-selective membrane, which adversely affects the sensor's sensitivity and selectivity toward the targeted ion. Graphene is conventionally produced by wet chemistry and chemical vapor deposition which are usually complicated, expensive, and labor-intensive. Producing graphene by laser engraving on carbon-rich materials (mostly in the form of repeated aromatic rings) is an attractive approach to overcome the limitations of conventional production methods. The laser-engraving method is simple, precise, cost-effective, fast, scalable, safe, and highly reproducible. In this work, we produced graphene electrochemical electrodes using laser engraving technology. We characterized the produced graphene and employed the electrodes to develop three different sensors for detecting choline and calcium ions and pH levels for human and animal health applications. Choline is a vital infant nutrition factor, supporting brain and nervous system development and functions. Quantifying choline in infant formulas can ensure that infants receive enough choline to grow healthy. The calcium sensor will be used to detect calcium levels in cows' blood, which is important for diagnosing calcium imbalances in dairy cows and preventing milk fever. The pH sensor helps monitor different physiological processes, such as wound healing.
Methods: We produced the electrochemical electrodes by ablating a polyimide film (127 µm thickness) using a CO2 laser cutter machine with a 1060 nm laser wavelength. The engraving was conducted with an auto-focused laser beam with power and speed of 3 W and 105 mm/s, respectively. A choline-selective membrane was produced of a mixture of PVC (structural polymer), o-nitrophenyl-octyl-ether (plasticizer), Sodium tetrakis[3,5 bis(trifluoromethyl)phenyl]borate (ionic site), and Calix 4 arene (ionophore) in THF solvent. The membrane was cast on the electrode surface and dried overnight before measurements. The calcium selective membrane was prepared in the same way as choline but used as an ionophore. The graphene electrode was electrochemically modified for pH sensing by layers of IrO2 NPs. The deposition solution was prepared from IrCl4 using alkaline hydrolysis followed by acidic condensation. The deposition was conducted using cyclic voltammetry in a potential window between 0.6 to 0.65 V for 300 cycles.
Results and discussion:the laser engraving method successfully produced flexible electrochemical electrodes. The scanning electron microscopy images of the laser-engraved areas demonstrated the formation of three-dimensional highly porous graphene on the PI film. Raman spectroscopy revealed the formation of multiple graphene layers on the Pi film with some defects that can be attributed to the presence of oxygen during the engraving in ambient conditions. The graphene-based choline selective electrode demonstrated Nernstian response toward choline ions with a detection limit of 0.1 mM. Also, the sensor could quantify choline concentration in commercially available infant formulas with a measurement error of less than 5 %. The calcium-selective electrode exhibits high sensitivity with a detection limit of 0.01 mM. IrO_2-modified graphene electrode demonstrates a linear response in pH values between 4 and 10.

8:00 PM SB11.04.10
Measuring Electrodermal Activity Underwater using Graphene Electronic Tattoos WendyRossi[1], NingLiu[1], DmitryKireev[2] and DejiAkinwande[1]; [1]The University of Texas at Austin, United States; [2]University of Massachusetts Amherst, United States

Oxygen, while essential for human function, can be harmful in the context of underwater diving. Divers, to stay safe underwater, need to breathe pure, pressurized oxygen known as hyperbaric oxygen; however, breathing too much of this hyperbaric oxygen at certain depths and pressures risks the development of Central Nervous System Oxygen Toxicity (CNS-OT). CNS-OT can lead to sympathetic overstimulation and cause seizures, which are due to abnormal electrical activity in the brain. Electrodermal Activity (EDA) is a quantitative index of sympathetic nervous system activity measured through changes in skin conductance, which vary according to sweat levels caused by emotional arousal or stress. A significant surge in EDA amplitude is a precursor to epileptic seizures and used as an early indicator for CNS-OT risk. Developing a method to identify the onset of CNS-OT risk underwater means introducing a safety monitoring approach previously unavailable in diving. Currently, commercial EDA devices, while effective, lack the flexibility and wearability of GETs and are not waterproof. We propose a graphene electronic tattoo (GET) capable of EDA data processing while immersed in saltwater conditions through a four-part experimental process. First, we established a control group by measuring bioimpedance with uncovered GETs in air, DI water, and saltwater. Next, we found the best waterproofing sealant by comparing the baseline measurements of bare GETs to GETs covered individually by three sealants. After finding that Nexcare Skincrack Care (NCC) produced the clearest bioimpedance readings in each condition, we used this sealant for electrocardiogram measurements in the same fluid conditions to validate our GETs capacity for underwater measurements. Finally, we took EDA measurements using a Neulog device by simulating three emotional states: meditative, focused, and stressed through meditation, boring videos, and horror videos. We established an EDA baseline using the commercial electrodes in each emotional state in air then proceeded to measure EDA with our GET sealed by NCC in the conditions of air, DI, and saltwater. The maximum stimulated EDA change obtained by our graphene electrodes in saltwater is 0.217 µS with a response time of 4 seconds, which is comparable to the commercial electrodes in air with a similar response time. As a result, we find that the combination of NCC and a GET enabled successful EDA monitoring in seawater conditions, advancing GETs in underwater medicine.

8:00 PM SB11.04.11
3D-Printed Electronic Skin for Machine Learning-Powered Multimodal Health Surveillance YuSong and JihongMin; California Institute of Technology, United States

The amalgamation of transdisciplinary wearable technologies with physiochemical sensing capabilities and artificial intelligence promises to create powerful interpretive and predictive platforms for real-time health surveillance and accurate early diagnosis. However, construction of such multimodal devices involves multi-material processing and complex fabrication procedures that are difficult to be implemented wholly by traditional manufacturing techniques for at-home personalized application. Here, we present a universal semi-solid extrusion (SSE)-based 3D printing technology to fabricate an epifluidic elastic electronic skin (e^3-skin) with high-performance multimodal physiochemical sensing capabilities. The all-SSE printed wearable e3-skin is equipped to track vital signs (i.e., heart rate and temperature), analyze key biomarkers in sweat (i.e., glucose and alcohol), and is integrated with an energy storage module designed for untethered battery-free operation. We demonstrate that the e^3-skin can serve as a sustainable surveillance platform to capture real-time physiological state of individuals while performing regular daily activities such as diet challenges and strenuous exercises. We also featured at a pilot study that by coupling the information collected from the e^3- skin with machine learning, we were able to predict with over 90% accuracy an individual's degree of behavior impairments (i.e., reaction time and inhibitory control) after alcohol consumption. The e^3-skin paves the path for future autonomous manufacturing of customizable wearable systems which will enable widespread utility for regular health monitoring and clinical applications.

8:00 PM SB11.04.12
Scalable Fabrication of Soft MXene-Coated Fiber Microelectrodes for Bio Interfacing LingyiBi[1], RaghavGarg[2], NataliaNoriega[3], Ruocun (John)Wang[1], KseniiaVorotilo[1], JustinBurrell[2], HyunhoKim[1], ChristopherE. Shuck[1], AnhLe[2], FlaviaVitale[2], BhavikA. Patel[3] and YuryGogotsi[1]; [1]Drexel University, United States; [2]University of Pennsylvania, United States; [3]University of Brighton, United Kingdom

The development of flexible fiber-based microelectrodes opens up opportunities for long-term studying and modulating neural activities and diseases by increasing targeting precision while inducing fewer side effects, thanks to the minimized mechanical mismatch between artificial devices and soft tissues. However, the current manufacturing of such microfabrication faces scalability, reproducibility, and handling challenges, making large-scale deployment of fiber-based microelectrodes difficult. Moreover, few designs allow capturing both electrical and chemical signals, which are necessary for understanding and interacting with complex biological systems.

Here, we report a novel method that leverages the unique combinations of electrical conductivity, functional surfaces, and solution processibility of MXenes, a large family of 2D nanomaterials, to apply a thin layer of MXene coating continuously to commercial nylon filaments (30-300 µm in diameter) at a fast speed (up to 15 mm/s), resulting in a resistance down to 15 Ω/cm. The MXene-coated filaments can be batch-fabricated into arrays of fiber electrodes, encapsulated with Parylene C, and exposed only at the tip upon application for localized detection and stimulation. We demonstrated the usability of these multifunctional fiber electrodes for both *in-vivo* and *ex-vivo* studies, including neuromodulation and electrical sensing in a rat and H_2O_2 chemical sensing in bladder cells. These electrodes offer excellent performance, significantly simplified use, and improved flexibility (with no performance changes even when knotted). These versatile MXene filament microelectrodes offer a robust, miniaturized platform for monitoring and stimulating neural activities, facilitating a deeper understanding of health and disease.

SESSION SB11.05: 2D Transistors as Biosensors

8:30 AM +SB11.05.01
CRISPR-Powered Graphene Electronics for CRISPR Editing Quality Control KianaAran; Keck Graduate Institute, United States

The discovery of CRISPR technology has revolutionized the fields of transcriptional activation and repression, genome editing, gene-based therapeutics, and diagnostics. The applications of this technology have been rapidly expanding as researchers continue to discover new Cas enzymes, engineer high fidelity Cas orthologs, and modify and synthesize guide RNAs to efficiently direct these Cas enzymes to their targets. In this talk, we will introduce the first-generation DNA biosensors that combine CRISPR technology with the ultra-sensitivity of graphene-based field effect transistors (gFETs) to detect target DNA sequences within the whole genome without the need for DNA amplification. This technology, termed CRISPR-Chip™, utilizes the genome searching capability of Cas and reprogrammable RNA molecule to unzip the double-stranded DNA and bind to its target. This binding event causes a change in graphene conductivity which can be detected in real-time within the gFET construct. CRISPR-Chip was utilized to detect target genes within clinical samples obtained from patients with Duchenne Muscular Dystrophy (Cover of Nature BME-2019), and single cell point mutations in Sickle cell disease and ALS without the need for amplification (Nature BME 2021), within less than 30 minutes. The applications of this technology platform go beyond diagnostics. CRISPR-Chip can provide greater insights on the mechanism of CRISPR and can lead to safe and more effective utilization of this gene editing technology for therapeutic applications. By precisely predicting CRISPR editing outcomes based on key drivers of success like RNP stability and cleaving activity, the CRISPR-Chip enables us to confidently identify the best gRNAs, Cas proteins, and conditions for CRISPR gene editing experiment from the outset.

9:00 AM SB11.05.02
Microneedle Graphene Field-Effect Transistors for Wearable Biosensing MartinHolicky[1], BenjiFenech Salerno[1], AnthonyE. Cass[1] and FeliceTorrisi[1,2]; [1]Imperial College London, United Kingdom; [2]Universita' di Catania, Italy

Microneedle-based biosensing provides an attractive path towards continuous health monitoring - the use of microneedles causes substantially lower pain to the user than traditional hypodermic needles while providing accurate sensing information [1]. Due their small footprint and ease of application, such biosensors are easily worn with minimal nuisance to the user, enabling wearable health sensing anywhere and at any time. Graphene and other two-dimensional materials have emerged as a suitable platform for high performance printed electronics, enabling graphene field-effect transistors (GFETs) on ubiquitous substrates [2,3]. We have recently developed a scalable method for creating high resolution GFETs through spray-coating[4] and demonstrated their use in biosensing.

In this work, a new type of sensor is created by forming the GFETs directly on the tips of polycarbonate microneedles to enable biosensing of interstitial fluid within the skin. The GFETs are formed on the three-dimensional needles through a scalable combination of laser lithographic patterning and spray-coating and uses injection-moulded polycarbonate microneedles. The graphene channels are approximately 2000 µm wide and 80 µm long, with a resistance of 150 Ohms and display characteristic ambipolar modulation under solution gating. We fully characterise the sensors through microscopic and electrochemical methods and demonstrate their biosensing properties through in solution and in-vitro skin measurements. The results demonstrate a new class of sensors that can take advantage of the FET signal amplification directly in situ and enable the development of more sensitive and accurate microneedle biosensors in the future.

Microneedle-Based Potentiometric Sensing System for Continuous Monitoring of Multiple Electrolytes in Skin Interstitial Fluids HuijieLi and YiZhang; University of Connecticut, United States

Electrolytes play a pivotal role in regulating cardiovascular functions, hydration, and muscle activation. The current standards for monitoring electrolytes involve periodic sampling of blood and measurements using laboratory techniques, which are often uncomfortable/inconvenient to the subjects and add considerable expense to the management of their underlying disease conditions. The wide range of electrolytes in skin interstitial fluids (ISFs) and their correlations with those in plasma create exciting opportunities for applications such as electrolyte and circadian metabolism monitoring. However, it has been challenging to monitor these electrolytes in the skin ISFs. In this study, we report a minimally invasive microneedle-based potentiometric sensing system for multiplexed and continuous monitoring of Na^+ and K^+ in the skin ISFs. The potentiometric sensing system consists of a miniaturized stainless-steel hollow microneedle to prevent sensor delamination and a set of modified microneedle electrodes for multiplex monitoring. We demonstrate the measurement of Na^+ and K^+ in artificial ISFs with a fast response time, excellent reversibility and repeatability, adequate selectivity, and negligible potential interferences upon the addition of a physiologically relevant concentration of metabolites, dietary biomarkers, and nutrients. In addition, the sensor maintains the sensitivity after multiple insertions into the chicken skin model. Furthermore, the measurements in artificial ISFs using calibrated sensors confirm the accurate measurements of physiological electrolytes in artificial ISFs. Finally, the skin-mimicking phantom gel and chicken skin model experiments demonstrate the sensor's potential for minimally invasive monitoring of electrolytes in skin ISFs. The developed sensor platform can be adapted for a wide range of other applications, including real-time monitoring of nutrients, metabolites, and proteins.

9:30 AM *SB11.05.04
Graphene Transistors for Biosensing Applications AmaiaZurutuza; Graphenea, Spain

Over the past years, extensive efforts have been placed in the research and development of graphene-based applications, as a result certain applications have experienced an increased level of maturity and achieved higher technology readiness levels (TRLs) among them is that of sensors.

Graphene's electronic and mechanical properties make it an ideal candidate to be applied in various types of sensors. The market for sensors is extremely large since it includes many industries such as automotive, electronics and healthcare industries among others. Therefore, it is an excellent starting platform for graphene applications. For example, the COVID-19 pandemic demonstrated the urgent need for fast diagnostics in order to minimise and control its effects, here, biosensors based on graphene field effect transistors (GFETs) have shown great potential as a platform for future diagnostics.

During this talk, I will cover the fabrication of graphene at wafer scale (up to 200mm) and the use of graphene in various types of sensors including ion sensors (ISFETs) [1-3], gas sensors [4] and biosensors [5].

Mxene and Conjugated Polymer-Based Hybrid Systems for Electronic Biosensing SahikaInal; King Abdullah University of Science and Technology, Saudi Arabia

Among the existing two-dimensional materials, MXenes stand out for their excellent electrochemical properties. MXene-based inks and films hold great potential for the scalable production of skin-conformable electronics and for constructing electronic sensors and actuators that operate in physiological media. On the other hand, conjugated polymer films, due to their softness and conformability, enable seamless interfacing with the skin and cells. In this talk, I will demonstrate how the combination of soft conducting polymers and printed MXene electrodes brings together the best of both worlds for biointerfacing. The functionalized MXene films serve as multifunctional biosensing units for cation and protein sensing, as well as for capturing physiological signals. Conducting polymers act as both substrates and interconnects. In another platform, the incorporation of MXene as a co-dopant in a conjugated polymer structure results in hybrid films with remarkably high volumetric capacitance and stability. These microfabricated hybrid devices outperform their single-component counterparts in chronic biochemical sensing and stimulation applications. Our findings illustrate how MXene films can streamline the fabrication of next-generation bioelectronic platforms incorporating multimodal sensors.

11:00 AM SB11.06.02
Deformable and Stretchable EGaIn/Graphene-Based Electrochemical Biosensors DongwookLee, Don-HuiLee, Won-YongLee and JayoungKim; Yonsei University, Korea (the Republic of)

EGaIn has attactive properties for soft eletronics, such as wearable and implantable electronic devices for healthcare applications, due to its high conductivity and deformability near room temperature. However, the formation of an insulating native oxide film of EGaIn impedes its application to soft and stretchable electrochemical biosensors. Herein, we introduce reduced graphene oxide to EGaIn to achieve electrochemical stability and excellent conductivity as well as deformable properties. Graphene oxide easily undergoes galvanic replacement reaction on the surface of EGaIn particles forming reduced graphene oxide capped EGaIn core-shell particles (LM-RGO CSPs), which can be further fabricated to patternable stretchable electrochemical biosensing devices. The resulting deformable electrodes show excellent electrochemical conductivity and stability by preventing the native oxide film growth of EGaIn, even under repetitive stretching with 30% strain without any delamination of RGO. Also, the outer layer of RGO can be further decorated with metals which can effectively catalyze enzymatic reactions for glucose biosensing. In this talk, we will discuss the deformable mechanisms of LM-RGO CSPs-based electrochemical biosensors revealing specific interfacial attractions between RGO and LM, and excellent electrochemical biocatalytic activity for sensitive glucose detection under strains, based on sub-micro sized particle characteristics and their facilitated electron transfer between electrodes and glucose oxidase enzyme. We envision such an electrochemical device system can serve as a platform for multi-modal deformable wearable biosensing devices for healthcare applications, overcoming the inherent limitations of EGaIn as a soft conductor and taking advantage of the excellent conductivity of graphene.

11:15 AM SB11.06.03
The Effect of Partially Reduced Graphene Oxide on The Enzymatic Activity of Yeast RebeccaIsseroff[1], SophiaBracco[2], DominicRosiello[2], SergioRosa[2], SamSpecht[3] and MiriamRafailovich[1]; [1]Stony Brook University, The State University of New York, United States; [2]South Side High School, United States; [3]The Stony Brook School, United States

Enzyme biocatalysts are important for the synthesis of drugs, vitamins, and other products, but research is being done to increase their stability and activity. Previously we have found that partially reduced graphene oxide (pRGO) acts as an enzymatic enhancer for the catalytic activity of microbial transglutaminase in the cross-linking of gelatin. We now set out to determine whether graphene oxide (GO) and/or pRGO would have an effect on the enzymatic activity of yeast to decompose hydrogen peroxide, thereby testing whether these 2D materials are biocompatible with a living organism that produces an enzymatic reaction rather than just testing the effect on the enzyme itself.
A solution of pRGO reduced in a concentration of 18 mM sodium borohydride, as well as an unreduced GO solution, were compared with water as a control. While initial qualitative results suggested that GO had no effect on yeast's catalytic activity, H2O2 decomposition seemed to be enhanced by 18 mm pRGO. However, further quantitative measurements were conducted by collecting O2 by water displacement. Twenty milligrams of yeast were suspended in two milliliters of water containing 0.2% sucrose by weight and incubated at 41 degrees Celsius for 4 minutes. (As a third variable, twenty milligrams of yeast were suspended in two milliliters of water containing 0.2% sucrose by weight but with 0.5 ml pRGO added to the yeast + water before incubation.) Then, 5 ml of 3% H2O2 + 0.5 ml DI water for the control, and 5 ml of 3% H2O2 + 0.5 ml pRGO for the test solution, were added and the time it took to displace 25 ml of water was measured. After 5 minutes, an additional 4 ml of 3% H2O2 were added, and the time it took to displace 25 ml water was again measured, to determine whether the yeast maintained its activity. Results showed that yeast activated in water had the same rate of decomposition of H2O2 containing pRGO as the control containing no pRGO, but yeast incubated in water containing pRGO actually had a slower rate of H2O2 decomposition, both initially as well as retesting five minutes later by adding additional H2O2. Macroscopic changes observed in the pRGO-yeast include darkening of the yeast, suggesting incorporation of pRGO by the cells. Microscopic examination of pRGO-incubated yeast at various time points provides further insight on the biocompatibility of partially reduced graphene oxide with living cells.

11:30 AM *SB11.06.04
Advances in Pressure and Chemical Sensing with 2D Materials PaoloSamori; University of Strasbourg, France

Physical and chemical sensor bear a direct societal impact on well-being, which includes, among others, the monitoring of human's health, the quality and composition of the air we breathe, the water we drink, and the food we eat.
Physical sensors are essential components for the fabrication of devices for medical diagnosis and health monitoring, upon use of active materials with sensitivities in the low-pressure or medium-pressure range, respectively. In this framework, flexible piezoresistive pressure sensors are compatible with wearable technologies for digital healthcare, human-machine interfaces and robotics. Among active materials for pressure sensing, graphene-based materials are extremely promising because of their outstanding physical characteristics. Currently, a key challenge in pressure sensing is the sensitivity enhancement through the fine tuning of the active material's electro-mechanical properties. We have achieved this by combining chemically reduced graphene oxide (rGO) with (macro)molecular materials with controlled mechanical properties. Among these, the use of a polybenzoxazine thermoresist matrix in combination with rGO made it possible to tailor electrically conductive nanocomposites where the thermally triggered resist's polymerisation modulates the active material rigidity and consequently the piezoresistive response to pressure. [1]
In chemical sensing higher sensitivity, faster response time and fast recovery time can be achieved by using 2D materials as active components. Instead, selectivity can be achieved either through the optimization of the energy levels of the analyte with respect of those of the active material, as demonstrated via the fabrication of sensors of heavy metals[2] or polyaromatic molecules[3], or through the functionalization of the latter with supramolecular receptors ensuring a high discrimination of ions and small molecules in the sensing event.[4]
Strategies for simple integration of working devices with electrical read-outs will be presented.

Intracranial, Subcutaneous and Scalp Electroencephalography with Multiscale Arrays Based on 2D MXenes FlaviaVitale; University of Pennsylvania, United States

Electroencephalography (EEG) is commonly used for neurological diagnostics and monitoring, and in neuroscience research. Depending on the application and degree of invasiveness, EEG can be acquired with gelled electrodes placed on the scalp or invasively with intracranial electrodes. Recently, subcutaneous EEG has emerged as a minimally invasive, mobile, and reliable alternative solution for long-term epilepsy monitoring and seizure forecasting.
In this talk I will present multiscale arrays for intracranial, subcutaneous, and scalp EEG based on high-throughput liquid-phase processing of 2D $Ti_3C_2T_x$ MXene. Leveraging the colloidal stability of MXenes in aqueous dispersions, we have developed a rapid fabrication process to produce EEG arrays with fully customizable geometry, scale, and density. For scalp EEG, the devices feature 3D pillars of varying diameter and height fabricated from PVA aerogel templates infiltrated with $Ti_3C_2T_x$. Due to the high electrical conductivity (155 ± 4 Ω, n= 5), porosity, and surface area, these 3D electrodes can establish a low impedance interface with the scalp without the need for any gel or conductive adhesive (10 Hz impedance of 8 mm pillar electrodes: 2.1 ± 1.8 kΩ, n=5 participants).
To illustrate examples of applications of these multiscale MXene EEG arrays, I will present our most recent studies on intraoperative recordings in large animals and humans, longitudinal monitoring of post-traumatic epilepsy evolution with subcutaneous EEG in murine models, and clinical scalp EEG in epilepsy patients.

2:15 PM SB11.07.02
Wireless, Graphene-Based Multifunctional EEG and ECG Sensor for Clinical Monitoring JuyeongHong and Jong-HyunAhn; Yonsei University, Korea (the Republic of)

With the advent of advanced digital healthcare technologies, the need for imperceptible user-friendly portable devices for clinical monitoring of physiological anomalies has greatly increased. The brain and the heart are two major organs that would benefit greatly from such real-time monitoring apparatus, as the symptoms of various diseases readily manifest themselves in their operation. Brain diseases, such as stroke, epilepsy, and Parkinson's disease, and cardiovascular diseases, including arrhythmia, heart attacks, and atrial fibrillations, known for their high fatality, are among the many conditions where quick diagnosis and preventative measures may be taken via the continuous monitoring of the brain and the heart. As such, electroencephalogram (EEG) and electrocardiogram (ECG) have become an essential tool in the monitoring and diagnosis of patients. However, conventional monitoring devices are hard-pressed to facilitate prolonged real-time monitoring of patients. These devices typically fail to support the simultaneous monitoring of vitals on a single wearable device and causes discomfort owing to the bulky, wired electrodes and recording devices, thus limiting their daily use and leaving patients vulnerable to unpredictable medical emergencies. As such, in this research, a wireless, graphene-based EEG and ECG sensor for clinical monitoring is proposed. We demonstrate a simultaneous monitoring and analysis of EEG and ECG with improved accuracy for both clinical monitoring and brain-to-computer interface (BCI) applications. The ultrathin and imperceptible graphene-based electrodes exhibit lower contact impedance, high signal-to-noise ratio (SNR), and stable properties owing to the excellent mechanical and electrical properties of the constituent materials and structural design. Paired with a high-throughput portable wireless recording device for clinical monitoring, the system enables user-friendly, real-time monitoring of EEG and ECG for up to 11 hours on a single charge with accuracy and precision on par with that of conventional clinical systems. The simultaneous monitoring of both EEG and ECG enables accurate and holistic analysis of the patient's status. We also demonstrate a clinical BCI speller system augmented by deep neural networks to exhibit the diagnostic capabilities of the monitoring system. These personalized, wearable, and highly imperceptible devices are expected to aid in the advancement of daily healthcare for patients.

2:30 PM SB11.07.03
Stencil Printable Liquid Elastomer-Graphene-Based Respiration Sensors for Point-Of-Care Diagnostics SimranSharma and TitashMondal; IIT Kharagpur, India

Due to the rise in global health issues and the challenges that come with them, point-of-care (POC) monitoring has the potential caliber to mitigate life-threatening situations. Among various diseases, monitoring of respiration disorders seems crucial and achievable by utilizing low-cost sensing devices for POC diagnostics. One of the significant challenges for people living in rural areas is reaching an appropriate hospital with the requisite facilities. And at times, this time consumption leads to many fatal outcomes. To mitigate this issue, an industry-feasible process has been utilized to develop liquid elastomer and graphene-based stencil printable sensors. Understanding that the inhalation and exhalation process induces pressure gradient, it can be utilized to detect minor strains in a sensor attached to the mask. Besides strain, breath temperature and humidity can also impact the sensing output of graphene-based sensing devices. Therefore, a silicone encapsulant has been utilized to decouple humidity response, and a Wheatstone bridge has been utilized as a temperature compensation technique. Further owning to elastomer's negative glass transition temperature, developed sensors could remain flexible in sub-ambient temperatures and be used for respiration monitoring at such temperatures. Various breath patterns, including normal, fast, deep, and slow breathing, can be identified with the aid of a developed on-mask sensing device and major respiration signals such as respiration rate (RR), Depth of respiration (DR), inhalation time, exhalation time and average breathing time can be monitored.

A Wearable Nanobiosensor for Automatic, Non-Invasive and Wireless Monitoring of Systemic Inflammation JiaobingTu and WeiGao; California Institute of Technology, United States

Real-time monitoring of inflammatory proteins allows remote disease progression tracking and early intervention, thus improving patient outcomes and lowering economic burdens in chronic diseases. However, most current commercial protein sensing technologies rely on invasive blood draws, and require lengthy target incubation and labor-intensive washing steps to reach nanogram-level sensitivity. Although sweat is a non-invasive source for disease monitoring, wearable immunosensing is complex and sweat protein secretion is extremely underexplored, presenting a major challenge for personalized inflammation monitoring. Here, we present a wearable nanoengineered electrochemical biosensing technology that allows real-time and non-invasive analysis of a crucial inflammatory biomarker, C-reactive protein (CRP). Highly sensitive, selective, and fully automatic *in situ* inflammatory protein analysis across human activities was realized through seamless integration of a mesoporous graphene-gold nanoparticle modified immunosensor (coupled with thionine-tagged detector antibody-conjugated gold nanoparticles for signal transduction and amplification), autonomous sweat gland-driven microfluidics, and multimodal graphene sensor calibration. Through *in vitro* and *in vivo* clinical studies, we discovered the presence of CRP in chemically-induced human sweat and identified substantially elevated sweat CRP levels from patients with heart failure, chronic obstructive pulmonary disease, and active and past infections (e.g., COVID-19). We obtained a high correlation between sweat and blood CRP levels, demonstrating the potential of this technology toward non-invasive chronic disease management.

Thermal Drawing of Graphene-Integrated PVDF Fiber for Improved Performance in Wearable Triboelectric Nanogenerator Md Sazid BinSadeque, MahmudurRahman, Md MehdiHasan and MustafaOrdu; Bilkent University, Turkey

Triboelectric nanogenerators (TENG) exploit the phenomenon of triboelectrification enabling energy harvesting from low-frequency mechanical and biomechanical energy. Flexible ferroelectric polymers such as polyvinylidene difluoride (PVDF) are excellent candidates for fabricating a TENG device due to its high triboelectric charge density. Embedding 2D materials that have a high specific surface area into the PVDF matrix has proven to be an efficient strategy to affect surface morphology and friction property to improve the performance of TENG. Graphene and its derivatives have become a desired multi-functional material for fabricating high-performance TENGs. In this study, we demonstrate the successful fabrication of continuous PVDF graphene nanocomposite fiber via scalable thermal drawing process. Fibers were fabricated with varying concentration of graphene in the PVDF matrix (1 wt%, 3 wt% and 5 wt%) by optimizing the fiber drawing parameters. The 5 wt% graphene integrated PVDF TENG fiber generates peak power up to 12.08 µW, which is more than two times higher compared to pristine PVDF TENG (5.80 µW). This research will further expand our understanding on the dynamics of 2D nanomaterials into the polymer matrix of a thermally drawn fiber, leading to the performance optimization of wearable triboelectric devices and sensors.

Highly Piezoelectric, Biodegradable and Flexible Amino Acid Nanofibers for Medical Applications ThanhD. Nguyen; University of Connecticut, United States

Amino acid crystals are an attractive piezoelectric material as they have an ultra-high piezoelectric coefficient and possess an appealing safety profile for medical implant applications. Unfortunately, solvent-cast films made from glycine crystals are brittle, quickly dissolve in body fluid, and lack of crystal orientation control, reducing the overall piezoelectric effect. Here, we present a material processing strategy to create biodegradable, flexible, and piezoelectric nanofibers of glycine crystals embedded inside polycaprolactone (PCL). The glycine-PCL nanofibers film exhibits stable piezoelectric performance with a high ultrasound output of 334 kPa (under 0.15Vrms), which outperforms the state-of-the-art biodegradable transducers (Nguyen et al., highly piezoelectric, biodegradable and flexible amino acid nanofibers for medical applications, Science Advance, 2023). We employ this material to fabricate a biodegradable ultrasound transducer for facilitating the delivery of chemo-drug to the brain. The device significantly enhances the animal survival time (2-fold) in mice-bearing orthotopic glioblastoma models. The piezoelectric glycine-PCL presented herein could offer an excellent platform not only for glioblastoma therapy but also for developing medical implantation fields.

Electronic Skins with Air-Stable Ultraflexible Organic Photonic Devices TomoyukiYokota[1], KenjiroFukuda[2], SunghoonLee[2,1] and TakaoSomeya[1,2]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan

Inspired by the human skin, which is a large-area, multi-point, multi-modal, stretchable sensor, electronic skins that simultaneously detect pressure and thermal distribution have been developed. By improving its conformability, electronic skin can be directly attached on the human skins as next-generation wearables. In particular, ultraflexible organic photonic devices have been utilized as electronic skins that continuously monitor biological information in humans non-invasively. In this paper, we report recent progress of ultraflexible organic photonic devices that consist of organic light-emitting diodes and photodiodes. The environmental stability has been improved significantly using an inverted structure that does not employ atmospherically unstable cathode materials. We will also address issues and the future prospect of electronic skin using organic photonic devices.

A Flexible Optically Stimulated Synaptic Transistor Based on rGO-ZnO NRs Based Hybrid Channel AtanuBag and Nae-EungLee; Sungkyunkwan University, Korea (the Republic of)

Recently, sensory synapses, including a sensory receptor and synapse between sensory receptor and afferent neuron, have received much attention for neuromorphic sensing applications. It is essential to obtain multi-functionality such as synaptic plasticity, retention time, and high sensitivity to realize an artificial sensory synapse with sensing ability with synaptic properties. Herein, a flexible optical sensory synapse using field-effect transistor (FET) structure having reduced graphene oxide (rGO) as a conducting channel with vertically-grown ZnO nanorods (NRs) as a UV-responsive sensing material and ion-gel based on 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIM][TFSI]) as a gate dielectric layer was investigated. The hybrid channel of ZnO NRs and rGO in synaptic FET devices enhanced the electrical synaptic weight presumably due to increased electrical double layer capacitance caused by increased surface area. Under no electrical gate bias furthermore, photo-gating induced by UV exposure resulted in a high optical synaptic plasticity presumably due to the combined effect of slow oxygen permeation through ionic gel for recovery and high capacitance by ion-gel. The UV-responsive optical synapse based on the hybrid channel FET is promising for sensory synapses, which can be used for efficient neuromorphic photo-sensing applications.

8:15 AM *SB11.08.02
2D Materials-Based Acoustic Sensors and Actuators HeTian; Tsinghua University, China

There is a great demand of developing 2D materials-based wearable electronics. In this talk, I will introduce several wearable electronics: 1. Graphene-based thermoacoustic device can enable sound emission with transparent properties. 2. We have developed graphene artificial throat, which can help mute people to speak again. 3. We also have created Mxene-based eardrum with high sensitivity. Our work can great promote the wearable electronics toward practical applications.

8:45 AM *SB11.08.03
Skin-Integrated Wearable Sensors and Systems Shideh KabiriAmeri; Queen’s University, Canada

Skin-integrated wearable sensors and systems are a group of different types of sensors and their integrated electrical circuits that are laminated on skin and enable real time monitoring of the body and the surrounding environments for the applications in mobile health care, Internet of Things (IoT) and Human Machine Interfaces (HMI). The grand challenge in making reliable sensors and systems of such is the interface between conventional sensors and rigid electronics and soft, stretchable, and dynamic skin. Novel materials, designs and approaches are required to overcome this challenge. In this talk a group of nano materials based non-intrusive wearables with superior performance and visual imperceptibility and their applications for electroencephalography (EEG), electrocardiography (ECG), electromyography (EMG), Electrooculography (EOG), sensing skin temperature and hydration, human machine interface and IoT will be presented.

9:15 AM *SB11.08.04
Wearable Self-Powered Biosensors Based on 2D Materials on Textile Platforms KavyaSreeja Sadanandan, IevgeniiaKovalska, Mashael HababAlbuqami, AnaNeves, SaverioRusso and MonicaCraciun; University of Exeter, United Kingdom

Revolutionary advancements in healthcare and well-being rely on the integration of cutting-edge self-powered sensing technologies within textiles. A pivotal breakthrough in this field involves the emergence of nanoscale self-powered sensors specifically triboelectric nanogenerators (TENG). The underlying principle of TENGs lies in the combination of the triboelectric effect, based on the interaction between materials with different electronegativity and electrostatic induction. TENG devices have the capacity to effectively harness untapped energy resources, for example they can convert biomechanical energy from human movements such as walking, running, and breathing into electricity. TENG based biosensors are emerging as a viable alternative to battery-powered devices due to their self-powered and environmentally friendly properties. As a result, they are well-suited for wearable health monitoring applications, where they can behave as self-powered sensors. To pave the way for these transformative advancements, it is crucial to develop flexible, mechanically robust, lightweight, and resilient TENG biosensors.
In this invited talk, I will present our recent work on the solutions we explored to the design and fabrication of such generators, which possess the vital characteristics to meet the demands of practical applications. I will present several approaches for the development of textile-based triboelectric nanogenerators using 2D materials both as active sensing layers and as electrode materials. In our earlier work we demonstrated various methods to integrate graphene with textile substrates and create electrodes displaying displayed a good range of conductivity, and resilience to bending, compression and tension.
These textile electrodes are used in the fabrication of TENGs along with a triboelectric layer of polydimethylsiloxane (PDMS) polymer and nylon fabric as a counter triboelectric layer. Different parameters affecting the TENG output such as chemical modification of the PDMS layer, frequency, contact force, contact area and separation distance between the two triboelectric layers are studied to provide insights into the working mechanisms of the device and to enhance the TENG output. The flexible textile TENG presents a stable output performance under strong deformation and its sensitivity to movement was explored as wearable sensor to monitor biomechanical movements. Due to the conformation ability of the triboelectric sensors, they were able to be implemented on key moving parts of the human body and used to monitor biomechanical motion through electrical signals. The self-powered sensors demonstrate their potential for wearable bioelectronics, intelligent robotics, prostheses, and rehabilitation purposes. Furthermore, we have demonstrated the use of 2D Transition Metal Dichalcogenides materials for wearable sweat sensors of uric acid for applications in personalised healthcare. Among the emerging technologies for continuous monitoring wearable technologies, triboelectric nanogenerators have emerged as a particularly promising and innovative approach for self-powered sensors in the detection of sweat biomarkers.

These results show that the distinctive combination of electrical, morphological, and mechano-elastic properties positions these 2D materials attractive candidate for the development of self-powered sensing textile technologies.

Atomic-Scale Perspective at Alloy-Design for Additive Manufacturing DierkR. Raabe; Max Planck Institute for Iron Research, Germany

Additive Manufacturing is capable of producing highly complex parts directly from a computer file and raw material powders. Its disruptive potential lies in its ability to manufacture customised products with individualisation, complexity and weight reduction for free [1-3].
The lecture provides a brief overview of our research which aims to understand the impact of this manufacturing process on complex engineering alloys at the atomic- and nanoscale as well as to develop metallic materials suitable for and exploiting the unique characteristics of Additive Manufacturing.
While Additive Manufacturing, and in particular Laser Additive Manufacturing, is by now fairly well-established as a process to produce metallic parts, studies targeting the segregation and structural interface features at the atomic- and nanoscale for microstructure-optimisation of existing alloys and the design of novel advanced alloys tailored specifically to Laser Additive Manufacturing are still sparse. The established alloys currently in use do not exploit the enormous opportunities inherent in this technique at all, leaving a gap towards its further development.

Direct Ink Printing of Thermoelectric Materials DavidC. Dunand, MingChen, AlexanderProschel and YunjiaZhang; Northwestern University, United States

3D ink extrusion printing (i.e., direct ink writing) enables powder deposition in a layer-by-layer fashion, in air at ambient temperature, to create 3D complex geometries. For thermoelectric materials (TEs), this versatile manufacturing technique can unlock the potential of fully printed TE modules consisting of p-type and n-type TE legs. Recently, pre-alloyed particles (e.g., $Nb_{1-x}CoSb$) were suspended in inks, printed and then densified via sintering; also, bismuth and tellurium oxide particles deposited from inks resulted in Bi_2Te_3 after hydrogen reduction. Here, we demonstrate inks, containing blended elemental powders, which are printed into TE legs and reacted during sintering to synthesize the high-temperature TE phases $Yb_{14}MnSb_{11}$ and La_3Te_4. To build mechanically robust TE module with high density and phase purity, several approaches are explored during post treatments of printed green bodies. Infiltration of lower-melting elements in pre-sintered structures followed by annealing can close open porosity and help achieve targeted compositions. By blending low-melting elements like Sb into precursor powders, liquid phases are formed which facilitate interdiffusion and densification during sintering. For blended elemental powders, sublimation of elements with high vapor pressure (such as Yb and Te) during sintering introduces deviations from phase stoichiometry and formation of secondary phases. We demonstrate strategies - *via* addition of excess elements and/or binary compounds in precursors - to mitigate elemental losses and increase phase purities in sintered TE legs. We discuss the effects of microstructure and phase purity on the thermoelectric figure of merit (zT), which is controlled by the Seebeck coefficients and the electrical and thermal conductivities.

11:30 AM *SF01.01.03
Additive Manufacturing and Natural Medicine in Bone Regeneration: Opportunities and Challenges SusmitaBose; Washington State University, United States

An estimated one million bone grafting procedures are performed annually in the U.S. and a few million worldwide to repair fractures, cysts, bone defects, tumors, and hip and knee replacements. An increase in the number of procedures is strongly tied to increased musculoskeletal disorders, the aging population segment, and sports-related injuries. Sometimes, patient-matched devices are necessary for patients with special anatomical needs or concerns related to specific defect size complexity.
3D printing (3DP) or additive manufacturing (AM) is becoming essential in patient-matched implants due to lower cost and shorter manufacturing lead time. Additively manufactured components must be controlled and optimized carefully for their reproducibility, machine-to-machine part quality variations, and process-specific material properties. Establishing process property relationships for different AM techniques is vital to successfully implementing these manufacturing practices in biomedical devices. Complex biomaterials, e.g., calcium phosphate (CaP) ceramics compositionally similar to the inorganic part of the bone, show significant promise toward implant applications in both 3DP tissue engineering scaffolds and surface-modified hip and knee implants. It is worth noting that even with all the excitement on 3DP in recent years, *reliable and reproducible 3DP* ceramic *scaffold* manufacturing *is rare compared to* porous polymeric or metallic structures due to their ease of processability.
We have used extrusion-based and commercial binder jetting 3D Printing machines (ExOne, PA) with various ceramic powders for the past 25 years to critically identify and understand the

effects of process-property variations on 3DP CaP scaffolds. Our CaP scaffolds using 3DP have an average designed pore size of 300-400 microns, with 40 volume % porosity and compressive mechanical strength of >15 MPa, followed by NMC loading on those CaP scaffolds. We have designed and built a 3DP machine capable of printing high-viscosity slurry to directly print doped CaP–polymer scaffolds with similar inorganic composition as bone. 3D interconnected channels in CaP scaffolds provide pathways for micronutrients, improved cell-material interactions, and increased surface area, allowing improved mechanical interlocking between scaffolds and surrounding bone.
In vivo studies show improved osteogenesis, angiogenesis, and controlled drug delivery using natural medicinal compounds (NMCs) in these 3D-printed scaffolds and coatings. The use of NMCs in CaP or CaP-polymer composites can eliminate the need for autografts and related second-site surgery for harvesting. NMCs can also replace growth factors (GFs) and proteins for faster healing. NMCs work with CaPs and other materials, such as titanium metals, to enhance early-stage bone tissue ingrowth for applications in load-bearing or non-load-bearing implants. These systems show promise for use in orthopedic and dental devices while eliminating the need for autografts and the second site surgery for harvesting and improving current hip/knee implant lifetime. The presentation will address the design of next-generation bone tissue engineering scaffolds and hip/knee devices based on clinical needs in the fixation of bone disorders and scientific challenges.

SESSION SF01.02: Session II
Session Chairs: Sarah Wolff and Rayne Zheng
Monday Afternoon, November27, 2023
Sheraton, Second Floor, Republic B

1:30 PM *SF01.02.01
Advances in Additive Manufacturing of Architected and Functional Materials ChristopherM. Spadaccini; Lawrence Livermore National Laboratory, United States

In this presentation, we will cover some of the latest work in advanced and custom additive manufacturing processes for the fabrication of architected materials and functional structures. The concept of architected materials revolves around the notion that material properties are traditionally governed by the chemical composition and spatial arrangement of constituent elements at multiple length-scales. This usually limits material properties with respect to each other creating trade-offs when selecting materials for specific applications. For example, strength and density are inherently linked so that, in general, the more dense the material, the stronger it is in bulk form. We will review advanced additive micro- and nanomanufacturing techniques to create new material systems with previously unachievable property combinations. These processes include, but may not be limited to, projection microstereolithography (PuSL), direct ink writing (DIW), and electrophoretic deposition (EPD) as well as more advanced concepts such as volumetric additive manufacturing (VAM), computed axial lithography (CAL), parallel two-photon polymerization, liquid metal jetting, and diode-based additive manufacturing of metals (DiAM). The performance of the resulting material constructs is fundamentally controlled by geometry at multiple length-scales, from the nano- to the macroscale, rather than chemical composition alone. We have fabricated and will review the resulting properties of these mechanical metamaterials in polymers, metals, ceramics, and combinations thereof. These new processes and concepts can also be applied to functional materials such as those for supercapacitor electrodes, optical components, and even for fluidic system such as the recently published cellular fluidics concept. A review of these functional systems will be followed by a brief discussion of future directions.

2:00 PM SF01.02.02
Additively Manufacturing Smart Cellular Materials: Self-Healing Protection for Space Applications MarliniSimoes[1,2]; [1]California Institute of Technology, United States; [2]University of Cambridge, United Kingdom

Metallic cellular materials, such as lattices and honeycombs, are of interest in the design of lightweight and impact-resistant structures (high energy absorption capacity). However, the use of cellular materials in engineering applications has been hindered due to the challenges associated with the fabrication of such complex geometries. Additive manufacturing (AM) technologies have enabled the fabrication of geometries of significant complexity. Nevertheless, the design optimization of AM cellular materials for high strain rate loading scenarios remains relatively underdeveloped. Furthermore, even if those material structures dissipate energy efficiently during dynamic crushing, they do not recover their shape after impact. It is, therefore, necessary to understand the relationship between the AM process parameters, cellular material structures and dynamic performance, but also to develop the recovery of those structures after suffering an impact.
In this work, the opportunities created by additive manufacturing processes have been explored by: (1) studying the process-geometry-property interactions of metallic cellular materials, and (2) manufacturing cellular structures which can exhibit a “self-healing” functionality through shape memory effect. Firstly, quasi-static and dynamic mechanical testing on stainless steel 316L cellular geometries is combined with a wide range of material characterization techniques to understand the interplay between AM process parameters, geometry and high strain rate performance. Five cellular structures were investigated, finding that the geometry played a dominant role, relative to the Laser Powder Bed Fusion (LPBF) AM process. Secondly, bulk and complex cellular structures that exhibit shape memory effect have been successfully manufactured. A diamond lattice structure and a new auxetic structure obtained through topology optimization recovered up to 70% of their shape after impact. The main motivation and focus are on space applications to mitigate against impacts but this research is of relevance to a wide range of sectors: e.g., automotive crashworthiness, structural defence, and civil blast protection.

2:15 PM *SF01.04.06
Digital Twins Empower Everyone to Print Better Parts TarasankarDebRoy and TuhinMukherjee; The Pennsylvania State University, United States

Digital twins have garnered significant interest in the industry due to the scientific, technological, and commercial advantages they offer. This presentation addresses the fundamental elements of a digital twin for additive manufacturing, highlighting the roles of mechanistic models, machine learning, statistical models, sensing and control, and data. By utilizing digital twins, the current practice of trial and error qualification of metallic parts with expensive printing equipment and feedstock materials can be circumvented. The presentation also explores the detection and prevention of defects through diagnostic closed-loop process control, employing sensors to monitor key features like deposit geometry or peak temperature. In contrast to closed-loop control, digital twins are also employed offline for process planning, enabling the narrowing of the optimal process parameter window to achieve predetermined outcomes. This significantly reduces the need for extensive corrective actions during manufacturing. Finally, the presentation discusses the potential for expanded utilization of digital twins based on existing evidence, providing an outlook on future applications.

2:45 PMBREAK

3:15 PM *SF01.02.04
Additive Manufacturing as a Unique Platform for Fabrication of (Meta-)Materials with Complex Topologies and Designer Microstructures LorenzoValdevit; University of California, Irvine, United States

Additive Manufacturing (AM) is a family of disruptive technologies that allow rapid fabrication of parts of nearly arbitrary geometrical complexity without the need of expensive tooling, vastly simplifying production of elaborate assemblies for a wide range of industries. The established approach to materials design for additive manufacturing (AM) generally consists of attempting to reproduce the uniform structures and properties of conventionally processed materials. While this certainly helped facilitate material certification and rapid introduction of AM technologies in a number of industries, the opportunity to exploit the fundamentally local nature of AM processes to fabricate novel heterogeneous materials with accurately controlled distributions of properties remains largely untapped. Here we discuss two recent and exciting demonstration of this new AM-enabled design concept: (a) novel shell-based architected materials with topological disorder spanning multiple length-scales, and (b) metal/metal architected composites produced by Laser Powder Bed Fusion of stainless steel with locally tailorable microstructure and phase distributions.

3:45 PM *SF01.02.05
Programmable Strength and Damage-Tolerant Meta-Crystals for Safety Critical Applications Minh-Son (Son)Pham; Imperial College London, United Kingdom

Architected materials are lightweight with high specific strength and excellent energy absorption, holding great promise for a range of structural applications. However, the absolute strength of such materials is low due to the removal of base material, making them unsuitable for safety-critical applications in automobiles, aerospace and space. We recently developed a new approach in which the crystalline microstructure is mimicked to bring key metallurgical strengthening mechanisms to mesostructure scales, creating artificial crystals (i.e. meta-crystals) with new strengthening sources. This presentation will discuss a new horizon in which we synergistically combine the crystal-like architecture and metallurgical engineering (via heat treatments) to significantly push the strength and toughness of metallic meta-crystal for load-bearing and safety critical applications. The talk also discusses new ways of tuning mechanical behaviour to specific locations to enhance the spatial programming of local deformation.

4:15 PM SF01.02.06
Design of Three-Dimensional Complex Truss Metamaterials with Graph Neural Networks and Deep Reinforcement Learning MarcoMaurizi and RayneZheng; University of California, Berkeley, United States

The rapid development of additive manufacturing technologies has enabled the fabrication of truss metamaterials, i.e., a novel class of lightweight-yet-strong materials with engineered complex hierarchical structures. Manipulating the architecture over chemical composition dramatically expands the achievable materials design space, allowing to largely control the mechanical response of metamaterials. While methods such as topology optimization and machine learning have demonstrated to be powerful tools to discover structures with desired material properties, designing three-dimensional (3D) complex truss metamaterials with programmable mechanical behaviors is still a challenge. Here we propose a paradigm, based on graph neural networks (GNNs) and deep reinforcement learning, to design 3D truss metamaterials with programmable nonlinear quasi-static and dynamic responses. By combining the ability of our GNN-based model to accurately predict the mechanical response across multiple orders of magnitude and the explorative power of deep reinforcement learning, together with numerical simulations and mechanical testing, we inverse design truss metamaterials for compressive loading up to 30 % of strain and dynamic transmissibility with desired band gaps. Our method not only demonstrates a pathway to design mechanical metamaterials with desired mechanical behaviors but also provides a flexible framework that can be applied to tailor the response of 3D photonic or robotic metamaterials.

4:30 PM SF01.02.07
Tuning Local and Global Disorder in Architected Materials via Frequency-Based Noise AlexanderGroetsch, KateAinger and LorenzoValdevit; University of California, Irvine, United States

The beauty of architected materials lies in the opportunity to tune their properties *via* their geometrical and topological features [1-3]. We are not limited by the material constituents and can surpass classical engineering materials. Inspired by nature, where structural and mechanical heterogeneity enhances energy dissipation [4] and ductility [5], recent efforts in the metamaterials' community are targeted to harness the effect of irregularities to achieve superior functionalities [6]. These include stress de-localization and imperfection insensitivity, and recent advancements in additive manufacturing allow us to fabricate architectures that incorporate this randomness. However, current efforts to introduce disorder in metamaterials are often restricted to periodicity-disturbances on a global scale. Here, we propose a new design approach that allows us to study the influence of both local and global disorder on the material performance of periodic and random metamaterials. Shell-based topologies are used throughout as model architectures, due to their mechanical advantages (e.g., higher specific strength and energy absorption) over more common truss-based lattices [7]. The mathematically described shell topology is superimposed with frequency-based signals to disturb the "short-range" order, with different frequencies and amplitudes used to tune this local disorder parameter. Characteristic power spectral densities [8] of three frequency-based noise signals – white, pink, brown – are then used to tune the local disorder across the structure, thus introducing a global disorder gradient. To test the influence on both periodic and random metamaterials, triply periodic minimal surfaces (TPMS) and spinodal shell architectures are printed using two-photon lithography, which provides the necessary resolution to incorporate local features in the printing process. The impact of the various levels of disorder on the elasto-plastic behavior of the metamaterial is characterized by means of *in situ* micro-compression tests performed at different strain rates. Our approach allows us to study the effect of local disorder on globally periodic and random structures by overlaying local features with frequency-based signals. In addition, the charactersitic rates of power loss from three different colors of noise introduce a global and tunable disorder gradient opening up new opportunities to design highly multifunctional (meta-)materials.

Finite Element Analysis of Weathering Resistant Spherical Robot Shell Wei-LinWu, Yen ShuoChen and Fu-HsiangKo; National Yang Ming Chiao Tung University, Taiwan

With the fast pace of human civilization development, various types of robots, particularly autonomous amphibious robots, have seen significant advancements in recent research(1). As robots increasingly work in challenging environments to perform specialized tasks, it is critical to have a robot shell that can adapt to various conditions to ensure proper functioning of internal sensing components(2). Therefore, it's crucial to find a material with strong mechanical reliability and good optical properties.
This paper presents a proposed 3D printing resin for spherical robot shells with high transparency in the visible region. The use of 3D printing technology in creating various robots has gained widespread acceptance(3), and the stereolithography (SLA) method has many advantages over other methods, such as relative precision and higher mechanical strength(4). We also conducted a two-month accelerated corrosion test on our print samples. The weather resistance of the printable resin was then evaluated by measuring changes in surface tension, tensile strength, UV-visible and FTIR spectrums.
For the purpose of enhancing the impact resistance, we also performed a mechanical study of 3D printed shells with different layer structures through finite element analysis. The finite element technology has many advantages such as less time, manpower, energy and material resources(5). Our simulation results showed that a protective layer with larger holes offers better protection for the inner cooling ball compared to one with smaller holes, leading to a reduction of 80% in residual deformation energy compared to a single-layer ball.
Besides mechanical test, Passive cooling is an important consideration for the robot shell given the proper functioning of the internal electronic sensors. Recently, radiative daytime radiative cooling (PDRC) has become a high-profile topic due to the intensification of Earth's climate problems (6, 7). Because of the heat dissipation to outer space (3 K) through the 1st atmospheric transparency window (8–13 μm) and in the 2nd atmospheric transparency window (16–25 μm)(8). This approach requires the cooling material to have high emissivity around those atmospheric windows.
In this work, a multiple functional shell fabricated by stereolithography (SLA) technology was developed. we demonstrate the mechanical and weatherability of a spherical robot shell made of SLA 3D printed resin.

Stress Management by Design in Two-Photon Polymerization Printed Structures SarahM. Fess[1], DavidR. Harding[1,2], MarkBonino[1] and YongfengLu[3]; [1]University of Rochester's Laboratory for Laser Energetics, United States; [2]University of Rochester, United States; [3]University of Nebraska–Lincoln, United States

Two-photon polymerization (TPP)-printing millimeter size components with sub-micron features and resolution is an attractive alternative to traditional chemical and machining processes, as it holds potential for increased yields and high controllability. However, maintaining design fidelity can be a challenge in the face of stress-induced deformations which occur during and after the printing process, caused by localized volumetric shrinkage as polymer networks form. This is especially true when many print blocks must be stitched together to form a contiguous larger structure. The extent and manner of deformation can vary greatly depending on print conditions and structural design, even for a single resin, and can lead to misalignment and discontinuity at

the stitching boundaries.

Within the limitations of a commercially available TPP system and resin (Nanoscribe PPGT+/Zeiss 63x NA1.4/IP-Dip2) we seek to fabricate millimeter-scale thin-wall spherical shells with stochastic foam liners for laser-driven fusion experiments. For this application, it is important to maintain wall uniformity and structural integrity across stitching boundaries, and to minimize bulk out-of-roundness. Observed bulk structural shrinkage for IP-Dip2 is typically 5-10%, which can be compensated for by oversizing the design. However, individual high aspect ratio or cantilevered print blocks such thin-wall curved surfaces can deform by >10-µm over a 200-µm arc length. Here we present a method for preemptive stress management via design by using nTop software to section and pre-deform print blocks to correct for anticipated in situ polymerization shrinkage, to within 1.5-µm of the intended location, or on par with the stage repeatability. Characterization of the stitching boundaries via scanning electron microscopy (SEM) and atomic force microscopy (AFM) provides critical feedback for the design and print approach. The intended result is a printed structure with minimal stitching defects and high fidelity compared to the original design.

This material is based upon work supported by the Department of Energy National Nuclear Security Administration under Award Number DE-NA0003856, the University of Rochester, and the New York State Energy Research and Development Authority.

Investigating the Relationship between Quantified Cr_2B Phase Through Image Processing and Mechanical Properties for Metal 3D Printed Alloy DongyongPark, Hyeon JeongPark, Yoon SunLee and Young RokMoon; Korea Institute of Industrial Technology, Korea (the Republic of)

The relationship between the quantified Cr_2B phase through image processing and the mechanical properties of 3D printed 316L stainless steel with boron was investigated. The experimental conditions, including the boron content, feed rate, laser power, and scan speed, were designed using the Taguchi method. The formation of the Cr_2B phase with these processing conditions was quantified using image processing techniques. The algorithm used for image processing was based on the intensity difference between the Cr_2B phase and other phases.
Since the quantity of Cr_2B phase depends on the processing conditions, it directly affects the mechanical properties of the printed stainless steel with boron. The mechanical properties evaluated in this study included tensile strength and micro hardness measured using the Vickers hardness test. The identical processing conditions were used for both quantifying the Cr_2B phase and measuring the mechanical properties. The goal was to identify the relationship between the quantified Cr_2B phase and the mechanical properties.
It is generally known that a high amount of Cr_2B phase can deteriorate the mechanical properties of the material. Therefore, optimizing the processing conditions is crucial in achieving the desired mechanical properties. The results obtained from the signal-to-noise (S/N) ratio analysis for the quantified Cr_2B phase were compared with the S/N ratio results for the measured mechanical properties. This comparison helps in determining the influence of the Cr_2B phase on the mechanical properties and in finding the optimal processing conditions for obtaining the desired mechanical properties.

Laser Powder Bed Fusion Fabricated Near Grain-Oriented and Near Non-Oriented Silicon Steel: A Study on Texture Components and Magnetic Properties FanboMeng, ShengHuang, XiaojunShen and Christopher H. T.Lee; Nanyang Technological University, Singapore

The rapid development of additive manufacturing techniques has opened up new possibilities for the production of complex metallic components with tailored properties. Silicon steel, as the most widely used soft magnetic material, necessities different texture components to meet diverse requirements of various applications (i.e., static machine and rotating machine), and thus is typically categorized as grain-oriented and non-oriented. However, how to fabricate such types of silicon steel via laser powder bed fusion (LPBF) has not been comprehensively investigated until now. In this study, LPBFed near grain-oriented and near non-oriented Fe-3.5 wt.%Si silicon steel is obtained by designing processing parameters. The morphology of the molten pool is characterized through optical microscopy (OM) and scanning electron microscopy (SEM), and various texture features are explored using electron backscatter diffraction (EBSD). Besides, dynamic magnetic properties are assessed by conducting the alternating current (AC) method. The results indicate that the reduction of linear energy density (LED) and laser power induces the side morphology of the molten pool to change from large, flat, and well-overlapped to small, protuberant, and less-overlapped, where this change leads to the formation of an exceptionally pronounced <001>// building direction (BD) (i.e., θ-fiber texture) or random distribution of grain orientations, respectively. Meanwhile, by simultaneously decreasing the laser power and scanning speed, the top morphology of the molten pool transforms from a teardrop shape to an elliptical shape at the trailing edge, which ultimately causes a shift in the angle between the <001> crystallographic orientation of grains in the θ-fiber texture and the scanning direction from 45° to 30°. Moreover, samples with fewer defects (i.e., larger grain size and fewer pores) and a larger area fraction of <001> paralleling to applied magnetic field perform better in dynamic magnetic properties (specifically, higher permeability and flux density), although the extent of this superiority is limited by residual stress and high dislocation density in the as-built samples. This study provides insight into the correlation of processing parameters, texture evolution, and dynamic magnetic properties in LPBFed silicon steel. The results could provide a design reference for LPBFed soft magnetic materials, which further provides the possibility of utilizing additive manufacturing in assisting in fabricating electromagnetic machines.

Rigid and Tough Composite Additive Manufacturing using Co-Axial Material Extrusion of Hard Thermoplastic and Soft Elastomer TaeminKim and SanhaKim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Multi-material additive manufacturing (MMAM) can realize three-dimensional products with extreme complexity not only in their shape but also in their mechanical behavior. Direct writing, vat photopolymerization and material jet type AM techniques have shown their versatile capability to print multiple polymeric materials, yet materials are limited to UV-curable resins and thermoset polymers. Material extrusion 3D printers had also been attempted to print multiple thermoplastics, but the weak interfacial bond due to the cold-hot welding between one layer and the next causes poor overall mechanical properties. Herein, we invented a new multi-material extrusion 3D printer which can extrude thermoplastic polymers in a core/shell configuration. We design and fabricate the nozzle to independently feed three filaments from right, left, and center, which are heated up to melt and unite each other right before the extrusion. In particular, when we insert the right and left filament as the same material, we can print dual-material layer in a co-axial mode. Such strategy allows strong interfacial bond between the different filaments even when the two materials have large contrast in mechanical properties. As a result, we observe unprecedented properties with certain combinations. By extrusion printing the polylactic acid (PLA) and the thermoplastic polyurethane (TPU) in co-axial configuration, for example, we can realize a 3D specimen which exhibits stiff as the hard PLA yet elongates as the soft TPU before failure, therefore possess an extreme rigidness and toughness. In detail, the core/shell extrusion printing enables the brittle PLA core to elongate about 30 ~ 50 times more than their original fracture strain, and such super-ductility is driven by the chemical bond between the two extruded materials. We further investigate diverse thermoplastic polymer combinations and verify that such exceptional outcome is only possible when a strong interfacial adhesion develops via the existence of hydrogen bonds. We discuss the fracture mechanism of our extruded co-axial polymer fibers and the chemical aspects at the interface. We also show a more variety of functionality that can be realized by extruding three different filaments in the co-axial nozzle. Applications that are now possible via bi-material and tri-material extrusions show that co-axial multi-material extrusion 3D printing opens a new avenue toward versatile material design, for additive manufacturing of fully customizable protective wearable devices and artificial muscles.

Machine Learning-Based Predictive Model for Jet Flow Rate in Electrohydrodynamic Direct-Writing DongwoonShin, YongraeKim, Pil-HoLee and JoonphilChoi; Korea Institute of Machinery & Materials, Korea (the Republic of)

Electrohydrodynamic direct-writing (EDW), also known as near-field electrospinning, is an extrusion-based additive manufacturing (AM) approach. One of the prominent advantages of EDW over other extrusion-based printing techniques is its utilization of electric forces to deposit fibers with orders of magnitude smaller diameters compared to nozzle diameters, enabling much faster printing speeds. As a result, the fiber diameters achievable through EDW can range from the micro to nanometer scale. Furthermore, EDW employs polymer solutions in a liquid state as printing inks, which broadens the range of available polymers and solvents. Consequently, EDW has been employed to print various functional polymers, finding applications in diverse fields including fiber lithography platforms, energy harvesting, gas sensors, and scaffolds for tissue engineering.
Having precise control over the fiber diameter and shape is of great importance in order to tailor the desired properties of the printed fibers, such as electrical resistance, birefringence intensity, sensor sensitivity, and porosity. However, the Electrohydrodynamic direct-writing (EDW) technique has encountered challenges due to the lack of prediction methods for the printing outputs, including fiber diameters or deposition patterns. As a result, the EDW process has heavily relied on a time-consuming trial-and-error approach to achieve the desired fiber properties. Therefore, the development of practical and purposeful predictive models is crucial for driving innovation and potentially commercializing the EDW method, similar to other state-of-the-art extrusion-based additive manufacturing (AM) techniques. Nevertheless, due to the complex multiphysics mechanism of EDW and the wide range of process parameters involved, developing a predictive model to identify the optimal process parameters presents a highly challenging task.

Machine learning (ML) is a branch of artificial intelligence (AI) that involves an ML model learning the relationship between input and output features to uncover hidden patterns. The application of ML has gained significant popularity in additive manufacturing (AM) processes, particularly due to the complex physics involved in AM processes such as rapid evaporation, solidification, and ingestion, which surpasses traditional manufacturing methods. Unlike traditional physics-based equations that require explicit programming, ML models can learn these relationships, making them rapid, practical, and analytical prediction tools for AM processes. Consequently, ML-based models have been developed for tasks like geometrical design, process optimization, and anomaly detection in various AM techniques, including fused deposition modeling, power bed fusion, direct energy deposition, direct ink write, and aerosol jet printing. Moreover, ML-based models hold promise as potential candidates for optimizing the Electrohydrodynamic direct-writing (EDW) process, surpassing the capabilities of physics-based models in practical applications.
In this poster presentation, we will introduce a framework for developing an ML-based predictive model of jet flow rate in Electrohydrodynamic direct-writing (EDW). To accomplish this, a monitoring system was established to capture actual images of the jet profiles during the EDW process. Subsequently, image analysis techniques were employed to extract jet profile data, which was then utilized to train a multi-output regression model using artificial neural networks (ANNs). A comparison between the predicted and observed jet profiles demonstrated the model's high prediction accuracy. The proposed approach presented here represents a futuristic method for optimizing the EDW process and holds tremendous potential for realizing smart manufacturing of functional micro/nanofibers through EDW.

Challenges and Opportunities for Machine Learning Accelerated Materials Qualification for Brittle Particle Cold Spray ChengZeng, AndrewNeils, NathanPost and JackLesko; The Roux Institute at Northeastern University, United States

Brittle particle cold spray is a low-pressure and low-temperature manufacturing technique developed by TTEC, a company based in Virginia. It can produce dense brittle particle coatings at a high deposition rate and low-energy cost with unlimited thickness. Applications include high temperature thermal barrier coatings, all-solid-state batteries and corrosion resistant coatings. However, the application of this technique to new material systems currently requires extensive trial and error to get the correct size and morphology distributions and spray parameters. In order to accelerate qualification of new materials for this process improved understanding of the mechanics of particle impact and consolidation is required. The mechanism of impact consolidation can span in different length scales, ranging from atomic chemical bonding to mechanical interlocking. Moreover, the complex cold spray technique involves multiple physical phenomena, such as fluid dynamics, aerodynamics, heat transfer and deformation. A combined multiscale and multiphysics approach is needed to develop a thorough fundamental understanding of brittle particle cold spray. Recent advances in machine learning approaches have great potentials in improving our understanding for linkages between process-structure-property. Here, we review current multiscale and multiphysics methods, and machine learning algorithms for cold spray technology, and we discuss remaining challenges and present an outlook for future research opportunities in this area.

Conformal Direct Ink Write Additive Manufacturing via a 6-Axis Robotic Arm RobertLahaie, RoneishaHaney, JamesHardin and AnesiaAuguste; Air Force Research Lab, United States

Reliable printing of materials onto any surface, regardless of its shape, is a key enabling technology for many processes. Traditionally, most additive manufacturing techniques require a 3-axis gantry system which only moves planarly in the XYZ directions, limiting the type of print surface and the orientation achieved relative to the surface. Print direction and orientation is widely known to largely affect the material properties of additively manufactured components especially in prints using anisotropic materials. Recently, there has been increased interest in additive manufacturing using 6-axis robotic arms, however, research is limited on how the additional degrees of freedom of motion affect the material properties compared to a gantry system. This work investigates the effects on the anisotropic material properties by utilizing the additional degrees of freedom the robotic arm enables to maintain the direct ink write (DIW) nozzle constantly normal to a contouring surface. We compared the printed components produced by a 6-axis robotic system to a traditional 3-axis gantry system to investigate how remaining normal to the print surface affects the mechanical properties, fiber alignment, and geometrical accuracy. The research will compare the similarities and differences of the robotic system to the traditional gantry system using anisotropic carbon nanotube carbon fiber Epon 826 resin along a contoured surface, which has relevance on structural materials, electronics, and flexible devices.

Supramolecular Polymerization Enables Additive Manufacturing of Fatigue-Resistant, Tough Materials JiyunKim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Photopolymerization is being effectively applied in the field of 3D printing due to its fast and easy process for creating complex 3D objects. However, due to the rapid polymerization speed, polymer networks inevitably exhibit inhomogeneity, and applied stress becomes concentrated at those points. This leads to structural destruction and results in the low durability of 3D printed objects.
Here I present a supramolecularly polymerizable photopolymer enables tough 3D objects. We designed the photopolymer with stickers in its backbone, and these stickers assemble through hydrogen bonding, forming nanostructures even before light exposure. By using this photopolymer as a crosslinker to form a polymer network, applied stress can be effectively dissipated through sacrificial bonds in the nanostructures. As a result, the photopolymerized system exhibits superior mechanical properties such as stretchability, toughness, fracture toughness, and fatigue threshold, despite its inhomogeneity. Moreover, this photopolymer can be applied to various monomer systems to achieve desired characteristics and good mechanical properties. These results demonstrate that this photopolymer can be utilized as a versatile photocrosslinker in 3D printing applications.

Optimizing Process Parameters in Selective Laser Melting for Enhanced Mechanical Properties of 17-4PH Stainless Steel KyuHyunKim and In-SukChoi; Seoul National University, Korea (the Republic of)

Selective Laser Melting (SLM) is a key technique in metal 3D printing, involving the repeated melting of metal powder using a laser, followed by its layer-by-layer solidification. This technique enables the fabrication of products with intricate designs and complex geometries, making it indispensable in high-precision industries such as aerospace, automotive, and healthcare. However, the rapid heating and cooling during the layering process could induce porosity and changes in the microstructure, which may significantly reduce the durability and strength of the components.

In this study, we examined the influence of porosity and microstructure on the mechanical properties of components produced using 17-4PH stainless steel powder, a material predominantly employed in the aerospace sector. Initially, we modulated the energy density by varying laser power and scan speed, and monitored the evolution of porosity via Optical Microscopy (OM). Following this, we analyzed the microstructure and phase fraction with Scanning Electron Microscopy (SEM) and Electron Backscatter Diffraction (EBSD), and investigated the correlation with mechanical properties derived from hardness and tensile tests. Ultimately, we aimed to identify optimal process parameters that minimize porosity and maximize mechanical performance through control of phase fraction changes.

The findings of this research underline the importance of porosity and microstructural control in SLM processes, as they significantly impact the quality of materials and performance of parts. This insight is anticipated to draw considerable attention, particularly in the aerospace industry, where high-strength components are of critical importance.

8:00 PM SF01.03.11
Impact of Nanoparticle Size and Loading on Printability of Polymer-Nanoparticle Composite Inks for Direct Ink Writing YunLi[1], AidanFlynn[1], ChristopherMasternick[1], BrandonKolanovic[1], BinLi[2] and BoLi[1]; [1]Villanova University, United States; [2]Wichita State University, United States

Direct ink writing (DIW) is a most inclusive 3D printing technology in which polymer can be mixed with different nanoparticles and create 3D structures with a wide range of mechanical properties and functionalities. The key challenge of DIW process is the creation of printable inks. Although a significant process has been made to develop printable recipes with different combinations nanoparticles, polymers, and solvents, two fundamental questions have not been elucidated: 1) how to evaluate the printability of the ink and 2) how nanoparticle size and loading affect ink printability. To bridge this gap, this work utilizes the SiO_2 nanoparticle-Polydimethylsiloxane (PDMS) system and evaluates three commonly used printability analysis methods—dual-layer printing analysis, ink rheology, and printing line width analysis. The influence of particle size (diameter = 26 nm-847 nm) and loading (0-66.67 wt.%) were systematically studied. Through the comparison, dual-layer printing analysis (DLPA), in which the merging behavior of two vertically stacked printing layer was analyzed, is found to be the most direct and reliable method to evaluate printability. The printability factor (Pr) in DLPA approaches 1 means less merging between layers and good printability and empirically Pr = 0.9 is set as a critical value for printable ink. To achieve this critical value, for 26 nm nanoparticles, a small loading of 2.91 wt% is required, while for 847 nm nanoparticles, 28.57 wt % is required. Increase the particle size will improve Pr but there is an upper limit under the fixed printing pressure and nozzle size. The highest printable particle loading is 66.7 wt% for 847 nm nanoparticles under 120 psi with a nozzle diameter of 300 μm. Our results conclude that nanoparticles can be utilized to tailor the DIW materials from soft bio gels to strong ceramics. Moreover, the comparison of different analysis methods highlights the need for developing generic standards to evaluate printability.

A Dimensional Analysis of a 15-5 PH Steel Part Built by Laser Powder Bed Fusion Process AbhishekKumar, SaurabhTripathi and CheruvuS. Kumar; Indian Institute of Technology, Kharagpur, India

With the increased functionality of additively made parts, the necessity for dimensional accuracy must be prioritised. Dimensional accuracy refers to how well the printed part fits the dimensions specified in the design. High dimensional accuracy is critical for ensuring functional fit, assembly, and overall quality of printed parts. Dimensional accuracy is affected by several factors, such as material shrinkage, layer thickness, resolution, thermal effects, machine calibration, and support structures. To compensate for shrinkage and thermal effects, beam offset is provided.The aim of the present experimental study is to do the dimensional analysis of a 3D-printed part using LPBF. The parts were made with chamfers to measure and calculate the dimensional accuracy of the part at different settings of the hatch-contour. In this experiment, an experiment-based design approach was adopted in which the process parameters, such as hatch offset, contour offset, minimum vector length, and hatch contour offset, were varied. The effect of these process parameters was studied. The prepared samples with different values of hatch offset and contour offset are cleaned, and a clear image of their chamfer at each corner is taken using an optical microscope. Then, using the ImageJ software, the shortest and longest lengths of the chamfer are measured and recorded. Scanning electron microscopy is also used to see the effect in the best case. It is then calculated how much they deviate from the theoretical length we got from the CAD file. It can be concluded that dimensional errors increase with an increase in hatch offset. In this case, a hatch offset of 0.03 mm, contour offset of 0.32 mm yield the minimum error in dimension.

8:00 PM SF01.03.13
Ultrahigh-Strain-Rate Tribological Nonlinearity and Adhesion Mechanism of Diblock Copolymers for Polymer-Based Cold Spray AraKim[1], SinanMüftü[2], EdwinThomas[3] and Jae-HwangLee[1,1]; [1]University of Massachusetts Amherst, United States; [2]Northeastern University, United States; [3]Texas A&M University, United States

The adhesive strength between feedstock microparticles and pre-deposited layers and the collision-induced material behaviors determine the quality of cold-sprayed products. Unlike ductile metals, polymers having weak intermolecular interactions present severe nonlinear dynamic response due to their rate-dependent and temperature-dependent material characteristics resulting from the relatively slow macromolecular dynamics with low phase transition temperature The distinctive complexity requires a comprehensive understanding of the collision-induced rheological changes near the collision interface, affecting interfacial friction and determining adhesion during impact. However, the interfacial response during ultrahigh-strain rate (UHSR) collision has not been thoroughly studied. As an experimental approach to gain deeper insight into the collision-induced rheological characteristics of polymeric microparticles at the collision interface, the angled laser-induced projectile impact test (θ-LIPIT) with an off-normal incidence angle was introduced in this work. A colliding microparticle with 45 degrees of the incidence angle undergoes moderately distributed compression and shear motions without arresting at the target substrate during the UHSR collisions.
Controlling or predicting the dynamic nonlinearity of polymers resulting from the rate- and temperature-dependent material properties is crucial for the applications of polymers in cold spray additive manufacturing. Therefore, diblock copolymers consisting of mechanically distinctive multi-domains are intriguing materials as their material properties are tailorable by adjusting the volume fraction of the respective chain blocks. Polystyrene-block-polydimethylsiloxane copolymers having glassy- and rubbery-domains are used for microparticle production. Using a lab-built ultrasonic atomization system, block copolymer solutions are solidified into spherical microspheres with 10 – 30 μm diameters via spraying and hot-air solvent drying. These microparticles are then impacted onto rigid substrates such as silicon wafers during the θ-LIPIT.
Due to the relatively large incidence angle and diameters, adhesion of microspheres does not occur in the θ-LIPIT but minor polymeric residues are occasionally found on the surface of the substrate. Impact and rebound velocities are decomposed along the horizontal and vertical directions to the collision surface, and the resultant coefficients of restitution are used to quantify the effective coefficient of friction representing the UHSR rheological changes of a microparticle at the collision interface.
The effective coefficients of friction obtained from the θ-LIPIT reveal that the collision-induced rheological changes resulting from thermal softening near the collision interface determine the tribological nonlinearity during the UHSR event. Furthermore, It is further thought that this rheological response could alter the adhesion strength of the polymer microparticles by increasing chain mobility. The rheological changes of polymeric microparticles are thus thought to determine their adhesion behavior as the compression-induced shear stress flow along the tangential direction to the collision surface is expected to generate thermal softening in the material near the interface.
Systematically conducted research with θ-LIPIT demonstrates the collision-induced rheological changes near the interface and the resultant tribological conditions for adhesion during UHSR collisions. The demonstrated methodology in this study is expected to be utilized to examine the cold spray applicability of polymers and to predict spraying conditions for cold spray using solid-state consolidations of feedstock powders.

Metrology of Shrinkage-Induced Deformation in Structures Made using Two-Photon Polymerization MarkBonino, DavidR. Harding, SarahM. Fess, MadelynJ. Jeske and MitchellJ. Anthamatten; University of Rochester, United States

Two-photon-polymerization (TPP) printing provides a deterministic method compared to traditional processes for fabricating millimeter-size spherical and hemispherical polymer parts with nanometer precision. The small print field ($<0.2 \times 0.2$ mm^2) needed to achieve the highest resolution, however, requires individual blocks be printed and “stitched” together to achieve the final component. A consequence of this methodology is that shrinkage from polymerization and the residual stresses in the printed polymer create a misalignment of up to 10 μm with the adjacent print block; these offsets need to be reduced to less than 1 μm. Fortunately, the TPP process is sufficiently precise that the misalignments can be compensated in the design, provided the magnitudes and locations are accurately known.

This presentation describes the metrology used to characterize highly curved surfaces (radius of curvature <1 mm) of spherical and hemispherical structures. The change in curvature of individual print blocks along their lengths and widths is quantified for different laser doses (combination of laser power and scan speed) and print-block sizes, and is used to optimize the printing conditions for improved surface roughness and sphericity. Atomic force microscopy and variable-pressure scanning electron microscopy are used to acquire the data. The quality control and metrology techniques applied to TPP shells are presented.

This material is based upon work supported by the Department of Energy National Nuclear Security Administration under Award Number DE-NA0003856, the University of Rochester, and the New York State Energy Research and Development Authority.

8:00 PM SF01.03.15
Reducing the Anisotropy in Fused Filament Fabrication Additive Manufacturing by Blending a Diels-Alder Covalent Adaptable Network with Polycaprolactone DerekJ. Bischoff and MichaelE. Mackay; University of Delaware, United States

Additive manufacturing (AM) is an emerging polymer processing technique that allows users to create complex geometries and customized parts with ease in addition to rapidly iterate on prototype designs, making it a valuable tool for product development. The most popular AM technique is based on material extrusion where spools of thermoplastic filament are the raw material that is fed into a hot end where it is melted and extruded through a nozzle on the order of 0.4mm in diameter. The deposited tracks of material are stacked on top of each other in a layer-by-layer sequential manner to build the object. A variety of thermoplastics are commercially available such as polylactic acid (PLA), acrylonitrile butadiene styrene (ABS), and polyethylene terephthalate glycol (PETG) to use on consumer grade desktop machines such as a Prusa i3 MK3S. A limiting factor of these materials is the high degree of anisotropy when 3D printed, as determined by printing tensile testing specimen where the interface between tracks is either parallel (stronger) or perpendicular (weaker) to the tensile stress. The mechanical strength of printed objects is limited by the healing that occurs at the interface. Since interfaces are required to build in the Z-direction off the bed, the term Z-strength is typically used. Due to the highly non-isothermal nature of the printing process, the thermoplastic material only remains above T_g, enabling the reptation and entanglement of polymer chains across the interface, for a brief period of time, on the order of a second. To eliminate the anisotropy in printed objects, new materials specifically designed for AM are necessary that shift the strengthening mechanism from polymer chain diffusion to something else.

Thermosets are the other major class of polymers that contain crosslinked chains to form a network architecture. The static crosslinks that offer improved mechanical properties and dimensional stability prevent thermosets from flowing, making them incompatible with the AM process. By using reversible covalent bonds in place of static crosslinks, thermosets are transformed into covalent adaptable networks (CANs). CANs behave as thermosets when the reversible covalent bonds are in their adduct state, but can flow when the bond exchange reaction is activated upon exposure to an appropriate level of stimulus (heat, light, pH, etc.). One such reversibly dynamic covalent bond is made from the Diels-Alder (DA) reaction between furan and maleimide functionalities. When exposed to a thermal stimulus, the covalent bonds begin to dissociate and exchange, enabling the CAN to flow as a viscoelastic fluid at elevated temperatures. Upon cooling, the material recovers crosslinking density and the rate of bond exchange slows. CANs have been used successfully in the AM literature to reduce the anisotropy in printed objects since covalent bonds form between tracks, however, they typically require specialized machines using cold air on the build plate to cool the object or use a syringe loaded with the material, necessitating a custom feed system different from the usual thermoplastic spools. In this work, a highly crosslinked DA CAN is blended with polycaprolactone (PCL) to create a

semi-interpenetrating polymer network (IPN) that has enough flexibility to be extruded into a spool to be used in commercially available 3D printers without modification. Without the PCL, the DA CAN is too stiff preventing it from being spooled. The CAN/PCL semi-IPN is shown to reduce the degree of anisotropy from >60% in PLA for example to only 11%. Microscopy of the cross sections reveal that the void space typically found in between tracks of material has vanished and is attributed to the viscosity of the material at the printing temperature. The fracture surfaces reveal that a ductile failure mechanism takes place in the tensile testing specimen, improving the toughness of the material compared to pure DA CAN.

Development of Filament Manufacturing Technology and Selection of 3D Printing Process Parameters for Biodegradable Material Blends to Optimize Print Quality PiotrMakula, AnnaDmitruk, PawelKaczynski, JoannaM. Ludwiczak and MateuszSkwarski; Wroclaw University of Science and Technology, Poland

Biodegradable materials are increasingly being used, with their utilization being legislated in some cases and a conscious choice of users in others. Poly(lactic acid) (PLA) is a commonly used biodegradable material for 3D printing in Fused Filament Fabrication (FFF) technology. Besides its print hardness, the low purchase cost also contributes to its popularity. The study has shown that effective utilization of mixtures of Poly(lactic acid) (PLA) with poly(butyleneadipate-co-terephthalate) (PBAT) or thermoplastic starch (TPS) for 3D printing is possible. The aim of their production is to modify the mechanical properties of PLA by increasing its flexibility while maintaining the biodegradability of the material.
After analyzing the literature, a successful attempt was made to produce a filament with a diameter of 2.85 mm, which was later used to manufacture samples. The material, after the extrusion process, underwent three consecutive drawing operations through a die on a specially adapted drawing machine. These operations were carried out to reduce and stabilize the filament diameter. The mixtures were prepared in the following mass ratios:
PLA50%-PBAT50%(PBAT50)
PLA30%-PBAT70(PBAT70)
PLA50%-TPS50%(TPS50)
PLA30%-TPS70(TPS70)
The printer parameters were calibrated before starting the sample printing, which ensured the correct structure of the prints. The tensile tests were initially conducted on the elements printed perpendicularly to the tensile axis. During the printing process, temperatures ranging from 190-27degree Celsius [C] were set, with a step of 1C. The aim of that test was to determine the optimal temperature that provides the best layer bonding. At the most optimal temperatures (PBAT50 - 230C , PBAT70 - 220C, TPS50 - 210C, TPS70 - 210C), the samples were destroyed by brittle fractures rather than layer delamination.
The next research step was to test the strength of longitudinally printed samples. The experiment showed that when the layers were arranged in this orientation, the material strength was comparable to the homogeneous material obtained through injection molding. The PBAT50 material exhibited layer delamination during stretching, but it did not fracture in a brittle manner. In the case of the second material, PBAT70, the samples behaved like a typical ductile material during stretching. They stretched evenly along their entire length, and no local necking occurred. Mixtures of TPS with PLA, when printed like the previous samples, exhibited more brittle fractures. However, the mechanical values were comparable to those of homogeneous samples.
In the summary of the study, a comparison was made between the obtained results and the results obtained from tests on homogeneous samples produced by injection molding. The results show that the material printed perpendicular to the stretching axis can withstand a 70% of the strength of the homogeneous material. The same result was obtained for all mixtures. Longitudinally printed samples achieved similar results in terms of strength and the shape of the stress-strain curve. However, they present a faster decrease in strength immediately after exceeding the yield point.
The conducted research can be effectively utilized in further studies and to model the behavior of the material for finite element analysis methods.

Study on the Multifunctional Sandwich Structure Fabricated by 3D Printing Hui-JinUm[1], Na-HyunJeon[1] and Hak-SungKim[1,2]; [1]Hanyang University, Korea (the Republic of); [2]Hanyang Research Center for Advanced Semiconductor Packaging, Korea (the Republic of)

Reducing fuel and energy consumption, greenhouse gas emissions, and other air pollutants is a major goal for the global transportation sector, including aerospace, automobiles, and railways. As an approach to achieving this goal, there has recently been a growing movement to change internal combustion engines to hybrid or electric engines. Secondary batteries, such as lithium batteries, are mainly used as energy sources for electric vehicles (EVs), so studies are being conducted to increase mileage. One way to increase mileage is to have a high-capacity battery, which requires more space for batteries and increases the weight of the electric vehicle. For this reason, reducing the weight of the structure is essential to achieve longer mileage. There is a growing interest in structural design using fiber-reinforced plastic composites instead of steel and aluminum. Especially, carbon fiber-reinforced plastic composites (CFRP) with high specific strength and non-rigidity are in the spotlight.
To achieve higher mechanical load-bearing properties using lightweight materials such as CFRP, a sandwich structure consisting of skins and cores can be applied to the structural design. The core of the sandwich structure mainly uses low-density plastic foam or consists of a lattice structure to increase bending properties while lowering the overall weight of the structure. These sandwich structures can be applied to multifunctional structures that can increase energy storage capacity and save space for electric vehicles. The sandwich structure of the neutral axis is hardly affected by the load, so the battery can be integrated into that position to provide reliable energy storage. Thomas et al. integrated a LiPo battery into a foam-core sandwich structure and analyzed mechanical properties through the bending test. However, the flexural failure strength of the multifunctional sandwich structure was reduced by 57% and the bending load partially increased the battery's internal resistance. In other words, the load-bearing properties and energy storage capabilities of multifunctional structures are in conflict with each other.
In this study, the multifunctional sandwich structure using lattice structure cores was designed and manufactured to overcome these limitations. 3D printing technology using continuous carbon fiber filament was applied to implement a lattice structure of complex shapes. The multi-functional composite sandwich structure was manufactured by embedding a LiPo battery using an empty space in the 3D-printed corrugated lattice core. Static and cyclic 3-point bending tests were conducted for analysis of the mechanical characteristics. The battery capacity change was analyzed through battery charge/discharge test before and after the mechanical tests. For the 3D-printed corrugated sandwich structure, the mechanical characteristics were maintained regardless of whether the battery was embedded or not, and the battery was not damaged by external loads. In other words, the battery damage caused by external loads was minimized by utilizing the empty space of the core of the lattice structure, and the degradation of mechanical characteristics was minimized.

Carbon Quantum Materials for Two-Photon Polymerization: A New Approach in Rapid Additive Manufacturing ArunJaiswal[1,1], SwetaRani[1], GauravP. Singh[1], MahbubHassan[2], AklimaNasrin[2], VincentG. Gomes[2], SumitSaxena[1,1] and ShobhaShukla[1,1]; [1]Indian Institute of Technology Bombay, India; [2]The University of Sydney, Australia

3D/4D additive manufacturing technologies have played a crucial role in the development of various miniature sensors, lab-on-a-chip devices and other ultracompact devices, due to their capabilities of generating functional elements with well-defined geometries and subwavelength resolutions. These functional nanostructures incorporating novel nanomaterials formulations are pivotal in the realization of next-generation technologies, and are derived from doped/functionalized materials exhibiting specific response towards external stimulants. The overall response depends on the nanostructure constituents as well as their structural attributes. Material formualtions and fabrication capabilities are crucial for further development of such structures. Vat polymerization-based fabrication techniques, especially two-photon polymerization-based nanofabrication allows simultaneous exploitation of structural and material attributes, and hence has emerged as popular choice for realization of 2D/3D/4D elements of the functional devices. Two-photon lithography is well established in terms of its fabrication capabilities, but the responsivity of the structures towards each agent is dependent on a specific dopant, and to attain multifunctional structures, more and more number of dopants are required to be incorporated into the resin. However, the addition of multiple dopants is not recommended for vat polymerization-based systems, as it affects the stability of the resin, interferes with the excitation beam and degrades the printing performance. Additionally, few dopants such as metal/semiconductor nanoparticles offer limited solubility and hence tend to settle, resulting in non-uniform doping of the fabricated structures. To address these issues there is a need of development of a material system with minimal components, providing multifunctional attributes. In this context we report use of carbon nanomaterials as multifunctional additives in two-photon polymerizable resin formulation. The proposed resin allows tailoring of the responsivity of the micro/nanostructures just by simple surface engineering of the carbon nanomaterials. In this work, we demonstrate the multimodality of carbon nanomaterial wherein they i) facilitate two-photon upconversion, (ii) enable efficient two-photon polymerization of acrylates and (iii) are responsible for the fluorescent staining of the polymerized structures. This work paves pathways towards implementation of multifunctional nanomaterials for development of the next-generation smart devices.

On-Demand Rapid Fabrication of Components using Forward Operating Base Aluminum Waste DanyangZheng, YutaoWang, MishraBrajendra and JianyuLiang; Worcester Polytechnic Institute, United States

According to the study conducted by the US Army Research Laboratory (ARL), and the US Natick Soldier Research Development, and Engineering Center (NSRDEC), aluminum waste makes up the Second largest category of metals in solid waste generated on forward operating bases (FOB). Therefore, an agile manufacturing process that can reclaim and recycle aluminum waste on battlefields is highly desirable. In this project, a 3D printing-enabled rapid-casting manufacturing process was developed to reuse Al waste and a mobile foundry system based on this process has been designed.
This remanufacturing process includes three main stages: the preparation stage, the casting stage, and the post-treatment stage. It starts from the 3D design of the casting mold, using advanced software to conduct a simulation to minimize the defects in the cast parts. Then 3D printing is used to fabricate the polymer pattern according to the design. These polymer patterns are covered with coating. After drying, the patterns are removed by a burn-out process to obtain the needed cast molds. On the other hand, the waste metal alloys from FOBs are collected and sorted. The harmful impurities are removed. The Al wastes are then blended according to the desired composition of the target product. This composition can be further adjusted during the melting process.
After the molten metal with the desired composition is obtained, it is poured into the cast molds. Finally, after the solidification of the metal, the mold is removed, and necessary post-treatments are conducted to ensure the quality of the parts. The information obtained from qualify control can be used as feedback to further improve the mold design and the composition adjustment for re-alloying.
A mobile foundry design that places this rapid casting process in standard-sized shipping containers as developed to efficiently convert battlefield waste into valuable products. The mobile system consists of three containers: the first for investment preparation, the second for casting and heat treatment, and the third for product characterization. A simulation has been conducted to ensure the safety of the casting container.
In this presentation, the results and outcomes of this project will be discussed. The lessons learned and future work will be introduced.

8:00 PM SF01.03.20
3D Printing and Biocementation of Hierarchical Porous Ceramics AlessandroDutto, ElenaTervoort and AndréR. Studart; ETH Zürich, Switzerland

Novel low-cost and low-energy strategies for the consolidation of ceramic materials are demanded to reduce the environmental impact of the building sector. Living building materials containing soil microorganisms have shown to be a promising strategy to bind together aggregates or sand-based materials into bricks at room temperature taking advantage of the microbially induced precipitation of calcite (MICP).
The effectiveness of the precipitated calcite network in providing the required structural integrity relies on the uniform distribution and activity of the microbes, as well as the availability and diffusion of nutrients and precursors for the MICP throughout the bulk of the material. Current technologies overcome the limits of diffusion by actively pumping a calcifying solution and by optimizing the calcification setup. Despite the commercial use of this approach, partial clogging or the formation of an outer calcite shell hinder the access of further precursors and thus remain unsolved challenges of this technology.
Here, we take advantage of additive manufacturing to develop and study a bio-cementation process to create strong, porous ceramics at room temperature. Hierarchical porous structures were produced via direct ink writing of cellular grids using bacteria-laden suspensions of ceramic hollow spheres. The effect of geometry, bacterial concentration, and calcification time on the bio-cementation process and the resulting mechanical properties were investigated. The presence of a millemeter-sized open porosity was found to be essential to maintain a high permeability to the precursors during the entire process, ensuring an optimal MICP throughout the material.
The presence of porosities at multiple length scales has a beneficial effect on both the biocementation process itself and on the mechanical efficiency of the produced structures. Combining 3D printed hierarchical porous structures with the low-energy consolidation process of MICP, allows us to produce strong, porous ceramics with reduced environmental impact.

Mechanical Characterization of Additively Manufactured Ceramic Nanocomposites Reinforced by Boron Nitride Nanotubes DingliWang, NasimAnjum and ChanghongKe; State University of New York at Binghamton, United States

Ceramic materials face significant challenges in industrial applications due to their inherent fragility and limited manufacturability. These limitations can potentially be overcome through the use of reinforcements and additive manufacturing (AM) techniques. Boron nitride nanotubes (BNNTs) exhibit many exceptional structural and physical properties, making them promising candidates for reinforcing ceramics and creating lightweight, strong, and durable ceramic materials. These characteristics are attractive to a number of industries, such as aerospace, automotive, and biomedical sectors. The reinforcement potential of BNNTs for ceramic composites is supported by our recent findings of efficient interfacial load transfer in BNNT-ceramic nanocomposites, which is attributed to the partially ionic B-N bonding and the resulting rugged anisotropic energy landscape. Here, we investigate the bulk mechanical properties of AM-produced BNNT-reinforced silica (SiO_2) nanocomposites. Our study aims to elucidate how the superior interfacial load transfer characteristics observed at the nanoscale translate into enhancements in the bulk mechanical properties of these nanocomposites. The BNNT-silica nanocomposites employed in our study are additively manufactured using digital light processing (DLP) techniques. Our study shows that the addition of a small quantity of BNNTs can substantially enhance the AM-produced ceramic nanocomposite's bulk mechanical properties (flexural modulus and strength, and fracture toughness). We further analyze the local interfacial load transfer within the AM nanocomposite through *in situ* Raman micromechanical measurements. The findings provide valuable insights into the role of the nanotube-ceramic interfacial strength in enhancing the mechanical properties of the nanocomposite. Our research contributes to a better understanding of the relationship between process, structure, and properties in AM-produced ceramic nanocomposites and the development of durable and reliable ceramics technology.

8:00 PM SF01.03.22
High Pressure Heat Treatment for Porosity Reduction of Binder Jet 17-4 PH Stainless Steel EllenTroyanosky, ChuhaoLi, RichardSisson and JianyuLiang; Worcester Polytechnic Institute, United States

The age hardenable 17-4 PH stainless steel has been additively manufactured (AM) using the binder jet (BJ) method. To achieve comparable mechanical properties to wrought steel, the porosity must be reduced in the AM steel. Two sets of BJ, one starting with high porosity and the other low porosity, are treated to the traditional 900H age hardening treatment or a combined hot isostatic pressing (HIP) and 900H treatment, referred to as High Pressure Heat Treatment (HPHT). The effects of change in porosity and pore morphology on the microstructure, mechanical properties, and distortion are examined. These experimental results indicate that the HPHT process is more effective than the 900H treatment at reducing porosity and improving performance.

Dual Material Fused Filament Fabrication via Core−Shell Die Design AhmadNaqi[1,2] and MichaelE. Mackay[1,1]; [1]University of Delaware, United States; [2]Kuwait University, Kuwait

In this work a fused filament fabrication (FFF) die design, capable of extruding two thermoplastics simultaneously in a core−shell configuration, is demonstrated as a means to produce composite structures in a single step. Despite the enormous advancements in 3D printing, fabrication of FFF objects with a composite structure remains a challenge due to the difficulty in finding dies to extrude such structures. We used polyethylene terephthalate glycol (PETG) and high-density polyethylene (HDPE) filaments to perform core−shell 3D printing. HDPE is one of the most commonly produced plastics but rarely used in FFF due to the severe warpage caused by volume changes upon its crystallization. Rheological and thermal analyses suggest the use of HDPE as a shell material due to its extremely short reptation time and sharp melting peak that facilitate superior surface contact and interlayer weld strength at the interface between neighboring FFF tracks. PETG is a commonly used 3D printing filament with excellent printability and sufficient zero shear viscosity to help maintain the extruded filament shape against shrinkage induced by the HDPE shell.

Impact and tensile properties of core−shell objects revealed tremendous improvements in the impact resistance and toughness especially at 30 vol % HDPE shell with 1280% and 150% enhancement in impact resistance when compared to individual components: PETG and HDPE, respectively. Scanning electron microscopy was used to analyze the fracture morphology of the tested specimens to obtain an understanding of the fracture mechanism leading to the increased impact resistance. Using this die design can help open avenues of fabricating high impact resistance materials suitable for high performance applications and using HDPE in 3D printed objects with its superior solvent resistance.

8:00 PM SF01.03.24
Anisotropic Macro- and Micro-Mechanical Creep Properties of Additively Manufactured Ti–6Al–4V ELI Alloy Jeong-RimLee[1], Min-SuLee[1], Si MoYeon[2], Chung-SooKim[2] and Tea-SungJun[1]; [1]Incheon National University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

The present study investigates the nanoindentation-based creep behavior of Ti-6Al-4V extra low interstitial (ELI) alloy fabricated using laser powder bed fusion (L-PBF) at ambient temperature. Nanoindentation creep tests were performed on both the vertical and horizontal planes with respect to the building direction for the as-built and stress-relieved samples. Various

peak loads (100, 200, 300 mN) were applied with a holding time of 1000 s using a spherical indenter. Creep parameters, such as creep rate and creep stress exponent, were analyzed using the Oliver and Pharr method.
The results of the nanoindentation creep tests indicated that the horizontal plane exhibited higher creep resistance than the vertical plane in the as-built sample. However, the creep behavior of the stress-relieved sample showed greater sensitivity in the horizontal plane, consistent with macroscale time-dependent responses. To understand the underlying factors contributing to the anisotropic creep behavior at different deformation scales and stress relief conditions, the microstructure, residual stress, and dislocation density were further investigated.
Characterization results revealed that the horizontal plane exhibited higher hardness compared to the vertical plane, attributed to the higher dislocation density and compressive residual stress in the as-built condition. The observed variations in macro- and micro-creep properties can be attributed to microstructural characteristics. The creep deformation at ambient temperature induced by the nanoindenter is primarily governed by dislocation motion, while creep at the macroscale is significantly influenced by morphologies such as layer bands, β grain boundaries, and melting pool boundaries or defects. These findings contribute to a better understanding of the multi-scale creep behavior in additively manufactured Ti-6Al-4V ELI alloy.

8:00 PM SF01.03.25
Laser Powder Bed Fusion of TiB_2-Reinforced 316L Stainless Steel Composites with Excellent Mechanical Properties WuxianYang[1], JianLiu[1], WenChen[1] and TianyiLi[2]; [1]University of Massachusetts at Amherst, United States; [2]Argonne National Laboratory, United States

Laser powder bed fusion (LPBF) additive manufacturing is an emerging technology that enables melting and consolidating powders layer by layer, which has high potential in developing novel alloys with highly refined microstructures. This study discusses the unique microstructure and superior mechanical properties of additively manufactured 316L steel composites reinforced by various amounts of TiB_2 ceramic phase. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), and *in situ* synchrotron X-ray diffraction are used to analyze the microstructure and deformation behavior of the 316L/TiB_2 composites. The TiB_2 particles are homogeneously distributed in the 316L matrix. The 3 vol.% TiB_2 reinforced sample exhibits a high ultimate tensile strength over 1.3 GPa with a large uniform elongation of 18%. Such mechanical properties well surpass those of other additively manufactured 316L steel composites. Hence, the LPBF process shows high potential for fabricating advanced ceramic-reinforced metal matrix composites with outstanding mechanical properties.

8:00 PM SF01.03.26
An Investigation into the Tribocorrosion Behaviour of Additively Manufactured CoCrMo for Human Joint Implants QingyueShi[1], MichaelBryant[2], ConnorMyant[1] and BorutLampret[1]; [1]Imperial College London, United Kingdom; [2]University of Leeds, United Kingdom

CoCrMo alloys are widely used for medical implants such as hip, knee and shoulder replacements thanks to their high-wear resistance and corrosion resistance. The introduction of additive manufacturing methods, such as selective laser melting (SLM) allows for the fabrication of CoCrMo implants with complex geometries, overcoming the limitations of conventional machining for CoCrMo and offering unprecedented design freedom for patient-specific implants.
SLM involves melting alloy powders layer by layer, subjecting them to multiple thermal cycles of remelting and solidification. Previous studies have reported distinctive microstructural characteristics and the presence of pores in SLM CoCrMo alloys, leading to anisotropic properties. [1,2] Ensuring the longevity and biocompatibility of implants is crucial, as the degradation of metal materials due to wear in artificial joints can potentially trigger adverse physiological reactions in patients. However, despite the importance of this issue, the tribocorrosion performance of SLM CoCrMo alloys in biological environments remains poorly understood. This knowledge gap highlights the need for an investigation into the tribocorrosion behaviours of SLM CoCrMo alloys for joint replacement applications.
In this study, specimens were 3D printed using an Aconity*MIDI* SLM machine. To isolate and manifest the effect of spatial anisotropy in the laser melting process, bidirectional linear laser paths without rotations on each layer were used. Employing three different build orientations, three surfaces with distinct microstructural characteristics due to their anisotropy were prepared. Their tribocorrosion behaviour was assessed using a reciprocating sliding tribometer integrated with a 3-electrode electrochemical cell to quantify corrosion in situ. Tests were conducted in 30 g/L Bovine Calf Serum + PBS to simulate the body fluid in joints. Surface examinations and wear scar analyses were performed to gain a further understanding of the tribocorrosion mechanisms. For comparison, cast CoCrMo specimens were also included as a control group.
The findings indicate that the choice of build orientation is a critical factor in controlling the microstructure of SLM CoCrMo alloys, consequently, the tribocorrosion behaviour of the SLM CoCrMo. The post-tribocorrosion analysis provides valuable insights into the underlying tribocorrosion mechanisms, shedding light on the factors that contribute to the degradation and performance of the SLM CoCrMo. In comparison to cast CoCrMo, SLM CoCrMo demonstrated inferior tribocorrosion performance but tuneable qualities.
In conclusion, this study addresses the knowledge gap regarding the tribocorrosion behaviour of 3D printed CoCrMo alloys for joint replacement applications by investigating the effects of build orientation on microstructure and tribocorrosion performance. The findings emphasize the potential to optimize the additive manufacturing process to achieve improved performance and enhanced tribocorrosion resistance of CoCrMo implants. Ultimately, this study contributes to the advancement of joint replacement technologies, enabling the development of more reliable and long-lasting implants.

Urethane-Water-Cellulose Composite: Improving Mechanical Properties of Urethane-Based Photorucable Resin for Stereolithography 3D-Printing AkiraKudo[1], AtsuyaFujita[2], KazuyaEguchi[2], KotaMatsuhashi[1], KotaToyama[1], TakeharuYoshii[1], DmitriLouzguine[1], HirotomoNishihara[1], MingweiChen[3] and SatokoKuwano[2]; [1]Tohoku University, Japan; [2]Tohoku Gakuin University, Japan; [3]Johns Hopkins University, United States

3D printing has become one of the most attractive fabrication techniques in materials science and engineering, offering its immense degree of freedom in designing complicated architectures with feature sizes smaller than millimeters or even micrometers. Since the earliest stage of 3D printing, polymeric materials, especially thermoplastic polymers for fused deposition modeling (FDM) and photocurable resins for stereolithography (SLA), have been playing a major role in this field. As the utility of 3D printing expands, eco-friendly development of these polymeric materials will garner increasing attention.
In this presentation, we introduce a composite photocurable resin compatible with SLA 3D printing based on urethane, water and cellulose. A commercially available urethane-based photocurable resin was homogeneously mixed with water and printed into microhoneycomb architectures at a mass ratio of resin:water=3:1. We demonstrated that, despite a considerable portion (20-25% by mass) replaced by water, adding water increased compressive strength and stiffness of fabricated microhoneycomb architectures by 50% or more. Miscibility of urethane-based resin with water also enabled homogeneous dispersion of cellulose nanofibers (CNFs), which would not disperse in pure urethane-based resin. Microhoneycombs made of the urethane-water-cellulose composite showed even more improved properties than the ones without CNFs, achieving strength of 7.5MPa and stiffness of 80MPa at 0.25 $g \cdot cm^{-3}$. Structural characterization by Raman spectroscopy, Fourier transform infrared (FTIR) absorption spectroscopy and optical microscopy was performed to investigate the origin of this unintuitive enhancement in mechanical properties and the impact on microstructures brought by water.
Using water and cellulose, both of which are natural materials, out results can inspire a simple, sustainable and high-performance polymeric material compatible with SLA 3D printing.

8:00 PM SF01.03.28
Effects of Printing Direction and Layer Thickness on the Mechanical Properties of 3D Printed Polymer Laminates AmmarBatwa and YaningLi; Northeastern University, United States

For polymeric additive manufacturing (AM), printing direction and layer thickness are critical processing parameters that directly impacts the effective mechanical properties of the final polymeric laminates fabricated via polymer jetting AM technology. To fully exploit AM potential for fabricating polymeric composites, it's crucial to have a deep understanding of the effects of these factors during the printing processes. This research aims at evaluating the effects of printing direction and layer thickness on the effective mechanical properties of 3D printed polymer laminates.
The printing direction is defined via the angle of the specimens relative to the movement of the print head. Specimens of stratified composites fabricated via combining glassy and rubbery polymer layers with various layer thickness are designed and fabricated via a multi-material 3D printer (Stratasys Connex3). Mechanical experiments are conducted to evaluate both the layer thickness and printing directions collectively influence the overall mechanical properties of the designs. Digital Image Correlation (DIC) is used to track the local and overall strain of the specimens during deformation. The micro-structures of the specimens are explored via Scanning Electron Microscope (SEM) imaging. Nanoindentation experiments are performed to quantify the transition in stiffness across dissimilar material interface. The results show a significant correlation between the mechanical properties of the final printed laminates, the properties of the dissimilar interface/interphase, and the printing direction and layer thickness.

Heterostructured Mechanical Metamaterials Inspired by the Shell of Strombus Gigas JuzhengChen[1], HaoWu[1], JingzhuoZhou[1], ZiyongLi[1], RongFan[1], RobertoBallarini[2] and

YangLu[1,3]; [1]City University of Hong Kong, Hong Kong; [2]University of Houston, United States; [3]The University of Hong Kong, Hong Kong

The shells of molluscs have been shown to be strong and tough as a result of various types of architectural design that effectively control the evolution of shear bands and cracks during deformation. The crossed-lamellar design of the shell of *Strombus gigas*, whose hierarchy consists of four distinct lamellar-shaped features, represents the toughest of all seashells. A mechanical metamaterial that replicates the natural structure of this queen conch is anticipated to circumvent the renowned trade-off between strength-conductivity and strength-density. Here we introduce the architectural concepts of dimensional discreteness and interactive discreteness, inspired by the crossed-lamellar design, to instruct the design of bio-inspired metamaterials. The shear bands formed by the newly created metamaterial are effectively discrete and confined within an individual plank-like zone during compression. The mechanical properties are shown to be linearly proportional to the level of architectural discreteness, resulting in a progressive deformation with cross-layer hysteresis. A spring-based model is proposed that is in excellent qualitative agreement with experimental observation, that validates the superiority of the architectural discreteness-based paradigm, and that is capable of translating abstract designs into vivid layouts of spring systems with broad generality. The results have far-reaching implications for the design of strong mechanical metamaterials from a brand-new perspective.

8:00 PM SF01.03.30

Controlling Microstructures and Modulus in Direct Ink Writing of Stainless Steel for Biomedical Applications HavvaE. Aysal[1], BrianK. Paul[2], Chih-hungChang[2] and KostantinosSierros[1]; [1]West Virginia University, United States; [2]Oregon State University, United States

As metals are employed in additive manufacturing at an accelerated pace, environmentally friendly, and less-cost 3D printing processes are required. Direct ink writing (DIW) is a highly versatile technique that utilizes solution-based formulations, known as inks, which exhibit shear-thinning behavior and can accommodate a wide variety of unique precursors. In this study, we present environmentally safe binders for aqueous bio-based metal inks, specifically exploring cellulose-based binders engineered for rheological compatibility with DIW.

Furthermore, we investigate the use of novel inks to control the microstructures of the printed product. The effects of ink formulation, processing parameters, and post-processing techniques on the microstructure and mechanical properties of the printed objects are being explored. Specifically, the capability to modify the organic components of the ink to control porosity is demonstrated, enabling the creation of microstructures with different surface properties.

Stainless steels (SS) have been in use as biomaterials for a long time. SS alloys, commonly utilized in biomedical implants, offer advantages such as affordability, availability, biocompatibility, and high strength. However, the presence of toxic nickel in SS poses a significant concern, particularly for patients sensitive to nickel. Therefore, ongoing research aims to develop nickel-free SS alternatives. In our study, we propose SS420 as a potential substitute, considering its suitability for biomedical applications.

In addition to biocompatibility, satisfactory mechanical properties, and osseointegration are essential factors to consider. Mechanical properties such as hardness, tensile strength, Young's modulus, and elongation play a crucial role in determining the suitability of a metallic material. The occurrence of implant fractures resulting from mechanical failures can be attributed to biomechanical incompatibility. Therefore, it is expected that the material used as a bone substitute exhibits mechanical properties comparable to those of natural bone. Osseointegration, which refers to the ability of a material to effectively bond with the bone and surrounding tissues, is a crucial aspect in the use of metallic alloys for bone applications. Porous steels have demonstrated favorable integration with bone implants. However, increasing the porosity of steel can lead to a decrease in its modulus. To address this issue and improve the stiffness of printed stainless steel to match that of bone, we propose the application of a metal-organic framework (MOF) coating to the SS. This coating will allow us to investigate the impact of surface roughness on stiffness. Through further examination of the effects of increased surface roughness on the mechanical properties of the printed SS, our objective is to advance the development of materials with enhanced compatibility for biomedical applications.

8:00 PM SF01.03.31

Effect of Solidification Rate on Microstructure and Mechanical Properties of Additively Manufactured $AlCrFe_2Ni_2$ High-Entropy Alloys ShengbiaoZhang[1], ChenyangLi[2], WeiChen[2] and WenChen[1]; [1]University of Massachusetts Amherst, United States; [2]Illinois Institute of Technology, United States

The development of high-entropy alloys (HEAs) has attracted significant attention due to their potential for enhanced mechanical properties. However, the formation of undesired intermetallics in HEAs limits their practical applications. Additive manufacturing (AM) offers a promising approach to overcome this limitation by providing unique thermomechanical processing conditions that result in far-from-equilibrium solidification microstructures, leading to exceptional material properties. To fully harness the benefits of AM and HEAs, understanding the processing-structure-property relationship is crucial but challenging due to the complex phase selection and non-equilibrium microstructures formed during AM. In this study, we investigated the effect of solidification rate on the microstructure and mechanical properties of a laser additively manufactured $AlCrFe_2Ni_2$ HEA. By varying the laser scan speed, we observed distinct solidification features, including partitionless single-phase, anomalous eutectic, and coupled lamellar eutectic microstructures. These microstructures offer a wide range of strength-ductility combinations. Thermodynamic modeling and molecular dynamics simulations are performed to gain insights into the solidification mode transition from partitionless through anomalous eutectic to coupled eutectic as the solidification rate continuously decreases. Our findings demonstrate that AM enables access of a rich variety of phase and microstructure space for HEAs, expanding the material design possibilities for technologically relevant alloys.

8:00 PM SF01.03.32

Investigation of Structure-Processing Relationships in Metal Additive Manufacturing Through Featurization of Microstructural Images DipayanSanpui[1,2], AnirbanChandra[1,2], SukritiManna[1,2], Partha SarathiDutta[1,2], MariaK. Chan[1], HenryChan[1,2] and SubramanianSankaranarayanan[1,2]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Chicago, United States

The understanding and prediction of accurate property-structure-processing relationships is essential in designing robust, reliable parts and assemblies, both forward and inverse. The direct mapping of process parameters to property values can be plausible in some cases, but it is often hampered by poor microstructural control. Therefore exploring a straightforward relationship between processing conditions and microstructural features can offer important physical insights and assist the overall design procedure. In this work, we present an automated high-throughput approach towards simulating an AM process that is uncertainty-aware, can characterize microstructural images, and extract appropriate features and descriptors. We used a kinetic Monte Carlo (KMC) based model of the AM process to simulate microstructural evolution for a variety of processing conditions, having utmost relevance with the experimental conditions. We perform a parametric study by selecting four input processing parameters in KMC simulations (velocity, hatch spacing, melt-pool width, and tail length) to explore the relationship between microstructural features and processing conditions. As a first step towards the exploration of microstructural features and processing conditions, we performed a parametric study by selecting the four input processing parameters in KMC simulations (velocity, hatch spacing, melt-pool width, and tail length). With systematic variations of the process parameters, a large number of simulations were performed for obtaining a diverse set of microstructural images. Subsequently we performed thorough analysis of the simulated images and extracted meaningful descriptors using conventional algorithms and an off-the-rack image processing tool, the Watershed algorithm. Finally, we present an approach towards discussion of the ability of various quantitative microstructural features to differentiate between the obtained microstructures. For accurate featurization of microstructural images, we focus on a set of six most relevant microstructural descriptors: Orientation, Aspect ratio, Perimeter-Area ratio, Equivalent diameter, Two-point statistics and chord length distribution (CLD) in two dimensions. As byproducts of our featurization algorithm, we realize many-to-one mapping is a necessity for representation of microstructural images unambiguously, multiple descriptors are therefore required to unambiguously map processing conditions to typical descriptors. Depending on the differentiability of the distributions of the microstructural features, a unique score can be allotted to a particular grain profile. This unique value of the metric or score can be further utilized to propel the inverse design problems. Defining a unique score is impossible if the four dominant microstructural features do not differ across the chosen processing conditions. Hence our research work provides very important information, in both qualitative and quantitative aspects, that would help in the proper understanding of microstructural representations. Appropriately characterized microstructural representations can then be utilized for development of data-driven models for predictive control of grain profiles, resulting in tailored mechanical or thermal properties of additively manufactured parts.

8:00 PM SF01.03.33

Embedded 3D Printing of Soft Materials and Ultrafine Hair Structures WonsikEom[1], MohammadA. Hossain[1], VidushParasramka[1], RyanW. Siu[1], JeongminKim[1], KatherineSanders[2], DakotaPiorkowski[3], AndrewLowe[3], MichaelD. Volder[2], DouglasS. Fudge[3], RandyH. Ewoldt[1] and SamehTawfick[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Cambridge, United Kingdom; [3]Chapman University, United States

Embedded 3D printing enables the direct ink writing of ultrasoft materials which, due to gravity, cannot support their own weight in air. For this reason, embedded 3D printing is a platform to replicate nature's complex, branching, and tortuous fibrous structures. However, this recent technology has been limited by a complex interplay of factors such as interfacial tension ratios between the printing materials and the support gel, the viscosity of the ink, and the yield stress of the gel. Because of these complexities, the minimum feature diameter is limited to around 50 µm. Recently, a feature diameter of 8 µm was achieved by tailoring the interfacial tension. This limitation prevents the accurate replication of natural structures, many of which feature dimensions at the micrometer scale, such as long aspect ratio mechanosensing stereocilia and the hairs on the feet of beetles and geckos.
Here, we introduce solvent exchange between the ink and the support gel as a key mechanism to expand the capabilities of embedded 3D printing and allow the fabrication of ultrafine and tortuous structures from a variety of soft materials. This method facilitates the immediate solidification of the extruded polymer solution upon its interaction with the gel's solvent, enabling the printing of ultrafine features as small as 2.1 µm in diameter. Our work exploits the rheological underpinnings that make such precision possible. We elucidate the critical roles played by the

gel's yield stress and solvent concentration in achieving this high resolution, thereby offering a comprehensive understanding of the mechanics behind this proposed approach.
Solvent-exchange extends to the versatility of materials available for embedded 3D printing. We demonstrate printing of soft thermoplastic elastomers like styrene-ethylene-butylene-styrene (SEBS) copolymers as well as rigid polymers such as polyvinyl chloride (PVC), and electrically conductive carbon nanotube composites. We applied this method to produce intricate hair arrays, thereby meeting the requirements for bio-mimicking applications. These arrays feature fibers with diameters less than 2 µm and lengths exceeding 1500 µm.
In summary, the solvent exchange method presents a notable advancement in polymer 3D printing. The solvent exchange of direct ink writing embedded in support gels enables the fabrication of biomimetic high ultrafine tortuous structures, overcomes previous resolution limitations, and expands the palette of polymeric materials available for printing. This capability opens new avenues for replicating nature's intricate fibrous morphologies towards the design of new architected composite materials. This work was sponsored by the Defense Advanced Research Project Agency (DARPA), under contract no. N660012124036.

8:00 PM SF01.03.34
A Flexible Capacitive Pressure Sensor with High Sensitivity and Linear Response using Size-Distributed Microshere YusakuTagawa[1], SunghoonLee[2], TakaoSomeya[1] and TomoyukiYokota[1]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan

Flexible pressure sensors enable to measurement various biological signals for long-term monitoring. Obtaining plantar pressure distributions and body weight measurements through wearable devices is significant for healthcare applications and monitoring various diseases such as diabetes, obesity, and heart failure. To detect the planter pressure of such disease patients, wearable, flexible pressure sensors with a high-pressure sensitivity range (1 MPa) can provide precise critical biomedical information.[1]
Among the various flexible pressure sensors, capacitive pressure sensors are among the most promising candidates owing to their simple fabrication process, rapid response, small hysteresis, and low power consumption. Despite these advantages, typical silicone rubber has a relatively low dielectric constant (2-3), contributing to low sensitivity. Therefore, porous structures at the dielectric layer and dielectric/conductor interface are essential for higher sensitivity because they reduce the initial dielectric constant and compression modulus.[2] On the other hand, essential characteristics of stable operation, such as linearity over a wide range, have yet to be dealt with enough.[3] Balancing the linear response and high sensitivity in porous structures remains challenging owing to the sensitivity saturation of porous materials. To the author's knowledge, no capacitive pressure sensor with porous structures that maintains linearity up to 1 MPa with a high sensitivity ($> 10^{-3}$ kPa^{-1}) exists.[4][5]
This study proposes a capacitive flexible pressure sensor containing thermoplastic microspheres (TPM) with linearity and high sensitivity over a wide pressure range. The TPM expanded at relatively low temperatures (95–125 °C) and increased 50 times in volume. The TPM-containing Polydimethylsiloxane (PDMS) was spin-coated to fabricate an elastomeric membrane with a homogeneous porous structure. Notably, the TPM has a large size distribution with the temperature increasing. This size distribution variety of porous TPM may contribute to the high sensitivity and enhance the linear response owing to the deformation of different sizes of porous under the different pressure. Owing to this characteristic of TPM, we achieved a pressure sensor with a high sensitivity (3.1×10^{-3} kPa^{-1}) while maintaining linearity ($R^2 = 0.996$) under a high compression pressure (1 MPa).
Furthermore, the sensor responded within 100 ms under 140 kPa and indicated the durability by 10000 cyclic loadings. As a pressure distribution application, we implemented 3 × 3 multichannel pressure sensors with a large area (3.4 cm × 3.4 cm) to demonstrate the uniformity of the materials. In addition, we fabricated geta wearables that can detect body weight. As a result, a 4.9 kPa load fluctuation can be detected equally well in a high and low weight range without sensitivity compensation systems, such as non-linear fitting, which implies the significant potential to achieve reliable and simple wearable applications.

Printing Three Dimensional Refractory Metal Patterns in Ambient Air: Toward High Temperature Sensors JichuanYu, ZeWang, ChuxiongHu and XiningZang; Tsinghua University, China

Refractory metals offer exceptional benefits for high temperature electronics including high-temperature resistance, corrosion resistance and excellent mechanical strength, while their high melting temperature and poor processibility poses challenges to manufacturing. Here we report a direct ink writing and tar-mediated laser sintering (DIW-TMLS) technique to fabricate three-dimensional refractory metal devices for high temperature applications. Metallic inks with high viscosity and enhanced light absorbance are designed by utilizing coal tar as binder. The printed patterns are sintered into oxidation-free porous metallic structures using a low-power (< 10 W) laser in ambient environment, and three-dimensional freestanding architectures can be rapidly fabricated by one step. Several applications are presented, including a fractal pattern-based strain gauge, an electrically small antenna patterned on a hemisphere, and a wireless temperature sensor that can work up to 350 °C and withstand burning flames. The DIW-TMLS technique paves a viable route for rapid patterning of various metal materials with wide applicability, high flexibility and three-dimensional conformability, expanding the possibilities of harsh environment sensors.

Source Design for Vapor-Based Additive Manufacturing of Drug Substance Particles EvaPontrelli and MaxShtein; University of Michigan, United States

Additive manufacturing provides a precise, material-efficient, and rapid route to complex structures for a growing scope of applications. The novel vapor-based process described here offers new additive manufacturing capabilities for formulation-ready active pharmaceutical ingredients. This technique deposits material by jetting organic vapor and an inert carrier gas through a nozzle onto a substrate, where the organic condenses. The deposited material has ultra-fine particle sizes, which leads to enhanced bioavailability. Engineering particle size and morphology requires tight control over vapor flux at the substrate. Stable vapor flux also enables precise, flexible dosing of active ingredients, which is essential for pediatric dosing, high potency drugs, and personalization of medicines, but difficult to achieve with traditional solid oral dosing and formulation approaches.

While tight control of feed location is easily accomplished using traditional 3D printer hardware, achieving a stable vapor flux is difficult, yet crucial. The source can be operated near vapor-solid or vapor-liquid equilibrium, allowing use of carrier gas flow as a linear control of flux. Faster flow rates drive the system away from equilibrium, presenting boundaries on the process window. In this talk we describe an apparatus configuration that can enable high, yet stable, deposition rates, linear control of rate, and greatly facilitated material handling.

8:00 PM SF01.03.37
Electrically-Driven Textile using Hierarchical Aramid Fiber AbdullahIslam and ShenqiangRen; University of Maryland, United States

High strength and flexible electronic textiles promise in aerospace, robotics, and extreme environment applications, while it is indispensable to develop functionally integrated fiber building blocks with the durable materials performance. Here we report multifunctional sensory e-textiles driven by using copper-grafted polyaramid (Kevlar®) fiber networks for the integrated electromagnetic interference shielding, thermal and pressure response sensing. The hierarchical structural design and synthesis of flexible conductive networks is accomplished via the synergistic coordination between molecular copper complex and Kevlar® fibers, which facilitate long-term cyclability, stability, and washability. Superior Joule heating capabilities with a rapid thermal response under a low driving voltage (a heating-up rate of 6 degrees C/s and a cooling-down rate of 5.8 degrees C/s), together with a high level of EMI shielding (80 dB from 8 GHz to 13 GHz), are resulted from its multilayer vertically-aligned structure with continuous percolation of conductive coating. This work presents a new and feasible grafting approach for the large-scale fabrication of multifunctional wearable e-textiles for use in extreme environments.

8:00 PM SF01.03.38
Fully Printed 2D Material-Based Memristors AlessandroGrillo[1], ZixingPeng[1], AnielloPelella[2], MatthewBoyes[1], XiaoyuXiao[1], MinghaoZhao[1], JingjingWang[1], ZhirunHu[1], AntonioDi Bartolomeo[2] and CinziaCasiraghi[1]; [1]Univeristy of Manchester, United Kingdom; [2]University of Salerno, Italy

The von Neumann architecture relies on separate entities for the processing and memory functions, so these units engage in extensive and continuous data exchange. However, in the last few years the production and use of information has been growing dramatically, leading to a new brain-inspired computing paradigm, where data storage and process are done by the same unit. In this framework, the memristor, which is a circuit element that can store information due to the phenomenon of resistive switching between two resistance states upon application of an external electric field, is gaining significant attention as non-volatile memory. 2D materials (2DMs) are very attractive for the next-generation memristors,[1,2] due to their flexibility, transparency, and compatibility with solution-based processing, enabling to use techniques such as inkjet printing for the cost-effective, and scalable integration of devices onto flexible substrates, like paper and plastic.
In this study, we printed silver as the bottom electrode, graphene (Gr) as the top electrode and MoS_2 as dielectric, creating an Ag/MoS_2/Gr heterostructure.[3] After optimization of the fabrication process, the fully printed Ag/MoS_2/Gr memristors on silicon exhibit performance comparable with those achieved in printed devices using silver electrodes or other nanomaterials like TiO_2 and ZrO_2 on rigid substrates.[4] Furthermore, the same device, when printed on Kapton, displays stable memristic behaviour up to 3% of strain. The memristor resistance switching is attributed to the formation of Ag conductive filaments, which can be suppressed by integrating graphene grown by chemical vapour deposition (CVD) onto the silver electrode. Temperature-dependent electrical measurements starting from 200 K show that the memristic behaviour appears at temperature of ~ 300K, confirming that an energy threshold is needed to form the conductive filament. Interestingly, the CVD Gr integration also significantly reduces hysteresis, suggesting that CVD Gr not only serves as a barrier against ion migration but also improves

the interface between the electrode and the dielectric layer, enhancing the reliability and reproducibility of the devices.

Printed Electrochemical Cu^{2+} and Cd^{2+} Ion-Selective Electrodes for Combinatoric Multi-Heavy Metal Ion Sensing Applications ManinderKaur, PriyaVinayak, Henam SylviaS. Devi, BhaskarMitra and MadhusudanSingh; Indian Institute of Technology Delhi, India

Requirements for onsite monitoring of heavy metals in utility water supply and in effluents include low sensor drift, and high sensitivity.
While it is standard practice to detect ions in lower ppb ranges using laboratory analytical techniques including atomic absorption/emission spectroscopy and inductively coupled plasma-mass spectrometry, these techniques require careful sample preparation, a skilled operator and potentially long turnaround times for measurements from the site to the lab. Recognizing the health hazards posed by heavy metals, regulatory agencies like the Environmental Protection Agency (EPA) have specified permissible exposure limits for copper (1.3 ppm[1]) and cadmium (5 ppb[2]). Previous work [1] has demonstrated the efficacy of low-cost potentiometric ion-selective electrodes for ppb-level detection of such species. Given several such ions of concern, and well-known and significant cross-sensitivities[3] exist amongst them, and with other ions deemed to be safe for human health at naturally occuring levels, it is essential to develop multi-sensor chips for combinatoric sensing of heavy metal ions, possibly aided by machine learning (ML) methods. While individual ion-selective electrodes with custom sensing films can in principle be fabricated, traditional lithographic techniques are a) inapplicable (owing to foundry process contamination), and b) complex (owing to demands for a potentially large number of sensing layers). Thus, multi-ion sensors production at scale needed for realtime regulatory monitoring requires an alternative fabrication technology. In this work, we have used an inkjet printed CdS film to detect copper and cadmium ions in water. Cadmium acetate precursor (98%, Sigma Aldrich) was added (70°C, 15min) to ethylene glycol (98%, Qualigens), followed by addition of thiourea (99%, Sigma-Aldrich) under constant stirring (70°C, 3 hr), resulting in a bright yellow product (CdS). Elemental composition of the ink was validated by energy dispersive X-ray analysis (EDX, Hitachi), and powder X-ray diffraction (PXRD, Rigaku Ultima, Cu-Kα, 1.54Å) indicating the formation of a pure hexagonal phase (ICDD: 96-900-8863) of CdS. Hydrodynamic nanoparticle size measurements (dynamic light scattering, Malvern Zetasizer) yield a value of 40.63±4 nm, indicating suitability for inkjet printing (Fujifilm Dimatix DMP2850, DMC11610 cartridge) through the nozzle diameter (20 µm). Glass substrates with thermally evaporated Cr (10Å)/Au (1000Å) were subjected to standard DI/solvent clean, followed by an ozone exposure (Novascan PSO-UV4, 5 min), before multiple printing with a 15µm drop spacing using a custom waveform to achieve a film thickness of 150 nm. Test spiked solutions (with fixed 0.1 M KNO_3) with decadal concentration variation were formed with for two analyte series using copper($Cu(NO_3)_2.3H_2O$) and cadmium ions ($Cd(NO_3)_2$.$4H_2O$) with testing starting with the most concentrated spiked solution (0.01 M), and ending with the most dilute solution (10^{-9} M) in each series. Potentiometry measurements (PARSTAT MC 1000) for detection of Cu^{2+} yield a detection limit of 1.8 ppb in thelinear working range of 10^{-3} M to 10^{-9} M with a sensitivity of ~40 mV/p[Cu^{2+}] (based on weighted linear fit) and a response time of 50-60 seconds. Corresponding measurements for Cd^{2+} yield a detection limit of 10 ppb in a wider linear working range of 10^{-2} M to 10^{-7} M with the sensitivity of ~19 mV/p[Cd^2+] and response time of 80-90 sec. The printing process has been demonstrated on a variety of substrates - poly dimethyl siloxane (PDMS) and polyethylene terephthalate (PET). Work is ongoing to demonstrate working sensors on these substrates to enable use of flexible substrates in applications requiring conformal shapes, such as inner surfaces of utility pipes.

Soft Pressure Sensor Fabricated by Implementation of Ultrathin Silicon Strain Sensors on 3D-Printed Cantilever Structures for Cyber Physical System Car Seats SeiichiTakamatsu, JunyaNakagawa and ToshihiroItoh; The University of Tokyo, Japan

To monitor the posture and driving behaviors of drivers in autonomous vehicles, we developed a car seat embedded with a soft pressure sensor array beneath its urethane foam layer. The soft pressure sensors feature a cantilever structure formed using a 3D printer, at the root of which thin MEMS piezoresistive sensors are wired. Monitoring the health and cognitive state of drivers is crucial, especially in the context of semi-autonomous vehicles up to Level 3. Traditional techniques often employ cameras and vital sensors to detect behavior, fatigue, and drowsiness. However, these methods can be limited due to factors such as lighting conditions and the driver's attire. Given that car seats are in direct contact with drivers, there is growing interest in embedding pressure sensor arrays within them to measure body pressure distribution. These sensors can complement cameras for a more robust driver-monitoring system. Previous research has shown that analyzing body pressure distribution can estimate a driver’s attention and fatigue levels effectively. Driver posture, which is intricately linked to comfort, influences alertness; deteriorating comfort could lead to distractions. Also, there is a known correlation between a driver's alertness level, fatigue, and their driving posture. Despite its potential, current pressure sensor technology has limitations. Most research relies on expensive and uncomfortable electrostatic capacitive sensors, costing around $2000 per seat. This has led to a demand for low-cost, comfortable pressure sensors that can be integrated under the car seat's urethane foam layer. However, placing sensors under the urethane foam is challenging. The foam's nonlinear deformation under load leads to reduced sensor sensitivity and inconsistent output. The foam material disperses the applied force between the sensor and its surrounding substrate, affecting the sensor's performance. To be effective, a pressure sensor array needs to maintain high sensitivity levels (0-10 kPa) and produce near-linear outputs in response to the applied force. This study developed a car seat equipped with a pressure sensor array beneath the urethane foam to monitor the driver's posture and driving behavior. Urethane foam exhibits nonlinear behavior, such as maintaining constant stress in response to varying displacement in the plateau region. Sensors placed under the urethane foam face challenges like producing nonlinear output signals and low sensitivity. In this research, we combined a low-cost pressure sensor, made of a 3D printer and MEMS sensors, with a unique embedding structure beneath the foam and a stress-concentrating design. This new driver-monitoring device aims to overcome the issues associated with sensitivity and linearity. The developed soft cover is attached to the pressure sensors to concentrate stress from the urethane foam. Additionally, the area surrounding each sensor includes a base of the same height to prevent geometrically nonlinear responses. The sensors are integrated into the car seat's urethane foam in an array. The proposed pressure sensor exhibits a sensitivity range of 0-20 kPa. Through experiments, we demonstrated that the prototype sensor array could detect changes in the driver's posture as well as braking actions. The sensors in this structure hold promise for future applications in intelligent car seats for autonomous vehicles.

Computer Vision enabled Eye-In-Hand Robotic *In-Situ* Bioprinting of Multimaterials for Fast Wound RepairSeolhaJeong and Su RyonShin; Harvard Medical School, United States

Current *in-situ* printing techniques depend on pre-determined printing paths in order to directly build complex functional architectures at injured areas, limiting adaptability in clinical scenarios. We present INSIGHT (**IN**telligence *in-**SI**tu* printing **G**uided by Eye-in **H**and robot **T**echnology), an innovative computer vision enabled system that combines a depth camera with a 6-degree of freedom robot arm, empowering it to identify arbitrary areas at various angles without pre-designed code and calibration procedures. Layer-by-layer volumetric printing approach is performed by dynamic image recognition based on color and contour differences, which achieves highly accurate printing through real-time adjustments and is capable of continuous targeting of multiple wounds. Dual printing modes, extrusion and spray printing, are designed for rapid printing with seamless switching between different bioinks. Through *in vivo* tests, INSIGHT demonstrates its practicality for targeting and treating diabetic wounds, highlighting its adaptability to enable customized care for rapid emergency treatment of trauma patients. In this research, as targeting to treat a diabetic wound healing, a microgel based bioink is introduced, which is mixed with a plant protein-based oxygenating microparticles and mesenchymal stem cells in order to boost angiogenesis and immune response at initial wound healing stage. We not only demonstrate the practicality for targeting and treating diabetic wounds using our system, highlighting its adaptability to enable customized care for rapid emergency treatment of trauma patients, but also verifying the efficiency of the combination of the oxygenated ink and the stem cells in wound repair.

Printable Silicone Elastomers to Provide Magnetic Resonance Imaging Contrast for Medical Phantoms MichaelAvery, YasmineOsmani, BenDickie, StephenEdmondson and BrianDerby; University of Manchester, United Kingdom

Phantoms are manufactured structures which mimic the properties of objects that are characterised by a range of different medical imaging technologies. They have a number of applications, including: standards for instrument calibration, reference samples to ensure common performance from multiple site experimentation, replacement for animal studies or human volunteers during training or technique development. Phantom development for magnetic resonance imaging (MRI) is particularly challenging because the imaging modality is the relaxation of the nuclear magnetic resonance excitation of protons that are ubiquitous in biological systems and these relaxation times (T1 and T2) are much longer than in conventional polymeric materials

because of the presence of water and the soft matter nature of biological tissue. Thus, conventional MRI phantoms are based on aqueous solutions or weak gelling biological materials, e.g. alginates, agarose or carageen gels, doped with paramagnetic ions to further control the relaxation times. The phantoms themselves are thus limited to simple shapes, e.g. spherical or cylindrical cavities, and have poor long term stability.
The use of MRI to guide radiological or surgical procedures requires more advanced shape control for the next generation of medical phantoms. This is particularly the case for surgical training but also for the generation of large datasets for machine learning where precise robotic control of beam placement and motion from intense X-Ray sources is desired for use in clinical radiology such as the MRI-Linac. The ability to replicate the unavoidable motion of internal organs (e.g. heart and lungs), while also mimicking complex tissue geometries, MR imaging properties and radiation response of tissues, is critical for advancing MR-Linac treatment. These medical challenges can be achieved by developing and engineering 3D-printed silicone soft-robotic “4D” phantoms, enabling a transformational step-change in the manufacture and function of medical phantoms. A successful soft robotic phantom must display the appropriate balance of mechanical properties, MRI contrast and manufacturability. Here we present materials development for 3D printable silicone material that work towards overcoming this challenge.
Robotic phantoms must present MRI relaxation times that simulate biological tissues, typically assessed using the time constants and for longitudinal and transverse relaxation respectively. . Human tissue relaxation times can range from 600 – 3000 ms for and 35.-.240 ms for , although the precise range depends on the magnetic field used during a particular MRI scan. a Therefore phantom materials should allow for significant and tunability. For soft robot fabrication, the challenge is to develop compositions that achieve the desired relaxation values while also maintaining mechanical properties comparable to those human tissues and pre-cure viscoelasticity suitable for printing.
Two strategies to achieve these desired material properties have been investigated, both following the principles of formulation of material blends using readily available commercial materials. The first uses commercial silicones that have been successfully used to print soft robotic structures but modified by blending with short chain, relatively mobile silicone oils. This gives good control of T1 and T2 but has limited long term stability of property variation due to the mobility of the sort-chain oils within the polymer network. The second approach uses a multiphase composite concept rather than a blended composition. Both methods have been used with Direct Write Extrusion printing to fabricate 3D structures with defined variation of materials and these have been used in pre-clinical MRI scanners to demonstrate good imaging quality.

Strengthen Composite with 3D Aligned Carbon Fiber via Embedded 3D Printing QiyiChen and RayneZheng; University of California, Berkeley, United States

The orientation of fibrous fillers, induced by shear forces during extrusion, has been demonstrated to significantly enhance mechanical properties, electrical/thermal conductivity, microwave attenuation etc., albeit primarily in a two-dimensional (2D) x-y plane. In this study, we present a novel approach for achieving fiber alignment in a three-dimensional (3D) context, with an emphasis on the Z-direction, by utilizing embedded 3D printing techniques. This process involves the extrusion and suspension of composite inks within a viscoelastic gel medium, during which the alignment of the fiber can be controlled *via* velocity ratio, nozzle size, fiber dispersion etc. By selectively align the fiber in a 3D pattern, the mechanical properties, and conductivity can be largely improved and tuned.

Microstructural Evolution Simulations in Additive Manufacturing and Post Heat-Treatment of Aluminum Alloys JiwonPark, Joo-HeeKang and Chang-SeokOh; Korea Institute of Materials Science, Korea (the Republic of)

The extreme solidification condition in metal additive manufacturing causes out-of-equilibrium phase transformation and unique microstructures: i) vertically connected grains across several layers along the building direction, ii) severe segregation of alloying elements on the inter-dendritic region and the absence of secondary phases, which expect to be formed under equilibrium condition. These microstructural features are of great importance in tailoring the desired properties. This work simulated the microstructural evolution of as-built and post heat-treated Al-Si-Mg alloy in a phase-field approach. Local grain orientation selection and growth morphology under rapid solidification and extreme thermal gradient conditions are studied and compared to electron back-scatter diffraction analysis. Then, the precipitation behavior of Si from super-saturated solidification microstructure is investigated. The formation of Si precipitate demonstrated above the solution-treatment temperature, which experimentally occurs. It reveals that the precise digital twin of mesoscale microstructure can be fabricated by phase-field modeling with specified thermal conditions.

The Effect of *In-Situ* Laser Surface Nitriding on Dynamic Load Transfer and Stress Development in Additive Built Ti6Al4V Hip Implant using Finite Element AnalysisAnkitPorwal[1,2]; [1]IIT Kharagpur, India; [2]Indian Institute of Technology Kharagpur, India

The force developed during human activity generates dynamic stress over the prosthetic. Change in stress with time causes stress shielding in the bone and prosthetic system. Lowering the stress shielding improved the prosthetic performance. This presented work aims to investigate the effect of in-situ laser surface nitrided additive build Ti6Al4V hip implant stem using the finite element method. A finite element 3D model consisting of femur and hip implants with variable laser surface nitrided region was considered for the analysis. Dynamic loads developed during standing up, regular walking and stair climbing used for load condition. These dynamic loads are applied as a cyclic load dependent overtime on the implants to calculate load transfer and stress development. The analysis shows that the remelted surface transmits higher loads than the untreated implants during activities. Thus, in-situ laser surface nitriding reduces the stress shielding in bone and prosthetic system and improve implant performance.

8:00 PM SF01.03.47
On The Development of Bio-Compatible, Chemically Recyclable, 3D-Printable Silicones SenecaJ. Velling[1], HongyiZhang[2,1], SammyShaker[1] and JuliaR. Greer[1,1]; [1]California Institute of Technology, United States; [2]Tsinghua University, China

Silicone is a versatile polymer material with many desirable characteristics, such as corrosion resistance, thermal stability, low toxicity, and its electrically insulating nature. It has widespread application in commercial, medical, and research scenarios. However, its irreversibly 3D crosslinked structure has impeded its recycling and manufacturing through thermoplastic extrusion-based 3D printing techniques. Similarly, its high gas permeability and crosslinking has prevented its application in UV-curing-based additve manufacturing techniques. Previously, it was reported that the photoinitiated thiol-ene click chemistry, where a thiol and an alkene connect to form a thioester, allowed the UV-crosslinking of mercaptan-functionalized polysiloxane and vinyl- terminated polysiloxane thereby enabling the use of stereolithography 3D printing of silicone elastomers. Separately, introduction of disulfide moieties in polymer chains was shown to facilitate the chemical degradation of the cured material through base-catalyzed thiol-disulfide exchange reactions. This work targes the develop a chemically recyclable, 3D-printable silicone materials by integrating the thiol- disulfide exchange mechanisms within a photoinitiated thiol-ene silicone system. We show that disulfide moieties can be introduced into mercaptan-functionalized polysiloxanes through a clean and facile iodide-catalyzed oxidative coupling reaction, and the resulting partially oxidized mercaptan- functionalized polysiloxanes, when mixed with vinyl-functionalized polysiloxane and photoinitiators, can be UV-cured to form disulfide-containing silicone networks. Ongoing work focuses on performing chemical degradation on the cured disulfide-containing silicone, examining the viability of self-healing in such silicone elastomers via phosphine-catalyzed disulfide metathesis, and characterizing the thermomechanical properties of silicones prepared from the recrosslinking of recycled polysiloxane oligomer. Together, these efforts will make possible the additive manufacturing of complex functional structures (eg. microfluidic devices, cell scaffolds, O-rings and gaskets) from highly oxygen-permeable, hydrophobic, thermally and chemically resistant Silicones capable of self-healing and chemical recycling.

8:00 PM SF01.03.48
Synthesis of Scaffolded Carbon Electrodes via Catalytic Graphitization EthanKlein, SammyShaker, YuchunSun, SenecaJ. Velling and JuliaR. Greer; California Institute of Technology, United States

Graphitic electrodes are widely used in lithium-ion batteries due to their electrical performance and resistance to chemical degradation. However, the inherent geometry of slurry-based graphite electrodes limits the ability to tune key parameters, such as the diffusion length within the electrode, the path of ions in the electrolyte/electrode region, the extent of active material loading, and the overall mechanical strength. By contrast, electrodes with scaffolded three-dimensional (3D) structures offer freedom over such tunable parameters. While the tunability of scaffolded electrodes may appear attractive, there exists a tradeoff: current 3D printing techniques used to fabricate such scaffolded electrodes offer limited control over the intrinsic material properties, namely the crystal phase and microstructure. In turn, improvements in diffusion length and the intercalation of lithium ions within the electrode are still limited. Achieving the desired microstructure and phase control requires significant thermal activation, with temperatures greater than 3000°C in the case of carbon, that is infeasible in most tube furnaces and especially challenging for larger samples.

Here, we offer a repeatable method for microstructural and crystal phase tuning of scaffolded carbon electrodes via catalytic graphitization. Electrodes are 3D printed using a hygroscopic resin capable of swelling in an aqueous solution, offering significant compositional control in post-printing. In this study, samples are submerged in a solution of nickel salts, where the 3D printed polymer swells with nickel cations and water to produce a hydrogel. These samples are then pyrolyzed in a vacuum furnace between 800-1000°C to form a carbon electrode, in which the presence of nickel catalytically produces graphite.

In this study, we first investigate the impact of the aqueous nickel concentration on the resultant nickel incorporated in the pyrolyzed electrodes. We also examine how the nickel concentration

leads to the presence of a crystalline graphite phase, as opposed to the glassy carbon phase typically observed during pyrolysis. X-Ray Diffraction (XRD) patterns display pure glassy carbon at zero nickel concentration, while both glassy and graphitic carbon signatures appear as nickel incorporation increases. The ratio of graphite (G) to disorder (D) Raman peaks improves from less than 1:1 to greater than 10:1 in catalytically produced samples. Future studies using Transmission Electron Microscopy (TEM), in-situ high temperature TEM, electrochemical cycling, and capacity measurements are discussed. We also compare the electrochemical performance of slurry and scaffolded electrodes with varying degrees of graphitic microstructure and architectural features.

Laser Powder Bed Fusion of Mixed Powders ChristopherHutchinson, HuikaiLi, ErinBrodie and SebastianThomas; Monash University, Australia

Laser powder bed fusion (LPBF) of metals is a popular mode of additive manufacturing (AM) that has the advantage of producing complex shapes with little or no additional processing. However, an important limitation is that the metallic microstructures obtained are usually relatively simple solidification structures and there are few means available to enrich this without subjecting the components to subsequent thermal processing routines, which has its own difficulties due to dimensional control. This limits the microstructural complexity that can be achieved in components fabricated by LPBF and hence the properties obtainable.
In this work, we present and validate a physically-based model to predict the chemical distribution resulting from LPBF of physically mixed powders of different compositions. We demonstrate that mixing of powders with different compositions can be used to generate a deliberately controlled, mesoscale chemical heterogeneity in LPBF that allows the formation of multiphase microstructures and delivers new microstructural complexity to LPBF. A duplex stainless steel, consisting of equal fractions of ferrite and austenite in the as-built state is used as a demonstration of the approach.
The model describing the chemical distribution in the consolidated build can be extended to describe remelting effects and exploited for the design of spatially varying microstructures. This provides a path towards generating architectured materials from random mixes of initial powders. Examples of using spatially controlled remelting to generate architecture materials for random powder mixtures will be shown.
This opens up an interesting path for delivering microstructural complexity to LPBF of metals.

8:30 AM *SF01.04.02
Multiscale Process Control in Metal Additive Manufacturing ManyaliboMatthews; Lawrence Livermore National Laboratory, United States

Tremendous gains have been made over the past several years to improve understanding of defect formation in laser powder bed fusion (LPBF) processes and develop predictive material models that can guide process optimization. However, while control of defects may be achievable at a given length scale for a given material, there remain significant challenges in efficiently predicting and mitigating defects wholistically across length scales, e.g. grain-, melt pool-, feature-, part-scale. In this talk I will present efforts to improve the efficiency and accuracy of predictive models that describe defect formation across the multiple relevant length scales found in LPBF. Beyond predictions, effective means to implement defect mitigation solutions are also required. Efforts to manipulate the optothermal coupling in both custom and commercial LPBF systems will be discussed that begin to address such requirements. Prepared by LLNL under Contract DE-AC52-07NA27344.

The Use of Mechanically Derived Powders for Additive Manufacturing: Flow and Function DavidF. Bahr[1] and JohnE. Barnes[2]; [1]Purdue University, United States; [2]Metal Powder Works, United States

Metal additive manufacturing (AM) provides the opportunity of “on demand” customizable fabrication to minimize supply chain constraints. However, powder availability could become a similar constraint, and creating affordable regional sources for low-embodied energy powders will be a crucial step in distributed manufacturing. Current gas or water atomization processes methods for form metal powders (which are then often remelted in powder bed fusion) adds significant energy budget to the process. First, atomized powders are regularly sorted so that only a portion of the powder produced reaches the AM user. Secondly, if the alloy already exists in solid form, the energy needed to melt to form the powder form is an energetically “hungry” step. A powder creation method using cold mechanically derived (CMD) of particulates can create a wide range of alloy compositions with approximately 90% less embodied energy than gas atomization (GA). CMD powder is often less spherical than GA powders, and thus the powder flow characteristics in common powder bed systems must be demonstrated. Our study has shown that the flowability of Al 7075 and Copper 14500 powders made via GA and MF are similar at rates appropriate for powder bed additive methods. Particle morphology descriptions (size and shape) do not strongly correlate to tap density in this case, which suggests under common AM bed filling processes the bed density will be similar in both cases. Morphology comparisons and particle size/shape distributions were made by comparing large particle statistics, rather than solely comparing mean particle size. Laser powder bed fusion tensile specimens were formed from AL 7075 and heat treated to T6; the GA and CMD powders showed equivalent tensile test performance to both each other and conventionally wrought 7075.

9:15 AM SF01.04.04
High Absorptivity Nanotextured Powders for Metal 3D Printing OttmanTertuliano[1], PhilipDePond[2,3], AndrewLee[2], JihoHong[2], DavidDoan[2], MarkL. Brongersma[2], WendyGu[2], ManyaliboMatthews[3], WeiCai[2] and AdrianLew[2]; [1]University of Pennsylvania, United States; [2]Stanford University, United States; [3]Lawrence Livermore National Laboratory, United States

The widespread application of metal additive manufacturing (AM) is limited by the ability to control the complex interactions between the energy source and the feedstock material. Here we develop a scalable process to introduce nanoscale grooves to the surface of copper powders which increases the powder absorptivity by up to 70% during laser powder bed fusion. The absorptivity increase enables printing of pure copper structures with densities up to 92% using laser energy densities as low as 82 J/mm^3. We demonstrate similar effects in silver and tungsten. Simulations show the enhanced powder absorptivity results from plasmon-enabled light concentration in nanoscale grooves combined with multiple scattering events. The approach taken here demonstrates a general method to enhance the absorptivity and printability of reflective metal powders at low energy densities by changing the surface morphology of the feedstock without altering its composition.

9:30 AM *SF01.04.05
Additive Manufacturing: Technology Maturation and Synchrotron X-Ray Microscopy Insights AnthonyD. Rollett; Carnegie Mellon University, United States

Additive manufacturing (AM), aka 3D printing is a relatively new technology that has given rise to the “maker culture” and an intense interest in design. That has carried over into metals AM, which has jumped almost immediately into manufacturing of actual parts in a variety of alloys. In doing so it has liberated thinking about part design albeit within certain constraints and complex components have been deployed that were previously inaccessible, e.g., high temperature heat exchangers (HX). An example is described of the co-design of HX against printing constraints, alongside evolution in alloy choice. Nothing is ever as simple as it seems, however, and the reliability of parts that must carry load depends on the internal micro-structure, especially with respect to fatigue loading. This motivates detailed study of all aspects of materials microstructure ranging from defect structures to strain, all of which is ideally suited to the use of intense sources of high energy x-rays as only third generation light sources can deliver. Computed tomography (CT) has revealed the presence of porosity in all additively manufactured metals examined to date and confirmed that appropriate process control can limit it. CT has also provided data on surface condition that we are trying to link to fatigue performance. High speed radiography reveals even more crucial details of how laser light generates vapor cavities that can deposit voids past a critical instability point. “Hot” cracking has been imaged as it happens during the solidification process, which offers the possibility finding printing recipes for alloys previously considered off-limits to 3D printing. High speed, high resolution diffraction in stainless steel, alloy 718 and Ti-6Al-4V reveals unexpected solidification and precipitation sequences. Diffraction microscopy reveals the highly strained nature of printed metals and how microstructure and internal strain state evolves during subsequent annealing. Permeating all these activities is machine learning as an invaluable tool and aid to the researcher.

Support from multiple agencies is gratefully acknowledged, including NASA, DOE/BES, DOE/NNSA, ONR, NSF, OEA, Commonwealth of Pennsylvania, and Ametek.

10:30 AM *SF01.02.03

Intelligentsia of Additively Manufactured Hierarchical Materials JuliaR. Greer[1,2], WidiantoMoestopo[1], MaxA. Saccone[1], SeolaLee[1], MatiasKagias[1,2], WenxinZhang[1] and WeitingDeng[1]; [1]California Institute of Technology, United States; [2]Kavli Nanoscience Institute, United States

Creation of reconfigurable and multifunctional materials can be achieved by incorporating architecture into material design. In our research, we design and fabricate three-dimensional (3D) nano- and micro-architected materials that can exhibit superior and often tunable thermal, photonic, electrochemical, biochemical, and mechanical properties at extremely low mass densities, often lighter than aerogels, which reners them useful and enabling in technological applications. Dominant properties of such structural meta-materials are driven by their multi-scale hierarchy: from characteristic material microstructure (atoms) to individual constituents (nanometers) to structural components (microns) to overall architectures (macroscale).
Our research is focused on fabrication and synthesis of nano- and micro-architected materials using 3D lithography, nanofabrication, and additive manufacturing (AM) techniques, as well as on investigating their mechanical, biochemical, electrochemical, electromechanical, and thermal properties as a function of architecture, constituent materials, and microstructural detail. Additive manufacturing (AM) represents a set of processes that fabricate complex 3D structures using a layer-by-layer approach, with some advanced methods attaining nanometer resolution and the creation of unique, multifunctional materials and shapes derived from a *photoinitiation-based chemical reaction* of custom-synthesized resins and thermal post-processing. A type of AM, vat polymerization, has allowed for using hydrogels as precursors, and exploiting novel material properties, especially those that arise at the nano-scale and do not occur in conventional materials. The focus of this talk is on additive manufacturing via vat polymerization and function-containing chemical synthesis to create 3D nano- and micro-architected metals, ceramics, multifunctional metal oxides (nano-photonics, photocatalytic, piezoelectric, etc.), and metal-containing polymer complexes, etc., as well as demonstrate their potential in some real-use biomedical, protective, and sensing applications. I will describe how the choice of architecture, material, and external stimulus can elicit stimulus-responsive, reconfigurable, and multifunctional response.

11:00 AM SF01.04.07
Designing Against Failure in Additive Manufacturing: From Fracture in Monolithic Samples to Designing Functionally Graded Materials AllisonM. Beese; The Pennsylvania State University, United States

To adopt metallic materials made by additive manufacturing (AM), it is critical to understand, and design against fracture, particularly under complex stress states accessed in service, and with the possible presence of internal pores. Additionally, when designing functionally graded materials (FGMs) in which composition is deliberately varied with position within a component to result in spatially tailored properties, it is critical to avoid deleterious phase formation and solidification cracking during fabrication. This talk will describe our approach for studying the combined effects of stress state and internal pores on the fracture behavior of stainless steel 316 and Ti-6Al-4V manufactured using laser powder bed fusion AM, providing a pathway for designing against failure under realistic conditions. Additionally, it will describe our framework for considering deleterious phase formation and crack susceptibility when designing compositional pathways for FGMs, and more broadly, compositions amenable to AM in general.

11:15 AM *SF01.04.08
Laser Powder Bed Fusion of Fe-Based Shape Memory Alloys ChristianLeinenbach[1,2], IreneFerretto[1], DohyungKim[3] and WookjinLee[4]; [1]EMPA, Switzerland; [2]EPFL, Switzerland; [3]KITECH, Korea (the Republic of); [4]Pusan National University, Korea (the Republic of)

Shape memory alloys (SMAs) are materials characterized by a shape memory effect (SME) and pseudo-elasticity (PE). The SME occurs when a deformed material can recover the original shape upon heating, and PE describes the recovery of a large nonlinear elastic strain upon loading and unloading. The most widely studied SMA by far is NiTi, but the high cost of raw materials and processing of Ni-Ti alloys represents the main drawback of this class of materials and limits its applications to small parts. From the processing side, laser powder bed fusion (LPBF) is an attractive manufacturing technique for SMAs, as it allows for the fabrication of structures with complex geometries. Several efforts have been devoted towards the development of unique three-dimensional (3D) structures with additional functionalities made by LPBF from NiTi alloys, e.g. lattice structures or structural metamaterials, but LPBF of NiTi SMAs with the desired functionalities remains challenging because they have a very high sensitivity to composition change.
A cheaper alternative are e.g. Fe-Mn-Si based alloys, which have been studied with regard to their application for large parts in civil engineering. In the Fe-Mn-Si system, the mechanism responsible for the shape recovery is a martensitic transformation from the γ-fcc phase (austenite) to the ε-hcp phase and its reversion. Up until now, additive manufacturing of Fe-based SMAs has been only scarcely studied.
This presentation will summarize some of our recent activities in the field LPBF of Fe-Mn-Si based SMA. First, the fundamentals of the process-microstructure-property relationships governing the Fe-Mn-Si alloys manufactured via LPBF, which were characterized using techniques such as in situ neutron diffraction and in situ EBSD, will be presented and strategies to manipulate the microstructure and thereby the shape memory properties will be demonstrated. Based on these results, parts with additional functionalities deriving from specifically designed geometries such as enhanced energy absorption and damping capabilities for applications in e.g. civil or structural engineering, are designed and combined with the shape memory properties of the SMAs.

11:45 AM SF01.04.09
Additively Manufacturing Nanolamellar Eutectic High-Entropy Alloys with Anisotropic Mechanical Behaviors YuZou; University of Toronto, Canada

Eutectic high entropy alloys (EHEA) with alternating FCC and BCC-based phases offer an excellent combination of strength and ductility. AM allows for the fabrication of ultrafine nanolamellar EHEA with directional growth. In this study, we investigate the effect of orientation on the deformation, strengthening, and fracture mechanisms of directional EHEA manufactured by additive manufacturing using in situ synchrotron-based high-energy X-ray diffraction during tensile test. Our findings show that the sample along the lamellar direction exhibits the best combination of strength and ductility due to the continuous stimulated strengthening ability of the B2 and FCC phases in the near equal strain condition. The strengthening of the B2 phase is mainly caused by the formation of martensitic phases, while the strengthening of the FCC phase is mainly caused by back stress. Additionally, the sample shows higher crack and void tolerance than the other samples. Our research sheds light on a better understanding of the co-deformation behavior of dual-phase EHEAs made by AM.

SESSION SF01.05: Session IV

1:30 PM *SF01.05.01
Mechanics of Extremely Heterogeneous Materials by Additive Manufacturing TingZhu; Georgia Institute of Technology, United States

Our recent studies of additively manufactured alloys (Nature, 608, 62–68, 2022; Nature Materials, 17, 63-71, 2018) have raised fundamental questions on the role of extremely complex microstructural heterogeneities in the mechanical behavior of these novel material systems. We combine mechanics modeling and experimental characterization to elucidate the strengthening effects of microstructural gradients and resultant plastic strain gradients in additively materials alloys. We quantitatively compare the results from crystal plasticity modeling and in situ synchrotron X-ray experiment, highlighting the less recognized concept of different types of back-stress hardening and various stages of extra back-stress hardening in materials with extremely complex microstructural heterogeneities. Mechanistic insights are gained for further enhancing the strength-ductility synergy in the design of materials with extremely heterogeneous microstructures.

Improving Measurement and Classification of SLM Feedstock Powders by X-Ray Microscopy and Machine Learning DanielSinclair, EshanGanju and NikhileshChawla; Purdue University, United States

Metal Additive Manufacturing (AM) has introduced revolutionary changes in design, production, and innovation sectors over the past decade. This transformative technology, including Laser Powder Bed Fusion (LPBF), Direct Energy Deposition (DED), Binder Jetting (BJ), Metal Extrusion (ME), and Sheet Lamination (SL), has enabled significant advances in aerospace, automotive, medical, energy, and tooling industries. Out of the five, LPBF is favored for its near-net-shape printing, high dimensional accuracy, superior mechanical characteristics, and swift prototype assembly. Within LPBF, Selective Laser Melting (SLM) has gained significant traction in commercial, industrial, and defense applications, specifically for Al alloys. The reliability of SLM parts is often compromised due to defects originating from irregular feedstock powders originating from re-use of powder feedstock or differences in feedstock sources. To accommodate the variation in feedstock required to meet the increasing demands of manufacturing, advanced granulometric methods which are sensitive to varying powder morphologies (as seen in recycled or composite powders) are needed. Lab-scale 3D X-ray Computed Tomography (XCT) presents a viable solution for feedstock powder characterization, enabling non-

destructive quantification of changes within recycled particles. Our research delved into a gas-atomized AA7050 feedstock powder with unusual powder morphologies and titanium additives (AA7050-RAM2). Through the synergy of lab-scale x-ray microscopy and automated watershed segmentation, we were able to quantify the shapes and sizes of particles in an aluminum alloy (AA7050-RAM2) powder feedstock. Additionally, to describe nonstandard particles more accurately, we introduced novel 3D shape factors. Furthermore, to optimize efficiency and capture an extensive range of powder morphologies, we compared automated classification methodologies for the feedstock using a combination of algorithmic clustering and the Random Forests machine learning algorithm. Our research provides significant insights into enhancing the consistency and reliability of SLM-fabricated parts. It does this by delivering a nuanced understanding feedstock powder morphology and by proposing innovative classification methods. These insights are poised to assist in broadening LPBF's application and furthering advancing metal additive manufacturing.

2:15 PM *SF01.05.03
Development of a Low Thermal-Budget, Distortion-Free Process for Binder-Jet 3D Print-and-Sinter Alloys ChristopherA. Schuh[1,2], ChristianOliver[1,2], YannickNaunheim[1] and JasperLienhard[2]; [1]Massachusetts Institute of Technology, United States; [2]Foundation Alloy, Inc., United States

Binder-jet printing and sintering is a pathway to scalable, high-volume, low-cost manufacturing of complex metal parts. It also presents an opportunity to design new alloys produced entirely in the solid state, thus using less energy and involving less residual stress and distortion than other modes of metal 3D printing. This talk will review research aimed at such alloy and process development, with an emphasis on understanding and tailoring sintering mechanisms to effect low-temperature consolidation. New alloys based on Mo- and Ni- will be highlighted, and processing advantages in terms of energy and shape retention elaborated. Finally, the properties of these alloys will be evaluated and opportunities for alloy substitution discussed.

2:45 PM SF01.05.04
Addictive Manufacturing of Novel Aluminum Alloys: Structure and Properties LinLiu, JingyuXu and ChengZhang; Huazhong University of Science and Technology, China

Additive manufacturing (AM) offers significant advantages over conventional manufacturing techniques in processing Al alloys, however, high-strength Al alloys produced by AM commonly encounter a few challenges including poor processibility and undesirable microstructures with coarse columnar grains and micro-cracks, leading to poor mechanical properties. Here, we demonstrate that these issues can be largely resolved by micro-alloying of Zr element in the Al-based alloys. In this study, a series of novel Al-1Fe-0.6Cu-xZr alloys with different content of Zr (x=0.3, 0.6, 0.8, 1.3at%) are designed and fabricated by laser powder bed fusion (LPBF). It is observed that the LPBF Al alloys all exhibit notably heterogeneous structures with alternate distribution of coarse grain zones (CGZs) and fine grain zones (FGZs). With increasing Zr content, the grain size in both CGZs and FGZs gradually decreases and the columnar-to-equiaxed transition (CET) occurs in the CGZs, which make the processibility be improved for the Al alloys with higher Zr content. To understand the formation of the heterogenous structures and the correlation between microstructure and mechanical properties, the LPBF Al-Fe-Cu-1.3Zr alloy was selected, as am example, for detailed investigations. It is revealed that the formation of FGZs, locating at the low boundaries of the molten pools, is attributed to the pre-formed Al3Zr nanocrystals, which sever as nuclei and results in the refinement of grain size, while the CGZs are formed at the interior of molten pools, where no Al3Zr precipitates are formed, leading to the formation of relatively coarse grain size. In addition, Fe/Cu co-segregation appears at the GBs in both FGZs and CGZs although Cu and Fe are thermodynamically immiscible. As a result, these unique microstructures allow the LPBF-processed Al-Fe-Cu-1.3Zr alloy to have high strength at both room temperature and elevated temperatures. For example, the yield strength reaches 500 MPa at room temperature and 163 MPa at 573 K, respectively, both are higher than those of additive manufactured Al-based alloys reported thus far. The findings in this work provide a guild for design of novel Al alloys with good processability and advanced mechanical properties for additive manufacturing.

3:00 PMBREAK

Additive Manufacturing: Transforming Engineering Design Through Functionally Integrated Materials, *In-Situ* Imaging, and Alternative Feedstock MaterialsJulieM. Schoenung[1] and XinWang[2]; [1]University of California, Irvine, United States; [2]The University of Alabama, United States

This presentation will provide an overview of various aspects of additive manufacturing that can lead to transformative materials and engineering design. Directed energy deposition (DED) additive manufacturing enables the precise control of composition for the development of functionally integrated materials (FIMs) with site-specific functionality. This compositional control is enabled by the powder injection delivery system that allows for the sequential and / or co-deposition of multiple feedstock powders through individual powder feeders. This strategy provides a path to the rapid development of novel alloys and components with location-dependent chemical composition and properties. The FIMs concept is demonstrated using two material systems: stainless steel 316L with Haynes 282 nickel superalloy, and nickel with nickel-aluminum. Extensive characterization of microstructure, interfaces, diffusion zones, grain boundary morphology and texture, chemical composition and phase transformations provides insight into the fundamental materials science governing the solidification process and consequential component performance in FIMs. DED also entails complex particle-laser-melt pool interactions due to the powder injection mechanism. In-situ imaging using both thermal imaging and high-speed video provides insight into these complex interactions, as highlighted here for various examples including nickel superalloy powder and TiC reinforcement particles. Lastly, the benefits of using recycled and repurposed alternative feedstock materials are considered.

4:00 PM SF01.05.06
Additive Manufacturing of Co-Based Superalloys via Direct Ink Writing JianLiu[1], ZhiyuZhang[2], ShuaiGuan[1], JonathanPoplawsky[3], TianyiLi[4], YangYang[2] and WenChen[1]; [1]University of Massachusetts Amherst, United States; [2]The Pennsylvania State University, United States; [3]Oak Ridge National Laboratory, United States; [4]Argonne National Laboratory, United States

Additive manufacturing of superalloys enables innovative, geometrically complex designs combined with excellent mechanical properties. Here, we developed an additive manufacturing method based on direct ink writing (DIW), to fabricate a high-performance Co-based superalloy. The ink consists of metal powders, polymer binders, and volatile solvents. The deposited architectures are thermally sintered to near-full density, followed by ageing. The sintered Co-based superalloy exhibits a homogeneous microstructure of equiaxed grains with MC carbides uniformly distributed in the FCC matrix, which leads to a high ultimate tensile stress in excess of 1.2 GPa and a large tensile ductility over 20% at room temperature. The outstanding combination of strength and ductility originates from the coherent γ′ nanoprecipitates and deformation-induced stacking faults, as revealed by in situ synchrotron X-ray diffraction and high-resolution transmission electron microscopy. The introduced additive manufacturing approach provides new opportunities to print a wide range of superalloys for high-temperature applications.

4:15 PM *SF01.05.07
Understanding Ultrahigh-Rate Behavior of Macromolecules for Advances in Polymer-Based Cold Spray Additive Manufacturing Jae-HwangLee[1,2], AraKim[1] and AnuraagGangineri Padmanaban[1]; [1]University of Massachuesetts, United States; [2]University of Massachusetts Amherst, United States

The solid-state coating and additive manufacturing of polymers are feasible by the cold spray (CS) technique, in which solid feedstock powders or microparticles (μPs) conveyed by a high-speed gas stream are subjected to a head-on collision against a stationary surface at transonic or supersonic velocities. Due to the ultrahigh-strain-rate (UHSR) viscoplastic deformation upon collision, polymer μPs can be consolidated without volumetric melting or phase transition. In CS, μP adhesion is accomplished by the highly localized thermal softening (or melting), and other inelastic mechanisms, especially brittle fracture, may also become significant. As local temperature fields, the consequence of impact-induced plastic strains, are coupled with temperature-dependent mechanical properties, the UHR adiabatic plasticity of polymers is inherently nonlinear and is very difficult to predict via the time-temperature superposition.
In this talk, we will introduce our recent efforts to understand the UHSR behavior of polymer μPs through single-particle experiments realized by laser-induced projectile impact testing (LIPIT). For glassy polymers modeled by polystyrene of various molecular weights (MWs), the MW-dependent interplay of the primary inelastic mechanisms is systematically and comprehensively investigated through ultrafast optical images from LIPIT. Due to the ambivalent effect of MW on fracture toughness and interfacial rheology, our study demonstrates that the proper selection of MW is crucial for the feasibility of the solvent-free and solid-state deposition of glassy polymers. Meanwhile, LIPIT experiments with an incidence angle of 45° are conducted to investigate the tribological response at the contact interface. We elucidate the strain-dependent tribological properties of deblock copolymers under extremely dynamic collisions and the correlation between friction and adhesion properties at the nanosecond time scale. Furthermore, we demonstrate that phase-separated deblock copolymers can be ordered via collision-induced shear flows. The extended knowledge from our study about the UHSR behavior of polymers will be crucial for advances in polymer-based CS additive manufacturing that can also open opportunities for creating novel materials properties.

Correlations Between Porosity, Spatter and Process Metrics for Powder Bed Fusion Laser Beam Metallic Additive ManufacturingJ.-A.S. Hocker[1], JosephN. Zalameda[1], BrodanRichter[1], AndrewR. Kitahara[2], Sang-HyonChu[1] and EdwardH. Glaessgen[1]; [1]NASA Langley Research Ctr, United States; [2]Analytical Mechanics Associates, United States

The large scale and deposition sequence of powder bed fusion laser-based metallic (PBF-LB/M) additive manufacturing (AM) create tremendous computational challenges for establishing precise ‘process-structure’ correlations throughout the process. A recent approach, AM model-based process metrics (AM-PM), has addressed the challenge by applying analytical reduced-order models to the heat source position. AM-PMs can reveal quantifiable trends in space and time throughout the PBF-LB/M process. The AM-PMs furnished by the reduced-order models were evaluated against high-speed imaging (coaxial with the laser beam) of weld melt pools, and metrics from ex-situ metallography of the welds. The presentation will discuss how AM-PMs, such as melt pool width, correlate with measurements from in-situ imaging and ex-situ metallography

8:00 PM SF01.06.01
Additive Material Transfer using On-Demand Adhesion Modulation in a Self-Assembled Nanofluidic Structure SeongjaeKim[1], Ji-hunJeong[2], Hyun JunRyu[1] and SanhaKim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

Transfer printing is one of the attractive routes toward additive manufacturing of flexible/stretchable electronics, micro/nanophotonic devices, micro-LED displays, and healthcare sensors via assembling micro/nano components. However, a major challenge in micro/nano transfer printing is achieving both high throughput and yield. An important factor in minimizing the transfer failure is the adhesion contrast between the picking and placing stages, particularly when manipulating microscopic substances that cannot be placed using gravitational force alone. Accordingly, realizing the large contrast in surface adhesion and its rapid transition is essential for the assembly of miniaturized parts.
Herein, we propose a novel nanofluidic device enabling manipulation of micro components via capillary grasping and releasing mechanism. We fabricate the surface via vertical self-assembly of carbon nanotubes which allows liquids to infiltrate into the nanoscale channels when a strong gripping force is necessary and rapidly evaporate the fluid when a weak releasing force is needed. We quantitatively characterize the adhesive strength and find that the structure can exhibit high adhesion as liquid infiltrates the channel (~17.4 kPa) while it can switch into low adhesion as the surface is fully dried (< 0.1 kPa). The adhesive behavior is evaluated using atomic force microscopy and capacitive force sensing, resulting in an adhesion contrast of greater than 100-fold. Due to the nature of the liquid-solid interface, a minimal preload of 0.8 kPa is sufficient to enable the picking and placing which is particularly ideal for physical-contact-based manipulation of delicate electronic components. Our study demonstrates the successful transfer of μLED chiplets, ultrathin films, and CNT supraparticles, as well as the application of strain sensors by transferring CNT particles onto a flexible PDMS substrate. To further elucidate insights into the underlying mechanism, we develop a mechanics model to analyze the adhesive force with respect to the types of liquid and contact time. Furthermore, we implemented a radiative heater to accelerate the evaporation process, enabling rapid pick-and-place operations that can be completed within a few seconds. Finite-element simulation and experiments reveal that the nanoscale fluid channels of our vertically aligned nanofiber structures are advantageous over planar surfaces by increasing the efficiency of heat transfer. We believe that this study provides a new route toward additive manufacturing of unconventional freeform devices via rapid and reliable assembly of micrometer-sized elements.

8:00 PM SF01.06.02
Selective Gene Expression in Hydrogel Suspended Escherichia Coli Through Optogenetics by Spatiotemporally Controlled Light for the Purposes of Additive Manufacturing BorutLampret, AndreasHadjimitsis, Guy-BartStan and ConnorMyant; Imperial College London, United Kingdom

Natural and engineered biology offer an immense diversity of biological materials with a wide range of properties and benefits. Nature employs biological materials on all scales and forms various complex structures to further diversify the macroscopic properties of materials. Advances in the ability to manipulate genetic material have enabled the utilization of microbes in production of these biological materials and in combination with additive manufacturing one could attempt to artificially create such complex structures. However, most biological materials are not suitable for use with conventional additive manufacturing. While there have been significant advances in the field of bioprinting, great effort is still required to develop the so-called bioinks, which support both the printing process and the encapsulated cells’ survivability.

To combat these challenges a novel method of additive manufacturing is explored, which can employ microbial cell factories suspended in hydrogel and optogenetics to selectively deposit the desired biological or synthetic material in a three-dimensional (3D) volume. Genetically engineered Escherichia coli that produces a synthetic light response system, CcaSR v3.0, was used in order to allow for spatially selective gene expression. A custom designed system was built to both house the hydrogel suspended E. coli and to provide and shape green and red light, which were used to interact with the cells. Green light was used to induce gene expression and red light was used to suppress gene expression. Localized gene expression was achieved within the hydrogel build volume with proper overlap of the green and red light and with the help of a predictive model describing the behaviour of the CcaSR system in response to light. To enable the process of additive manufacturing, a series of spatiotemporal illumination procedures were developed, and their behaviour investigated.

This approach of 3D printing is unique in that is shifts the burden of material from the bioink to the cells, which changes material engineering to bioengineering. This approach effectively exploits the cells for in-situ material production. As the cells are suspended in a hydrogel medium, any mechanical stress during the printing process is eliminated. Provided that the cells’ engineered metabolism is not toxic, chemical stress is also eliminated. As opposed to conventional polymerisation, which generates cytotoxic free radicals.

This talk focuses on illumination procedures and slicing methods, which enable the cells to exhibit gene expression in complex 3D geometry within the volume. This system allows for near volumetric 3D printing in a sense that there is no requirement for supports or flat two-dimensional slicing of objects. A concrete example of gene expression in the shape of a double helix will be presented and discussed. Furthermore, both the spatial and temporal resolution limitations of the 3D printing method and system will be discussed along with proposed solutions. This research is the first stepping stone towards a novel bioprinting approach, which can expand the 3D printing material library to biological materials and could also be implemented in tissue engineering through optogenetics.

3D Printing of Photoconductive Zinc Oxide-Based Photoresins OzanKarakaya[1,2], LuisA. Ruiz-Preciado[1,2], PeterKrebsbach[1,2], KaiXia[1,2], ChristianRainer[1,2], AliTunc[1,2], UliLemmer[1,2,3] and GerardoHernandez-Sosa[1,2,3]; [1]Light Technology Institute, Karlsruhe Institute of Technology, Germany; [2]InnovationLab, Germany; [3]Institute of Microstructure Technology, Karlsruhe Institute of Technology, Germany

The interest in 3D-printed functional microstructures has significantly increased over the past decade due to their potential utilization in microelectronics, photonics, optoelectronics, and biological applications.[1] Compared to commonly used additive manufacturing techniques such as fused deposition modeling and selective laser sintering, light-based 3D Printed methods (Stereolithography) offer faster processing and higher spatial resolution.[2,3] However, for light-based 3D printing, mainly 3D structures based on organic polymers have been assembled due to the limited availability of multifunctional (e.g. conducting, semiconducting, etc.) photoresins. One of the main challenges that have been encountered when designing functional photoresins is the undesired light absorption of the ink, which leads to relatively low spatial resolution or crosslinking efficiency.[4]

Here we use an approach for designing a multifunctional photoresin to fabricate 3D-printed ZnO microstructures by mixing a commercial photoresin with a Zinc-based metal-organic complex. This material doesn’t have any optical absorption that interferes with the photoresin photopolymerization process and can be transformed to ZnO at low annealing temperatures (< 200 °C). The utilized functional resin is comprised of a commercial photoresin into which the ZnO precursor, a stabilizer, and an organic solvent are added. Additionally, high zinc loading is possible by using a stabilizer in the precursor solution which can lead to high ZnO conversion hence better optoelectronic properties. Depending on the material ratio and optimized composition which favors both printing resolution and optoelectronic properties can be prepared. After printing of the photoresin by Digital Light Processing (DLP) (27 μm resolution, 25 μm slice thickness), the 3D structure is thermally annealed to transform into a Polymer/ZnO composite. Structural and morphological characterization has been performed by scanning electron microscopy and x-ray diffraction showing percolative paths of ZnO in the polymer matrix and good crystalline quality.
Optoelectronic characterization of the 3D printed Polymer/ZnO composite yielded Zinc based 3D printed photodetectors exhibiting photocurrents off 0.5 nA and an on/off ratio of 250 when excited at a wavelength of 395 nm. Reference thin-film samples deposited on glass substrates showed ZnO-based UV-photodetectors exhibiting a photocurrent of 5 nA and an on/off ratio of 600 when excited at the same wavelength.

In future work, we plan to extend the obtained results towards its use in the Direct Laser Writing (DLW) process to obtain micro-architected 3D ZnO structures which will be potentially used in applications such as miniaturized optoelectronic and bioelectronic devices.

***In-Situ* Alignment Behavior of Anisotropic NdFeB Magnets in Extrusion-Based 3D Printing Process**YongraeKim, DongwoonShin, TaehoHa, JoonphilChoi, SegonHeo, Yeo-UlSong, ChangwooLee, Pil-HoLee and Min-KyoJung; Korea Institute of Machinery and Materials, Korea (the Republic of)

Permanent magnet materials play a vital role in numerous electronic devices, ranging from electric vehicles and wind turbines to smartphones and smartwatches. Their ability to efficiently convert electrical energy into mechanical energy makes them essential components in modern technology. With the increasing demand for high-performance magnets with diverse shapes, driven by the trend towards miniaturization and lightweight design, there is a need to explore innovative manufacturing techniques which can meet these requirements and improve overall efficiency.

Currently, the production of permanent magnets primarily uses two main methods: sintering and polymer-bonded techniques. Sintered magnets exhibit superior magnetic properties compared to bonded magnets because of their higher density and crystalline structure. However, they possess inherent limitations, including poor corrosion resistance, limited shape complexity, and higher energy consumption during the manufacturing process. On the other hand, bonded magnets are created by combining magnetic powders and polymer binders through compression molding, extrusion, or injection molding. Compression molding allows for magnets with high filler ratios, but it is restricted to producing magnets with simple shapes. Injection molding, although capable of fabricating magnets with complex geometries, results in material waste and requires additional tooling processes.

To overcome these challenges and advance the production of bonded magnets, our research utilizes the additive manufacturing technique known as Fused Deposition Modeling (FDM). Unlike conventional methods that use filament, we employ powders or pellets consisting of binder polymers and anisotropic magnet fillers in our process. This approach reduces process time by skipping the filament manufacturing step and allows for control of the filler ratio. It also enables the creation of complex-shaped bonded magnets and addresses the limitations of conventional manufacturing techniques. Moreover, during the layer-by-layer printing process, we incorporate an in-situ electromagnetic alignment method to orient the anisotropic magnetic fillers along the desired magnetization axis. This alignment technology determines the orientation of the magnetic filler during processing, resulting in bonded magnets with superior magnetic properties, including improved remanence, coercivity, and energy products.

In our presentation, we will provide a comprehensive overview of the FDM-based bonded magnet fabrication process and discuss the crucial parameters involved. One significant parameter is the printing temperature, which determines the viscosity and flow characteristics of the binder polymer and affects the overall quality and integrity of the printed magnet. Additionally, the application of in-situ magnetic fields during the printing process plays a crucial role in aligning the anisotropic magnetic fillers with the magnetization axis and influences the final magnetic properties of the fabricated magnet. Understanding and controlling these variables is essential for achieving magnets with optimal performance.

Continuing our research and development efforts, we aim to further optimize the FDM-based bonded magnet fabrication method. Our goal is to improve the magnetic properties of the magnets produced while increasing the complexity of their small, lightweight, and shaped forms. To achieve these goals, we will explore various aspects, including the formulation of magnet fillers, binder polymers, and their interactions, as well as the optimization of printing parameters and post-processing techniques. By continuously improving this additive manufacturing approach, we aim to provide an efficient and sustainable method for producing high-performance bonded magnets tailored to the specific requirements of modern electronic devices.

8:00 PM SF01.06.05

3D Printing of Fluidic Systems with Soft Tissue-Like Membranes YafengYu[1], YiPan[1], YantingShen[1], JingxuanTian[1,2], RuotongZhang[1], WeiGuo[1,2], ChangLi[1] and AndersonShum[1,2]; [1]The University of Hong Kong, China; [2]Advanced Biomedical Instrumentation Centre, Hong Kong Science Park, China

As a natural fluidic system, blood vessel networks can adjust blood compositions by modulating physicochemical reactions between vessel walls and blood. Such biomimetic strategy in regulating fluids remains underexplored in synthetic systems, despite its relevance to spatiotemporal fluid modulation. The challenge is to build synthetic channels with functionalizable, vessel tissue-like walls. In this work, we produce a fluidic system with soft, membranous, and semipermeable channel walls, thus enabling functional compartmentalization for physical transport of fluids or for chemical reactions with fluids. An extrusion-based 3D printer was utilized to deposit one aqueous solution within another, where oppositely charged polymers self-assemble on the interface between these two solutions to generate channel-like structures. The channel walls are functionalizable for localized physicochemical reactions, for instance, by placing solutions of small molecules beside channels or locally immobilizing enzymes on the outer channel walls. Thus, fluid compositions inside are spatiotemporally programmable: As a demonstration, by modulating interplays between fluids and channels over space, the glucose concentration increases in the upstream fluid and decreases in the midstream channel, and the carbon dioxide concentration decreases in the downstream fluid. Our proposed fluidic system mimics the biofluid regulation in natural systems, inspiring platforms as in-vitro tissue models to synthesize biologically relevant molecules and screen drugs.

8:00 PM SF01.06.06

Three-Dimensionally Printed, Vertical Full-Color Display Pixels for Multiplexed Anticounterfeiting ShiqiHu and Ji TaeKim; The University of Hong Kong, Hong Kong

Since counterfeiting has emerged as a global issue, novel and advanced strategies are in great demand for data storage and encryption to prevent information leakage. To this end, various materials, structuring strategies, and data processing algorithms have been devised. Creating high-resolution, sophisticated anticounterfeiting patterns has mostly relied on photolithography, nanoimprinting, and laser engraving, which are energy-intensive and/or chemically deleterious, difficult to perform on valuable products[1–4]. Alternatively, inkjet printing has also been utilized by taking advantage of its cost-effectiveness and high compatibility with ink and substrate materials. However, the resulting patterns are easily duplicated due to their simple geometry constrained in-plane. Advancing the structural complexity for improving security level remains a longstanding challenge. The utilization of luminescent materials is a strategy to advance anticounterfeiting labels. The intrinsic or stimulus-responsive optical properties of semiconductor quantum dots, perovskites, or organic dyes can be exploited to configure multilevel anticounterfeiting[5,6]. A luminescent-based anticounterfeiting label consists of an array of pixels which are the fundamental element to encode/display information. Each pixel is typically composed of red, green, and blue subpixels with lateral patchwork to render multi-channel information encryption. However, this lateral configuration is unavoidable for the existence of a subpixel pitch, not only being easily copied but also limiting the improvement of pixel density.

Herein, we propose vertically stacked multicolor micropixels for high-resolution, multiplexed anticounterfeiting. The micropixel is produced by sequentially stacking luminescent dye-doped red-green-blue (RGB) subpixels, realized with high-resolution 3D printing. Our 3D printing approach based on the use of a femtoliter ink meniscus enables vertical stacking of micron-sized subpixels without the existence of a subpixel pitch, drastically increasing the pixel density up to 13,400 pixels per inch (PPI), which is not easily attainable by the traditional lateral subpixel layout. Furthermore, a full-scale color synthesis for each micropixel is achieved by modulating the height ratio of R, G, and B subpixels, which is reflected in the CIE 1931 diagram. These features create high-resolution, multiplexed anticounterfeiting labels, inaccessible by conventional optical imaging, and 3D printing offers the simplest, most versatile route to manufacture. This work demonstrates the exceptional inclusivity of 3D printing to construct vertically stacked structures and highlights the possibility to devise 3D printing for photonic device manufacturing.

Fabrication of Multifunctional Wearable E-Textile Platform using Multi-Head 3D Printing Process KyusoonPak and StevePark; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In recent decades, attempts have continued to data various senses felt by the human body. Among these various senses, sensor studies for the tactile sense have been conducted in a way that applies soft electronics due to the ranges and types of tactile senses, and the fact that human skin has many curved parts. However, most existing studies involve materials that are unideal to detect touch and human posture, and there were thus many limitations to their application to the dynamic human body. In this study, to solve the aforementioned problems, a wearable tactile sensor was manufactured using textile(clothes) worn by mankind for a long time as a substrate. The weaving method using coating yarn, used in the study of most textile-touch sensors, has the disadvantages of a complicated process and difficulty in customization. Therefore, in this study, strain sensors, electrodes, and temperature sensors made of organic materials were directly 3D-printed on the substrate of clothes and textiles. we developed a solution-based ink for manufactured tactile sensors. The ink can quickly fabricate sensors and electrodes and applied the 3D printing process to produce fabric-based electronics. Through this method, the process could be simplified and the waste of materials could be reduced, and it was possible to manufacture sensors in the forms desired by the user. In addition, physical deformation of the electrode could be maintained by utilizing the excellent elasticity of the textile without changing the excellent

resistance value (0.2 Ω ~ 0.4 Ω) using polystyrene, a hard material that is fundamentally controlled. In addition, by optimizing the degree of permeation into the textile according to viscosity, electrodes printed on both sides could be connected or separated at a point desired by the user. We evaluated the performance of each sensor and applied the integrated sensor to the Battle Dress Uniform (BDU) to measure the surrounding environment of the actual soldier in real time. Through this study, a method of printing the solution directly on the textile was attempted, and we are sure that it will be possible to promote great progress in integration through the use of both sides by controlling the degree of absorption of the solution into the textile through the viscosity.

8:00 PM SF01.06.08
3D-Printed Single-Material Carbon Nanotube Thermocouple Microdevices ZhuoranWang and Ji TaeKim; The University of Hong Kong, Hong Kong

Miniaturized thermocouples have emerged as an essential component for the power generation or thermal management of microelectronic devices due to their capability to convert heat to electricity. Recently, extensive research focused on the structural design of micro-thermocouples to improve the thermoelectric performance, and one resulting insight is that a three-dimensional (3D) geometry can be beneficial in terms of integration density and thermal contact efficiency [1]. However, the construction of a 3D micro-thermocouple typically comprising two dissimilar materials suffers not only from the process complexity with high cost but also from the low mechanical strength of the junction.

Here, we have developed a micro 3D printing method for fabricating a single-material carbon nanotube (CNT) thermocouple device. The device is configured with an electrical junction of two freestanding CNT microwires with different widths, by exploiting the size-dependent Seebeck coefficient at the electron mean free path scale [2, 3] instead of using two different materials. The developed micro 3D printing method that uses a femtoliter ink meniscus enables a single-step, continuous, high-resolution (< 1 μm) manufacturing of CNT micro-thermocouples in three dimensions. This greatly ensures structural robustness, cost-effectiveness, and design flexibility, which have not been attained by other traditional manufacturing approaches, reinforcing practicality. In this talk, we will present the experimental results including the fabrication and characterization of 3D CNT micro-thermocouples, and discuss the prospects of our work for potential applications.

Parameter Optimization for Bioprinting of Cell-Laden Gelatin Methacryloyl Bioinks Guided by Support Vector Machine ZhouquanFu[1] and WeiSun[1,2]; [1]Drexel University, United States; [2]Tsinghua University, China

3D bioprinting is an emerging and fast-growing interdisciplinary field which uses biomaterials, living cells, and/or bioactive factors (i.e., bioinks) to construct biological models, biological living systems, and therapeutic products. The printing and post-printing processes encompass printer parameter tuning (e.g., temperature, speed), assessing printability (fidelity and cell survivability), and fostering the maturation and integration of the printed tissue. Each of these stages can be influenced by an extensive array of factors, including the type of cells and biomaterials utilized, the printing parameters, and the intended function of the bioprinted tissue or organ. The complexity of the process, combined with the multitude of variables, presents a significant challenge for manual optimization and control. Owing to the intrinsic difficulties in the 3D structure formation posed by the soft biomaterials and the encapsulated cells, bioprinting has unique requirements for the biomaterial properties and process parameters to maintain high cell viability and structural fidelity. Currently, trial-and-error experimentation has been dominantly used to find “optimal” printing parameters and bioink parameters, which is costly and time consuming. In our study, a uniform design-of-experiment method was used to select only 12 parameters (out of 64) as the training data set. Then experimentations on the 12 parameters were conducted, followed by the data labelling as good or bad print based on the printability score and cell viability score. Then the support vector machine (SVM) classifier algorithm was trained on the 12 data and then a process map was generated by the SVM prediction on the entire data space. Our method was tested effective and quick to find parameters that can yield good printing results with high cell viability.

8:00 PM SF01.06.10
Thermal Conductivity Measurement for Aligned Particle Monolayers EvanToth, JessicaFaust and RandallM. Erb; Northeastern University, United States

Thermal management poses serious design and size limitations for high power density electronics, and relatively few material options that are both dielectric and thermally conductive can be processed easily (e.g., hexagonal boron nitride, diamond). Hexagonal boron nitride has strong dielectric properties and a theoretical thermal conductivity on par with copper, imbuing it with strong potential for use in power electronics and low-loss RF systems -- especially in thin layers. Hexagonal boron nitride (sometimes called ‘white graphene’) has excellent in-plane phonon transport, and to exploit this we use a surface assembly technique to create percolated platelet-thick monolayers. Induced planar alignment of the individual platelets at high volume loadings transforms a disjoint collection of particles into a thermally percolated plane for heat to preferentially travel *within* (x-y) but not *through* (z). Regarding conductive behavior, monolayers are particularly interesting due to their low dimensional (2D) morphology but, in turn, make extracting useful thermal parameters (diffusivity, conductivity) significantly difficult with current measurement techniques. Convential methods like thermal interface measurement and laser flash either cannot accurately measure in-plane heat flow or require highly custom software/hardware for an otherwise highly inaccessible instrument. In this work, we modify the semi-transient method developed by Angstrom in 1861 to measure the thermal diffusivity of 2D materials with the aim of thermally characterizing monolayer composites and more generally to allow for simple planar measurement of thermal diffusivity.

8:00 PM SF01.06.11
High Resolution Magnetorheological Devices for Advanced Applications Fabricated by Additive Manufacturing Technologies AnderGarcia[1], CarmenR. Tubio[1], AinaraGomez[2], JoanesBerasategui[2], MounirBou-Ali[2], JonGutierrez[1,3] and SenentxuLanceros-Mendez[1,4]; [1]BCMaterials, Basque Center for Materials, Applications and Nanostructures, Spain; [2]Mondragon University, Spain; [3]University of the Basque Country, Spain; [4]Ikerbasque, Basque Foundation for Science, Spain

Magnetorheological elastomers (MREs) can modify their mechanical properties (mainly elastic moduli) in response to a magnetic field. These materials, comprising a polymeric matrix and inorganic magnetic fillers, have traditionally found use in large scale applications (such as dampers and isolators) that sacrifice accuracy for performance and fabrication simplicity.

With additive manufacturing (AM) technologies, however, complex structures could be fabricated through different techniques, such as direct ink writing (DIW), that allow to achieve higher pattern resolutions and allow new and exciting applications in the field of healthcare, automotive and printed electronics. The issue with traditionally designed MREs is that are typically based on carbonyl iron microparticles that, albeit their high saturation magnetization and low coercivity, are not suitable for AM due to their size and hinder high resolution patterns.

Thus, a transition should be made into using nanoparticles (NPs) for high-resolution applications. To this end, we have studied the impact that magnetic properties, concentration, shape, and orientation have on the performance of nanoparticle based MREs, in order to achieve the optimize performing material compatible with AM.

Nanoparticles with different values of saturation magnetization, coercivity, and remanence have been selected to fabricate the MREs. Six different fillers were tested: $CoFe_2O_4$, Fe_3O_4, Co, Ni and $Ni_{80}Fe_{17}Mo_3$ (Permalloy). The magnetorheological (MR) effect achieved for the Fe_3O_4 composite was the highest one at 18%, and comparable to other composites reported in the literature, but with a lower content of magnetic material (only 6 vol% versus 20 vol%), which is expected to improve the processing and integration of the MRE. Moreover, by using different concentrations (20 wt%, 40 wt% and 60 wt%) of the Permalloy filler, we obtained a linear relationship between MR effect and filler concentration, increasing from 8% at 20 wt% to almost 30% at 60 wt%. However, this increase in performance should be carefully balanced with the variation of the mechanical properties.

Further, Fe_3O_4 nanorods (NRs) have been synthesized with an aspect ratio of 10 to compare with the 70 nm sized cubic Fe_3O_4 NPs. Anisotropic MREs (A-MREs) were then fabricated by curing the composite inside a magnetic field to achieve a preferential orientation and compared them with isotropic MREs (I-MREs) cured without the presence of the magnetic field. The results of the relative magnetorheological effect confirmed that the A-MREs exhibit higher values of the MR effect, as it increased from 12% to 27% in the case of the NPs and from 8.3% to 17% in the case of the NRs. Interestingly, these results imply that lower aspect ratios are more suitable to enhance the MR effect in anisotropic composites, since the relative increase between oriented and non-oriented samples was 125% for the NPs and 104% for the NRs.

The suitability of these materials for DIW additive manufactured devices has been further evaluated in Fe_3O_4-based MREs. We fabricated a fully printed patterned device combining magnetoelectric and magnetorheological properties, where the conversion from applied magnetic field to output voltage could be manipulated by taking advantage of the change in mechanical properties and magnetostriction of the magnetorheological layer.

8:00 PM SF01.06.12
Additive Manufacturing of Flexible Photonic Waveguides with Active Components MaxineOng, YuShu, MaxJenkins, HarishBhaskaran and PeterBruce; University of Oxford, United Kingdom

An emerging research direction in flexible devices is in photonics. Having the ability to manipulate and deform photonic devices gives the additional benefit of controlling light-matter interaction. Flexible photonic devices are seen in applications such as interconnects, detectors and bio-photonic sensors, where the mechanical flexibility of the devices is exploited. However, there are still many challenges associated with the fabrication due to the poor compatibility of available flexible substrates to conventional methodologies.
In this work, we demonstrate the fabrication of polymeric waveguides on flexible substrates and the integration of active components (e.g. 2D materials, phase-change materials) through additive manufacturing, such as direct laser writing and pick-and-place. These have potential optoelectronic applications in photodetection, and memory devices that can be seamlessly affixed to conformal surfaces.

8:00 PM SF01.06.13
Mechanism of Cellulose Ester as an Anti-Wash Admixture of Cement for Underwater 3D Printing TianyiWang and YaxinAn; Louisiana State University, United States

Underwater 3D printing of cement presents a significant challenge due to issues such as washout or segregation of cement. To address this problem, the addition of anti-wash admixtures has been explored to increase the printability of cementitious materials. Among these admixtures, cellulose ester has gained wide recognition for its effectiveness in improving the underwater printability of cement. Only a small amount of cellulose ester (<1 wt%) could significantly improve the underwater printability of cement. However, the underlying mechanism of how cellulose ester enhances the cohesiveness of cement is little understood. To shed light on the mechanism, we performed atomistic molecular dynamics simulations of cellulose ester with cement. Specifically, we characterized the conformation of cellulose ester and examined the interface between cellulose ester and cement. To gain insights into the thermodynamic properties of cellulose ester on the cement surface, we calculated the potential of mean force for an oligomer of cellulose ester. Additionally, we investigated the effects of the number of acetylation groups and the degree of polymerization of cellulose ester. This work presented an atom-level understanding of the interplay between cement and cellulose ester, which holds great potential for the optimization of anti-wash admixtures for underwater 3D printing.

8:00 PM SF01.06.14
Expanding the Toolbox of PhotoROMP Additive Manufacturing AlexCommisso, AnnikaJansen and SamuelLeguizamon; Sandia National Labs, United States

Stereolithographic additive manufacturing (SLA) processes provide agility and complex design development of components necessary for a wide range of critical applications. Yet this technique is limited to a small subset of monomers that traditionally produce polymer materials with poor thermal and mechanical properties. Conversely, ring-opening metathesis polymerization (ROMP) can produce relatively tough, high T_g thermosets using latent ruthenium catalysts. Furthermore, spatiotemporal control of the polymerization using photosensitizers affords high resolution patterning of high T_g thermosets using photoROMP. Dicyclopentadiene (DCPD), an inexpensive but robust photoROMP monomer, has been featured in SLA resins to generate highly complex three-dimensional geometries at print speeds approaching industry-leading standards using continuous SLA techniques. However, the minimal exploration into the monomer space in photoROMP and ROMP SLA hinders the utility of ROMP polymers as the DCPD-based resins are generally non-processable, non-degradable, and lack other useful functionalities that have previously been imbued in polymeric materials. By examining the strained olefin monomer space for their photopolymerization kinetics, material properties, and print fidelity, we have identified potential routes to rapid SLA of functional polymers using photoROMP.

8:00 PM SF01.06.15
Additively Manufactured Ceramic Combustor for Power-Plant Scale Electricity Generation ShomikVerma, MehdiPishahang, KyleBuznitsky, AlinaLaPotin, SantoshShanbogue and AsegunHenry; Massachusetts Institute of Technology, United States

Existing power plants have many downsides, as they have low efficiency, emit CO2, and include high-temperature rotating machinery requiring frequency maintenance. However, they are dispatchable, which provides a direct benefit over variable renewable energy resources such as solar. The ideal technology would be both dispatchable and solid-state. A recent alternative is fuel cells, which can directly extract the chemical energy in fuels into electricity with electrochemistry, but they require expensive catalysts and have low power density.

Combustion-powered thermophotovoltaics is a promising alternative for power generation. In this system, a combustor is designed that preheats air above the auto-ignition point of a fuel, such that the mixture combusts upon contact. The heat from combustion is used to heat up an emitter to ultra-hot temperatures, and the emitter radiates heat to the TPV cell. The TPV cell converts the emitted light to electricity. If hydrogen is used as the fuel source, the electricity produced is clean, creating a solid-state, catalyst-free method of generating electricity.
When combined with high-efficiency, high-power density TPV cells, this combustion-TPV system has the potential to be high-performing. However, there are many challenges in the system design, for example that high temperatures (2000C) are required, hefty insulation is needed to prevent heat loss, and cost may be high.

Thus, this study addresses three key challenges in the combustor design: materials identification, scalable design, and fabrication with additive manufacturing.

For materials identification, the objective of the material is to limit thermal stresses when a thermal gradient is applied, meaning the product of Young's modulus and coefficient of thermal expansion must be low. The material's yield strength must also be high, so that it does not fracture when a thermal stress is present. Due to the extreme environments present, the material should also be oxidation resistant and have high service temperature. Thus, oxides are the best option, and yttria-stabilized zirconia (YSZ) is identified as the candidate material due to its reduction resistance in the presence of high-temperature hydrogen.

Next, we design a high-efficiency combustor with 93% combustion efficiency using YSZ, enabled by milli-scale channels and a large surface area to volume ratio. The combustor also features a near-isothermal emitter wall at approximately 2000C. It is also modular, enabling vertical and horizontal stacking to reach the large length scales required for cheap insulation and grid-scale power generation.

However, the intricate internal geometries enabling the effective heat transfer within the device necessitate additive manufacturing. Because this technique can be expensive, two techniques are used to ensure cost-competitiveness. One is maximizing the power output per volume of the device, which is enabled by a large emitter surface area surrounded by high-power density TPV cells. Another is design for manufacturing, in which the device is 3D printed in 3 sections which are joined together in post-processing. This enables parallel processing and easier access to the internal channels, which would otherwise be difficult to clear. One challenge of this stacking method is how to properly join the slices, and a leak-proof joining methodology is developed to solve this.

Based on these improvements, we achieve a predicted cost per power of $0.30/W, which is significantly less than the cost of a natural gas turbine at $1/W, and leaves room for balance-of-plant costs such as pollution control, TPV cooling, and electronics.

Overall, in this work we push the boundaries of ceramic additive manufacturing to develop a next-generation power plant based on hydrogen combustion coupled with thermophotovoltaics.

8:00 PM SF01.06.16
Two Photon Lithography Assisted Fluorescence Sensor for Sensitive Detection of Lead Ions in Water ArchanaT[1], SwetaRani[2], Rahul KumarDas[1,1], GauravP. Singh[1], SumitSaxena[1,2,1] and ShobhaShukla[1,2,1]; [1]IIT Bombay, India; [2]IITBombay- Monash Academy, India

Lead has been involved in various human activities for a long time without realizing its detrimental effects on both the environment and human beings; arising even from exposure to trace amounts. The exposure to lead ions from water contamination, pipelines, gasoline exhausts, smelting plants, paints, consumer products have ability to cause serious health conditions like neurobiological disorder in fetus and children, muscle paralysis by calcium ion inhibition, anemia, cancer etc. Various International organizations (WHO, EU, ISI) have defined a permissible limit of 10ppb on the concentration of lead in water. According to the World Health Organization (WHO), approximately 600,000 deaths per year worldwide can be attributed to lead exposure. These alarming statistics underscore the urgent need for accurate and sensitive detection techniques to enable early intervention and prevention. The conventional techniques like absorption spectrometry (AAS), plasma optical emission spectroscopy, electrochemical methods, X-ray fluorescence spectrometry, and flame absorption spectroscopy are used for the detection of Lead ions in water. Over the past decades, researchers have been exploring various methods of detection mechanism over the conventional techniques as they are bulky, prone to interference, involves complex sample preparation, require skills and training to operate and interpret the results. Advanced sensing technologies, such as electrochemical sensors and optical sensors, have shown promise in the rapid and sensitive detection of lead ions. These sensors offer real-time monitoring capabilities and high sensitivity, ensuring that lead levels in water are promptly. Additionally, miniaturization in terms of the sensors is preferred over bulky conventional spectrometric techniques. Hence there is an exigent need to develop a miniaturized sensor with high sensitivity and performance.

In response to this challenge, our research proposes a novel approach involving a cyclodextrin-decorated Carbon Quantum Dots (CQD) platform for lead ion detection in real samples. The integration of cyclodextrin, a cyclic oligosaccharide, with CQDs enhances the selectivity and sensitivity of the sensor towards lead ions. To facilitate practical application, the sensor has been incorporated into a polymer matrix, enabling fluorescence-based analyte detection. Fabrication of miniaturized sensors is accomplished using Two-Photon Lithography, a versatile and precise technique capable of creating intricate structures at the micro and nanoscale. Through extensive investigations, we have explored various parameters to optimize the sensor's performance, ensuring its accuracy and reliability in detecting lead ions. In conclusion, our work addresses the critical need for reliable lead detection methods. By utilizing advanced sensing technologies, optimizing sensor performance, and emphasizing affordability and portability, we aim to contribute to the protection of public health from the detrimental effects of lead exposure in water sources.

8:00 PM SF01.06.17

Maximizing Photosynthetic Current Density of 3D Printable Thylakoid-PEDOT:PSS Composite Inks Through Bayesian Optimization JongHyunKim, JaeHyoungYun and WonHyoungRyu; Yonsei University, Korea (the Republic of)

Thylakoid membranes (TM) isolated from living plants can produce high energy electrons through photosynthesis under sunlight. If placed near an electrode, the high energy electrons can be harvested and put to practical use, creating an eco-friendly power cell. Recently our group has demonstrated TM-embedded 3D printable ink based on a conductive polymer, poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) [1]. Compared to the conventional post-electrode-deposition methods, the pre-embedment method allowed drastic increase in TM-electrode contact. While this previous study has focused on optimizing electrode geometry, in this work, we seek to optimize the electrode material itself to reach maximum current density. However, in achieving high current density, the two key parameters: the electron production rate and electrode conductivity, are always in tradeoff. Denser TM embedment surely increases photosynthesis but decreases electrode conductivity as it interrupts the conductive networks of PEDOT, responsible for charge flow. Addition of secondary dopants, such as dimethyl sulfoxide (DMSO), boosts conductivity by facilitating phase separation between PEDOT and PSS chains, but such organic solvents are prone to damage TMs. Post treatments of dry-annealing in PEDOT:PSS electrodes are considered essential in formulating and crystallizing PEDOT-rich domains [2], but heat treatments can damage the protein structures in TM. As multiple correlated factors in the material and manufacturing process account for the overall current density of the power cell, it is not only laborious but also very difficult to optimize each parameters. Therefore, we implemented Bayesian optimization, a technique used widely in Machine Learning, to simultaneously fine tune the concentrations of TM, PEDOT:PSS, and DMSO, along with dry-annealing time and temperature. To stay within 3D printable boundaries, we conducted rheological studies of the ink composites and set their lower boundaries to where their storage modulus is just above the loss modulus. Their upper boundaries were set at a nozzle clogging point referenced from the previous work on 3D printing PEDOT:PSS [3]. Additionally, we conducted a parametric study of gradual heating of drop casted TM on ITO glass. The upper boundary of the temperature parameter was set as 150ºC , where no current was longer measured form TM. In each iteration step of the Bayesian optimization, the ink was mixed thoroughly, screen printed with fixed volume on an ITO glass substrate, and dry-annealed in oven. The current density value, measured through cyclic amperometry, was fed into the Bayesian optimizer and the experimenter received back the next sampling point. As the experiment prolonged, the Bayesian optimizer attempted to find the global maxima of the surrogate model built from these current density values.

Digital Light Processing 3D Printed Thermochromic and Thermoresistive Sensors Based on Soybean Oil and Ionic Liquids CristianMendes-Felipe[1,2], DanielaCorreia[3], MohammadTariq[4], JoséEsperança[4], MarcoSangermano[2] and SenentxuLanceros-Mendez[1]; [1]BCMaterials - Basque Center for Materials, Applications and Nanostructures, Spain; [2]Politecnico di Torino, Italy; [3]University of Minho, Portugal; [4]Universidade Nova de Lisboa, Portugal

Additive Manufacturing (AM) has revolutionized the field of manufacturing by enabling the fabrication of complex three-dimensional structures with unprecedented design freedom. This work focuses on Digital Light Processing (DLP), for the processing of soybean oil-based materials. The use of reactive solvents and the study of suitable inks for printing purposes are explored, allowing or enhance the performance, sustainability and versatility of AM processes.
Soybean oil-based materials have gained significant attention due to their renewable nature, biodegradability, and potential for sustainable manufacturing. By formulating soybean oil-based resins and optimizing the processing parameters, digital light processing techniques can effectively harness the advantages of these materials. The incorporation of reactive solvents in the formulation allows for controlled material properties, including viscosity, curing kinetics, and mechanical strength, facilitating precise material design for specific applications.
To achieve successful printing of soybean oil-based resins, it is essential to develop compatible and stable inks. The study delves into the investigation of suitable ink formulations for DLP-based AM, considering factors such as ink rheology, surface tension, and photocuring behaviour. By understanding the ink characteristics, printing parameters can be optimized, ensuring high-quality prints, and expanding the range of printable materials. Thus, different reactive diluents including isobornyl acrylate or lauryl acrylate are added decreasing that the viscosity of soybean oil and reaching proper values for DLP printing, together with enhance the photopolymerization process. Furthermore, the thermal and mechanical properties of printed materials are tested showing a wide range of both properties depending on the reactive diluent content. Also, high quality 3D printed parts are observed in all cases.
Additionally, this work explores the integration of thermochromic materials, specifically ionic liquids, into the AM process to obtain functional 3D structures for sensor applications. Thermochromic materials exhibit reversible colour changes in response to temperature variations, enabling the development of smart and responsive sensors. The incorporation of ionic liquids with thermochromic properties provides an avenue to achieve enhanced sensitivity and precise control of the thermochromic response in printed sensor structures without the ascribed problems of using thermochromic nano- or microparticles. Bis(1-butyl-3-methylimidazolium) tetrachloronickelate ($[Bmim]_2[NiCl_4]$) ionic liquid is easily dispersed in quantities up to a 40 wt.% filler content. All prepared materials present humidity dependent thermochromism from colourless to blue and this colour variation is thermally activated and humidity governed, being 55% the minimum value of the relative humidity for colour change to occur. Further, the electrical conductivity increases with increasing IL content and decreases with increasing temperature, demonstrating also the applicability of the materials as thermoresistive sensors.
The proposed research contributes thus to the advancement of AM techniques by expanding the materials palette to include soybean oil-based resins, optimizing ink formulations for DLP printing, and exploring the functional integration of thermochromic ionic liquids in sensor applications. The findings from this study hold great potential for the development of sustainable, customizable, and intelligent 3D-printed structures with broad applications in fields such as sensing, robotics, and biomedical engineering.

8:00 PM SF01.06.19

3D-Printed Fused Silica Glass Hollow Microneedle Arrays – From Fabrication to Transdermal Applications YanwenJia and ZiyongLi; City University of Hong Kong, Hong Kong

Microneedle arrays (MNAs), a micron-scale device that recently emerged, are being recognized for their significant potential in enhancing transdermal delivery and extracting interstitial tissue fluid (ISF). Advanced 3D printing techniques have been utilized to fabricate MNAs with enhanced functionality, improved performance, and increased structural flexibility; however, the current 3D-printed MNAs are primarily composed of polymers that suffer from high costs, low durability, and poor robustness. To overcome the constraint, we integrate fused silica glass with projection micro-stereolithography (PμSL) 3D printing technology for the fabrication of transparent and high-quality fused silica glass MNAs with micron resolution, high stiffness, and excellent optical properties for the first time. The *in vitro* penetration test suggests that the 3D-printed fused silica glass MNAs are capable of piercing skin safely and smoothly. ISF extraction test demonstrates its ability to extract sufficient model biomarkers-contained fluid in a short time under capillary force. We confirmed its potential in further transdermal applications. In the future, 3D-printed fused silica glass MNAs, coupled with technology like microfluid, could be applied in precise drug delivery, intelligent transdermal biosensing, real-time monitoring, etc.

8:00 PM SF01.06.20

Ink Optimization and Pattern Design for Fast Charge Electrode Through R2R Printing HongliZhu and YingWang; Northeastern University, United States

Reducing the tortuosity of electrodes through vertical channels establishing is a recognized method to improve the ion transfer kinetics and enhance the fast chargeability of electrodes. Concurrently, investigating the relationship between channel structure on the electrochemical performance of electrodes is meaningful for optimizing the structure of fast-charging electrodes. In order to realize these demands, screen printing is a promising technology to fabricate low-tortuosity electrodes with precisely optimized structures on a large scale. However, the lack of suitable screen printable electrode inks slows the development of screen printing structural designable electrodes. An ideal industrial screen printing electrode ink should be high solid content, outstanding printability, and well particle dispersion to satisfy the demands on industrial cost reduction, printing quality improvement, and battery performance guarantee.
Herein, printing quality evaluation, rheological properties analysis, X-ray computed tomography characterization, coarse-grained molecular dynamics simulation, and electrochemical properties comparison were applied to reveal the underlying relationship among the status of molecular chains, screen printability of inks, and electrochemical performance of electrodes. In particular, the twisted molecular chains function as additional networks that pull certain particles within the electrode ink onto the mesh, reducing its screen-printability. Furthermore, the

internal architectural integrity of electrodes and sufficiently uniform dispersion of electrode components renders screen-printed electrodes with superior electrochemical performances. Based on recognizing and illustrating the relevance of the molecular chain state in high-solid-content ink for screen printability, we recommended a unique two-step approach for opening the twisted molecular chains of 60 % solid content $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ cathode ink and printed the corresponding electrodes. At the current rate of 6C, screen-printed electrodes using optimized ink exhibited a 33% larger charge capacity with a mass loading of 6.5 mg/cm^2 than that produced with chains-twisted ink. Additionally, according to the mechanisms of the two-step approach, we disclosed an optimization strategy for modifying inks for various printing conditions. This concept facilitates the integration of screen printing with the production of functional electrodes and can be applied to other purposes.
Further, we have successfully printed a series of high-precision vertical channels using our developed inks, systematically and comprehensively investigating the effects of the structure of vertical channels on rate performance enhancement for fast-charging electrodes. Through electrochemical evaluation, we demonstrated that 1) the staggered configuration of vertical channels improves the high-rate charge capabilities of electrodes, and 2) the decreasing channel diameter and edge distances improve the electrodes' rate performances. Specifically, the optimized electrode performed a charge capacity that is two- and seven-times greater than the conventional bar-coated electrodes at 4 and 6 C, respectively. Additionally, neutron computed tomography was applied to reveal that the Li^+ was homogeneously spread along the printed channels during the charging and discharging, which enhanced the average ion transfer kinetic of whole electrodes. The optimized channels can facilitate ion diffusion in the horizontal direction and ion transfer in the vertical direction for screen-printed electrodes, thereby maximizing the overall charge transfer kinetics of electrodes. Although more developments in screen printing technology are required to refine the resolution and further structural design for screen-printed electrodes, our researches suggest a reasonable method for optimization, industrialization, and commercialization of low-tortuosity electrodes for fast-charging LIBs.

8:00 PM SF01.06.21
***In-Situ* Analysis of Photobase Initiated Networks for Two-Photon Polymerization**MadelynP. Jeske[1,2], DavidR. Harding[2], MitchellJ. Anthamatten[1], AofeiMao[3], XiHuang[3] and YongfengLu[3]; [1]University of Rochester, United States; [2]Laboratory for Laser Energetics, United States; [3]University of Nebraska–Lincoln, United States

Two-photon-polymerization (TPP) performance is demonstrated in resins that polymerize via “click” chemistry – a process that has no unreacted component. Additionally, for the first time, a photobase (PBG) initiator was used in place of a free-radical photo-initiator to facilitate the reaction; a change that produced a more ordered and stiffer polymer network structure with an elastic moduli of 30 MPa and 2-10 MPa at 70ºC, respectively. Structures with shape-memory behavior, and capable of surviving 12% strain at the ultimate tensile stress, were printed with sub-micrometer resolution and were robust enough to withstand several shape-memory cycles.
The click chemistry is based on thiol-ene Michael Addition chemistry and works with either a base or free radical initiators. Raman spectroscopy data from TPP samples show that networks formed with the PBG initiator have a higher selectivity for thiol-ene coupling than do networks formed with a free-radical initiator, which results in increased crosslinking density. Using Coherent Anti-Stokes Raman Spectroscopy to probe the location of the photo-initiators during the polymerization process (with ~0.4 mm spatial resolution) provides insight into the diffusion kinetics that affects the print-resolution.

Additive Manufacturing of Amorphous Soft Magnetic Composites AnnaLangham[1], MitraL. Taheri[1,2], GeorgiaLeigh[1], CalebAndrews[1] and SebastianLech[1]; [1]Johns Hopkins University, United States; [2]Pacific Northwest National Laboratory, United States

Electric motors play a vital role in various industries ranging from aerospace to the energy sectors. Enhancing the efficiency and power density of electric motors has become a critical objective, currently limited by high losses in the motor’s magnetic core. State of the art commercial cores use steel laminates for their soft magnetic performance, relative ease of manufacture, and low cost of production. High eddy current loss in steel laminates necessitates research and development effort into other materials, such as amorphous soft magnetic composites (ASMCs), which have excellent soft magnetic characteristics like high magnetic saturation, and high relative permeability while also offering reduced losses. To date, the integration of ASMCs have been limited by the manufacturing challenges posed by traditional manufacturing methods. The goal of this work is to use Directed Energy Deposition additive manufacturing (DED) to obtain an amorphous microstructure suitable. Metglas 2605HB1M flake, a commercially available metallic glass known for its incredible relative permeability values and low losses, is explored as a potential material system. The microstructure and magnetic properties of DED printed Metglas flake, high purity Iron (Ancorsteel 1000b) and a 50/50 compositional blend of the Metglas and Ancorsteel are compared.

8:00 PM SF01.06.23
Fabricating Micro Pore X-Ray Optics with Additive Manufacturing Techniques AnissaBenzaid-Williams, JohnW. Boley and BrianWalsh; Boston University, United States

Micro pore x-ray optics (lobster-eye optics, MPOs) are ideal for certain x-ray astronomy applications due to their large field of view. MPOs require high aspect ratio features and smooth reflective surfaces to focus x-rays optimally with a smaller overall size and mass than Wolter type x-ray optics. MPOs are typically produced with traditional manufacturing methods, by stretching square glass pores which are then bundled, machined, etched, and slumped over a spherical mold. During this manufacturing process errors can be introduced, resulting in defects such as pore misalignment and pore deformation, and the resulting optics are limited in overall size, which reduces their field of view. Producing MPOs via additive manufacturing is of interest due to the speed, flexibility, and improving resolutions of 3D printing techniques. Direct ink writing (DIW) and continuous liquid interface production (CLIP) allow for large printing areas, so optics of a larger size can be produced without introducing issues of misalignment. This poster covers work done toward fabricating MPOs using DIW, CLIP, and two photon polymerization (TPP) techniques. It includes an overview and comparison of the benefits, drawbacks, and progress made toward manufacturing MPOs with each of these techniques. Evaluated attributes include optic size, print resolution, print speed, surface roughness of pore walls, and squareness of printed pores.

3D Printed Resins with Photo-Polymerization-Induced Phase Separation: Structure and Mechanical Properties LaurenZakrzewski, KantaPurkaysta, ChulsungBae and CatalinR. Picu; Rensselaer Polytechnic Institute, United States

In this work we develop heterogeneous acrylic-based photosensitive resins with superior strength and toughness for 3D printing applications. The enhanced toughness is obtained by exploiting the polymerization-induced phase separation of linear polymer (polypropylene glycol) which creates soft domains of sub-micron dimensions. The development of these materials has three steps: (i) development of the base photo-curable resin composition, (ii) gaining control on phase separation in cast samples, and (iii) 3D printing (using SLA) with phase separation. The talk will outline the chemistry and technology developed, and the effect of process parameters on the multiscale structure and mechanical properties of the 3D printed samples. Heterogeneous thermosets are an emerging class of materials whose properties may be tailored to exceed those of the commerical, nominally homogeneous thermosets.

8:00 PM SF01.06.25
***In-Situ* Piezoelectricity Enhancement in 3D Printed MoS_2 PVDF Nanocomposites**Rifat HasanRupom[1], Md NurulIslam[1], PashupatiR. Adhikari[1], ZorianaDemchuk[2], IvanPopov[2], AlexeiSokolov[2], H. FelixWu[2], RigobertoC. Advincula[3], NarendraB. Dahotre[1], YijieJiang[1] and WonbongChoi[1]; [1]University of North Texas, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Tennessee Knoxville, United States

For sensing and energy harvesting of 3D conformal structures, flexible and high-performance piezoelectric devices are extremely desirable. Here, we demonstrate dramatically improved piezoelectricity in polyvinylidene fluoride (PVDF) due to in-situ dipole alignment of PVDF within PVDF-two dimensional molybdenum disulfide (2D MoS_2) composite via 3D printing. We take use of the shear stress-induced dipole poling of PVDF and 2D MoS_2 alignment during 3D printing to increase piezoelectricity without any post-poling procedure. The results demonstrate an impressive increase of more than eight times in the piezoelectric coefficient (d_{33}) for 3D printed PVDF-8wt% MoS_2 composite over cast pristine PVDF. According to microstructural analysis and finite element simulation, the increased volume fraction of the phase in PVDF, filler fraction, heterogeneous strain distribution around PVDF-MoS_2 interfaces, and strain transfer to the nanofillers are all responsible for the enhancement of piezoelectric property. Our findings offer a promising way to develop and create high-performance 3D piezoelectric devices for mechanical-electronic conformal devices and next-generation sensors using 3D printing.

8:00 PM SF01.06.26
3D-Printed Polymer-Based Conformal Space Radiation Shield with Heat Dissipation YueXiao[1], AnZou[1], DavidCarlson[1], RobertHayes[2] and PuZhang[3]; [1]Advanced Cooling Technologies, Inc., United States; [2]North Carolina State University, United States; [3]Binghamton University, The State University of New York, United States

With the rapid development of SmallSats/CubeSats and space computing, the current aluminum (Al) bulk shielding technology poses challenges in Size, Weight, and Power (SWaP) requirements. The bulk shielding thickness is determined by the electronics with the least radiation resistance, which prohibits wider adoption of Commercial-off-the-shelf (COTS) electronics and results in increased system weight. In addition, the absence of advanced thermal management technologies for SmallSats/CubeSats largely limits the adoption of high-power, low-price, and readily available COTS electronics. To address these challenges, we developed an innovative 3D-printed, lightweight polymer composite radiation shield comprising of a Metal Oxide Polymer Composite (MOPC) layer and a Fiber Reinforced Polymer Composite (FRPC) layer. Specifically, the MOPC utilizes high-atomic-number metal oxides that are infused into the base polymer to achieve superior radiation attenuation performance than Al. FRPC utilizes aligned carbon fibers in the same base polymer to achieve high in-plane thermal conductivity for electronics heat dissipation. In addition, such a shield is manufactured by the advanced five-axis Direct Ink Writing (DIW) 3D printer for further improved thermal transport and structural

strength. Further, the 3D-printed shield enables locally enhanced spot shielding to provide additional radiation shielding for sensitive electronics without increasing the overall shield thickness. For MOPC, we have achieved an up to 7.4x increase in photon mass attenuation coefficient compared with Al and 18%–26% weight reduction for electron attenuation compared with Al at GEO. For FRPC, we achieved 2.55 W/m-K in-plane thermal conductivity, which is ~4x higher than the base polymer. Overall, the shield prototype can achieve 7 °C reduction in CPU temperature or a 22.5% increase in CPU power, and if spot shielding is utilized, an estimated 62% weight reduction for 1U CubeSat systems can be achieved.

8:00 PM SF01.06.27

Advancing the Performance of Zinc Ion Battery (ZIB) Through Additive Manufacturing of Tailored Structured Electrode Design with Hierarchical Porosity and Microchannel Md NurulIslam[1], NishatS. Sayor[2], Rifat HasanRupom[2], PashupatiR. Adhikari[2], RigobertoC. Advincula[3], NarendraB. Dahotre[2], YijieJiang[2] and WonbongChoi[2,2]; [1]The University of Oklahoma, United States; [2]University of North Texas, United States; [3]The University of Tennessee, Knoxville, United States

Due to its abundant, high volumetric capacity, and stable redox potential in water, Zn holds significant potential as an anode material for revitalizing rechargeable batteries beyond lithium-ion battery systems. Nevertheless, the use of alkaline Zn anodes is hindered by issues such as limited cycling durability and the growth of Zn dendrites, which result in short circuits and compromise both the performance and safety of the batteries. In recent years, additive manufacturing has emerged as a viable solution to address dendrite formation in zinc-ion batteries. This approach involves fabricating tailored electrode structures using the direct ink writing (DIW) 3D printing technique. By controlling pore sizes, distribution, and connectivity, 3D-printed Zn structures can provide a highly interconnected high surface area, allowing for improved electrolyte accessibility to electrode surfaces while accommodating its volume change.
In this study, we present a fully 3D-printed flexible zinc-ion battery (ZIB) with an engineered pore structure and surface area. First, we developed a Zn-based ink for the anode and a V2O5 ink for the cathode using high-power vacuum mixing, ensuring suitable rheological properties for direct ink writing (DIW) 3D printing. We conducted a comprehensive analysis of the ink formulation, rheological characteristics, and device performance to describe formulation-rheology-printability–functional properties relationships. A remarkable 6-fold improvement in areal capacity is achieved in 3D printed Zn-V2O5 battery with control samples. Additionally, printing-induced directional channels into the electrodes provide high Zn ion diffusion towards the cathode resulting in the high specific capacity of 190 mAh/g at 1 mA/cm2 and long-term cyclic stability. In this presentation, we will discuss the tailored structured electrode design with hierarchical porosity and microchannel, ink formulation-rheology-3D printability relationship, and the electrochemical performance of the additively manufactured zinc ion battery.

8:00 PM SF01.06.28

Enhancing Foam Resilience and Performance Through Graded Stiffness via Viscous Thread Printing DanielRevier[1], BrettEmery[1,2], MasaNakura-Fan[1], VivekSarkar[1] and JeffreyLipton[2,1]; [1]University of Washington, United States; [2]Northeastern University, United States

Foams have found widespread use in various fields including padding, insulation, and noise isolation. Many applications demand the use of multi-stiffness foams to enhance comfort or performance. Traditional bonding techniques involving foams of different densities often result in stress concentrations and undesirable boundary effects at the lamination interface. Furthermore, creating controlled, smooth gradients in foam properties is a challenging task for conventional and Additive Manufacturing processes.
In this study, we present an innovative approach to produce heterogeneous, open-celled foams with spatially graded stiffness using a method known as viscous thread printing (VTP). We use piece-wise continuous linear gradients between different stiffnesses, effectively mitigating unwanted boundary effects. The adjustment of material properties and microstructure is achieved by altering the travel speed and/or nozzle height during extrusion.
The method was employed to fabricate discrete components and those with linear gradients ranging from 0 to 60 mm in length. It was observed that dogbone samples with gradients exhibited higher resilience in plane under tension, while also showing a reduced tendency to form cracks at the nominal interface. This approach was successfully applied to thermoplastic polyurethane (TPU) and Nylon.
Mechanical properties under tension were found to be generally unaffected by the presence of a transition length, including tensile modulus, fracture strain, fracture stress, toughness, yield stress, and local stiffness. This suggests that the rule of mixtures would apply to the manufacturing of graded-stiffness foams. Although the properties were consistent, a significant impact was noted on the failure location, which typically occurred outside of the transition region.
Our findings pave the way for the broader application of graded-stiffness foams in various industries, significantly enhancing their performance and durability while reducing the potential for stress-related failure.

8:00 PM SF01.06.29

Alteration of Melt Pool Flows Depending on the Surfactants on Ceramic Coatings Built by Laser Cladding SuminSong[1], YeonghwanSong[1], TaebumKim[1], JeonghoHan[2] and KyuntaekCho[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

As qualities of ceramic coatings manufactured by laser cladding are superior due to few pores and cracks compared to that of thermal sprayed ceramic coatings, it has been spotlighted as one of the appropriate methods for building ceramic layers. Although understanding melt pool flows is important to build high-quality ceramic layers, studies on melt pool of ceramic layers which consist of metal intermediate layers and its flow alteration depending on the existence of surfactants (e.g., sulfur, oxygen, etc.) are insufficient. In this study, experimental studies were conducted to find out the effect of surfactant on melt pool flows of intermediate layers and extent of defects in ceramic layers.
In order to identify penetrated depth of coating layers and extent of coating defects, Ni intermediate layer and Al_2O_3 ceramic layer were manufactured under same process conditions using N_2 or mixture of Ar and O_2 gas, which were observed by OM and SEM. In addition, Vickers hardness tests and Ball-on-disk tests were performed to compare mechanical and wear properties depending on the surfactant. As oxygen was added in the shielding gas, penetration and diluted area became deeper and larger due to alteration of convection flows from outward to inward. Decrease of defects was observed at the metal intermediate layer manufactured under surfactant atmosphere, which resulted in building stable ceramic coatings with high hardness. As a result, wear resistance of ceramic layer built under surfactant atmosphere could be improved, which could be attributed to the surfactant effect on the melt pool flows.

8:00 PM SF01.06.30

Development of Study Protocol Frameworks for Data-Driven Digital Twin Development for Direct Ink Write Hein HtetAung[1,1], BrianAu[2], AlexCaviness[2], Robert WilliamCerda[2], Jayvic CristianJimenez[1,2], KristenJ. Hernandez[1,1], ThomasCiardi[1,1], PawanK. Tripathi[1,1], BrianGiera[2], RogerH. French[1,1,1] and LauraBruckman[1,1]; [1]Case Western Reserve University, United States; [2]Lawrence Livermore National Laboratory, United States

Direct Ink Write (DIW) is an advanced manufacturing technique that allows 3D printing of complex parts. DIW ‘ink’ is a multi-material combination of a polymer base and a filler that shear thins upon extrusion and then hardens upon lay down.[1] DIW process parameters and optimization of machine operations are being investigated to ensure large-scale and rapid production of high-fidelity parts. A study protocol for DIW scientific investigations is developed to identify a standardized workflow to investigate DIW process-space parameters and the resulting part characteristics. The data streams generated during DIW part fabrication are massive and rich with information, yet could be overwhelming, becoming a bottleneck for extracting research insights due to the terabyte sizes. Therefore, we use automated analysis pipelines on FAIRified datasets, implemented in our CRADLE^{TM} Distributed and High Performance Computing Cluster, where we can ingest, perform exploratory data analysis to identify parameter correlations and develop numerous data-driven models to identify useful inferential and predictive modeling approaches to this challenging problem.
Inferential models with trained model parameters, quantified variances and confidence intervals enable us to identify the mechatronic factors leading to both desirable and undesirable part properties. These models serve as a platform to build data-driven Digital Twins (ddDTs) for a virtual representation of the physical printed part, including its historical variances and defects. With continuous two-way communication between the real-world DIW system and the ddDT, the data obtained from the real-world system can update the ddDT and the simulations from ddDT can be used to update and drive the process parameters of the real-world system to obtain desired and improved part properties over production runs. The work herein demonstrates how our materials data science and data-driven digital twin approach using rigorous study protocols, establishes standardized data collection, FAIRified dataset management and model generation that allow us to integrate both historical and current data, across multiple DIW tools and production runs to quantify printed parts characteristics and variances.

This material is based upon research in the Materials Data Science for Stockpile Stewardship Center of Excellence (MDS3-COE), and supported by the Department of Energy's National Nuclear Security Administration under Award Number(s) DE-NA0004104.

Multi-Material Nanoscale 3D Fabrication Based on Femtosecond Light Sheets Shih-ChiChen; Chinese University of Hong Kong, Hong Kong

A major challenge in nanotechnology is to fabricate complex 3D structures with desired materials. Despite the many great efforts, the material choices are still largely limited to polymeric materials or metals. A fabrication solution for a wider class of materials without compromising the existing structural complexity, nanoscale feature sizes, and material functions remains a critical challenge. In this seminar, I will present our recent works on the parallelization of ultrafast lasers for 3D nanofabrication, achieving a record setting resolution (20 nm), laser patterning rate (300 mm^3/hr), and wide material library. Specifically, an arbitrarily programmable femtosecond light sheet is generated based on the principle of spatial and temporal focusing to perform parallel material processing. We first demonstrate the use of the femtosecond light sheet to perform micro-laser machining on different materials, and next to fabricate complex 3D structures via two-photon polymerization. Lastly, by combining the femtosecond light sheets and swellable hydrogels, we further demonstrate a greatly expanded material library to include metals, metal oxides, semiconductors, dielectric materials etc. This has enabled the fabrication of nanometer-scale 3D functional devices. Our new methods provide an effective and low-cost solution to scale-up the fabrication of functional micro- and nano-structures (~$1.5/$mm^3$). This means our technology may play a large role in fields such as healthcare, clean energy and water, computing, and telecommunications.

8:30 AM *SF01.07.02
Additive Manufacturing of Multi-Material Architectures: From Structural to Electronic and Robotic Materials Xiaoyu (Rayne)Zheng; University of California, Berkeley, United States

Abstract Additive manufacturing has shown the promise of freedom of designs, enabling parts customization and tailorable properties where superior structural performances can be achieved by a fraction of weight density compared to bulk material. However, it is presently difficult to directly print different materials (structural, dielectric, conducting and ferroelectrics) to create a complex device with multiple functionalities that responds to multiple stimuli. Unlike biological systems where functions, including sensing, actuation, and control, are closely integrated, few materials have comparable system complexity.

In this talk, I will present a suite of new multi-material additive manufacturing processes and design methodologies to create materials with prescribed structural and functional behaviors. The structural materials consist of a network of micro-unit cells which collectively influence new mechanical behaviors (from high-strength, lightweight to toughening) not seen in their native counterpart. When combined with an electronic and functional phase, these materials turn themselves into a robot and is capable of motions with multiple degrees of freedom and amplification of displacement in a prescribed direction in response to an electric field (and vice versa), and thus, programmed motions with self-sensing and feedback control. I will present the manufacturing and synthesis of these materials, as well as their mechanics and design methods underpinning their novel behaviors.

9:00 AM SF01.07.03
One-Photon Three-Dimensional Printed Fused Silica Glass with Sub-Micron Features ZiyongLi[1] and YangLu[2]; [1]City University of Hong Kong, Hong Kong; [2]The University of Hong Kong, Hong Kong

Glass made from silica has a history of thousands of years, and its applications have accompanied the evolution of human civilization. From everyday life to cutting-edge industries, such as micro-optics, micro-electronics, and micro-fluidics, necessitates the high-precision manufacturing of three-dimensional (3D) fused silica glass objects. Advanced 3D printing technologies have emerged as a powerful tool for fabricating arbitrary glass objects with ultimate freedom and precision. Stereolithography and femtosecond direct writing showed their capability in shaping 3D glass objects with ~50 μm and ~100 nm features, respectively, however, to efficiently fabricating glass structures with centimeter size and sub-micron features still remains challenge. Presented here, our study demonstrates that the gap can be effectively bridged by engineering of appropriate materials, 3D printing based on one-photon micro-stereolithography (OμSL), allows the flexible creation of transparent and high-performance fused silica glass components with sophisticated, 3D sub-micron architectures. The methodology facilitates the construction of fused silica glass components with arbitrary 3D-specific geometries featuring fine details as small as 900 nm, while also enabling rapid prototyping of structures of several millimeters. This offers unprecedented possibilities across a range of applications, including micro-optics, microfluidics, mechanical metamaterials, and engineered surfaces.

9:15 AM *SF01.07.04
Nanoparticle Enabled Additive Manufacturing WendyGu, JohnKulikowski, DavidDoan, QiLi, MingqiShuai, LuisDelfin Manriquez and AndrewLee; Stanford University, United States

Nanoparticles have unique optical, thermal, chemical reactivity and phase transitions that can be used to enhance additive manufacturing processes. This can be used to fabricate nanoscale architected materials with superior mechanical properties due to material size effects. First, I will present a novel two-photon lithography resin that is used to print nanocomposites, nanoporous carbon and nanostructured silk. The key ingredients in the resin are metallic nanoclusters that serve as both photoinitiators and inorganic precursors, and have pressure-dependent optical properties. Nanocomposite honeycomb, octet and shell-based lattices are fabricated that have a combination of high strength per weight, energy absorption and recoverability beyond other nano and micro-lattices due to a unique strain hardening behavior. Then, I will present our development of a particle ink laser melting (PILM) additive manufacturing system, in which a colloidal nanoparticle ink is combined with a laser-powder bed fusion machine to enable low power printing of metals and ceramics. This is used to print conductive copper electrodes and piezoelectric elements directly on printed circuit boards (PCB).

Probing Material Transformation Volumetrically in Computed Axial Lithography HaydenTaylor, Sui ManLuk, Chi ChungLi and JosephToombs; University of California, Berkeley, United States

Volumetric additive manufacturing processes such as computed axial lithography (CAL) are promising for the rapid production of 3D geometries in a wide range of photopolymer and nanocomposite materials. In CAL, light dose is reconstructed tomographically by projecting a video image into a rotating volume of precursor material. Practically, this reconstruction approach exposes the bulk of the precursor (and not just the target geometry) to background illumination. The reconstructed dose distribution is also not perfectly sharp at the boundary of the component. Consequently, there is a range of degrees of conversion throughout the volume at any given moment, and it is very important to terminate the printing process accurately to be able to recover the desired geometry. In-process volumetric monitoring of refractive index can be valuable for this purpose, because most precursor materials exhibit refractive index increases during conversion to the solid state. We will review a set of Schlieren-based techniques we previously introduced for real-time material conversion observations. We will also discuss recent work developing a volumetric temperature monitoring technique based on fluorescence imaging. The evolution of temperature within a CAL volume can serve as an indicator of material conversion dynamics and can influence the quality of printed components.

10:45 AM SF01.07.06
A New Family of 3D Auxetic Mechanical Metamaterials with High Resilience and Elastic Hysteresis TiantianLi and YaningLi; Northeastern University, United States

A new family of high resilient 3D auxetic mechanical metamaterials are designed. The new designs show remarkable resilience under large deformation together with significant hysteresis under cyclic compressive loading-unloading. Both isotropic and anisotropic designs are created. The 3D isotropic design shows ideal isotropy with negative Poisson's ratio close to -1 in all loading directions, as rarely seen in existing mechanical metamaterials. Also, the anisotropic mechanical properties including the effective stiffness and effective Poisson's ratio can be tuned in a wide range. In addition, new designs can also show a unique simultaneous twisting and shrinking behavior under uni-axial compression. An integrated experimental, analytical and numerical approach is applied to quantify the effective mechanical properties of the new designs. Systematic FE simulations and analytical analyses are performed. The new designs are also fabricated, and mechanical experiments were performed on selected designs. These novel properties make 3D keyed-brick mechanical metamaterials be a potential candidate as engineering material with unique properties beneficial from negative Poisson's ratio, damping material for energy absorption, impact resistant material under special loading conditions.

11:00 AM SF01.07.07
Additive Manufacturing of Iron and Iron-Alloy Lattices for Magnetic Nanoparticle Capture SammyShaker[1], AndriiSyrota[2], ColinYee[3], VitaliyL. Rayz[4], StevenHetts[3] and JuliaR. Greer[1,1]; [1]California Institute of Technology, United States; [2]Université Paris-Saclay, France; [3]University of California, San Francisco, United States; [4]Purdue University, United States

Magnetic nanoparticles are of widespread interest for medical therapies ranging from internal thermal treatments to vector agents for genetic modification to MRI contrast agents.[1] One of the standout applications for magnetic nanoparticles in medical therapies involves the capture of small molecule chemotherapeutics, particularly doxorubicin, via surface functionalization. While rapid capture of doxorubicin by functionalized nanoparticles has been demonstrated *in vitro*, sequestration of the nanoparticles, especially *in vivo*, has proven a more complicated task.[2] Sequestration of nanoparticles in a biological flow such as that found in a blood vessel will require a device that can maximize capture while minimizing flow disruptions and pressure

drop across the device. Device designs consisting of solid cylindrical magnets mounted on catheters inevitably obstruct and disrupt the flow as it passes through the blood vessel. Synthesizing microarchitected magnets could allow for favorable flow properties while also allowing for magnetic nanoparticle sequestration; such architected magnetic materials are underexplored in the literature.[3,4] Traditional subtractive methods of manufacturing often obstruct these explorations due to difficulties in attaining desired feature resolutions as well as rapid modification of alloy composition; on the other hand, additive manufacturing allows for flexibility in design and composition. Hydrogel infusion additive manufacturing (HIAM) is capable of synthesizing architected metal lattices. We demonstrate HIAM derived magnetic monolithic microarchitected lattices composed of iron, iron-nickel, and copper-iron-nickel alloys in the shape of a twisted honeycomb prism with a major face diameter of 3-4 mm and a beam thickness of 40-50 um optimized to minimize *in vivo* flow disruption.[4,5] We perform multiphysics simulations of the process of magnetite nanoparticle capture and compare the resulting capture efficiency to *in vitro* magnetite nanoparticle capture experiments that demonstrated a preliminary capture efficiency of 10-20%. In addition, we apply vibrating sample magnetometry (VSM) to demonstrate coercivities in the range of 10-100 Oe and remnant magnetizations of 100 Gauss in the synthesized lattices. Powder X-ray diffraction (pXRD) shows a bulk metallic phase with body-centered cubic symmetry for the iron lattice and face-centered cubic symmetry for the iron-nickel and copper-nickel-iron lattices; internal microstructures are characterized by electron backscattered diffraction (EBSD). Finally, we determine the final phase composition via energy dispersive X-ray spectroscopy (EDS).

11:15 AM SF01.07.08
Controlling Solidification Microstructure of Aluminum Alloys using Eutectic/Peritectic Reactions in Laser Powder Bed Fusion Process NaokiTakata[1], TakanobuMiyawaki[1], YueCheng[1], AsukaSuzuki[1], MakotoKobashi[1] and MasakiKato[2]; [1]Nagoya University, Japan; [2]Aichi Center for Industry and Science Technology, Japan

In recent, laser powder bed fusion (L-PBF) has emerged as one of the most representative metal additive manufacturing techniques capable of producing metallic components by using a scanning laser beam to melt consecutive bedded-powder layers selectively. The L-PBF process enables the fabrication of aluminum (Al) alloys with superior and anomalous mechanical properties. Such unique properties were responsible for the formation of non-equilibrium microstructure and metastable phases in rapid solidification (at an extremely high cooling rate of 10^5-10^7 K/s) during the L-PBF process. It has been reported that the L-PBF processed Al-Fe alloys with a near eutectic composition exhibited significantly refined solidification microstructures, contributing to high mechanical performance. In the eutectic reaction in rapid solidification, alloy elements could be partitioned into a liquid phase rather than a primary solidified phase, resulting in the enhanced formation of the second solid phase (Al_6Fe phase in an Al-Fe system). It is assumed that alloy elements might be partitioned into the primary solidified α-Al phase (rather than the liquid phase) through a peritectic reaction in rapid solidification. The partitioned solute elements in the α-Al supersaturated solid solutions would play a significant role in solid-solution strengthening (or strengthening by atomistic clusters in the α-Al matrix). These insights can open an opportunity for controlling refined microstructures of Al alloys by elemental partitioning via solidification paths of eutectic or peritectic reactions in the L-PBF process. In this concept, we have selected alloy elements exhibiting different solidification paths in Al-X binary phase diagrams. Cu and Ti elements were used as third alloy elements for the Al-Fe-X ternary system in the present study. Cu element exhibits a eutectic reaction in an Al-Cu binary system (partition coefficient, $k_{Cu}^{S/L} < 1$) and forms $(Al,Cu)_6Fe$ phase in an Al-Fe-Cu ternary system. In contrast, Ti element exhibits a peritectic reaction in an Al-Ti binary system (partition coefficient, $k_{Ti}^{S/L} > 1$) and independently forms the Al_3Ti phase (no partitioning into the Al_6Fe phase). Based on the alloy element selections, we designed two ternary alloy compositions of Al–2.5Fe–2Cu and Al–2.5Fe–1.5Ti (mass%) available to the L-PBF process utilizing the thermodynamic calculations.
In this study, L-PBF processing was performed using gas-atomized ternary alloy powders with an average particle size of about 20 mm. Rectangular alloy samples were fabricated using a ProX DMP 200 machine (3D Systems, USA) under a wide range of laser scan speeds (0.6 ~ 1.4 m/s) and laser power (102 ~ 204 W). The results of measuring the sample density provided the optimum laser parameter sets for the manufacturing of both alloy samples with high relative densities above 99 %, indicating high L-PBF processability for the Al–Fe–Cu and Al–Fe–Ti ternary alloy powders. The L-PBF processed both alloys exhibited microstructure consisting of a number of melt pools in which regions locally melted and rapidly solidified due to scanning laser irradiation. The added Cu element was partitioned into the refined Al_6Fe phase, resulting in the formation of $(Al,Cu)_6Fe$ phase with an orthorhombic structure (*oC*24). A certain amount of solute Cu (approximately 0.6 %) was detected in the a-Al matrix. A higher solute Ti content above 1 % was detected in the α-Al matrix of the L-PBF processed Al–Fe–Ti ternary alloy. Such a trend appeared more significantly in relatively coarsened cellular microstructures along melt-pool boundaries. These results indicate that the elemental distribution could be controlled via different solidification paths in the L-PBF process. Mechanical properties of the L-PBF processed ternary alloys will be presented and discussed in terms of Cu or Ti elemental distribution in the refined solidification microstructures.

Effect of Scanning Strategies and Alloying Elements on Microstructure and Mechanical Properties of Tungsten Fabricated by Laser Powder-Bed Fusion HyejiIm, SamuelPrice and IanD. McCue; Northwestern University, United States

Laser-powder bed fusion (L-PBF), one of the metal additive manufacturing (AM) techniques, of fusion-facing materials can help overcome the challenges associated with poor machinability and difficulties in casting for complex-shaped and/or thin-walled components. Additive manufacturing experience large thermal strain during cooling and passing through its ductile-to-brittle transition. This leads to high number of cracks of additively manufactured tungsten.
Here, we report on the enhanced microstructure and mechanical properties for tungsten-based alloys by alloying titanium and iron through L-PBF. Prototype alloys were selected using CALPHAD-based thermodynamic predictions. Various scanning strategies were employed to minimize the thermal strain during printing. The addition of titanium and iron increased density as well as increased strength and ductility.

How Does Nanostructural Engineering via Additive Manufacturing Open New Opportunities in Materials Design?RebeccaA. Gallivan, MircoNydegger, NikolausPorenta, MaxenceMenétrey and RalphSpolenak; ETH Zürich, Switzerland

Architecting microstructural features like grain size, porosity, and phase, pushes the limits of material properties – even breaking away from traditional property tradeoffs as exemplified by nanotwinned nanocrystalline copper which shows improved strength without the loss in ductility. Additive manufacturing has enabled new pathways for spatial control of microstructures, promising enhanced capabilities for materials design through microstructural engineering. However, these benefits are most pronounced in nanostructured materials where features of interest lie in the submicron lengthscales. Leveraging the nanoscale multi-material resolution of the electrohydrodynamic redox printing (EHD-RP) technique, we demonstrate new methods for nanostructuring materials in 3D geometries and explore new opportunities for nanocomposite design. Focusing on Cu, Zn, and Ag-based compositions, we will discuss the role of nanostructured features like nanoporosity, phase segregation, and oxide nanoparticle dispersion on micromechanical properties such as strength, ductility, and failure behavior in order to more fully understand the engineering opportunities afforded through complex spatial control of microstructure. As a key tool in the materials design afforded by additive manufacturing, insights into nanostructural engineering lay the foundation for fully utilizing the promise of design flexibility for advanced materials.

1:45 PM SF01.08.02
Hf-Driven Microstructural Changes and Hot Cracking Prevention of Ni-Based Superalloy During Laser-Based Direct Energy Deposition KenHeeRyou[1], HyejiIm[1,2], JiwonPark[3] and Pyuck-PaChoi[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Northwestern University, United States; [3]Korea Institute of Materials Science, Korea (the Republic of)

The Ni-based superalloy for high-temperature, such as Inconel 738 is an improper alloy for additive manufacturing because of frequent hot cracking resulting from high amounts of Al and Ti. As a solution to hot cracking, the Hf has been proposed as the alloying element of Ni-based superalloy for the improvement of castability and printability. However, the detailed microstructural changes and the hot cracking prevention mechanisms were not clarified yet. The hot cracking was not observed above a certain amount of added Hf at the laser-based direct energy deposition of Inconel 738 alloy. To investigate the microstructure of Hf-added Inconel 738 and the effect of Hf on hot cracking prevention, multi-scale characterizations were

conducted including various electron microscopy and atom probe tomography besides phase-field modeling. Therefore, much more active side-branching in secondary dendrite arms was observed. It is considered that it results in the easy interconnection between the dendrites. Consequently, we attributed that the prevention of hot cracking could be possible by decreasing cracking susceptibility by changing solidification sequences.

Microstructural Evolution in Metallic Alloys under Additive Manufacturing Conditions AmyClarke[1,2]; [1]Colorado School of Mines, United States; [2]Los Alamos National Laboratory, United States

In metal additive manufacturing (AM), an alloy (in powder or wire form) is melted by a rapidly moving heat source. A solid layer forms upon cooling, and successive layers are built by melting and solidification to form a three-dimensional part. AM processes typically produce large temperature gradients, high solidification rates, and repeated cycles of heating and cooling. The local processing conditions experienced during AM (e.g., thermal gradients and solid-liquid interface velocities during solidification) dictate microscopic structure (i.e., microstructure) evolution. Here we visualize melt pool dynamics and solidification during simulated AM by real-time imaging (e.g., synchrotron x-ray and dynamic transmission electron microscopy) and computational modeling to link local processing conditions to microstructural evolution. We also highlight novel microstructures produced by solid-state phase transformations. A deeper understanding of solidification and solid-state phase transformations under AM conditions is needed to optimize processing parameters across AM technologies, control microstructural evolution and resulting properties, and design metallic alloys for AM.

3:30 PM *SF01.08.04
Deciphering the Strength and Ductility of Additively Manufactured Materials Yinmin (Morris)Wang; University of California Los Angeles, United States

Additive manufacturing (AM, aka 3D printing) involves unique processing conditions and thus offers opportunities to produce materials with tailored strength and ductility. However, the highly nonconventional microstructural features created by AM techniques impose tremendous challenges to decipher the strength scaling law and other materials properties. This talk will describe our recent effort to investigate and understand the strength and ductility of several model materials systems including pure copper, 316L stainless steel, and medium entropy alloys. All these materials were fabricated by laser powder-bed-fusion. In all these cases, we observe a hierarchical microstructure and multiple length scales that render a myriad of strengthening mechanisms. These interesting microstructures include solidification enabled cellular structures, low-angle grain boundaries, and dense dislocations. High uniform tensile elongation is also observed in many cases due to the progressive work-hardening mechanisms triggered by these hierarchically heterogeneous microstructures. We will further elaborate the influence of residual stresses on mechanical behavior and conclude with some outstanding issues that call for future research.

4:00 PM *SF01.08.05
From Complex Geometries to Complex Microstructures: New Opportunities for Materials Design MatteoSeita[1], ShuboGao[2] and KarlSofinowski[2]; [1]University of Cambridge, United Kingdom; [2]Nanyang Technological University, United States

One of the main drivers for the adoption of additive manufacturing (AM) in industry is the ability to build parts with complex—and previously unattainable—geometries. This paradigm has enabled the production of high-performance components with optimized strength-to-weight ratio, or with internal features for enhanced functionality. The disruptive potential of AM, however, goes beyond complexity of shape. Because materials are formed at the microscopic scale following a bottom-up manufacturing approach, AM offers the opportunity to make parts with complex—and previously unattainable—microstructures. Since the relationships between these complex microstructures and the resulting materials properties are difficult to unveil, this unique feature has yet to be capitalized on in current industrial applications. However, it may be the key to design the materials which will enable the applications of tomorrow. In this talk, I will present a few examples of the microstructure complexity offered by AM, including chiral crystals and alloys with controlled defect patterns. I will discuss the mechanisms that drive the formation of such complex microstructures and propose possible applications which these materials may enable.

4:30 PM SF01.08.06
Developing a Framework to Qualify Additively Manufactured Ceramics: Effect of Sintering Temperature on Feature Resolution, Shrinkage, and Flexural Properties LindseyBezek and Kwan-SooLee; Los Alamos National Laboratory, United States

Functional applications for additively manufactured ceramic parts are currently limited by both material constraints and knowledge of process-structure-property relationships. One challenge for developing new ceramics for additive manufacturing (AM) is determining a post-process debinding and sintering strategy that yields parts with sufficient mechanical strength while mitigating defects and unpredictable shrinkage. This work investigates how maximum sintering temperature (varied between 900°C and 1300°C) affects material and mechanical properties of parts fabricated using a commercial silica-based resin and the vat photopolymerization AM process. A custom test artifact was designed to probe dimensional accuracy and survivability of features of different sizes, shapes, and orientations. The shrinkage of cubes with 1 cm sides was generally proportional to sintering temperature and did not exceed 18% in any dimension. The shrinkage was more isotropic up to 1100°C, but at higher temperatures, Z shrinkage was typically ~30% higher than X and Y shrinkage. Parts with higher maximum sintering temperatures experienced higher flexural strength and lower strain at break in three point bend testing. Regardless of maximum sintering temperature, most parts exhibited some degree of cracking or delamination. X-ray computed tomography was used to probe internal porosity, and several voids were observed even when sintered to 1300°C. Fundamental understanding of how sintering affects parts' structure and properties will enable development of a framework to qualify ceramic AM materials and processes. This knowledge will facilitate predictable part performance, helping to ensure reliability of future parts for functional applications.

4:45 PM SF01.08.07
Design of Alloys for Green Body Printing and Sintering YannickNaunheim and ChristopherA. Schuh; Massachusetts Institute of Technology, United States

Additive manufacturing is an emerging pathway to produce metallic materials, usually by processing a well-established commercial alloy via a powder-based approach. In this talk, we invert this approach: we selectively tailor and adjust the chemical composition of an alloy powder to make it suitable for rapid low-temperature solid-state consolidation. Acceleration of the consolidation process is based on two mechanisms: Nanocrystallinity achieved by high energy ball-milling accelerates diffusion at low temperatures, while phase evolution through diffusional demixing and remixing of a second solute-rich phase can encourage the formation and growth of interparticle necks upon heating. Computational thermodynamics provide the basis for the alloy design process to take maximum advantage of these effects. Sintered and heat treated microstructures and their mechanical properties are presented and discussed for the case of nickel-rich alloys.

SESSION SF01.09: Session VII
Session Chairs: Zachary Cordero and Wendy Gu
Thursday Morning, November30, 2023
Sheraton, Second Floor, Republic B

8:00 AM *SF01.09.01
Merging the Computational and Experimental Gravity Poles of the Alloy Development Process: From Alloy Design to *In-Situ* Alloying of Custom Al Alloys for Laser Powder Bed FusionFedericoBosio[1], GiuseppeDel Guercio[1], ChinmayPhutela[1], MarcoSimonelli[2] and NesmaAboulkhair[1,2]; [1]Technology Innovation Institute, United Arab Emirates; [2]The University of Nottingham, United Kingdom

Recent progress in metal additive manufacturing (AM) emphasised the need to develop next-generation alloys leveraging the non-equilibrium dynamics of rapid cooling processes. This raised the awareness among the leading industrial players of the AM scene that boosting the material palette for AM is the way to unlock the full potential of additive manufacturing in vital application sectors, such as aerospace, energy, and defence. In fact, functional parts with enhanced strength, good electrical and thermal resistance, and low density are often targeted for these critical applications, and the current alloys in the market might not meet these requirements. Therefore, driven by these motivations, novel aluminium alloy grades for use in Laser Powder Bed Fusion (PBF-LB) are currently sought.

An industrially relevant commercial Al alloy system used in targeted industrial sectors was selected in the alloy design stage. The chemical composition of such alloy was tweaked by adding a

reinforcing transition metal (TM) element that enhanced the master alloy's strength by multiple strengthening mechanisms. Computational design tools based on the CALPHAD approach enabled the chemical process window's fast selection for the new aluminium grades. The solidification trajectories of various TM-dosed Al grades were assessed for conditions deviating from the equilibrium using the Scheil-Gulliver assumptions to predict the alloy's precipitation sequence, crack sensitivity, and printability.

The computational predictions were empirically corroborated with targeted experiments involving arc-melted buttons' production in generating the corresponding Al-TM master alloys. The microstructure resulting from the fast-cooling rates of the PBF-LB process was simulated by surface remelting in an industrial printer. Hierarchical microstructure investigations conducted at all length scales from macro- to nano showed a satisfactory level of correlation with computational predictions, and the final transition metal element amount was eventually established based on considerations involving strengthening mechanisms, hot crack sensitivity, PBF-LB processability, and heat-treatment design strategies.

The developed Al-TM alloy was then manufactured by laser powder bed fusion in-situ alloying achieving near fully dense samples. At this stage, nano-particles were introduced in the newly developed metal matrix to further enhance strength and its thermal stability at temperatures higher than 300 degrees celsius. The process-structure-performance relationships of the Al-xTM alloy with and without nanoparticle additions were deeply studied at the possible environmental working conditions (RT and elevated temperatures).

The outcomes of this research prove that new high-strength Al alloy compositions can be established by exploring unconventional design spaces enabled by the fast-cooling rates of additive proces**ses**. The combined computational-experimental method utilised in this study provided a fast and robust guidance towards the development of printable high-strength Al alloys for Laser Powder Bedd Fusion.

8:30 AM *SF01.09.02
Directional Recrystallization of Additively Manufactured Superalloys ZacharyC. Cordero; Massachusetts Institute of Technology, United States

Metal additive manufacturing processes can create intricate components that are difficult to form with conventional processing methods; however, the as-printed materials often have fine grain structures that result in poor high-temperature creep properties, especially compared to directionally solidified materials. Here, we address this limitation in an exemplary additively manufactured Ni-base superalloy by converting the fine as-printed grain structure to a coarse columnar one via directional recrystallization. The present results demonstrate how directional recrystallization of additively manufactured Ni-base superalloys can achieve large columnar grains with enhanced creep resistance, manipulate crystallographic texture to minimize thermal stresses expected in service, and functionally grade the grain structure in net-shaped parts to selectively enhance fatigue or creep performance.

9:00 AM SF01.09.03
A Process–Structure Correlation Between the Beam Crossing Interval and the Size of Meltpool in the Laser Powder Bed Fusion Process Chang-EunKim[1], ClaraL. Druzgalski[1], AlexandraLoaiza[2], DavidF. Bahr[2], GabeGuss[1], VincenzoLordi[1], PatrickG. Allen[1], RebeccaJ. Dylla-Spears[1] and ManyaliboMatthews[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Purdue University, United States

The laser powder bed fusion process creates a unique microstructure that impacts the property of printed parts. We asked whether the time interval between neighboring meltpool track was a critical parameter that dictates the process--structure relationship. We used metallography, machine learning, and laser toolpath trajectory analyses to collect the data needed to establish a correlation. We found a clear negative correlation between the size of meltpools and the proposed timing descriptor, as `beam crossing interval (BCI)'. The observed correlation paves a way to enable a data-driven model to control the microstructure of metal part printed by the laser powder bed fusion. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract No. DE-AC52-07NA27344.

9:15 AM SF01.09.04
Predicting Defect Formation in Additive Manufacturing using Inferences and Statistical Modeling ErikaI. Barcelos, Mohommad RedadMehdi, KristenJ. Hernandez, PawanK. Tripathi, Hein HtetAung, LauraBruckman, AnirbanMondal and RogerH. French; Case Western Reserve University, United States

Datasets originated from experimental research tend to be small. Performing experiments is expensive, time consuming and often the available resources are limited. Therefore, developing a framework to design, plan and optimize experiments is essential for a more efficient, reliable and cost-effective for experimental research. Statistical Learning approaches represent a promising alternative to address the challenges associated with limited and sparse experimental datasets. It consists of applying modeling approaches to explore and understand the data and relationships via statistical and exploratory data analysis. Laser Powder Bed Fusion (LPBF) is one of the most common Additive Manufacturing methods used in the fabrication of metal parts. The process can generate highly customizable parts having complex shapes and geometries with the generation of minimum waste, which represents an important benefit over traditional subtractive technologies. Nonetheless, it is highly susceptible to defect formation due to the complexity of the printing process and non optimal process parameters. In this work, we explore different statistical learning approaches and evaluate their capabilities in predicting defects in a LPBF experiment. In-situ and ex-situ data from pyrometry, radiography and machine parameters were integrated, FAIRified and ingested into our CRADE/HPC distributed environment. Feature selection and importance ranking were performed using correlation analysis and network structural Modeling (netSEM). Different Statistical Learning approaches were evaluated including Robust Regression based methods and Generalized Additive Modeling (GAM). These techniques were applied for predictions and inference, i.e. understanding and quantifying relationships between variables. This work brings a new perspective to experimental research that generates small datasets. It shows that even when there is a limited number of available data points, statistical analysis can be applied for an accurate and reliable data analysis and statistical modeling can be successfully used to estimate and predict future outcomes.

9:30 AMBREAK

10:00 AM *SF01.09.05
3D Nanoprinting of Functional Crystalline Materials Ji TaeKim; The University of Hong Kong, Hong Kong

Can 3D printing become an innovative strategy for manufacturing electronic and photonic integrated circuits? A key prerequisite is to acquire high-quality crystalline functional materials that are 3D printable at the nanoscale. Here, we present our solvent-engineering-assisted 3D printing method that enables freeform, nanoscale structuring of diverse crystalline materials. The method exploits a femtoliter ink meniscus to guide material crystallization in three dimensions with the aid of in-situ solvent engineering, fabricating freestanding nanostructures with programmed shape, composition, and crystallinity. This scheme has pioneered new 3D printing materials that can be used for integrating electronic and photonic circuits, including metal halide perovskites [1-3], peptides [4,5], metal-organic frameworks [6], and nanoparticle clusters [7]. Successful demonstrations of 3D-printed real devices such as bright nano-displays [8], lasers, anticounterfeiting labels [2,3], biosensors [7], and micro-thermometers [9] have proven the practicality of our method. In this talk, I will discuss our experimental/theoretical studies on how to develop the nanoscale 3D printing method, and the prospects of our work for potential applications in IC (integrated circuit) manufacturing.

3D Printed Schwarzites: From Pure Mathematics to Macroscale Applications LeviC. Felix[1], RaphaelTromer[1], CristianoF. Woellner[2], VarleiRodrigues[1], PulickelAjayan[3], ChandraS. Tiwary[4] and DouglasS. Galvao[1]; [1]State University of Campinas, Brazil; [2]Federal University of Parana, Brazil; [3]Rice University, United States; [4]Indian Institute of Technology, India

Additive manufacturing, sometimes called 3D Printing, can create structures of great complexity. It has been exploited in many areas, in particular, in materials science.
In this work, we present a comprehensive multi-scale (from atomic to macroscale 3D Printed models) study of the structural and mechanical properties of some Schwarzites families. Schwarzites are crystalline porous carbon structures with negative Gaussian curvatures. They were proposed by Mackay and Terrones [1] and name Schwarzites after the German

mathematician Hermann Schwarz and his works on triple periodic minimum surfaces (TPMS).
We have carried out DFT and molecular dynamics simulations of atomic models. These geometrically optimized models were used to create corresponding macroscale models that were 3D Printed using fused deposition modeling (FDM). We have used different polymers (acrylonitrile butadiene styrene (ABS) and polylactic acid (PLA)).
The MD and 3D Printed results for the profiles of the stress-strain curves are quite similar, showing that the deformation mechanisms are scale independent and are dominated by topological features.
The 3D Printed models were successfully tested for macroscale applications, such as large deformations sensors and filters for water remediations of micro and nano plastics [4,5]

Sustainable Graphene-Based Inks for Screen Printable Piezoresistive and Thermoresistive Sensing MiguelFranco[1], AMotealleh[2], CarlosCosta[1], LHilliou[1], NikolaPerinka[3], ClarisseRibeiro[1], JulioViana[1], PedroCosta[1] and SenentxuLanceros-Mendez[3,4,1]; [1]University of Minho, Portugal; [2]LayerOne AS, Norway; [3]BCMaterials, Basque Center for Materials, Applications and Nanostructures, Spain; [4]Ikerbasque, Basque Foundation for Science, Spain

Graphene-based conductive inks are increasingly being used for printed and conformable electronics. In the present work, rGO has been used both in pristine form and doped with nitrogen (N-rGO), the latter allowing to increase the electrical conductivity.
Basd on the aforementioned graphene types, polymer-based conductive inks have been developed based on cellulose or polyvinylpyrrolidone (PVP) as polymer binders and water or dihydrolevoglucosenone (Cyrene) as green solvents, respectively.
Screen-printable inks have been optimized in terms of viscosity and adhesion properties, leading to printed films with sheet resistance up to 1 $k\Omega\ sq^{-1}$. Further, graphene:PVP composite inks are also biocompatible and nontoxic, being suitable for biomedical applications.[1]
The developed graphene-based inks have been applied by screen-printing for the development of both conductive track and sensing elements. For the latter, thermoresistive temperature and piezoresistive force and deformation sensors have been developed, as well as multitouch capacitive sensing devices.[2,3]

Site-and Shape-Selective Synthesis of Nanocale Heterostructures Based on Combinations of Direct-Writing and Nano-Micro-CVD SvenBarth, FabrizioPorrati and MichaelHuth; Goethe University Frankfurt, Germany

Recent advancements in additive manufacturing enable the fabrication of free-shaped 3D objects with very high accuracy using focused electron beam-and focused ion beam-induced deposition (FEBID and FIBID).[1] We demonstrate the formation of 3D core-shell heterostructures by combination of direct-write 3D FEBID scaffolds and the successive site-selective chemical vapor deposition (CVD). In particular, conductive 3D nanobridges are printed by FEBID and used as resistors allowing deposition induced by Joule heating. The successful combination of both approaches is demonstrated using two material systems of specific physical properties.[2] The fabrication of complex 3D core-shell heterostructures promises to add new functionalities by combining free-shaped 3D nanostructure writing with thin film deposition of materials with different properties. Specifically, shape-dependent and topological physical properties can be investigated by this highly adaptable approach.

Aerosol-Jet Printed Stretchable Micro-Scale Strain Sensor DiandianZhang[1], QingshenJing[2] and SohiniKar-Narayan[1]; [1]Department of Materials Science & Metallurgy, United Kingdom; [2]University of Glasgow, United Kingdom

Small wearable strain sensors are capable of collecting mechanical signals from the human body and local environments, providing numerous insights into various applications, such as human physiology research, healthcare monitoring and smart human-robotic interactions [1][2][3].
Here we have developed an aerosol-jet printed microscale wearable sensor for small-area skin deformation sensing. This sensor is thin and flexible to adapt to the skin curvature and highly customisable due to its novel direct-print manufacturing technique. The sensor is composed of two ultra-thin Polydimethylsiloxane (PDMS) films embedded with aerosol-jet printed poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) as the soft conductive sensing components. The printed circuit includes sensing units which are designed to be the same size as the target area for surface strain detection. When a strain is applied, the sensing polymer develops cracks leading to an increase in the resistance of the circuit. This is the mechanism through which the external mechanical stimuli are converted into electrical signals. The sensing polymer is restored upon removal of the strain and is found to be capable of prolonged and continuous measurement of multiple strain cycles.
The performance of the sensor was characterized by applying mechanical stimuli to the sensor using a linear motor. The deformation on the sensing arrays was in the vertical range of 0-500 μm and caused an increase to the resistance of 100 ohms, corresponding to force applied in the range of 0-0.05 N.

11:30 AM SF01.09.10
3D Printing of Nanomaterial-Based Devices with Metamaterial-Inspired Near-Field Electromagnetic Structure SamuelHales[1], JaredAnklam[1], YangXin[2], CordeliaLatham[1], TianXi[2], DerrickWong[1], LeiBinLi[1], JohnHo[2] and Yong LinKong[1]; [1]University of Utah, United States; [2]National University of Singapore, Singapore

The ability to 3D print nanomaterials enables the creation of freeform architecture and devices with an unprecedented level of functional integration. However, the possible material integration and geometrical configuration remain limited by the inability to selectively anneal printed nanomaterials, especially on temperature-sensitive substrates. Indeed, thermal annealing is a critical process that dictates 3D printed device performance by (1) merging otherwise disconnected nanomaterials, (2) reducing defects and interfaces, (3) removing polymeric additives, and (4) improving contact between printed layers. Here we demonstrate the ability to selectively and locally anneal 3D printed nanomaterials *in situ* on a broad range of temperature-sensitive substrates by focusing near-field electromagnetic waves to submillimeter resolution using a metamaterial-inspired near-field electromagnetic structure (Meta-NFS). This near-field electromagnetic wave printing (NFP) enables exceptional control of printed nanomaterial annealing parameters, allowing the creation of spatially freeform microstructure where the electronic and mechanical properties can be locally programmed. We envision that NFP significantly broadens the possible class of materials compatible with an additive manufacturing process, enabling the creation of hybrid multi-functional constructs and the printing of functional electronics even on temperature-sensitive substrates.

3D Printing with a 3D Printed Digital Material Filament for Programming Functional Gradients Sang-JoonAhn, HowonLee and KyuJinCho; Seoul National University, Korea (the Republic of)

Three-dimensional (3D) printing attracts growing attention as a promising method for manufacturing functionally graded materials (FGMs). Fused deposition modeling (FDM) 3D printing is widely available, but due to its simple process, creating spatial gradation of diverse properties using FDM is challenging. Here, we present a 3D printed digital material (DM) filament that is structured towards 3D printing of FGMs, utilizing only a readily available FDM printer and filaments. The DM filament consists of multiple base materials combined with specific concentrations and distributions, which are 3D printed using FDM process. When the DM filament is supplied to the same printer, its constituent materials are homogeneously blended during extrusion, resulting in the desired properties in the final structure. This blended FDM (b-FDM) printing enables spatial programming of material properties in extreme variations, including mechanical strength, electrical conductivity, and color. The b-FDM with DM filaments can be readily adopted to any standard FDM printer, enabling low-cost production of FGMs.

Thermoformable All-Ceramics Through AM and Particle Assembly RandallM. Erb, JasonBice and EchoSt. Germain; Northeastern University, United States

Thermoforming processing, traditionally reserved for thermoplastic polymers and sheet metals, has been extended here to boron-based all-ceramics. Specifically, sintered boron nitride composite sheets manufactured via a combined vibration and tape-casting photopolymerization process exhibited highly oriented microstructure which allowed these preform sheets to flow as viscous Bingham pseudoplastics during compression molding. These sintered all-ceramic preforms are thermoformed into thin, complex parts with features down to 200 µm. Further, a new workflow is leveraged to generate bespoke all-ceramic heat spreaders that can be press-fit onto printed circuit boards and outperform metal heat sinks as a low-profile thermal management solution. This work offers a route for other all-ceramics that may be thermoformed through first fabricating pre-forms with highly-ordered anisotropic microstructures.

Photo-Polymerizing Heterogeneities to Self-Shape Ceramics ZizhenDing[1], HalaZreiqat[2] and MohammadMirkhalaf[1]; [1]Queensland University of Technology, Australia; [2]The University of Sydney, Australia

Ceramics with complex shapes are desired in many applications, including architectural design and construction, protective systems, molds for gas turbines, and biomaterials. 3D printing through photopolymerization is amongst the most powerful approaches to make ceramics with complex shapes. However, these procedures are usually difficult to implement, are time-consuming, require further processing, and result in material waste. To address these challenges, we developed a simple, fast, and low-waste self-shaping procedure to make ceramics with complex shapes. The approach draws on a principle that the amount of shrinkage a ceramic undergoes during sintering is a function of the concentration of particles in the ceramic resin: the higher the concentration, the less the shrinkage. By printing components with inhomogeneous concentrations of particles, the parts with higher concentrations shrink less during sintering, resulting in well-controlled shape changes. This approach does not require extensive instrumentation and can be used for a wide range of ceramics. We then developed a material- and scale-independent mechanical model, which predicted the shape changes accurately. The model can be used as a tool to design the self-shaping experiments, potentially for a large variety of ceramics and glasses.

2:15 PM *SF01.10.03
High-Throughput Printing of Combinatorial Materials from Aerosols YanliangZhang; University of Notre Dame, United States

The development of new materials and their compositional and microstructural optimizations are essential to next-generation technologies such as clean energy and environmental sustainability. However, materials discovery and optimization have been a frustratingly slow process. The Edisonian trial-and-error process is time-consuming and resource-inefficient, particularly when contrasted to vast materials design spaces. While traditional combinatorial deposition methods can generate material libraries, it suffers from limited material options and inability to leverage immense breakthroughs in nanomaterials synthesis. Here we present a high-throughput combinatorial printing (HTCP) method capable of fabricating materials with compositional gradients with microscale spatial resolution. The *in situ* "mix and print" in the aerosol phase allows instantaneous tuning of the mixing ratio of a broad range of materials on the fly, which is an important feature unobtainable in conventional multi-materials printing using feedstocks in liquid/liquid or solid/solid phases. We demonstrate a variety of high-throughput printing strategies and applications in combinatorial materials discovery, functional grading, and chemical reaction, enabling materials explorations of doped chalcogenides and compositionally graded materials with gradient properties. The versatile aerosol based HTCP enables universal printing and integration of a broad range of materials including metals, semiconductors, dielectrics, as well as polymers and biomaterials, leading to facile fabrication of multifunctional and flexible/wearable devices for energy conversion/storage, sensing, and health monitoring. The ability to combine the top-down design freedom of additive manufacturing with bottom-up control over the local material compositions promises compositionally complex materials inaccessible via conventional manufacturing approaches. The fabrication freedom and data-rich nature of HTCP along with machine learning and artificial intelligence guided design strategies is expected to accelerate the discovery and development of a broad range of materials with intriguing and unprecedented properties for emerging applications.

2:45 PM SF01.10.04
High-Throughput Printing and Post-Processing Approaches for Realization of Novel Flexible Magnetoresistive Sensors MykolaVinnichenko[1], ClemensVoigt[1], Eduardo SergioOliveros Mata[2], SindyMosch[1], YevhenZabila[2], MorrisOtt[3], MarcoFritsch[1], ThomasPreussner[3] and DenysMakarov[2]; [1]Fraunhofer IKTS, Germany; [2]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [3]Fraunhofer FEP, Germany

The research in the field of additive manufacturing is increasingly focusing on realization of electrically conductive interconnects, passive and active components such as resistors, capacitors, inductors, and application-specific electronic devices [1]. The additive manufacturing technologies are offering high design flexibility and high throughput, are material saving and have a great potential of the production cost reduction. The flexible printed magnetoresistive (MR) sensors based on various physical principles are novel components in printed electronics demonstrated in recent years using additive manufacturing methods [2]. However, the large-scale manufacturing of these sensors and their industrial uptake are hampered by the lack of commercially available magneto-resistive inks and scalable post-printing processing methods to enable optimal functionality of the components.
Our work is focused on establishing a fully additive approach for realization of flexible MR-sensors and their arrays. We address the complete process chain from MR-material particles selection/preparation, through the ink formulation, printing and post processing of the structures, their characterization and demonstration of defined use cases. Two types of materials were used to formulate MR-inks: i) commercially available µm-size spherical Bi particles showing non-saturating large magnetoresistance (LMR), and (ii) permalloy (Py) flakes of own development showing anisotropic magnetoresistance (AMR). In the latter case, a method was developed to ensure a production of the particles with 100 nm thickness and in-plane dimensions of a few micrometers with a yield of approx. 2.7 g/day which can be further upscaled. It is based upon large-area PVD deposition of the corresponding materials as thin films onto glass substrates coated with a special sacrificial layer, following lift-off process of the thin films, and their ultrasonic milling. Based on these powder materials, screen-printing compatible inks were formulated with solid fraction as high as 82-90 wt.% (Bi particles) and 21 wt.% (Py flakes). Electrical contacts were realized either using commercially available or IKTS-proprietary Ag inks. Different layouts of LMR and AMR sensors were created and printed on flexible polymer foils (PET, PI).
The core of our approach is a combination of scalable printing methods (screen-, dispenser-, inkjet-printing) with high power diode laser post-processing. The line-shaped laser beam was generated by microoptically optimized high-power diode laser array operating in the near-infrared spectral range using continuous wave mode. In contrast to standard furnace heating this approach enables treatment on the millisecond time scale, preventing temperature-induced damages of sensitive substrates and permitting selective sintering of printed films in air. The laser beam was swept along the printed structures to remove the organic phase and sinter particles of the magnetoresistive material. Depending on the type of material, the dwell time was varied from 3 to 20 ms and the laser intensity from 0.8 to 2.0 kW/cm^2. In case of Bi-based LMR material, the sensors with a strong linear response within a broad magnetic field range 100 mT - 7 T were achieved. The resulting magnetic field sensors based on Py flakes showed a very promising AMR effect in the range of 0.5% at much lower magnetic fields of 2-3 mT. The applicability of the sensors and their arrays for contactless switching and flexible human-machine interfaces is demonstrated. The relationship between the sensor manufacturing parameters and the resulting structure and properties is analyzed to define pathways to further improvement of their performance.

Towards Inline Property Prediction in Material Extrusion-Fabricated Structures with Limited Information AmyPeterson, DavidKazmer, AhmedAdisa and AustinColon; University of Massachusetts Lowell, United States

Modeling polymer material extrusion additive manufacturing (AM) for prediction of mechanical properties requires substantial training data, and many modeling approaches are computationally intensive. This work investigates measurement and modeling approaches to enable inline property prediction in filament-fed material extrusion AM, commonly referred to as fused filament fabrication (FFF). We explore what kinds and how much information is necessary to create an acceptably accurate model, and to output accurate predictions. We also performed detailed analysis of the types of fracture that occurred across a range of processing conditions and relate this mechanical behavior to print conditions. This work contributes to efforts towards higher reliability, higher performance additively manufactured parts.

4:00 PM SF01.10.06
3D Printing of Continuous Fiber-Reinforced Thermoset Composites KaiYu; University of Colorado Denver, United States

3D printing revolutionizes the fabrication of continuous fiber-reinforced composites by eliminating the need for molds, offering exceptional design flexibility, and reducing manufacturing costs per part. This technology is particularly well-suited for rapid prototyping and the development of composite products. With 3D printing, users can easily create composites with customized fiber distribution and selective reinforcements. Additionally, the incorporation of functional fibers enables the integration of various functionalities directly into the printed objects. However, there is no robust design of printer for continuous fiber reinforced thermoset composites, especially for the thermally curable composites that are widely used in the industry.
In this work, we developed a versatile 3D printing method for continuous-fiber thermoset composites based on direct ink writing (DIW). It leverages the shear stress imposed on the fiber to enable the ready extrusion of composite filaments and can be applied to print most thermally curable and photo-curable resins and commercially available fibers. Two deposition pressures are applied to the DIW printer head: one for resin extrusion and another to prevent resin backflow. The printing speed can be precisely controlled by adjusting the magnitude of the deposition pressures, while the fiber content of the composites is regulated by using needles of different diameters. After printing, the thermally curable composites undergo post-heating to fully polymerize the thermoset matrix, resulting in excellent mechanical strength attributed to the covalent bonding among filaments.
Moreover, by utilizing a UV-curable resin with rapid curing mechanisms, we can achieve high fiber content and faster manufacturing speeds in composite 3D printing. To enhance the printing process, we have integrated the DIW printer head design with a six-axis robotic arm for composite printing. This integration has enabled us to achieve a significantly higher fiber volume fraction, reaching approximately 50%. Furthermore, I will show that the recently emerged two-stage UV-curable resin is an ideal material candidate to dramatically promote the glass transition temperatures, mechanical strength, and interfacial bonding strength of 3D printed composites, which are desirable for high-performance engineering applications.
Overall, the developed printing method allows the composite parts to be designed quickly to meet unique specifications, as well as providing new functions in 4D printing, biomedical printing, and the printing of functional devices.

4:15 PM SF01.10.07
Novel Fast Cure Silicone Inks for Single-Step, Support-Free 3D Printing of Tall, Overhanging and High Aspect Ratio Structures AnnaGuell Izard, LemuelX. Pérez Pérez, ToddH. Weisgraber, IlseVan Meerbeek, A. MelodyGolobic, EricB. Duoss and JeremyM. Lenhardt; LLNL, United States

Silicone elastomers have a broad variety of applications, such as soft robotics, biomedical devices, and structural metamaterials. The extrusion-based method known as direct ink write (DIW), has enabled the production of additively manufactured silicone structures. However, this method is limited to manufacturing mostly planar or pseudo-three-dimensional (3D) structures. Due to the low self-supporting capabilities of extruded strands for traditional silicone-based “inks”, obtaining tall or overhanging structures, or structures comprised by thin walls is not feasible. Here, we demonstrate a novel Fast Cure silicone-based ink that enables manufacturing of complex three-dimensional structures. The Fast Cure ink is a two-part mixture and silicone structures are produced by inline mixing and co-extrusion of a part containing a catalyst (part A) and a part containing a crosslinker (part B). By the virtue of crosslinking, the extruded strands rapidly rigidize, increasing their self-supportive capacity. Hence, we can obtain structures with superior shape retention and realize previously unobtainable parts that are tall, high aspect ratio, and have overhanging features. These minimal sag parts are achieved without requiring extra curing or mechanisms, support structures, or suspension baths. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-849618.

4:30 PM SF01.10.08
3D Printed BioPE Textile for Low Temperature Applications VolodymyrKorolovych, DuoXu, AmyHuynh and SvetlanaV. Boriskina; Massachusetts Institute of Technology, United States

The developments in polymer material synthesis and manufacturing processes are re-shaping the textile industry, ushering in a new textile manufacturing paradigm, namely implementation of digital and sustainable manufacturing approaches, such as fused deposition modelling (FDM) 3D printing. In recent years, 3D printing of polymers on textiles has shown a lot of potential to optimize complex designs, automate manufacturing as well as to develop new textile functionalities and aesthetic elements. Most popular polymers printed on textiles include polylactic acid, acrylonitrile butadiene styrene, nylon, polycarbonate, glycol modified poly-ethylene terephthalate, and thermoplastic polyurethane. They are usually printed on a dissimilar textile material, which leads to poor adhesion between the printed parts and the fabric. In addition, poly-material nature of the state-of-the-art 3D printed textiles often makes it impossible to separate and reclaim their ingredients at the end of the product lifecycle. Furthermore, conventional 3D printable polymers are typically stiff and have poor thermal management properties, which may cause thermo-physiological wear discomfort of 3D printed textiles. Overcoming these challenges will significantly improve wear comfort, sustainability of 3D printed textile and drastically expand their functionality.

This work aims to develop bioderived, low-carbon-footprint monomaterial 3D printed textile platform for low temperature applications in defense and aerospace industries. We explore the role of the nanostructure of bioderived polyethylene (bioPE) 3D printed structures in engineering their tensile and elastic performance at extremely low temperatures (down to -70 °C). A range of bioPE yarns and textile with various 3D printed patterns and different nano-scale structure has been fabricated via a combination of a scalable fiber melt-extrusion method and fused deposition modelling. These yarns and textiles have been characterized by their tensile and viscoelastic performance, as well as classified according to their meso- and nanoscale structure. Wide angle (WAXS) and small angle (SAXS) X-ray scattering techniques confirmed that by precise engineering of bioPE material nanostructure, we can tune the material crystallinity degree from ~60% to ~80% and to achieve high degree of crystalline domain orientation along the fiber axis. This tunability of the fiber nanostructure translates into tunable elongation at break (up to ~100%) and tensile strength (up to ~180 MPa) values of the bioPE yarns at -70 °C. We further show that mono-material bioPE 3D printed textiles exhibit great adhesion between the printed parts and the fabric, together with high flexibility and durability. In addition, bioPE 3D printed textiles are fully recyclable into a high-value and utility material stock. Overall, our work provides novel route towards development of lightweight, multifunctional bioPE 3D printed textiles with potential applications from uniforms and wearables to aerospace suits, while offering lower environmental footprint in production and full mechanical recyclability.

This work was supported by the Advanced Functional Fabrics of America (AFFOA) and the US Army Research Office. We thank Brandon Henry, Michael Lampkin, Tony DeLaHoz and Jeff Haggard from Hills Inc. for help with the PE yarns fabrication and Braskem for providing bio-derived PE resins. A.H. was supported by NSF GRFP. Useful discussions with Leslie Yan, Michael Rein, and Michelle Farrington are gratefully acknowledged. We also thank Steven Kooi for his help with equipment installation.

4:45 PM SF01.10.09
Infrared Scanning Near-Field Spectroscopic Studies of Self-Assembled Nanostructures Based on Photo-Crosslinkable Block Copolymers Nadinevon Coelln, BrittaWeidinger, ChristianHuck, IreneU. Wacker, RasmusSchroeder, EvaBlasco and PetraTegeder; Heidelberg University, Germany

Block copolymers, i.e., chemically distinct polymer blocks which are covalently bond, are known for their ability to self-assemble into a variety of morphologies on the nanometer scale.[1] The self-assembly of block copolymers has been extensively investigated for 2D films,[2,3] however, less attention has been paid to 3D bulk morphologies as well as light-based 3D printed microstructures. To achieve long-range ordered samples in thermodynamic equilibrium, in this work, 3D bulk morphologies were prepared via solvent annealing and 3D printed microstructures were fabricated from pre-self-assembled block copolymer inks.

Infrared scanning near-field optical microscopy (IR-SNOM) offers the unique possibility of infrared chemical imaging and spectroscopy with a spatial resolution down to ~20 nm.[4] When irradiating a well-defined diblock copolymer consisting of polystyrene and a methacrylate-based copolymer decorated with photo-crosslinkable units at an independently addressable absorption band of a polymer block, chemical imaging of the blocks’ nano-ordered spatial arrangement is possible.

Here, the internal nanostructure of self-assembled 3D bulk morphologies with lamellar nanostructures is studied by means of IR-SNOM. When selectively exciting each polymer block, a switch of the relative optical phase, related to the local absorption, is observed, revealing a strong phase segregation via spectroscopic contrast. A successful correlation with scanning electron microscopy (SEM) measurements, performed after post-staining with ruthenium tetroxide, furthermore demonstrates, that ruthenium tetroxide creates a specific metal stain for polystyrene. These studies are extended to cylindrical nanostructures as well as two-photon laser printed microstructures exhibiting complex geometry and hierarchically nano-ordered structures.

Influence of Diffusion on Print Fidelity in Vat Polymerization 3D Printing—Acrylate-Chain vs Thiolene-Step Growth Chemistry BhavanaDeore[1], ChantalPaquet[1], HendrickdeHaan[2], ThomasLacelle[1], LauraDickson[1], KatieSampson[1] and YujieZhang[1]; [1]National Research Council Canada, Canada; [2]Ontario Tech University, Canada

3D printing is an emerging additive manufacturing technology poised to transform both design and manufacturing due to its ability to customize design and generate structural complexity not possible using traditional manufacturing processes. Light-based 3D printing techniques, such as SLA, DLP or tomographic printing, use patterned light to trigger polymerizations within a volume of a photoresin and thus producing 3D objects. The process of printing in a vat of resin using light that varies temporally and spatially creates dynamics within the resin that ultimately influences properties of the printed part. In this work, we present how concentration gradients and changes in miscibilities during printing causes phase separation and diffusion of species that effect the printing process. The dynamics created by 3D printing are complex with factors governing the extent of the diffusion of inhibiting and reactive species include the geometry and dimensions of the printed features, the viscosity of the resin, rates of polymerization and gelation point. These factors are in turn governed by the formulation and on the type of polymerization i.e., step growth vs. chain growth. By tuning the formulations, changes in diffusitivity, viscosity and gelation rates can be control and therefore allow control over phase separation or deviations from nominal print dimensions. The results are supported by modeling allowing us to identify the underlying mechanism behind each.

On-Demand Printing of Metallic Polymer Composite Microstructures via Hybrid 3D Printing YeowonYoon, YoungwooLee, YangXu and YongChen; University of Southern California, United States

On-demand printing of microstructures using polymer composites can enhance the materials' functionality with tailored properties. Especially metallic polymer composites have been used in a wide range of applications, including electronics, energy solutions, soft robotics, and four-dimensional printing due to their mechanical strength, high electrical/thermal conductivity, and ferromagnetic behavior. However, current manufacturing challenges limit the concentration of the filler materials in these metallic polymer composites to be low so low viscous slurry can be used in printing. In this study, a novel hybrid additive manufacturing (AM) process is developed to print a highly concentrated metallic polymer composite with over 80% metal particles within the polymer matrix. In this hybrid AM process, highly viscous slurry (~400,000 mPa×s) is printed using DDW, and metal (Iron)-polymer composites are fabricated at designed locations in both discrete and continuous manner so functional material portions can be well defined. In addition, DLP-based VPP is used to print bulk matrix portions using photopolymers to build intricate matrix structures at a fast building speed. An extensive range of composite inks including various photopolymers can be employed in this hybrid 3D printing process to fabricate functional structures with adjustable mechanical properties and multifunctional characteristics. The printing parameters of this hybrid process have been studied, including nozzle height, dispensing speed, and different surface conditions. Using ferromagnetic particles (44 μm) with soft and elastic photopolymer resins, magnetic-actuated grippers were fabricated to demonstrate design functions. The developed 3D printing approach offers a promising route to manufacture metallic polymer composites with tunable magnetic and mechanical properties, which could have potential applications in soft-form sensors, actuators, and biomedical devices.

8:45 AM SF01.11.03
Strategies for Integrating Metal Nanoparticles with Two Photon Polymerization Process JisunIm[1], LiuYaan[2,3], QinHu[2], GustavoTrindade[4,2], RickyWildman[2], RichardHague[2], LyudmilaTuryanska[2] and ChristopherTuck[2]; [1]University of Warwick, United Kingdom; [2]University of Nottingham, United Kingdom; [3]University of Exeter, United Kingdom; [4]National Physical Laboratory, United Kingdom

A femtosecond laser-induced two photon polymerization (2PP) is a high-resolution additive manufacturing technology that allows for the creation of highly precise and complex microstructures with submicron resolution. This technology has revolutionised the creation of micro- and nano-scale structures, leading to the emergence of new products and technologies. However, the limited availability of functional materials, especially metal nanoparticles that are suitable for use in this process, hinders the technology's full exploitation. Here we propose three complementary strategies for the integration of metal nanoparticles (MeNPs) with 2PP processes to fabricate nanoparticle-polymer composites and metal nanoparticle-decorated surface patterns in microscale: 1) in-situ formation of MeNPs through a single-step photoreduction process, 2) integration of pre-formed MeNPs into 2PP resin, and 3) site-selective MeNPs decoration of 3D 2PP structures. We demonstrate successful fabrication of high-fidelity structures with incorporated MeNPs and provide detailed morphological and compositional analysis including advanced time-of-flight secondary ion mass spectrometry (ToF-SIMS) mapping results. These complementary strategies open up a broad range of prospective applications from metamaterials and nano/micro-photonics to optoelectronics and biomedicine.

9:00 AM SF01.11.05
Interpenetrating Networks with Tuned Thermal and Mechanical Properties by Multiphoton Lithography PaulinaSzymoniak[1], DorotheeSilbernagl[1], ZeynabTavasolyzadeh[1], HeinzSturm[1,2] and IevgeniiaTopolniak[1]; [1]Federal Institute for Materials Research and Testing (BAM), Germany; [2]Technical University of Berlin, Germany

Multiphoton lithography (MPL) has recently attracted significant research interest as a versatile tool capable of fabricating 2D and 3D micro- and nanoscopic features with high spatial resolution. The integrity of MPL microstructures, or their ability to respond to external stimuli, is of critical importance. Often, the mechanically flexible micro-objects are expected to be capable of shape morphing, bending, or other motion to ensure their functionality. However, achieving the desired properties of MPL-manufactured micro components for a specific application still remains challenging.
In this work, we present new MPL materials based on epoxy-acrylate interpenetrating networks (IPNs). We aim at fabrication 3D microstructures, whose properties can be easily tuned by varying the ratio of the IPN components and fabrication parameters. The studied mixtures consist of polyethylene glycol diacrylate (PEGDA) and cycloaliphatic epoxide functional groups. Consequently, tryarylsylfonium salt and cyclopentanone photoinitiator tailored for MPL were used to ensure cationic and radical polymerization, respectively. The resulting library of 3D microstructures was investigated for their thermal and mechanical properties using highly sensitive space-resolved methods. For the first time, we were able to evaluate the glass transition behavior of 3D MPL microstructures using fast scanning calorimetry. The influence of both IPN composition and fabrication parameters on glass transition temperature and material fragility was demonstrated. AFM force-distance curve and intermodulation methods were used to characterize the micromechanical properties with lateral resolution of the techniques in the range of 1 micron and 4 nm, respectively. The elastic-plastic behavior of the microarchitectures was evaluated and explained in terms of IPN morphology and thermal properties. The fabricated 3D IPN microstructures exhibit higher structural strength and integrity compared to PEGDA. In addition, IPNs exhibit high to full elastic recovery (up to 100%) with bulk modulus in the range of 4 to 6 MPa. This makes IPNs a good base material for modeling microstructures with intricate 3D designs for biomimetics and scaffold engineering.
The effects of composition and MPL microfabrication parameters on the resulting IPN properties give us a better understanding of the underlying mechanisms and microfabrication-structure-property relationships. Moreover, our funding supports the further development of IPN systems as versatile and easily tunable MPL materials.

9:15 AM SF01.11.06
4D Printing of Free-Standing Carbon Fiber-Reinforced Shape Memory Polymer Composites via Frontal Polymerization Hyeon-JuJang and Woong-RyeolYu; Seoul National University, Korea (the Republic of)

Continuous carbon fiber-reinforced polymer composites have been used in various industries, such as automobiles and aerospace, due to their high strength performance and lightweight. With the emergence of 3D printing technology, there has been a growing interest in utilizing this technique to fabricate continuous carbon fiber-reinforced plastics, particularly thermoplastic composites. In this study, we developed a 3D printing process for fabricating free-standing continuous carbon fiber-reinforced shape memory polymer composites without supports using frontal polymerization. Frontal polymerization is a self-catalytic exothermic reaction that converts monomers into polymers without external energy supply. One of the key challenges in

printing continuous carbon fiber-reinforced shape memory polymer is to achieve a high degree of resin impregnation of carbon fibers to ensure optimal physical properties. We enhanced the degree of impregnation by developing an *in situ* pin-assisted printing head. Subsequently, we investigated the printability of frontal polymer with continuous carbon fibers with a focus on the degree of impregnation. Finally, the newly developed 3D printing system was evaluated characterizing the mechanical properties of the printed composites including their shape memory performance.

9:30 AM SF01.11.07
Embedded 3D Printing of Mechanically Robust Ionogel Composites AlexanderQ. Kane, EunBiOh and RyanL. Truby; Northwestern University, United States

Multifunctional materials with programmable mechanical properties and electronic/ionic conductivities are required for many emerging applications, including soft electronics, robotics, structural batteries, and more. Additive manufacturing has revolutionized our ability to fabricate these materials, which often require complex 3D forms. Poly(ionic liquid) composites are an emerging structural electrolyte that provide a wide electrochemical window and high ionic conductivity. However, poor intrinsic mechanical properties (e.g. Young's modulus) limit the printability of precise functional poly(ionic liquid) architectures, hindering their potential utility as materials for the aforementioned applications. Moreover, existing light-based 3D printing methods are often incompatible with filler particles that can enhance the mechanical properties of poly(ionic liquids) or provide additional functionalities. In this work, we present a method for overcoming the challenges of 3D printing poly(ionic liquids) via embedded 3D (EMB3D) printing. Our integrated material design and manufacturing process produces free-form, lightweight, and flexible poly(ionic liquid) composites that are mechanically robust under cyclic compression. We demonstrate the modularity of our methods by showcasing multimaterial printing with various particle fillers (e.g., carbon black, hexagonal boron nitride, and fumed silica) and poly(ionic liquid)s. We anticipate our contributions will open new avenues for fabricating complex, architected solid electrolytes for soft sensors and robots, wearable devices, solid-state batteries, and more.

9:45 AM SF01.11.08
Discovery of New Strengthening Law in Nanocomposite Reinforced by Ceramic Nanoarchitected Materials GwangminBae[1], Dong GyuKang[2], ChanguiAhn[3], DaehoKim[2], Hyeon GyunNam[2], GayeaHyun[2], DongchanJang[2], Seung MinHan[2] and SeokwooJeon[1]; [1]Korea University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Engineers have long sought to utilize the exceptional mechanical properties achieved by size effect at the macroscopic level, as the strengthening effect derived from size is exclusive to the nanoscale realm. In this work, we present a novel approach to harness the size-induced strengthening effect and apply it on a macroscopic scale in a three-dimensional (3D) metal/ceramic/metal (MCM) nanocomposite. 3D Ni matrix nanocomposites embedding nanoscale Al_2O_3 nanoarchitectures were produced in a large area (~1 inch) using Proximity-field nanopatterning (PnP) and material conversion techniques. Ceramic thin-shell nanoarchitected materials (t < 100 nm), utilized by a reinforcement of metal nanocomposite, perfectly separate 1st and 2nd metal layers. 1st and 2nd metals are densely infiltrated in and out of the ceramic nanoarchitected materials without defects. The 3D Ni/Al_2O_3/Ni nanocomposite exhibits a significantly higher compressive strength, surpassing the upper bounds predicted by conventional rule of mixture by approximately 30%. This remarkable strength is attributed to the extrinsic size effect of the ceramic nanoarchitected materials. By integrating the size-induced strengthening of ceramics into the traditional strengthening models of composites, a new strengthening model is derived and experimentally validated using the 3D Ni/Al_2O_3/Ni nanocomposite system. The utilization of size-induced strengthening in nanomaterials allows the 3D MCM nanocomposite system to offer a novel approach for enhancing the mechanical properties of bulk materials.

10:30 AM SF01.11.09
3D-Printed Microarray Biosensor for Real-Time Monitoring in Interstitial Fluid Jean WonKwak, TuanTrinh, AlexanderD. White, YueXu, H. TomSoh and JosephM. DeSimone; Stanford University, United States

Real-time tracking of biochemical biomarkers in the body can provide personalized healthcare information. Microneedles, as a promising platform, enable continuous access to interstitial fluid in the dermal region through a minimally invasive and painless approach. However, wearable microneedle-based sensors face limitations, including the lack of reagent loading capacity due to conventional fabrication processes (e.g., microfabrication, molding) and deficiencies in continuous sensing capabilities caused by restricted biorecognition elements. Here we present a microarray biosensor (MAB) that integrates 3D-printing technology with biochemical sensing techniques for continuous and real-time monitoring of small molecules, such as cortisol and lactate. The MAB leverages the Continuous Liquid Interface Production (CLIP) to achieve tunable geometries, enabling utilization of the void volume of each microarray projection. These voids facilitate loading of hydrogel membranes, where optical molecular switches are immobilized within the network, enhancing signal detection and providing biochemical protection. Additionally, the MAB allows omnidirectional diffusion of targeted analytes while offering mechanical support during insertion. Ex vivo and in vivo evaluations are underway to validate the performance of the MAB in an effort to demonstrate its potential to provide comprehensive information about our bodies for precise prognosis and diagnosis of our health.

10:45 AM SF01.11.10
Towards a 3D Solid–State Na–Ion Battery using a Direct Ink Writing–Infiltration Approach ShreyasPathreeker[1], ShahryarMooraj[2], SelinaLiu[1], WilliamR. Fullerton[3], HyeongjunKoh[1], WenChen[2], RussellJ. Composto[1], EricA. Stach[1], ChristopherY. Li[3] and EricDetsi[1]; [1]University of Pennsylvania, United States; [2]University of Massachusetts Amherst, United States; [3]Drexel University, United States

3D solid–state batteries based on porous materials offer significant advantages over conventional 2D batteries, namely, high areal energy and high power density due to their increased surface area and intimate contact between cell components. They can also exhibit enhanced safety due to the high modulus of the solid electrolyte, which is known to suppress dendrite growth. The fabrication of 3D batteries calls for innovative, sustainable, non–roll–to–roll manufacturing approaches. We describe a three–step fabrication approach comprising direct ink writing, Capillary Rise Infiltration (CaRI), and vacuum–assisted infiltration for the development of a 3D solid–state battery. Pre–alloyed $NiMn_2$ powder mixed with a porogen is 3D printed into lattices, and sintering time and temperature are optimized to create a porous $NiMn_2$ 3D lattice comprising two different pore sizes in the range of 5 µm–10 µm and 150 µm–200 µm, respectively. Partial oxidation of the porous lattice generates a $Na_{2/3}[Ni_{1/3}Mn_{2/3}]O_2$ (NNMO) layer, which serves as the cathode. Following this step, capillary–rise infiltration (CaRI) of an optimized poly(glycidyl methacrylate)–poly(ethylene glycol) (PGMA–PEG6k) electrolyte solution is used to deposit the polymer electrolyte within the small pores of the lattice. Thermal crosslinking between the epoxide groups on the PGMA backbone and amine end groups of the PEG within the pores yields a dense composite of solid polymer electrolyte in conformal contact with the pore surfaces. To deposit the anode in the large pores of the 3D lattice, vacuum–assisted infiltration of $Na_{80}K_{20}$ metal is carried out, thereby completing the battery. Notably, this sequential fabrication approach uses zero solvent and polymer binder during either cathode (NNMO) or anode ($Na_{80}K_{20}$) deposition, which is in remarkable contrast to conventional slurry–casting methods that require the use of both N–methyl–pyrrolidone (NMP) and a polymer binder such as polyvinylidene fluoride (PVDF). Focused ion beam (FIB) milling, scanning electron microscopy (SEM), and energy dispersive x–ray spectroscopy (EDS) on the 3D matrix reveal excellent scaffold–polymer–anode contact, confirming the formation of robust interfaces that are necessary for battery application, which is currently being investigated. This work underscores the importance of cross–cutting collaborative research in materials science for emerging energy applications. Acknowledgements: We gratefully acknowledge funding from the NSF via grant number FMRG–2134715. This work was carried out in part at the Singh Center for Nanotechnology, which is supported by the NSF National Nanotechnology Coordinated Infrastructure Program under grant number NNCI–2025608.

11:00 AM SF01.11.11
End-To-End Performance Analysis of 3D Printed Luminescent Devices for Energy Conversion Applications ShomikVerma[1] and RachelEvans[2]; [1]Massachusetts Institute of Technology, United States; [2]University of Cambridge, United Kingdom

In recent years, there has been increasing urgency to develop cheap, efficient solar devices. However, most solar modules are large, bulky, and rectangular, making integration into the built environment non-trivial. A promising technological solution that may help solve this problem is the luminescent solar concentrator (LSC). A typical LSC is a plastic slab that absorbs sunlight and re-emits light of a tailored wavelength towards its edges, where solar cells can be installed. Because LSCs are colorful, semi-transparent, and modular, they hold great potential in reducing the cost and barrier to entry of solar technologies. However, they suffer from significant optical losses limiting their efficiency. Many novel device shapes have been proposed to improve light transport pathways in LSCs, but these often rely on expensive or wasteful fabrication techniques.

A potential solution to this is 3D printing, which has gained immense traction as an alternative manufacturing technology. 3D printing has many benefits including accessibility, rapid prototyping, and fabrication of completely new designs. This study presents an end-to-end performance analysis methodology to evaluate new LSC designs that can take advantage of this novel manufacturing technology. This methodology is applied to some preliminary 3D printed parts as a proof of concept that can be applied to a wider variety of designs.

This study consists of 3 distinct steps: simulating the optical efficiency of the printed part, 3D printing the part with luminescent filament, and characterizing its optical efficiency experimentally.

Simulation of LSCs using ray tracing has been extensively investigated in the past; however, this has been limited to conventional, rectangular LSCs. Analyzing the performance of alternative

LSC geometries requires developing a novel methodology for evaluating device efficiency, as well as implementing parallelization techniques to reduce computation time for complex geometries.

Among the 3D printing technologies, fused deposition modeling (FDM) is the most accessible and widely used, but it is not known for producing transparent parts usable for optical applications. This thesis aims to solve some of the complications of FDM to develop a cheap, rapid, and accessible methodology for printing efficient LSCs.

Similar to modeling, device characterization has been limited to rectangular LSCs, so a standardized methodology for evaluating device efficiency has been developed, allowing for comparison between different device shapes.

The simulated results of this study indicate 3D printed devices have the potential to offer a twofold increase in efficiency over conventionally manufactured bulk devices. Actual 3D printed devices were measured to have similar efficiency to bulk devices (within 1%), but extrapolating the results to parts made with higher quality material also suggests some parts would have twice the efficiency of their bulk counterparts. 3D printed parts may have additional benefits in improving directionality of edge-emitted light, but this will have to be confirmed in future work.

Overall, 3D printing provides major benefits over conventional manufacturing techniques, as it introduces rapid prototyping by allowing experimental iteration and model validation, allows custom-built designs for easier integration into the built environment, and increases the optical efficiency of devices by improving light transport pathways. With further development, this technology can help make widespread solar adoption a reality.

11:15 AM SF01.11.12
Unique Mechanical Behaviors of Mechanical Metamaterials with Engineered Imperfections SiyaoLiu and YaningLi; Northeastern University, United States

Traditionally, imperfections are undesired in the materials and structures, because they often reduce the load-bearing capacity and cause premature failure. However, if imperfections are designed and engineered, they could generate unique new mechanical properties. In this investigation, we introduce patterned and hierarchical imperfections to lattice structures and find that the new designs show dramatically different mechanical properties under loads at different locations. Also, by utilizing the concept of tensegrity, the mechanical properties can be further controlled and tuned. In this investigation, new hybrid lattices are designed, which are composed of hard cells connected via engineering soft connections Upon external mechanical or thermal loads, the hard cells will either keep the orientation or rotate due to the chiral arrangement or the soft components. Both deformation mechanisms will contribute to the overall volume change of the material and are related to the loading type and location. Therefore, the pattern transformation will lead to a change in both mechanical properties and functionality related to the material structure. To further prove the concept, prototypes of selected designs are fabricated in both macro- and micro- scales. Quasi-static uniaxial compression experiments were conducted in both room temperature and elevated temperatures. Finite element simulations are performed to further quantify the mechanical behaviors.

SESSION SF01.12: Session X

Hynes, Level 2, Room 200

1:30 PM SF01.12.01
Materials Design for Charge-Programmed Additive Manufacturing of Antennas ZhenWang[1], JunboWang[2], ZhenpengXu[1], RyanHensleigh[2], YahyaRahmat-Samii[2] and RayneZheng[1]; [1]University of California, Berkeley, United States; [2]University of California, Los Angeles, United States

Additive manufacturing (AM) is emerging as a powerful tool for fabricating antennas particularly in the capability of creating arbitrary complex geometries without incorporating excessive materials owing to its unique materials build-up mechanism. Taking such benefits, 3D printed antennas, including horns, waveguides, and dielectric antennas, have been reported with enhanced performances in different aspects. These examples, however, are constructed mainly by single materials (either all-dielectric or all-metal). While multi-process AM can potentially perform conductive coating on 3D printed dielectric structure, the lack of selectivity and limited access to complex 3D geometries exclude a considerable amount of antennas from current AM approaches.
The charge-programmed multi-material 3D printing technique integrates multiple materials and functionalities into 3D devices, which is achieved by programmed volumetric deposition of one (or multiple) materials into arbitrary 3D micro-architectures. The printed structures had programmed surface charge regions, enabling the selective deposition of functional materials into complex 3D architectures based on localized electrostatic interactions. For antenna applications, charge-programmed AM can achieve sophisticated 3D architected lattice materials with interpenetrating dielectrics and metals, allowing free space for designing antennas being ultra-light and yet mechanically robust. In this paper, we present the materials design principles enabling charge-programmed multi-material printing of lightweight antennas with unique mechanical properties and competitive antenna performances.
CHARGE-PROGRAMMED SELECTIVE DEPOSITION
Charge-programmed selective deposition for the fabrication of antennas is based on a multi-material printing system. Resins with positive, negative, or neutral charge polarity were alternately solidified and bound to the previously built layer of the printed parts. The process was repeated layer by layer, pin-pointing multiple materials with different polarities into their designated coordination in 3D space. The charged surfaces immobilize the oppositely charged catalyst species, which in-situ catalyze the subsequent deposition of functional materials. In such a way, the printed objects obtained patterned structures that selectively integrated different functionalities in designated locations with a resolution as high as the 3D printer could achieve.
MATERIALS DESIGN FOR ANTENNA APPLICATION
Charge-programmed selective deposition allows a wide range of space for materials design. Particularly for antenna applications, a variety of combinations of conductivity and dielectric constant, the most crucial parameters, can be achieved, suggesting the versatility of the charge-programmed selective deposition for custom tailored antenna applications.
The composition of the negative resin directly influences the antenna performances which relies on the quality of the plated Cu layer as well as antenna's mechanical robustness. Based on the molecular configurations of the polymerized photo-monomers, the negative resins were formulated to deliver either stiffness or flexibility for the printed antennas. By tuning the composition of the resins, we achieved a balance between the cross-link density and charge density. This enabled a uniform catalyst distribution on the stiff and tough negative resins and consequently grew a crack-free conformal Cu coating on the surface, serving excellent electrical properties for a K-band horn antenna. By introducing flexible monomers, we fabricated transmitarray with considerable flexibility, which promises potential for deployable antennas.

1:45 PM SF01.12.02
Additive Manufacturing of Micro-Architected Metals via Hydrogel Infusion MaxA. Saccone[1,2], RebeccaA. Gallivan[1,3], KaiNarita[1], DarylW. Yee[1,4] and JuliaR. Greer[1]; [1]California Institute of Technology, United States; [2]Stanford University, United States; [3]ETH Zürich, Switzerland; [4]École Polytechnique Fédérale de Lausanne, Switzerland

Metal additive manufacturing (AM) has emerged as a uniquely powerful tool to produce complex and high-performance parts with applications from the aerospace to biomedical fields. Most existing metal AM techniques use heat to define part shape via thermally initiated melting or sintering. In contrast, we report a polymer-based AM technique, coined hydrogel infusion additive manufacturing (HIAM), that produces metals and alloys with microscale resolution via vat photopolymerization (VP). To fabricate micro-architected metal structures, we infuse 3D-architected hydrogels with aqueous metal precursors, then calcine and reduce the infused hydrogel scaffolds to create miniaturized metal replicas. Unlike previous VP strategies, which incorporate target materials or precursors into the photoresin during printing, HIAM does not require re-optimization of resins and curing parameters for different materials, enabling quick iteration, compositional tuning, and the ability to fabricate multimaterials. We demonstrate HIAM of micro-architected metals including copper, nickel, silver, cobalt, cupronickel alloys, high entropy alloys, and tungsten with critical dimensions of ~50 µm. This work shows how single architected gel scaffold can respond to a variety of chemical and thermal stimuli to transform into a vast array of metals, providing a pathway to create advanced micro-architected metals.

2:00 PM SF01.12.03
3D Printing and Processing of High-Performance Piezoelectrics for Ultrasound Transducer Applications HaotianLu[1,2], VictorCouedel[1] and RayneZheng[1]; [1]University of California, Berkeley, United States; [2]University of California, Los Angeles, United States

The performance of ultrasonic transducers is largely determined by the piezoelectric properties and geometries of their active elements. Due to the brittle nature of piezoceramics, existing processing tools for piezoelectric elements only achieve simple geometries, including flat disks, cylinders, cubes and rings. While advances in additive manufacturing give rise to the free-form fabrication of piezoceramics, the resultant transducers suffer from high porosity, weak piezoelectric responses, and limited geometrical flexibility. We introduce optimized piezoceramic

printing and processing strategies to produce highly responsive piezoelectric micro transducers that operate at ultrasonic frequencies. The 3D-printed dense piezoelectric elements achieve high piezoelectric coefficients and complex architectures. The resulting piezoelectric charge constant, d_{33}, and coupling factor, k_t, of the 3D printed piezoceramic reach 583 pC/N and 0.57, approaching the properties of pristine ceramics. The integrated printing of transducer packaging materials and 3D printed piezoceramics with microarchitectures create opportunities for miniaturized piezoelectric ultrasound transducers capable of acoustic focusing and localized cavitation within millimeter-sized channels, leading to miniaturized ultrasonic devices that enable a wide range of biomedical applications.

2:15 PM SF01.12.04
Three-Dimensional Printing of High-Sensitivity Micro-Architected Piezoelectric Hydrophones with Designed Beam Patterns VictorCouedel[1], HaotianLu[1,2] and RayneZheng[1]; [1]University of California, Berkeley, United States; [2]University of California, Los Angeles, United States

Piezoelectric hydrophones are crucial for underwater applications such as communication and seafloor mapping. Limited by the brittleness of piezoelectric ceramics, conventional manufacturing methods restrict hydrophones' shapes to simple geometries such as disks, cylinders, or spheres, which limits the sensitivity, directivity pattern, and working frequency bandwidth of the device.
Here, we present a new class of high-performance 3D printed piezoelectric hydrophones consisting of rationally designed micro-architectures. Using a high-resolution light-based printing process, and thanks to a liquid sealing sintering process, the piezoelectric coefficients and electromagnetic coupling factor can reach respectively 92% and 85% of the pristine material's values, the highest values among all existing 3D printing work.
We have developed a framework to artificially manipulate the piezoelectric coefficients of an architected material by modifying the spatial arrangement of unit cell struts. This can be harnessed to develop a new class of metamaterial hydrophones whose sensitivity can be locally manipulated. We take advantage of this framework to generate hydrophones with sensitivities ~10 dB higher than the commercial ones, and whose directivity patterns can be inversely designed.
This work holds great promises for high frequency sound localization without the need of hydrophone arrays, and for low frequency sound monitoring thanks to a hydrostatic figure of merit five times higher than the one of commercial transversely isotropic piezoelectric hydrophones.

2:30 PM SF01.12.05
The Role of Particle Microstructure and Polymer Configuration in 3D Printed Thermal Composites DanielBraconnier[1], EricWetzel[2], RyanDunn[2] and RandallM. Erb[1]; [1]Northeastern University, United States; [2]U.S. Army Research Laboratory, United States

While everyday device sizes continue to shrink, the power being packed into them increases drastically, driving internal heat generation to the point of overwhelming current thermal management solutions and limiting system-level performance. New thermal management materials and solutions are required to support higher energy density electronics; incumbent materials including metals like copper and aluminum satisfy many applications, however they are heavy and cannot be placed adjacent to electronics or in the proximity of radio frequency components. Additive manufacturing and fine-tuned composite creation can enable lightweight and geometrically complex thermal management solutions that provide a distinct advantage over current solutions. Here we present a collection of new understandings around process-structure-property relationships that will help enable higher performing thermal parts via additive manufacturing. This work focuses on the interplay between the filament composition, the processing conditions of fused filament fabrication (FFF), and the post-processing of printed parts (annealing). The goal of this research is to enable emergent properties in FFF printed composites through material interface and interphase engineering, flow-induced self-assembly of mesostructure, and temperature-induced self-assembly of polymeric nanostructure. The ability to locally control the thermal conductivity of FFF parts would enable a new class of advanced thermal management materials.

2:45 PM SF01.12.06
Radiation Shielding of Microelectronics via Additive Manufacturing AveryRosh[1], AustinCoon[1], DevonBeck[1], RichD'Onofrio[1], EthanCascio[2], KsenofonoKonomi[3], AndreaBarney[1], RobertLongton[1], PascaleGouker[1], MelissaSmith[1] and BradleyDuncan[1]; [1]Massachusetts Institute of Technology Lincoln Laboratory, United States; [2]Massachusetts General Hospital, United States; [3]University of Massachusetts Lowell, United States

The miniaturization of satellite systems has compounded the need to protect microelectronic components from damaging radiation. Current approaches to mitigate this damage, such as indiscriminate mass shielding, built-in redundancies, and radiation hardened electronics, introduce high SWaP-C (Size, Weight, and Power-Cost) penalties that reduce the overall performance of the satellite. Additive manufacturing provides an appealing strategy to print radiation shielding only on susceptible components within an electronic assembly. Utilizing direct ink writing, we are able to conformally print customized inks at room temperatures directly and selectively onto COTS (commercial-of-the-shelf) electronics. The suite of inks uses a flexible styrene-isoprene-styrene block copolymer binder that can be filled with particles of varying atomic densities for varying radiation shielding capabilities. Additionally, blended composites of both high and low Z fillers were created to investigate the performance in radiation attenuation depending on composition. We anticipate this low SWaP-C alternative to traditional shielding methods will enable the development of novel complex and compact satellite designs.

3:00 PMBREAK

3:30 PM SF01.12.07
High-Speed Fabrication of Intrinsically Flexible Perovskite Optoelectronic Devices on Diverse Substrates (Elastomer, Paper, Textiles, *etc.*) Using Printing and Direct WritingJunyiZhao and ChuanWang; Washington University in St. Louis, United States

Flexible optoelectronic devices built on thin elastomer substrates may find a wide range of applications in wearable electronics, soft robots, deformable displays, and more. While considerable efforts have been made to explore the potential of halide perovskites in high-performance light-emitting diodes (LEDs), existing fabrication techniques using rigid substrates cannot meet the growing demand for large-area flexible devices. In this work, we report a high-speed fabrication approach for intrinsically flexible perovskite LEDs (PeLEDs) directly printed on elastomer thin films. Using a highly scalable inkjet printing approach, each layer in the device, from the bottom anode to the top cathode, is patterned. In addition to elastomer, paper, and textiles commonly used in our daily lives also hold great potential as platforms for next-generation flexible and wearable electronics. Therefore, we have developed a versatile, scalable, and eco-friendly direct writing approach that enables multicolor PeLEDs (covering the entire visible spectrum) and perovskite photodetectors (PePDs) (both vertical-photodiode configuration and planar-photoconductor configuration) to be directly drawn onto various unconventional substrates (paper, textiles, plastic, rubber, metal, and common three-dimensional objects) in an ultrafast and mask-free manner. This is achieved by daily used ballpoint pens filled with our uniquely formulated inks of conductive polymers, metal nanowires, and perovskite/polymer composite for photoactive layers. The addition of an ionic polymer in the inks helps address the challenge of rough surface morphology on yarn and fiber networks, ensuring uniform printed film thickness and minimizing leakage current. Just like drawing with multicolor pens, by writing the above functional inks layer-by-layer, high-performance perovskite optoelectronic devices can be customized on almost any target substrate within minutes even by untrained individuals. Notably, the entire manufacturing was conducted in ambient conditions without the need for specific moisture and temperature control. The simplified device architecture and fabrication strategy significantly reduce the fabrication time compared to the hours or days required by conventional microfabrication processes. The written PeLEDs exhibit a brightness as high as 15,225 cd/m^2, a current efficiency of 6.65 cd/A, and a turn-on voltage of 2.4 V. The PePDs exhibit an on/off ratio over 10^4, and a response time of less than 15 ms. Owing to the extraordinary flexibility of each functional layer, the written LEDs on the paper substrate could be bent to a 1 mm extreme curvature radius for over 5000 cycles without decay in performance. Overall, this work paves the way for the practical application of perovskite optoelectronics in cost-effective and large-area scenarios, such as E-textile, E-paper, smart packaging, disposable electronics, and wearables.

Three-Dimensional Property Enhancement of Composites by Realization of Three-Dimensional Fiber Alignment via Embedded Direct Ink Writing QiyiChen and RayneZheng; University of California, Berkeley, United States

The orientation of fibrous fillers, induced by shear forces during extrusion, has been extensively demonstrated to exert a significant impact on various material properties such as mechanical properties, electrical conductivity, thermal conductivity, and microwave attenuation. However, these effects have primarily been observed in a two-dimensional (2D) x-y plane. In this study, we propose a novel approach to achieve fiber alignment in a three-dimensional (3D) context, specifically focusing on the Z-direction, by employing embedded 3D printing techniques. This methodology involves the extrusion and suspension of composite inks within a viscoelastic gel medium, allowing the control of fiber alignment through processing conditions such as velocity ratio, nozzle size, and fiber dispersion. By selectively aligning the fibers in a 3D pattern, it becomes possible to significantly enhance and tailor the mechanical properties and conductivity in a three-dimensional manner.

4:00 PM SF01.12.09
Direct Photopatterning of Metals on Polymer Surfaces at Ambient Conditions IvanB. Dimov[1], AntonioDomniguez Alfaro[1,2], TobiasNaegele[1] and GeorgeG. Malliaras[1]; [1]University of Cambridge, Department of Engineering, Electrical Division, United Kingdom; [2]University of Basque Country, Spain

Metal interconnects on polymer substrates are an integral part of many stretchable and flexible electronic devices. However, metal deposition typically involves harsh conditions, such as high vacuum and temperature. These requirements limit compatibility with many substrates and impede rapid prototyping and increases and energy requirements. Solution-phase depositing such metal features is an attractive alternative to conventional processes, especially when combined with a rapid additive manufacturing technique.
Here we present an aqueous gold ink, comprised of $H[AuCl_4]$ as a metal source, a reducing agent and a benign, nontoxic dye as an initiator, that allowed us to deposit gold onto silicone surfaces upon UV illumination at ambient conditions. Altering the reaction time and ink composition, we could tune the morphology of the deposited metal, between isolated nanoparticles and a continuous film. Using this ink, we deposit stretchable gold interconnects on pre-strained silicone, using solely UV illumination, achieving conductivity of 40% of bulk gold. We additionally used a commercial sterelithographic printer without any modifications as a maskless lithography system, allowing us to pattern conductive features of 300 µm. Investigating different substrates suggests a preference for polymers with reducible species on the surface. Lastly, we have successfully performed the reaction with $AgNO_3$ as a metal source, depositing silver on silicone. We are working towards 2-photon illumination, in order to increase resolution and expand to 3D metal structures.

4:15 PM SF01.12.10
Mechanical Properties of 3D Printed Wavy Fiber-Matrix Composites AmmarBatwa and YaningLi; Northeastern University, United States

We aim at exploring the influences of fiber waviness on the effective stiffness, strength, and toughness of 3D printed polymer composites with wavy-fibers embedded in soft matrix. Polymer fiber-matrix composites with fibers with various waviness are designed and fabricated via multi-material 3D printing. Quasi-static uni-axial tension experiments are conducted to characterize the stress-strain behavior of the designs. Systematic finite element (FE) simulations are also performed to explore the deformation mechanisms of the designs.
The results demonstrate an interesting mechanism for increasing toughness via controlling the waviness of the fibers. The structural-property relationship is quantified via a parametric study. To further evaluate the strain rate effects of the polymer fiber-matrix composites, uni-axial tension experiments under different loading rates are performed. Rate dependent material models are used in the FE simulations to capture the strain rate effects. The results under both static and dynamic loading provide design guidelines for this family of polymer composites fabricated via multi-material 3D printing.

Chemically Coalescing Liquid Metal Emulsions as 3D Printed Soft Conductors StephanieF. Zopf, ChloeKekedijan, RamonE. Sanchez, LuPing and JohnW. Boley; Boston University, United States

Patterning room temperature liquid metals as soft conductors requires nontrivial solutions due to its complex rheology. To facilitate material handling, liquid metals are often transformed into an emulsion by dispersing it as droplets within a continuous liquid. Oxides present on liquid metal droplets, however, render liquid metal emulsions nonconductive, which must be ‘activated’ through droplet coalescence for the ink to be conductive. Although liquid metal droplet coalescence in emulsion inks has been shown by using mechanical ([1], [2]), laser [3], and extreme thermal ([4], [5]) means, these modes of activation make it challenging to integrate with other materials and device components. This work presents a liquid metal emulsion ink that is 3D printable through direct ink writing (DIW), and can be activated chemically through the use of an active ingredient. It requires a low thermal stimulus (~80°C), which is compatible with commercial off the shelf electronic components. The ink developed in this work is able to retain its printed structure after being thermally activated. Coalescence through chemical etching of the oxides on the liquid metal droplets is evident through electrical conductivity measurements, scanning electron microscopy, nuclear magnetic resonance, and x-ray photoelectron spectroscopy characterization. Conductivities of formulated emulsions are precisely calculated using measured resistances combined with micron-level 3D scans with the maximum conductivity obtained of attempted formulations being 3.54×10^3 S/cm. Printability outcomes of emulsion inks with respect to formulated chemistries will be presented. Rheology for the most printable formulation with the highest conductivity shows that the ink is shear thinning and shear yielding and exhibits a high plateau modulus and high yield stress, giving it the ability to print features that span long distances. Lastly, an automated 3D print and electronic device assembly process will be shown to demonstrate the utility of this ink as a soft conductor for manufacturing integrated electronic systems.

4:45 PM SF01.12.12
Computational Discovery of Microstructured Composites with Optimal Strength-Toughness Trade-Offs BoleiDeng[1,2], BeichenLi[1], WanShou[3] and WojciechMatusik[1]; [1]Massachusetts Institute of Technology, United States; [2]Georgia Institute of Technology, United States; [3]University of Arkansas, Fayetteville, United States

The conflict between strength and toughness is a fundamental problem in engineering materials design. However, systematic discovery of microstructured composites with optimal strength-toughness trade-offs has never been demonstrated due to the discrepancies between simulation and reality and the lack of data-efficient exploration of the entire Pareto front. Here, we report a widely applicable pipeline harnessing physical experiments, numerical simulations and artificial neural networks to efficiently discover microstructured designs that are simultaneously tough and strong. Using a physics-based simulator with moderate complexity, our strategy runs a data-driven proposal-validation workflow in a nested-loop fashion to bridge the gap between simulation and reality in high sample efficiency. Without any prescribed expert knowledge of materials design, our approach automatically identifies existing toughness enhancement mechanisms that were traditionally discovered through trial-and-error or biomimicry. We provide a blueprint for the computational discovery of optimal designs, which inverts traditional scientific approaches, and is applicable to a wide range of research problems beyond composites, including polymer chemistry, fluid dynamics, meteorology, and robotics.

Additive Manufacturing of Carbon Nanotubes Reinforced Metal Matrix Composites LiCao; University of Dayton, United States

High-performance components are always highly demanded for modern aerospace applications due to their critical role in ensuring safety and efficiency. Developing metal matrix composites (MMCs) reinforced with nanomaterials is an effective strategy to enhance the properties of such functional components. Among the various reinforcements, 1D nanomaterials such as carbon nanotubes (CNTs) have attracted much attention due to their exceptional mechanical, thermal, and electrical properties. Meanwhile, Additive manufacturing (AM) offers innovative manufacturing techniques that can be used to construct complex and intricate structural components. Integrating advanced material development and AM techniques has drawn significant attention as it overcomes the limitations and challenges of conventional fabrication approaches. This research focuses on the development of CNTs reinforced nickel-based alloys using laser powder bed fusion, a popular AM technique. The result showed significant improvements in the yield strength, ultimate tensile strength, and elastic modulus of the 3D printed specimens when 2.5vol.% CNTs were incorporated, demonstrating the remarkable impact of CNTs on enhancing the performance of the metal-based alloys.

8:30 AM SF01.13.02
High-Fidelity Beetle-Inspired 3D-Printed Wings for Miniature Flapping Drones Bat-ElPinchasik, OrFilc, HagitGilon, ShmuelGershon and GalRibak; Tel Aviv University, Israel

Miniature flapping drones equipped with lightweight membranous wings have shown great potential for operating effectively in small spaces. Achieving optimal flight performance in these drones heavily relies on the appropriate design of their flexible wings. In this study, we explore the utilization of 3D-printing technology to fabricate high-fidelity, bioinspired wings and expedite the design process for miniature flapping drones.
Drawing inspiration from the wings of the rose chafer beetle, we employ a bioinspired approach to develop 3D-printed wings. By modulating the wing structure, we create twelve distinct wing models that feature variations in vein cross-section shape, tapering geometry, and membrane thickness. Through a comprehensive comparison of their mechanical and aerodynamic properties, we establish guidelines to correlate wing form and function.
Our findings reveal the following key insights: first, manipulating the cross-section shape of the veins provides a powerful tool for engineering in-plane and out-of-plane deformations.

Second, tapering veins enhance the wings' mechanical stability, improving their overall performance.
Experimental results demonstrate that the optimized wings exhibit a 16% increase in lift and a 27% improvement in lift production efficiency (N/Watts) when tested in a revolving wing setup. The successful design of lightweight, flexible, robust, and aerodynamically efficient wings poses a formidable engineering challenge that we aim to address through our bioinspired methodology. By reverse engineering these intricate structures, we contribute empirical knowledge to the field of wing design for miniature flapping drones.
Our work highlights the potential of bioinspiration and 3D-printing techniques to advance the development of miniature flapping drones with enhanced flight performance. The insights gained from this study provide valuable guidance for future advancements in the field of bioinspired wing design and optimization.

8:45 AM SF01.13.03
Halftone Stereolithography-Enabled 3D Printing to Regulate Rotating Actuation Performance ZhongkunZhao and HongtaoSun; Penn State University, United States

Halftone lithography has established itself as a novel technique in high-resolution 2D printing and imaging. In this study, we extended the application of halftone patterns to the realm of stereolithography-enabled 3D printing, enabling precise control over the material properties within 3D printed structures.[1-3] Our work focuses on the development of a halftone-enabled photo-stereolithography method to fabricate soft actuators using Shape Memory Polymers (SMPs). The underlying concept of halftone lithography in 3D printing involves the spatial modulation of polymerization, allowing the creation of intricate patterns within each layer. Rather than relying solely on volumetric or voxel-based 3D printing approaches, this technique utilizes halftone dots or pixels as building blocks to build up the designed 3D structures. More importantly, the integrated halftone patterns in the printed product can offer additional control over material properties and functional performance in addition to the constrained geometry. Specifically, by strategically arranging these dots, we can achieve different features incorporated into the printed structures, such as heterogeneity domains, high-strength inclusions, graded structures, and complex textures, providing a more degree of freedom to design and fabricate functional products particularly for the use of smart functional materials, compared to traditional layer-by-layer 3D printing methods. By controlling the distribution of halftone patterns, we fabricated fiber-shaped SMP actuators as rotation micro-engines, which can achieve high strength inclusions, or graded structures, allowing for regulating the mechanical properties and stimuli-responsive behaviors. Overall, the advancements in halftone lithography for 3D printing of shape memory polymers, driving innovation and opening up new avenues for designing dynamic, responsive, and highly tailored structures with tunable performance and functionality.

FAIRification of Additive Manufacturing Process Through Ontology Development and Linked Data KristenJ. Hernandez, Hein HtetAung, XuanjiYu, PawanK. Tripathi, ErikaI. Barcelos, RogerH. French and LauraBruckman; Case Western Reserve University, United States

In order to improve current knowledge on Additive Manufacturing process the use of computer science principles is of interest. In order to optimize datasets for data analysis is a difficult process, due in part to the multiple data sources and the different output formats from each data source. The FAIRification process represents an attractive alternative to overcome the challenges associated with the storage, integration and reusability of these datasets. FAIR principles describe a set of guidelines applied to data and metadata to ensure a proper and efficient data management system. When applied correctly, it ensures that data is properly stored, organized, accessible and reusable. A fundamental component in the development of a successful FAIR framework and the integration of datasets is the development of ontologies. Domain ontologies are standardized representations of properties and relationships in a field and provide a sharing and common understanding within the research community. Using FAIR principles and domain ontologies as the backbone of organizing and processing data, the use of automated extraction methods are more feasible and able to process data regardless of the original capturing method. Data from disparate sources need to be processed and extracted in a method that can capture the feature of interest as well as relate the feature in a linked manner to the original data output. Information in the Additive Manufacturing process of Laser Powder Bed Fusion is sparse and separated among multiple instrument data sources that both capture different features and represent it using different encoding methods. These different encoding methods have the same object in reference while having different material characteristics extractable from the data source. In order to process through large data spaces of disperite features, data must be organized in a machine-compatible method. Furthermore, data must be retrieved with an automated pipeline for the ability to extract measurement of specific variables in a verifiably reproducible manner. Many datasets are reliant on operator specific inputs and often unreproducible evaluation methods. By using a more data scientific approach and organization scheme of linking datasets, information on Additively Manufactured parts, in spite of its sparse data, can be used and expanded further data visualization and trend relationships through specific software development and application. Organizing and streamlining data outputs to a common data framework allows for automation of analysis, quick retrieval of digital representations of variables of interest and the framework for decision making using data driven methods as opposed to physics informed simulations.

8:55 AM SF01.13.05
Engineering a Thermally and Electrically Conductive, Biodegradable, Mechanically Sustainable Nanocomposite via 3D Printing XuyiZhou[1], Yu-ChungLin[2] and MiriamRafailovich[2]; [1]Shanghai Pinghe School, China; [2]Stony Brook University, The State University of New York, United States

The electronic industry has considerable demand for materials with good electrical and thermal conductivity, and for the convenience of manufacturing, it would be beneficial for the materials to have better mechanical properties in comparison to the currently actively researched material graphene nanoplatelets(GNPs). In response to such need, we intend to engineer nanocomposites with a blend of PLA, PBAT, and GNPs H-5 (average diameter of 5 microns) through 3D printing in this research. From the properties of individual materials, PLA is the currently commercialized 3D printing filament material; PBAT, as a ductile polymer, compensates for the brittleness of GNPs; GNPs H-5 contributes to good electrical and thermal conductivity. For environmental concerns, both PLA and PBAT are biodegradable polymers. From our previous studies, it had been concluded that the optimal ratio of PLA to PBAT is 1:3, creating percolation pathway for electrical conductivity. Contact angle tests and work of adhesion calculation indicated that GNPs preferred the phase of PBAT as opposed to PLA. The addition of PLA, at low concentration, would take up space and confine GNPs in PBAT, therefore improving electrical and thermal conductivity. Nevertheless, more PLA has the risk of making PBAT phase discontinuous. Inspired by this, in our research, we altered the concentration of GNPs (including 8wt.%, 12wt.%, 16wt.%, and 20wt.%) to find the composites with optimal thermal conductivity, electrical conductivity, and mechanical properties. The ratio of PLA to PBAT is fixed as 1:3. The 3D printing nozzle shear force is expected to further orientate the H-5 platelets.

Four-point electrical conductivity tests were performed on the 3D printed electrical test samples. As expected, electrical conductivity increases as GNPs concentration increases. For horizontally infilled samples, 8wt.% GNPs and 12wt.% GNPs samples were generally not electrically conductive. The electrical conductivity increases from 0 to 1.6 S/m when 16wt.% of GNPs is added. In addition, the orientation of infill during the 3D printing process has an effect on electrical conductivity. Vertically infilled samples are less electrically conductive than vertically infilled samples, however, the overall trend is similar. At 16wt.% GNPs, the electrical conductivity of horizontally infilled samples is approximately the value of Germanium, a classical semiconductor element. The thermal conductivity of samples were measured by a thermal camera while the samples were heated for a fixed interval of time. Thermal conductivity experiences minor increase as GNPs concentration increases. In comparison to pure PLA, 20wt.% GNPs samples are 350% as thermally conductive. Their thermal conductivity values are approximately the same as that of water at 50 Celsius degrees. This result support that an increase in the concentration of GNPs incurs an uplift in thermal conductivity. In the Instron test, the strain to stress diagram revealed the brittleness of high GNPs filling load samples. As the concentration of GNPs increases, the breaking elongation decreases, toughness decreases, and Young's Modulus increases. Such result suggests that at the microscopic level, GNPs block the entanglement between polymers in the composites, giving rise to the decrease in material ductility. We expect the ideal blend of PLA, PBAT, and GNPs H-5 to have the proportion between 12wt.% and 16wt.%. If the concentration of GNPs is above 16wt.%, the material will be too brittle according to the mechanical tests data. Otherwise, if the concentration of GNPs equals or is below 12wt.%, the electrical conductivity of the material will be comparatively low for practical use.

9:00 AM SF01.13.06
Printing Electronic Circuits and Devices via Hybrid Fused Filament Deposition of a TPU/Copper Composite RemiRafael and Paddy K. L.Chan; Hong Kong University, Hong Kong

Printing metals and polymers together to form complex electronic devices is difficult due to the large difference in fusion temperature between those materials. In a previous article, we have introduced a hybrid printing technique based on the fused filament deposition of a copper-polylactic acid composite followed by a step of laser sintering, to produce a conductive, porous copper material. This technology integrates together a conventional fused filament deposition printer and a 10-watt laser diode. The printer is used to deposit layer by layer a composite material containing a polymer matrix, copper, and copper oxide particles. After printing each layer, the laser diode is used to selectively sinter the composite. Under the effect of the laser, the polymer matrix is evaporated, and the copper oxide is reduced, forming a highly conductive, porous copper material.
However, in our precedent experiments, the out-off plane resistivity of this printed porous copper was high, and the applications were restricted to low dimensionality, 2.5D applications. More recently, we have investigated more composite materials and sintering conditions and developed a new TPU based composite. After sintering, this composite presents a resistivity as low a 10^{-5} Ω x cm in the in-plane direction and 10^{-4} Ω x cm in the transverse direction. As a result, we can now design and print completely embedded 3D electronic circuits and complex electronic components. We demonstrate these capabilities by making an embedded 3D circuit controlled by capacitive sensors.

9:15 AM SF01.13.07
Printable Ionic Liquid/Polymer Hybrid Materials for Sensors Applications DanielaCorreia[1], LilianaFernandes[2], NelsonPereira[2], MohammadTariq[3], JoséEsperança[3], CarmenR. Tubio[4] and SenentxuLanceros-Mendez[4,5]; [1]University of Minho, Portugal; [2]Center of Physics, University of Minho, Portugal; [3]Universidade Nova de Lisboa, Portugal; [4]BCMaterials, Spain; [5]Ikerbaske, Basque Foundation for Science, Spain

Multifunctional and smart materials are increasingly being required in nowadays society, needing a larger number and variety of sensors with improved performance, and more simple integration. Smart materials play an important role both in terms of economic aspects and sustainability, being suitable for a wide range of applications including sensors and actuators. In particular, printable smart and multifunctional materials allow novel applications, needed to fully take advantage of the Internet of Things (IoT) and Industry 4.0 concepts. The production of these materials trough printing technologies allows to develop flexible and conformable devices.
The combination of different polymers with salts commonly defined as ionic liquids (ILs) have emerged as a promising approach in different fields, including in the field of sensors and actuators [1-3]. ILs emerge therefore as an interesting approach to develop a new generation of materials with reduced environmental impact [1]. Further, ILs offer interesting and new possibilities to develop a wide variety of smart materials with different functionalities and properties (e.g. thermochromism, and high ionic conductivity) compatible with printing technologies [1].
In this work, the double functionality of ionic/polymer hybrid materials as humidity and thermochromic sensors is addressed. Humidity and thermochromic sensors have been developed based on different ILs and IL contents (5-20% wt.) of 1-butyl-3-methylimidazolium tetrachloroferrate ([Bmim][$FeCl_4$]) and bis(1-butyl-3-methylimidazolium) tetrachloronickelate ([$Bmim]_2[NiCl_4$]), respectively. The IL based inks have been prepared based on both into chemically, thermal and radiations matrix poly (vinylidene fluoride) (PVDF) as well as into sustainable bio-based polymer matrix (cellulose). The humidity sensing property of the [Bmim][$FeCl_4$] allows humidity sensors in the range from 35 to 90%, showing a linear resistance variation with increasing relative humidity. The sensitivity to humidity variations increases linearly with the IL content. The thermochromism of [$Bmim]_2[NiCl_4$] materials revealed a reversible thermochromism behavior (transparent to blue or vice versa) resulting from a thermally induced dehydration process, which promotes changes in the coordination number of Ni(II) from octahedral to tetrahedral structure. The developed materials represent a promising solution for the development of humidity, thermochromic and thermoresistive printable sensors, as demonstrated by the proof of concept applications that will be presented.

Additive Manufacturing of Anisotropic Graphene-Based Composites for Thermal Management Applications ShaniLigati Schleifer[1] and OrenRegev[1,2]; [1]Ben Gurion University of the Negev, Israel; [2]Ben-Gurion University of the Negev, Israel

The use of additive manufacturing (AM) for the rapid, facile creation of complex structures could provide thermal management solutions in the form of heat sinks and heat exchangers with high surface areas that facilitate heat dissipation. To prepare a heat sink with high thermal conductivity (TC), we use vat photopolymerization (VPP) of a polymer-based composite material with a low TC that is enhanced by loading with a graphene-based thermally conductive filler. Phase separation of the carbon-based filler, in this case graphene nanoplatelets (GNP), in the monomer printing solution is prevented by stabilizing the GNPs by the addition of a second fiber-like clay (sepiolite) filler, which traps the GNPs. This methodology enables the AM of a composite with a relatively high GNP concentration of 2.0 wt%, yielding a TC increase of 160% vs. the pristine polymer—an impressive accomplishment for VPP 3D printing. Moreover, this printing technique yields a material with anisotropic TC with a cross-plane/in-plane ($TC_{\perp}/TC_{=}$) ratio of 1.6, which is beneficial for thermal management systems required to dissipate the heat vertically from a heat source. Such VPP 3D-printed composites with high and anisotropic TC could be applied in thermal management systems made of lightweight and cost-effective materials.

Investigation of Faceted Solid-Liquid Interface Behavior During the Directional Solidification of Salol AnassyaRaad, NathalieBergeon, NathalieMangelinck-Noël and FatimaL. Mota; Aix-Marseille Université, IM2NP, UMR CNRS 7334, France

During solidification of materials, a microstructure forms at the solid-liquid interface that depends on both the physical parameters of the material (in particular the surface energy and kinetic

attachment anisotropies) and the processing parameters such as thermal gradient G, growth velocity v, and composition of the sample. The microstructure plays a critical role in determining the final properties of the material. One can distinguish two different macroscopic types of interface: rough where the kinetic attachment of atoms is fast and heat and solute diffusion in the liquid is dominant; and faceted where the kinetic attachment of atoms is anisotropic and slow and considered as the dominant effect. In this last, the crystals grow with smooth surfaces at the atomic scale, and facets at macroscopic scale. Despite numerous researches, particularly for semi-conductors such as silicon, the understanding of the faceted growth is still a significant challenge.
In this work, directional solidification experiments of organic transparent materials are used to evidence and analyze mechanisms involved during the growth of faceted solid-liquid interfaces. Such transparent model materials are chosen to have similar solid-liquid interface properties as technological materials studied, and thus to form similar microstructures, with the advantages of being transparent to visible light, so that common optical techniques can be used to follow their growth. We use salol, which is orthorhombic in structure and grows from its melt with a distinct macroscopic faceted interface because of its very high degree of anisotropy. Directional solidifications are performed in the ECODIS device a Bridgman furnace designed for thin samples geometries, equipped with an optical microscope to observe solid-liquid interface dynamics *in situ* and real time.
A highly faceted solid-liquid interface appears and keeps evolving till the end of the experiment. The facet angles are characterized and it shows that they correspond mostly to {1 1 1} and {1 0 0} crystallographic planes. Velocities of the different facets are measured and they vary with facet orientation relatively to the thermal gradient. These measurements allow to establish kinetic growth laws which depend on the crystallographic nature of the facet. Facets are also studied in terms of size evolution and distribution, which are affected by facet competition and interaction with defects.

10:45 AM SF02.01.02
Growth Dynamics of Three-Dimensional Grain Boundaries in Polycrystalline Solidification using DECLIC-DSI Facility FatimaL. Mota[1], YounggilSong[2], KaihuaJi[3], DamienTourret[4], AlainKarma[3] and NathalieBergeon[1]; [1]Aix-Marseille Université, IM2NP UMR CNRS, France; [2]Lawrence Livermore National Laboratory, United States; [3]Northeastern University, United States; [4]IMDEA Materials Institute, Spain

lloy microstructures formed by directional solidification are often polycrystalline, made up of a several large grains of different crystallographic orientations. Grain boundaries (GBs) have a crucial influence on the mechanical behavior of materials, by their peculiar interactions with dislocations, or by providing solute segregated regions prone to the formation of secondary phases. In technological alloys, GBs typically evolve in the solid state through a series of complex thermomechanical post-processes. However, their initial shape and existence goes back to the initial stage of solidification from the liquid phase. The importance of GBs is well-acknowledged at the macroscopic scale, and grain growth competition is already used in the design of technological components (e.g. grain selectors in single-crystal turbine blades). However, our understanding of GB selection during polycrystalline solidification remains qualitative at best, and a number of unanswered questions remain.
Until now, grains have been assumed to occupy distinct compact regions of 3D space separated by smooth borders on a scale larger than the cellular/dendritic array spacing. In this presentation, we report experimental observations revealing for the first time that cells from one grain can invade a nearby grain during polycrystalline growth. This unexpected invasion process causes grains to interpenetrate each other on the fine scale of the array spacing, and hence grain borders to become highly irregular. By computational modeling, we further reveal the ubiquitous nature of this invasion process by showing that it occurs for a wide range of grain misorientations beyond those studied experimentally. Those results fundamentally alter the traditional view that cellular/dendritic grains are distinct regions embedded in three-dimensional space.
Those unique observations are made possible by *in situ* visualization of the spatiotemporal evolution of the solid-liquid interface during directional solidification of a transparent organic alloy (Succinonitrile-0.24wt%Camphor) using the DECLIC-DSI experimental device installed onboard the International Space Station. Transparent alloys have similar solid-liquid interface properties as metallic alloys and thus form similar microstructures. The microgravity environment of the space station eliminates buoyancy-driven fluid convection and the associated large scale inhomogeneities of alloy composition, thereby facilitating quantitative comparisons with computational modeling in a purely diffusive regime.

Disorder to Order in Interface Patterns: Thermal Noise to Limit Cycle Transition in Dendrite Sidebranch Formation TrevorD. Lyons[1], LouiseS. Littles[2] and RohitTrivedi[3]; [1]Northeastern University, United States; [2]NASA, United States; [3]Iowa State University of Science and Technology, United States

Thin sample directional solidification experiments have been carried out in the model succinonitrile-camphor system to examine the origin of secondary branches in dendrite morphologies. Thermal noise at the dendrite tip creates interface instabilities which amplify to form sidebranches. This is accepted as the primary mode of sidebranching in dendritic growth from an undercooled melt and occurs in directional solidification of dendrites. The proposed limit cycle couples the growth of the tip with the initiation of the sidebranch. Directional solidification of curved interfaces is a driven dissipative system with the potential to form a limit cycle. Two sets of experiments were performed, the first holding velocity constant and evolving the gradient and the second imposing oscillating velocities around the natural period of sidebranching. Both experimental methods were found to characterize a transition from disordered sidebranching induced by thermal noise to ordered sidebranching produced by the limit cycle mechanisms. This is the first quantitative measurement of previously hypothesized limit cycle growth.

These experiment sets have been quantitatively analyzed for dynamic behavior seen in limit cycles. High-quality data sets of the tip and instability enable the measurement of the FFT and analysis through a power spectrum. At low gradients, the sidebranches are found to be excited by thermal noise far away from the tip. As the gradient increases and velocity is held constant, the distance between the instability and tip decreases until limit cycle growth is found between the tip of the primary dendrite and the first forming sidebranch. An alternative to the deterministic limit cycles seen in experiments of gradient evolution is a limit cycle actively driven through the square wave oscillation of velocity. Crucial observations of the solidified microstructure conclude that this produced periodic interconnected bridges between the primary dendrites. This is a finding with potentially significant implications for commercial applications.

Direct Observation of Growth and Interfacial Dynamics of Ice Nanocrystals with Cryo-Electron Microscopy MinyoungLee and JungwonPark; Seoul National University, Korea (the Republic of)

Ice at low temperatures exhibit structural polymorphs including hexagonal ice, cubic ice, or a hetero-crystalline mixture of the two phases. These polymorphs coexist at a broad range of temperatures, but exhibit distinct growth kinetics. While numerous studies, mainly based on spatially-averaged techniques, have investigated the structural properties of ice formed at low temperatures, mechanisms behind the growths of coexisting polymorphs and their interfacial properties have been difficult to probe individually. Here, we use *in-situ* cryo-electron microscopy and computational ice-dynamics simulations to directly observe ice formation and growth amidst amorphous ice. We reveal that nanoscale ice crystals exhibit polymorph-dependent growth kinetics, with hetero-crystalline ice exhibiting anisotropic growth based on accelerated growth of the prismatic planes. Fast-growing facets are associated with low-density interfaces that possess high surface energy, driving tetrahedral ordering of interfacial water molecules and accelerating growth. Our approach in observing ice crystallization, based on nanoscale techniques, improve our understanding on early stages of ice formation and the mechanistic roles of ice interfaces, providing important insight into various fields such as ice physics, cloud physics, or designing cryoprotective molecules.

Phase-Field Modeling of Ice-Templated Hierarchical Structures KaihuaJi[1], MingwangZhong[1], KaiyangYin[2], LouiseS. Littles[3], RohitTrivedi[4], Ulrike G. K.Wegst[1] and AlainKarma[1]; [1]Northeastern University, United States; [2]University of Freiburg, Germany; [3]NASA Marshall Space Flight Center, United States; [4]Iowa State University, United States

Directional solidification of aqueous solutions and slurries in a temperature gradient has emerged as a promising method to produce cellular materials through a phase separation of solutes or suspended particles between growing ice lamellae. Those ice-templated cellular materials are hierarchically organized into a honeycomb-like porous structure on the largest scale, lamellar cell walls at an intermediate scale, and different unilateral surface features including ridges and other more complex shapes reminiscent of living forms that decorate the cell walls on a yet smaller scale. While the strong anisotropy of ice-crystal growth has been hypothesized to play a role in shaping those structures, the mechanism by which they form has remained elusive. We report the results of a detailed phase-field simulation study of ice templating of binary mixtures that reproduces the salient features of those cellular materials and that sheds light on the mechanism by which anisotropic ice crystal growth shapes their hierarchical structure. The simulation results reveal that the flat side of lamellae forms because of slow faceted ice-crystal growth along the c-axis, while weakly anisotropic fast growth in other directions, including the basal plane, is responsible for the unilateral features. Diffusion-controlled morphological primary instabilities on the solid-liquid interface form a cellular structure on the atomically rough side of the lamellae, which template regularly spaced ridges while secondary instabilities of this structure are responsible for the more complex features. The simulation results are compared with experimentally obtained results by directional freezing of binary water mixtures containing small solutes. Good quantitative agreement is found for the lamellar spacing that is shown to obey the scaling law $\lambda \sim (VG)^{-1/2}$, where V and G are the local growth rate and temperature gradient, respectively. Preliminary simulation results are presented that address the basic question of how other solvents such as DMSO, which exhibit different anisotropic crystal growth properties than ice, can produce a rich variety of hierarchical structures.

Ice Crystal Growth and the Dynamics of Ice Templating by X-Ray Tomoscopy Paul H.Kamm[1,2], KaiyangYin[3], Tillmann R.Neu[1,2], Christian M.Schlepütz[4], FranciscoGarcia-Moreno[1,2] and Ulrike G. K.Wegst[5,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Technische Universität Berlin, Germany; [3]University of Freiburg, Germany; [4]Swiss

Light Source, Switzerland; [5]Northeastern University, United States

The physics of ice-crystal growth from the liquid phase and the complex dynamics of microstructure formation by ice-templating during the directional solidification of aqueous solutions and slurries, also termed freeze casting, has to date received comparatively little research attention. Recent advances in synchrotron-based X-ray tomoscopy, which is time-resolved X-ray tomography, enable us now to investigate in situ under well-defined experimental conditions the formation of the hierarchical architecture of freeze-cast materials. We can quantify in 3D ice crystal growth at high spatial and temporal resolution and observe the ice-templating mechanisms, which determine the morphology of the freeze-cast material. The performance-defining morphology is defined by a honeycomb-like material structure with lamellar cell walls that frequently are decorated with a range of unilateral surface features. Analyzing the tomoscopy data, we can determine, which features of the freeze-cast materials are templated by the slow faceted growth along the c-axis of the hexagonal ice-crystal, and which are templated by the slightly anisotropic fast crystal growth along the preferred a- and t-axes, both of which are characterized by atomically rough ice-water interfaces. Additionally, we can observe, which role secondary instabilities play in the formation of cell wall surface features. Important advantages, which in situ X-ray tomoscopy offers over post-mortem imaging and state-of-the-art simulation techniques, are that the dynamics of the structural evolution can be monitored over several minutes in a sample volume of several cubic millimeters so that also transient phenomena are captured.

SESSION SF02.02: Nanostructures

Dodecahedral Silica Cages and Their Assembly at Liquid-Liquid Interfaces and in Inks for 3D Printing UlrichWiesner; Cornell University, United States

Crystallization and assembly at interfaces are hallmarks of biological systems and have provided inspiration for researchers world-wide to understand and control materials formation from the atomic scale all the way to the macroscale. This presentation will focus on the formation of silica nanocage structures with dodecahedral symmetry around spherical micelles (zero-dimensional, 0D) as well as their assembly at liquid-liquid interfaces (two-dimensional, 2D) and in inks for direct and internal three-dimensional (3D) printing. Detection of silica nanocage structures with dodecahedral symmetry and diameters around 10 nm has been enabled by the first application of machine learning enabled single-particle reconstruction of tens of thousands of cryo-electron microscopy images to materials discovery.[1] Synthesis of mesoporous silica at an interface between two immiscible solvents under conditions favoring the formation of 2D superstructures of silica nanocages leads to the thinnest mesoporous silica films synthesized to date.[2] It will be demonstrated how orientational correlations between nanocage units increases with increasing layer number controlled via pH, while swelling with oil and mixed surfactants increase micelle size dispersity, leading to complex clathrate type structures in multilayer superstructures. Mesoporous 2D superstructures can be fabricated over macroscopic film dimensions and stacked on top of each other to generate mesoporous heterostructures enabling potential separation and catalytic properties not achievable via conventional bulk syntheses. Finally, ultrasmall silica nanocages are combined with digital light processing (DLP) technique for the direct 3D printing of hierarchically porous parts with arbitrary shapes, as well as tunable internal structures and high surface area. Via versatile and orthogonal cage surface modifications, it will be shown how this approach can be applied for the implementation and positioning of functionalities throughout 3D printed objects. Taking advantage of the internal porosity of the printed parts, an internal printing approach is demonstrated for the localized deposition of a guest material within a host matrix, enabling complex 3D material designs.

The Effect of Flame Temperature on Structure of Ceria-Supported Pt Nanoparticles in Flame-Assisted Spray Pyrolysis NaoyaMinegishi, PeizhouLi, TsuyoshiNagasawa and HidenoriKosaka; Tokyo Institute of Technology, Japan

Supported metal catalysts are used in many applications such as combustion gas purification catalysts, gas reforming systems, and chemical product synthesis processes. Supported metal catalysts generally have a structure with high specific surface area and high dispersion of precious metal to improve catalytic activity and economic efficiency. One of the big challenges in these catalysts is to prevent deterioration of catalytic activity caused by thermal aging and following aggregation of precious metal nanoparticles in high-temperature environment. To achieve both high thermal stability and high catalytic activity, it is necessary to properly control the oxide and metal particle sizes and metal/oxide interface structure. However, in the case of wet processes such as the impregnation method, precise structural control requires complex multi-step processes, which can be disadvantage toward practical application. The aim of this study is to synthesize supported metal catalysts with high catalytic activity and thermal stability in a simple process. For this purpose, we synthesized Pt/CeO_2 nanoparticles by flame-assisted spray pyrolysis using a burner diffusion flame, and the effects of material precursor concentration and flame conditions on the structure of the synthesized particles were investigated. In addition, the CO oxidation properties and thermal stability of the particles synthesized by flame-assisted spray pyrolysis were evaluated and compared with those of particles prepared by the impregnation method.
A coaxial flow diffusion flame burner with a double-tube structure was used for the particle synthesis experiments. A mixture of oxygen and nitrogen is supplied to the outer tube, and a mixture of nitrogen and methane containing a precursor solution atomized by an ultrasonic transducer (2.4 MHz) is supplied to the inner tube. The synthesized Pt/CeO_2 particles consisted of submicron-scale CeO_2 with 10 nm-scale Pt and aggregation of fine CeO_2 less than 10 nm with highly dispersed Pt (1 nm or less) [1]. When the flame temperature was varied by changing the ratio of oxygen and nitrogen supplied to the burner outer tube, more fine particles were produced at higher flame temperatures. Submicron-level particles may have formed by the droplet-to-particle route, in which the precursor droplets do not evaporate completely and nucleation occurs within the droplet. On the other hand, fine nanoparticles may have formed by the gas-to-particle route, in which the droplets completely evaporate and nucleation occurs in the gas phase. The evaporation of precursor droplets is enhanced at higher flame temperature, resulting in the sift of particle formation route from droplet-to-particle to gas-to-particle. The fine Pt/CeO_2 nanoparticles synthesized by the high-temperature flame showed CO catalytic activity comparable to that of particles prepared by the impregnation method. Moreover, the thermal stability of the Pt particles on CeO_2 by flame synthesis was better than that of the impregnation method.

Colloidal Metal-Halide Epitaxial Heterostructures: From Serendipity to Rational Design StefanoToso[1], MuhammadImran[1,2], DerekDardzinsky[3], NoaMarom[3] and LiberatoManna[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of Toronto, Canada; [3]Carnegie Mellon University, United States

Colloidal epitaxial heterostructures are nanoparticles made of two crystalline materials connected at an interface. These architectures profitably combine the properties of their components, and can express unique ones stemming from their interactions. Historically, heterostructures have produced major breakthroughs in the field of colloidal nanomaterials, with core/shell quantum dots being the most renowned examples. Indeed, heterostructures are often grown from isostructural materials like CdSe/CdS, where the only requirements are similar lattice parameters. However, the increasing number of heterostructures reported between non-isostructural materials points to the limits of this design strategy. In this talk, we will take the serendipitous discovery of heterostructures between lead halide perovskites ($CsPbX_3$) and lead sulfohalides ($Pb_4S_3X_2$) as a case study.[1,2] We will first identify empirical criteria behind the formation of these heterostructures by comparing them with other interfaces formed by lead halides.[3] Then, we will exploit in-situ spectroscopies performed directly in the liquid reaction medium to gain insight into the growth mechanism of these composite nanomaterials. As a next step, we will take advantage of such knowledge to master the synthesis of two competing nanomaterials ($Pb_4S_3Cl_2$ vs $Pb_3S_2Cl_2$) by exploiting heterostructures as phase-selective reaction intermediates.[4] This approach is inspired by the retrosynthetic strategies typical of organic chemistry, and provides advanced control over the product of colloidal syntheses. Finally, we will rationalize these results with the help of a novel computational tool, which we designed

specifically for predicting the formation of stable colloidal epitaxial heterostructures. By providing fundamental insights into the growth mechanism and stability of colloidal nanocrystal heterostructures, we hope to lower the barrier that separates the widely appealing properties of these fascinating composite nanomaterials from real-world applications.

Visualizing Interfacial Processes and Surface Instabilities in Nanoparticle Systems Through *In Situ* TEM and Artificial IntelligencePiyushHaluai[1], AdriaM. Morales[2], MatanLeibovich[2], MaiTan[1], SreyasMohan[2], YifanWang[1], CarlosFernandez-Granda[2] and PeterA. Crozier[1]; [1]Arizona State University, United States; [2]New York University, United States

Interfacial processes control not only crystal growth but also crystal dissolution. For example, during classic nucleation and growth, nuclei are forming and dissolving in solution and only when a seed crystal grows above the critical size, can a larger crystal evolve. The structural evolution of a crystal surface may be strongly influenced by the ambient environment. In small nanoparticles (<5 nm) in the presence of a surface stimuli, such as gas or liquid ambient, the thermodynamic driving force to minimize surface energy is continuously perturbed due to the adsorption and desorption associated with molecular exchange processes. This leads to an evolving interfacial energy landscape with the system constantly “chasing” an elusive energy minimum. The nanoparticle surface is far from equilibrium, but local energy minima give rise to a variety of short-lived metastable states. There is considerable interest in exploring the system evolution as it transitions between stable and less stable surface configurations. Not only is this of fundamental interest to materials science, but it may impact applications in fields where surface reactivity is important such as catalysis and corrosion. The recent development of direct electron detectors with high sensitivity and fast readout rates together with advances in AI based denoisers [1] now makes it possible to perform atomic resolution exploration of nanoparticle surface processes with time resolutions ultimately limited by detector readout speeds (0.0001 – 0.001 s is now common). We are investigating the surface dynamics of Pt nanoparticles with temporal resolutions of ~0.01 s under different ambient conditions. Typical kinetic pathways are observed to follow elementary surface transformation steps including atom column activity (e.g., adatom migration, adatom fluxionality, surface layer growth, surface layer fluxionality, surface layer removal), shearing (e.g., surface shear, subsurface shear creating or annihilating stacking faults). Since there is a tight connection between the surface and subsurface structure in small particles, instabilities in the surface structure can trigger instabilities in the entire nanoparticle crystal. The relationship between these different metastable states and kinetic pathway will be discussed in the presentation.

Observing Crystal Nucleation on Graphene via High-Speed Atomic-Resolution TEM Won ChulLee[1], JungwonPark[2] and PeterErcius[3]; [1]Hanyang University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Lawrence Berkeley National Laboratory, United States

Nucleation in atomic crystallization remains poorly understood despite advances in classical nucleation theory. The nucleation process has been described to involve a non-classical mechanism including a spontaneous transition from disordered to crystalline states, but a detailed understanding of dynamics requires further investigation. Here, using in-situ transmission electron microscopy of heterogenous nucleation of individual gold nanocrystals with millisecond temporal resolution, we show that the early stage of atomic crystallization proceeds through dynamic structural fluctuations between disordered and crystalline states, rather than through a single irreversible transition. Our experimental and theoretical analyses support that structural fluctuations originate from size-dependent thermodynamic stability of the two states in atomic clusters. These findings, based on dynamics in a real atomic system, reshape and improve our understanding of nucleation mechanisms in atomic crystallization.

The Onset of Crystallization of Aerosol Au Nanoparticles YiWang[1], SotirisE. Pratsinis[1] and EiriniGoudeli[2]; [1]ETH Zürich, Switzerland; [2]The University of Melbourne, Australia

Gold nanoparticles have versatile applications in catalysis, chemical and biological sensing, medicine (drug carrier, therapeutic agents and gene delivery), nanolithography and microelectronics [1]. The performance of these nanoparticles is heavily influenced by their crystalline characteristics. Even though Au nanoparticles are routinely made in the liquid phase, their gas-phase (aerosol) synthesis is most attractive for its proven scalability (25 t/h) and high-purity products (i.e. optical fibers) [2]. During aerosol synthesis, the formation of particles occurs at high temperatures, steep cooling rates and short residence times that affect considerably nanoparticle characteristics, including their crystallinity, size, and morphology [3].

Here, the gas-phase crystallization of Au nanoparticles is investigated by molecular dynamics (MD) using the embedded atom method (EAM) that is most relevant to their synthesis by aerosol processes (flame, plasma, laser, etc.). We elucidate the onset of crystallization and growth dynamics of 2.5 – 11 nm Au nanoparticles under isothermal conditions.

The relationship between Au melting point and particle size is used to validate the method.A metastable region of 200 - 300 K wide between the melting point and super-cooled solidifying temperature of Au is revealed as a function of particle size. The crystalline disorder parameters and potential energy are used to elucidate the isothermal crystallization dynamics of Au nanoparticles in three distinct stages at 500 – 800 K (subcritical cluster dynamics, onset of crystallization and crystal growth). The degree of crystallization (predominantly face-centered cubic (FCC) with some hexagonal close-packing (HCP)), is quantified from the local crystalline disorder. In the first stage, before the onset of crystallization, subcritical Au cluster form and deform continuously similar to the subcritical nucleation dynamics of liquid (i.e. water) droplets in the atmosphere. The onset of crystallization is detected by the steep rise of the retained atoms fraction (RAF) of the largest subcritical cluster. This increase is accompanied by a sharp drop of the amorphous fraction of the Au nanoparticle.

In the second stage, crystallization usually starts from the nanoparticle surface as a result of lower kinetic energy barriers there. 3D-snapshots of the Au particle reveal two crystallization nucleation pathways: (A) Catastrophic nucleation when crystallization takes place well below the Au supercooled solidifying temperature resulting in many small crystal domains within the nanoparticle; and (B) Accretion nucleation when crystallization takes place at temperatures near the super-cooled solidifying temperature where fewer nanocrystals are formed that gradually coalesce into larger crystal domains.

In the third stage, after the onset of crystallization, crystals grow via both accretion and cluster merging, with crystal domain reorganization after the crystalline transformation is completed. X-ray diffraction (XRD) patterns are generated, from which the dynamics of crystal growth are elucidated and compared to direct tracing of crystal sizes. The product crystal size is influenced largely by crystallization temperature, with the largest crystal size obtained when crystallization takes place near the supercooled solidifying temperature consistent with the literature [4].

The results of this study can facilitate the process design for aerosol synthesis of Au as well as other metal nanoparticles for optical, electronic, catalytic and biomedical applications.

Ni Nanostructures Formed via pH-Dependent Corrosion-Redeposition of Thin Nickel Films in Glycine-Based Solutions AyronA. Lima[1], DuberM. Murillo[1], Antonio AugustoG. von Zuben[1], DouglasS. de Oliveira[2] and MonicaA. Cotta[1]; [1]University of Campinas, Brazil; [2]Federal University of Parana, Brazil

Nickel (Ni) is an interesting material for several applications, due to qualities including resistance to high temperature, oxidation, and corrosion, which are also present at the nanoscale. In particular, Ni nanowires show many applications in biology, optical devices, solar cells, and sensors, among others. Ni nanostructures have been created so far using a variety of methods, including hydrothermal, laser ablation, and chemical vapor deposition techniques. In this study, we investigate the fabrication of Ni nanostructures via local corrosion of thin Ni films

deposited by physical vapor deposition. Slow Ni corrosion is achieved using water, glycine, and calcium chloride static solutions with various pH levels. After a considerable amount of time (24-48 hours) of contact between the Ni film and the solution, micron-sized, roughly circular isotropic corrosion patterns are observed. Scanning Electron Microscopy (SEM) images show that nanostructures form inside the corrosion patterns. Typically, a nanowire-like structure extends vertically from the center of most patterns; for those with larger diameters, very thin planar nanowires extend from this central structure. SEM-based Energy Dispersive Spectroscopy measurements reveal that the central nanostructure is made of Ni, while the composition of the thinner, planar nanowires cannot be resolved using this technique. Our findings via simulations suggest a process of corrosion starting at specific locations such as film defects, with subsequent Ni redeposition due to a radial Ni concentration gradient at the metal film-solution interface. Further studies should determine if this process can be made controllable as a new synthesis process of Ni nanostructures.

***Operando* Catalysis Studies from Model Systems to Real Catalysts**AndreasStierle[1,2]; [1]DESY, Germany; [2]University of Hamburg, Germany

The atomic structure determination of nano-objects with dimensions in the sub-100 nm regime is a formidable task for today's diffraction, imaging and scanning probe techniques. A detailed structural and compositional analysis is mandatory for a correlation with the nano-object's functionality e.g. as heterogeneous catalysts, magnetic storage material or light emitting device. In conventional x-ray diffraction experiments on powder samples the structural analysis is hampered by a random nanoparticle orientation and often by background scattering from the supporting material. We have therefore focused on the development of model systems based on epitaxial metal nanoparticles on single crystal oxide supports, which can be studied under ambient pressure catalytic reaction conditions. In the first part of my talk I will present different ensemble averaging synchrotron radiation based x-ray diffraction schemes. They deliver quantitative information on the nanoparticle size, shape and facet surface structures under operando reaction conditions for CO oxidation using high resolution reciprocal space mapping and high energy x-ray diffraction [1-4]. In the second part I will focus on experiments overcoming the ensemble average by single nanoparticle imaging and I will discuss future possibilities exploiting the high coherence of high energy photons available at fourth generation synchrotron radiation sources [5].

An *In Situ* Look at Interfacial Controls on Crystal Nucleation and AssemblyJamesJ. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Interfaces play a critical role in solution-based phenomena, such as ion segregation, mineral nucleation, and biomolecular and colloidal self-assembly. The interface alters the distribution of water and ions from that of the bulk, introduces an interfacial free energy that largely determines the free energy barrier for nucleation, and creates an entropic repulsion that acts like a volume exclusion force to drive colloidal assembly. The origin and characteristic length scales of these phenomena are inherently atomic-to-molecular but are manifest in ensemble dynamics and outcomes. Moreover, processes like nucleation and self-assembly arise from fluctuations, making the events that must be probed transient in nature. Consequently, in situ imaging techniques that can capture structure and its evolution, particularly at high speed and atomic-to-nm resolution, are required to build a quantitative picture of such processes. Here I use examples from and *in situ* TEM, high-speed AFM, and fast force mapping studies of interfacial structure, nucleation, and nanoparticle assembly to elucidate the mechanisms by which interfaces direct these processes, leading to unique pathways, materials and morphologies. The results reveal the importance of surface charge, organic ligands, chemical gradients, and solvent organization near interfaces in determining how ordered solids emerge from the solution.

9:00 AM SF02.03.02
Solvation Directed Dimensionality and Hierarchy Control in Solution Synthesis of Nanomaterials MariaSushko, LiliLiu and DuoSong; Pacific Northwest National Laboratory, United States

The development of structural hierarchy on various length scales during crystallization process is ubiquitous in biological systems and is common in synthetic nanomaterials. The driving forces for the formations of complex architectures range from local interfacial interactions, that modify interfacial speciation, local supersaturation, and nucleation barriers, to macroscopic interparticle forces. Although it is enticing to interpret the formation of hierarchical architectures as the assembly of independently nucleated building blocks, often crystallization pathways follow monomer-by-monomer addition with structural complexity arising from interfacial chemical coupling and strongly correlated fluctuation dynamics in the electric double layers. Here, we show that the development of structural hierarchy through heterogeneous nucleation is driven by dipolar and solvation forces. Specifically, coupled simulations and experimental studies revealed that dipole build up along the slow growth direction can trigger twinning and the development of branched architectures. Enthalpic solvation interactions were shown to either enhance or reduce the dipole moment of the nanoparticles and, thereby, control crystal morphology and architecture. The systematic studies of chemical coupling between different solvents and undercoordinated surface atoms of the growing nanocrystals revealed the mechanism of dimensionality control and the development of structural hierarchy in the absence of ligands or structure-directing agents.

9:15 AM *SF02.03.03
4D Structures of Colloidal Nanoparticles using Graphene Liquid Cell TEM and Self-Supervised Machine Learning Analysis JungwonPark; Seoul National University, Korea (the Republic of)

Colloidal nanocrystals containing a few tens to hundreds of atoms have applications in a range of areas, from electronics to catalysis and biological sensors. This versatility stems from the high sensitivity of nanocrystal properties to size, chemical composition, and shape, which are largely determined by the synthesis route by which they are produced. However, structure characterization based on bulk-originating methods is usually not enough because of the unique structural characteristics emerging at the nanoscale. Exposed surfaces, defects, dislocations, and quantum effects are dominant in nanocrystals of finite size. In addition, the ensemble of nanocrystals produced from conventional colloidal synthesis displays a large degree of heterogeneity in the atomic structures and has the effects of organic ligands and solvent molecules. Thus, understanding the structures of nanocrystals at a level where fundamental structure-property relationships can be linked requires new analysis methods that allow precise and reproducible determination of the positions of the constituent atoms of single nanocrystals directly from the solution phase. We developed a "one-particle Brownian 3D reconstruction method" for the analysis of the three-dimensional (3D) structures of colloidal nanocrystals based on graphene liquid cell electron microscopy. "One-particle Brownian 3D reconstruction" can be applied to not only uni-component metallic nanoparticles but also multi-component nanoparticles such as CdSe, PbSe, and FePt. We further extend 3D structure characterization approach to time-resolved domain such that colloidal nanoparticles undergoing structural transition in solution can be captured in time-resolved 3D resolution. To enable 3D and 4D reconstruction of colloidal nanoparticles directly from liquid phase TEM imaging, a sereis of large image data processing, a part of which is potentially enhanced by machine-learning based data analysis, is developed.

Observation of Amorphous-To-Crystalline Transition at the Single-Atom Level Jianwei (John)Miao; University of California Los Angeles, United States

The amorphous-to-crystalline transition is fundamental to many physical, chemical and biological phenomena, but is a challenging process to study at the atomic scale. An approach to overcome this challenge is atomic electron tomography (AET) (1). AET combines high-resolution tomographic tilt series with advanced computational algorithms to resolve the three-

dimensional (3D) atomic structure of materials without assuming crystallinity (2). We have recently advanced AET to determine the 3D atomic structure of amorphous materials and characterize the short- and medium-range order of the 3D atomic arrangement (3,4). In this talk, I will present our most recent results on the application of AET to observe the amorphous-to-crystalline transition in 3D at the atomic resolution. By using a carbothermal shock method (5), we trapped high entropy alloy nanoparticles at different stages of crystallization. We then used AET to determine the 3D atomic structure of the high entropy alloy nanoparticles as a function of crystallization. By quantitatively characterize the 3D atomic arrangement inside a large number of nuclei, we observed crystal nucleation pathways at the single-atom level. We expect that these experimental results not only open the door to study the amorphous-to-crystalline transition at the atomic scale, but also could transform our fundamental understanding of nucleation and crystal growth.

***In Situ* and *Operando* Multimodal Chemical Imaging of Materials Interfaces**Xiao-YingYu; Oak Ridge National Laboratory, United States

In situ and operando imaging is imperative in capturing material structural and compositional changes in working conditions as those in the real world. Development and integration of novel microfluidics and nanofluidics have significantly revolutionized nanoscale and microscale chemical imaging using electron microscopy (EM), offering morphological and elemental information of materials dynamically. Other advanced imaging and spectroscopy techniques offer additional insights into the material evolution besides EM. Among them, mass spectrometry (MS) and mass spectral imaging (MSI) provide attractive features and advancement in information depth and data volume of materials and interfaces dynamically. We developed a vacuum compatible microfluidic interface, System for Analysis at the Liquid Vacuum Interface (SALVI), to enable direct observations of the vacuum - liquid interface approximating the air - liquid and the solid - liquid interface using in situ time-of-flight secondary ion mass spectrometry (ToF-SIMS), scanning electron microscopy (SEM), vacuum ultraviolet single photon ionization mass spectrometry (VUV SPI-MS), nuclear magnetic resonance (NMR), and a multitude of spectroscopy and microscopy tools. In this talk, I will present a few examples including: 1) air - liquid interfaces in biology and the environment (e.g., single cells, biofilms, particles); 2) liquid - liquid interfaces in novel materials (i.e., CO_2 capture solvents, emulsions); and 3) solid - liquid interfaces using *in operando* imaging (i.e., redox reactions, lithium sulfur battery electrolyte). In situ multimodal chemical imaging capabilities lead to new directions and understanding in biological, environmental, and materials sciences.

Probing the Mass Transport in Iron-Air Batteries using *Operando* Electrochemical Transmission Electron MicroscopyHanglongWu[1], JosephS. Manser[2], MariaRonchi[2], JeffPoirier[2], Yet-MingChiang[1,2] and FrancesM. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Form Energy, United States

In a rechargeable battery, the transport of ions between the electrode and the electrolyte plays a crucial role in governing electrochemical kinetics and can strongly influence the battery performance. Studying the diffusion of metal ions during battery operation is therefore important in developing new battery designs aimed at mitigating existing technical challenges associated with mass transport, such as dendrite growth. To date, a wide range of techniques, including X-ray/neuron imaging, NMR spectroscopy, and electrochemical impedance spectroscopy, have been developed to study the diffusion phenomena of metal ions under operando conditions. Nevertheless, the experimental determination of the nanoscale spatial distribution of ionic concentration gradients remains a challenge.

Rechargeable alkaline iron-air batteries have recently emerged as the leading candidate for long-duration energy storage due to their environmental friendliness, low cost, safety, and scalability. Although the reverse rusting of iron in alkaline electrolytes has been extensively investigated over the last five decades, the transformation pathways of iron species during this process are still under debate. Specifically, the role of diffusion gradients of the initially formed soluble $HFeO_2^-$ species in governing the precipitation of amorphous $Fe(OH)_2$ passivation layers during anodic reactions remains poorly understood.

Here we present the use of operando electrochemical transmission electron microscopy (EC-TEM) as a probing technique to investigate the diffusion gradient during battery operation. Using the iron-air battery as a case study, we focus on studying the concentration gradient of the soluble iron ions, i.e., $HFeO_2^-$, formed during the anodic dissolution of body-centered cubic (BCC) iron at pH 14. We first discuss the importance of electrolyte volume in mitigating the ion diffusion limitations within the confined cell to achieve reproducible cyclic voltammograms. Subsequently, by manipulating the positioning of one or multiple counter electrodes (CE) relative to the iron anode along the electrolyte flow channel, we observe that iron dendrites can grow on these CE electrodes during battery discharge. The concentration gradient of $HFeO_2^-$ can therefore be estimated by quantifying the size/mass of these dendrites as a function of the distance from the anode. Our findings suggest that EC-TEM could serve as a useful tool for comprehending the effects of local ion concentration on the morphological evolution of the electrodes in the various battery systems during charge and discharge processes.

Cinematographic Recording and Analysis of the Whole Process of Crystal Nucleation/Growth at Millisecond Sub-Angstrom Resolution EiichiNakamura; The University of Tokyo, Japan

Chemical phenomena are complex events where a variety of molecules stochastically appear on time scales ranging from nanoseconds to hours. Studying the stochastic behavior of individual molecules requires unconventional methods that differ from the traditional ensemble- and time-averaged experimental techniques. Crystal nucleation/growth is no exception. Since 2004, we have spent considerable effort on developing the SMART-EM technique (Single Molecule Atomic Resolution Time-resolved Electron Microscopy, ref 1, 2). In this talk, I will discuss the cinematographic recording of the whole process of the nucleation and growth of NaCl crystal (ref 3, 4) and of the PAN carbon fiber formation by pyrolysis of polyacrylonitrile (ref 5). We are transforming chemistry from the macroscopic paradigm of thermodynamics to the microscopic statistical mechanical paradigm.

Dynamic DNA Nanodevices with Switchable Optical Properties SoojungLee[1], JasonKahn[2], DanielMcKeen[1] and OlegGang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States

Advancements in DNA nanotechnology have opened up the ability to fabricate nanomaterials with dynamic properties for applications in optics, medicine, and electronics. Such properties are defined by precisely controlled arrangements of functional nanocomponents. However, there remains a continual challenge in gaining dynamic control of nanoscale materials. DNA-based self-assembly offers a promising approach to form switchable three-dimensional (3D) clusters and large-scale ordered nanostructures that can encapsulate, organize and manipulate various types of nanoscale objects through programmable interactions.
Here we study the assembly, reconfiguration and optical response of a nanoscale device with stimuli-responsive and switchable properties. We utilized a 3D polyhedral DNA frame to establish a system that can switch between different conformations that allow for the manipulation of nanoparticles. Our previous studies have demonstrated that the optical output of a binary self-assembled system composed of gold nanoparticles (AuNP) and quantum dots depends on the interparticle separation distance. With this as a reference, we designed a structurally switchable 3D DNA frame for nanoparticle repositioning. By utilizing a DNA motif that acts as a manipulator, we show an ability to pass molecular information over a distance of tens of nanometers on a frame. We used this principle to investigate how this DNA device is able to direct nanoparticle reconfigurations and induce different optical responses. Interactions between the plasmonic and fluorescent particles were explored by testing various system designs. The structural reconfiguration of the system was examined by electron microscopy and small-angle X-ray scattering (SAXS), while spectroscopic measurements were applied to correlated optical responses with structural switching.

8:00 PM SF02.05.02
Enhancing Biosensor Performance by Optimizing Surface Coverage of the Self-Assembled Monolayer JaehyunKim, HonglinPiao, DaerlPark and Heon-JinChoi; Yonsei University, Korea (the Republic of)

Self-assembled monolayers (SAMs) are widely used in various fields such as nanotechnology, electronics, and biomedical applications. SAMs are a crucial component in the fabrication of biosensors, as they provide functional surfaces for the immobilization of biological recognition elements. However, non-uniform SAM coverage on biosensor substrates can lead to variability in detection and quantification, which can severely hamper the biosensor's performance. The method proposed in this research includes experimental SAM analysis and prediction of SAM formation results through fitted function. After fixing several deposition parameters such as concentration, temperature, we applied logistic functions to create a function for the deposition rate of SAMs. Using this function, deposition has clearly improved the uniformity of SAMs. This outcome, confirmed through various characterization techniques including atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS), leads to an enhanced biosensor performance in terms of sensitivity and selectivity. To validate the accuracy of our developed function, we employed a comparative approach using machine learning techniques. These techniques, known for their ability to predict complex patterns and interactions, served as a benchmark for our optimization function. Preliminary results indicate that the proposed function holds significant promise in optimizing SAM surface coverage, with performance comparable to or exceeding that of the machine learning models. The proposed methodology not only provides a more stable and predictable biosensor response but also contributes to the advancement in the broader field of biosensing technology. This new approach offers significant implications for the development of high-performance biosensors, enabling more precise and consistent biomedical diagnostics, environmental monitoring, and other related applications. We will show experimental evidences on our proposed approach from glucose monitoring system (GMS).

Temperature Measurements During Laser-Induced Graphitization of Polydimethylsiloxane MasatoKai, ShuichiroHayashi, KenKashikawa and MitsuhiroTerakawa; Keio University, Japan

Laser-induced graphitization of polymers has attracted attention as a technique to simultaneously form and pattern graphitic carbon on and/or inside polymers. Depending on the laser parameters, the morphology and the crystallinity of the formed graphitic carbon vary with photochemical and photothermal effects. However, the mechanism of laser-induced graphitization of polymers has not been revealed in detail. In this study, we measure the temperature of a polymer's surface during laser-induced graphitization to investigate the relationship between the laser parameter and the characteristics of the formed structure with regard to photothermal effects. An organosilicon polymer, polydimethylsiloxane (PDMS), was irradiated with high-repetition-rate femtosecond laser pulses at different laser scanning speeds. The temperature of the PDMS surface was measured using a thermography camera. Plano-convex lenses were located between the irradiated surface and the thermography camera for micro-thermographic measurements with a spatial resolution of ~40 μm. The morphology of the formed structure was observed using scanning electron microscopy (SEM), and the crystallinity of the structure was analyzed using Raman spectroscopy, respectively. SEM observations showed that the cross-sectional area of the formed structure increased with the decrease in scanning speed, suggesting that the amount of the energy absorbed by PDMS was positively correlated with the number of irradiated pulses per spot. Furthermore, for significantly low scanning speeds, the formation of cracks was observed in the formed structures, which may be attributable to the laser ablation induced by the excessive amount of energy absorbed by PDMS. Raman spectra showed peaks at ~1350, ~1600, and ~2700 cm^{-1} that corresponds to the D, G, and 2D bands, respectively, indicating the formation of graphitic carbon. Also, a peak at ~520 cm^{-1} was observed in the obtained Raman spectra in the case of significantly low scanning speeds, indicating the formation of crystalline silicon. Taking the results of SEM observations into account, it can be assumed that crystalline silicon was formed owing to the high temperature induced by the excessive amount of energy absorbed by PDMS. It was confirmed in temperature measurements that the measured temperature increased with the decrease in the scanning speed, suggesting the increase in the amount of energy absorbed by PDMS with the increase in the number of irradiated pulses per spot. However, in the case of significantly low scanning speeds, the measured temperatures kept constant regardless of the scanning speed, indicating the saturation of the temperature of the laser-irradiated area. The saturation of the temperature at significantly low scanning speeds cannot be explained solely by the change in the amount of the energy absorbed by PDMS. One possible explanation for the saturation is the change in the energy diffusion property of the laser-irradiated area with the change in the morphology and the material composition. It can be suggested from the obtained SEM images that the bulk density of the laser-irradiated area may be changed with the formation of cracks, changing the energy diffusion property of the laser-irradiated area. Moreover, considering the obtained Raman spectra, the formation of crystalline silicon in addition to the graphitic carbon may change the energy diffusion property of the laser-irradiated area.

8:00 PM SF02.05.04
Assembly of Short-Sequence Amphiphilic Peptoids into Helical Nanostructures with Controllable Supramolecular Chirality RenyuZheng[1,2], MingfeiZhao[3], JingshanDu[2], YichengZhou[2], ShuaiZhang[1], WenhaoZhou[1], AndrewFerguson[4] and Chun-LongChen[2]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States; [3]Los Alamos National Laboratory, United States; [4]The University of Chicago, United States

A long-standing challenge in biomimetic research is to create sophisticated hierarchical nanostructures that mimic the biomaterials found in living organisms. Self-assembly is a crucial process for creating these nanostructures, but the forces and dynamics governing the self-assembly of biomacromolecules, such as proteins and peptides, are complex. Developing sequence-defined synthetic polymers with simplified molecular interactions is a promising approach to synthesizing information-rich nanostructures and understanding their self-assembly mechanisms. Peptoid is a peptidomimetic molecule that moves the side group from α-carbon to nitrogen to keep the sequence programmability while simplifying the structure without backbone hydrogen donors and no backbone chirality. Previous studies have shown that amphiphilic peptoids can crystallize into highly ordered nanostructures, including nanoribbons, nanosheets, nanotubes, and nanohelices, by controlling peptoid-peptoid and peptoid-substrate interactions. However, achieving the predictable self-assembly of peptoids into designed nanostructures remains a significant challenge. In this study, we report a system of short tetramer peptoids to form crystalline peptoid helices. Due to the reduced hydrophobic interactions compared to those with six hydrophobic side chains, we showed that the self-assembly of these peptoids into nanohelices and other nanostructures are highly sensitive to the solution ionic strength and solvent condition, resulting in the formation of various nanostructures including nanohelices, nanohelix bundles, as well as nanotubes. We also demonstrate the control of supramolecular chirality of self-assembled peptoid nanohelices by using chiral polar groups with D- or L-configuration. By combining the synchrotron XRD results with molecular dynamic simulation studies, we showed the twisted form of bi-layer structures of these amphiphilic peptoids are the most stable form for those polar side chains to hide hydrophobic domains in the aqueous environment We further demonstrated that the organic cosolvent in the self-assembly could also affect the self-assembly morphology from nanohelices to nanotubes, which provides additional information on peptoid-solvent interactions as well as the self-assembly kinetics and thermodynamics. Our findings provide a facile system for controlling the twisting and stacking of peptoid amphiphiles into helical and tubular structures and suggest an approach for the precisely controlled synthesis of biomaterials.

8:00 PM SF02.05.05
Molecular Dynamics Characterization of Gas Diffusivity of CO2-CH4 in sI Clathrate Hydrates AliBeydoun, AlejandroD. Rey and PhillipServio; McGill University, Canada

Clathrate hydrates are cage-like water structures entrapping a gaseous guest molecule in their cavities. The need for alternative fuel sources has spurred an interest in methane hydrates as estimates predict that they account for two thirds of the fossil fuel global reserves. However, their exploitation is not without fault as methane hydrates occupy a crucial role in stabilizing the soil as well as being a potential major source of greenhouse gases. Fortunately, methane found in clathrate hydrates can be swapped with carbon dioxide (CO2), thus allowing for carbon sequestration, and rendering the production of methane effectively carbon neutral. The process has been shown to be feasible and resulting in the formation of stable CO2 hydrates, but the mechanism surrounding the exchange remains to be elucidated.
This presentation focuses on a system where pure methane sI hydrates are exposed to a front of CO2 dissolved in water. The system conditions are set to be favorable to the melting of methane hydrates and to the formation of CO2 hydrates. As the system evolves with time, methane escapes the lattice and CO2 diffuses into the latter, replacing methane in partially melted cages as well as forming new cages at the interface in a phenomenon known as co-growth. An analysis of the impact of temperature, pressure, and CO2 concentration on the diffusivity of CO2 and methane is conducted. It is followed by an analysis on how co-growth at the interface hinders diffusion and prohibits CO2 from diffusing deeper in the lattice. Previous work found in the literature has quantitatively described the impact of such impediment on the ultimate replacement ratio, but the presented research is the first quantify the effect on mass diffusivity. This work will also discuss the impact of water vacancies and of gas occupancy on mass diffusivity. To understand the effects of vacancies and gas occupancy on the thermodynamics of the system, the Gibbs free energy, the enthalpy, and the entropy are calculated. Our previous work quantified diffusivity in a CO2 filled hydrate system and the impact of such vacancies and serves as a basis

for comparison. The investigation also looks into how diffusion evolves from a non-Fickian process to a Fickian one. Finally, this work also tackles how the swapping mechanism between methane and CO2 differs near the interface from deeper strata with the hole-in-cage model dominating the latter.
The methodology is based on molecular dynamics. The Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) is used to perform simulations on a 3x3x3 methane hydrate lattice juxtaposing a CO2 front dissolved in water. The force fields used for methane, carbon dioxide, and water are OPLS-AA, EPM2, and TIP4P/ICE respectively. The LAMMPS software allows to quantify the mean squared displacement (MSD) which can be correlated to the mass diffusivity. Furthermore, LAMMPS computes primordial thermodynamics parameters such as the Free Gibbs energy, the entropy, and the enthalpy.

8:00 PM SF02.05.06
Investigation of the Amorphization Threshold by Ion Implantation as a Function of Energy and Implant Temperature in Silicon Substrates AriannaRivera[1], NoelKennedy[2], ChristopherHatem[2] and Kevin S.Jones[1]; [1]University of Florida, United States; [2]Applied Materials, Inc., United States

As semiconductor devices continue to scale, ion implantation processes must follow suit to confine fabrication to nanosized structures. One such process is ion-beam induced amorphization, namely in silicon devices. Pre-amorphizing implants are known to increase dopant solid solubility once post-annealed, increasing the active carrier concentration within the recrystallized layer. Because of this, they are often incorporated during the processing of top-off implants, used to decrease contact resistance. The mechanism of silicon-substrate amorphization mechanism varies with ion mass but for heavier ions, it is associated with the overlap of damage cascades induced by nuclear stopping. As such, it should show little dependence on the surface. However, if the point defect accumulation mechanism associated with light ions is active, then the surface may play a role. To better understand the amorphization mechanism at ultra-low energies, the critical threshold for amorphization is investigated for different implant temperatures and energies. Silicon substrates were implanted with Si^+ ions at low energies between 1 keV to 10 keV and implant temperature was varied ranging between 25°C to 150°C. The dose is kept constant at 3×10^{14} ions/cm^2 at a dose rate of 0.95 mA. The amorphous layer was studied by high resolution cross-sectional TEM and to SRIM simulations to determine the threshold damage density for amorphzation. By studying the amorphization extent at varying energies and implant temperatures, it was possible to observe how the amorphization layer thickness produced by the implant differs as the damage becomes closer to the surface. It was found that as the implant energy decreased, the threshold damage density for amorphization increased, suggesting a shift in the amorphization mechanism possibly induced by an increasing role of the surface. The role of implant temperature will also be presented.

8:00 PM SF02.05.07
Enhancing the Self-Assembly of Binary Colloidal Crystals with Confinement NathanHuang, RachaelS. Skye and JuliaDshemuchadse; Cornell University, United States

Photonic crystals with a bandgap in the visible-light range have been theorized to self-assemble from a binary colloidal dispersion but difficulties remain in robustly assembling high-quality crystals in quantities sufficient for large-scale applications. Computational methods give insight into the conditions under which photonic crystals can self-assemble. In this study, we performed hard-particle Monte Carlo simulations of tetrahedral and octahedral nanoparticles in spherical and flat-wall geometries to determine the influence of confinement on the process and products of crystallization compared to the bulk. Confinement was found to improve crystallization at non-ideal stoichiometries but did not lower the minimal packing fraction at which crystallization occurred throughout the system. Crystals formed under confinement exhibited higher crystallinity and lower quantities of secondary phase defects. These findings demonstrate the potential for enhanced control over the synthesis of novel materials with tailored structures and properties for photonic applications.

8:00 PM SF02.05.08
Valence State-Controlled Synthesis of Vanadium Oxide Nanocrystals MehnazTarannum and ShunjiEgusa; University of North Carolina at Charlotte, United States

Vanadium oxides are important materials with diverse applications, including catalysis, energy storage, and thermochromic devices. However, synthesis of vanadium oxide nanocrystals with a controlled valence state is a significant challenge due to the polyvalence of vanadium. In this work, we report a novel method for the valence-state controlled synthesis of vanadium oxide nanocrystals via a non-hydrothermal route. This method enables the synthesis of non-stoichiometric V_3O_5 ($V^{4+} + V^{3+}{}_2O_5$) nanocrystals, first time in the anosovite phase − a rare form of vanadium oxide that was only recently discovered in bulk form. This is a significant accomplishment, as non-stoichiometric V_3O_5 is known to be difficult to synthesize due to the narrow allowances in the vanadium-to-oxygen ratio ($1.666 - 1.668 \pm 0.002$). The crystal structures of the nanocrystals were confirmed using powder X-Ray diffraction technique. The electron microscopy images of the reaction intermediates at different time intervals during the nanocrystal formation revealed a slow nucleation process, followed by a subsequent fast growth via Ostwald ripening. We demonstrated formations of V_2O_3 nanocrystals ($V^{5+} \rightarrow V^{3+}$), in addition to the partial but precise reduction to V_3O_5 ($3V^{5+} \rightarrow V^{4+} + 2V^{3+}$) by controlling the vanadium precursor-to-alcohol-amine ratio. We assessed the reaction pathways by analyzing the reaction intermediates using Fourier transform infrared (FT-IR) spectroscopy. These studies are important to systematically understand the roles of different reaction parameters to establish a well-controlled synthesis of vanadium oxide nanocrystals.

8:00 PM SF02.05.09
Bimetallic ZnCo Metal-Organic Framework at NiCo-Layered Double Hydroxides for Multiple Storage and Capability Synergy All-Solid-State Supercapacitors NagehK. Allam; American University in Cairo, Egypt

Rational design and structural regulation of hybrid nanomaterials with superior electrochemical performance are crucial for developing sustainable energy storage platforms. Among these materials, NiCo-layered double hydroxides (NiCo-LDHs) demonstrate an exceptional charge storage capabilities owing to their tunable 2D lamellar structure, large interlayer spacing, and rich redox electrochemically active sites. However, NiCo-LDHs still suffer from sever agglomeration of their particles with limited charge transfer rates, resulting in an inadequate rate capability. In this study, bimetallic ZnCo-metal organic framework (MOF) tripods were grown on the surface of NiCo-LDH nanowires, which significantly reduced the self-agglomeration and stacking of the NiCo-LDH nanowire arrays, offering more accessible active sites for charge transfer and shortening the path for ion diffusion. The fabricated hybrid ZnCo-MOF@NiCo-LDH and its individual counterparts were tested as supercapacitor electrodes. The ZnCo-MOF@NiCo-LDH electrode demonstrated a remarkable specific capacitance of 1611 F g^{-1} at 2 A g^{-1} with an enhanced rate capability of 66% from 2 to 20 A g^{-1}. Moreover, an asymmetric all solid-state supercapacitor device was constructed using ZnCo-MOF@NiCo-LDH and palm tree-derived activated carbon (P-AC) as positive and negative poles, respectively. The constructed device can store a high specific energy of 44.5 Wh Kg^{-1} and deliver a specific power of 876.7 W Kg^{-1} with outstanding Columbic efficiency over 10,000 charging/discharging cycles at 15 A g^{-1}.

8:00 PM SF02.05.10
Substrate Van der Waals Force Effect on the Stability of Violet Phosphorous SarabpreetSingh[1], MahdiGhafarias[1], Hsin-YuKo[2], SampathGamage[1], RobertA. DiStasio Jr[2], MichaelSnure[3] and YohannesAbate[1]; [1]University of Georgia, United States; [2]Cornell University, United States; [3]Air Force Research Laboratory, United States

VdWs interaction of exfoliable materials with the substrate and how this interface force influences the interaction of vdWs materials with the surroundings have yet to be well understood. Here, we experimentally and theoretically unravel the role of vdWs forces between the recently rediscovered wide band gap p-type vdW semiconductor violet phosphorus (VP), with various substrates (including, SiO_2, mica, Si, Au) and quantify how VP stability in air and its interaction with its surroundings is influenced by the interface force. Using a combination of infrared nanoimaging and theoretical modelling we find three main factors that influence how VP interacts with its surroundings: the vdWs force at the interface, the hydrophobicity of the substrate, and substrate surface roughness. We found that VP can maintain its stability for a prolonged period if it is exfoliated on SiO_2 substrate, followed by mica and Au substrates, and is least stable when placed on a Si substrate. Our results could guide in the selection of substrates when vdW materials are prepared and more generally highlight the key role of interface force effects that could significantly alter physical properties of vdWs materials.

8:00 PM SF02.05.11
Characerization of Adeno-Associated Virus Loading and Aggregation Through use of SEC-MALS StephenRosa and LanceKasper; Agilent Technologies, United States

In recent years, adeno-associated viruses (AAVs) have been seeing an increase in use as delivery vehicles for gene-therapy type applications due to their ability to infiltrate a wide host of different cell types and overall lack of pathogenicity. Characterization of these AAVs remains a challenge with most of the current techniques that are commonly available. Using our new 20 angle multi-angle light scattering detector (MALS) and WinGPC software, we demonstrate using different concentration detectors in conjunction with the MALS that it is possible to accurately measure the load factor of several different AAVs. Furthermore, we are also able to accurately measure AAV size in solution as well as any aggregation that is occurring within the system.
Using different chemistries, it is possible to measure the composition of these AAV particles. Our new WinGPC software automatically calculates the incorporation of each of these components using its co-polymer module. This allows us to accurately determine the load factor of the AAV. When coupled to light scattering, we can measure the absolute molecular weight average as well as the radius of gyration of the AAV system. This data can provide a complete picture of capsid loading, total capsids, and aggregation with in the system, all run with a single SEC method.

8:00 PM SF02.05.13
Effect of Sulfate Regioposition on Ca^{2+}-Heparin Binding Thermodynamics and Implications for Nucleation of Sparingly Soluble Salts BrennaM. Knight, ConnorM. Gallagher,

MichaelD. Schulz, KevinJ. Edgar, LouisA. Madsen and PatriciaM. Dove; Virginia Tech, United States

Heparin is a sulfated glycomaterial of long-standing importance as an anticoagulant in biomedicine due to its antithrombin binding sequence. Many more protein binding sequences are identified in heparin and other glycosaminoglycans (GAGs) but are understudied relative to antithrombin. Heparin and sulfate-rich macromolecules are also widely associated with biological crystallization in diverse animals. However, the lack of systematic and quantitative studies is impeding the potential of furthering heparin applications as well as a mechanistic understanding of how functional groups modulate biomineralization. Using heparin as a model for understanding the role of sulfate groups associated with macromolecules in biological and synthetic settings, we test the hypothesis that the position of these groups influences Ca^{2+} binding to regulate calcite nucleation.
This experimental study employs isothermal titration calorimetry (ITC) to quantify the binding thermodynamics of Ca^{2+}-heparin interactions for a group of characterized heparin materials that differ by sulfate regioposition. Previous studies indicate Ca^{2+}-heparin interactions involve water molecule(s) and are independent of electrostatic interactions. Our preliminary ITC findings show the binding is entropically driven, supporting this model. We further observe sulfate position moderates K_{Ca2+} and dramatically alters binding stoichiometry.
In parallel experiments that measure the rate of nucleation of the sparingly soluble salt, $CaCO_3$, onto the corresponding heparin materials, we are determining the relationship between sulfate position and the interfacial energy barrier to calcite crystallization (γ_{cal}). Initial results suggest materials that more efficiently bind Ca^{2+} (i.e., require fewer repeat units per ion) present a higher barrier to nucleation. To better understand this interaction, we are also determining the dependence of NMR relaxation time and chemical shifts on Ca^{2+} concentration. This study highlights the potential for using sulfate position to tune and optimize the design of heparin-based materials for advanced material design and biomedical applications.

SESSION SF02.06: Colloidal Particle Assembly

DNA-Programmable Assembly in Bulk and at Liquid-Air and Liquid-Solid Interfaces OlegGang[1,2]; [1]Columbia University, United States; [2]Brookhaven National Laboratory, United States

Organizing diverse types of functional nanocomponents into the designed 3D architectures promises to enable new functions with a broad range of applications, from engineered biomaterials to photonic devices and energy materials. However, current methods are limited in their ability to create such 3D nanomaterials with prescribed structures and integration of different types of nanocomponents. Using sequence-specific interactions and structural plasticity of DNA we established a self-assembly platform for assembly of designed large-scale and finite-size nano-architectures from diverse inorganic and biomolecular nanocomponents. We applied in-situ and ex-situ methods to reveal the lattice formation processes in bulk and at the interfaces for DNA-programmable systems. By combining designed nanoscale anisotropic bonds and their DNA encoding, we developed assembly approaches that allow for the creation of periodic and hierarchical organizations from inorganic nanoparticles and proteins. The formed nanostructures were further transformed into inorganic 3D replicas via several nano-templating methods. The novel DNA-assembled nanomaterials were investigated for nano-optical, mechanical, electrical and biochemical functions. Furthermore, approaches for integration with surface-based devices were established.

9:00 AM SF02.06.02
Programmable Colloidal Kagome Superlattices for Anisotropic Light Emission ZhiweiLi and ChadA. Mirkin; Northwestern University, United States

DNA-mediated programmable assembly of nanomaterials has given rise to a diverse library of colloidal superlattices and crystals with precise phase and symmetry control. Design rules for colloidal crystallization have been extensively studied but most of them, regardless of structural complexity and phase diversity, are driven by thermodynamically favored processes that lead to maximum DNA hybridization and complete particle surface overlap. Here, we show that the assembly of non-space-filling bipyramids results in partial DNA surface matching and yields colloidal Kagome superlattices. In short, Au pentagonal bipyramids of different sizes are used as building blocks and modified with single-stranded DNA as programmable atom equivalents (PAEs). Driven by DNA hybridization, the bipyramids assemble into distorted Kagome lattices through partial surface matching, featuring shield-like lattices, lattice distortion, bipyramid twisting, and rhombohedral super unit cells. Characterization of these low-symmetry Kagome lattices reveals diverse lattice plasmon resonance modes, which are dependent on the light incident direction and polarization. We take advantage of the Kagome lattice plasmon resonance and report facet-dependent anisotropic light emission enabled by doping dyes into the Kagome lattices. Taken together, this work opens up new avenues towards designing and accessing exotic colloidal superlattices and thus new materials for anisotropic light emission, which has implications for emerging optical platforms such as coupled optics and sensing.

9:15 AM SF02.06.03
Mapping The Spatial Dependence of Surface Ligand Binding in Individual Nanoparticles ZhiYang[1], DuaaAnsari[1,2], ManuelPichardo[1] and MatthewJones[1,1]; [1]Rice University, United States; [2]The University of Texas at Austin, United States

While it is well-appreciated that surface ligands bind preferentially to certain locations on an inorganic nanoparticle (e.g.tips vs. flat facets), a quantitative understanding of this phenomenon is lacking. In this work, ligands are “tagged” with small gold nanoparticles so that their spatially-resolved binding positions can be measured in Cryogenic Transmission Electron Microscopy (CryoEM) images. Labeled thiol ligands were then exposed to hexadecyltrimethylammonium bromide (CTAB) modified gold triangular nanoprism particles, which present energetically distinct face, edge, and tip regions that we hypothesized would reveal different binding properties. By recording the relative positions of ~700 ligand binding events, an 3D energetic map of thiol chemisorption to gold nanoprisms could be generated, revealing a strong preference for edge and tip sites compared to {111} triangular faces. Interpreting these data as a thermodynamic measure of binding probability allows for the use of the Boltzmann distribution to calculate the Gibbs free energy differences between tips or edges relative to faces of -8.01 and -6.81 kJ/mol, respectively, from which relative binding constants can be calculated. This work establishes an experimental platform for quantifying the spatial preferences of ligand binding that, because of the superior resolution of modern TEM instruments, is limited in accuracy only by the effective size of the tag-ligand conjugate.

9:30 AM SF02.06.04
Interfacial Assembly of Ligand-Functionalized Nanoparticles into Low-Dimensional Architectures YilongZhou[1], BrianH. Lee[1], Tsung-YehTang[2] and GauravArya[1]; [1]Duke University, United States; [2]University of California, San Diego, United States

Self-assembly of nanoparticles (NPs) is a powerful approach for fabricating materials with unique architectures and properties. This is especially important for plasmonic, optical, and electronic applications where nanostructures need to be arranged in non-close packed clusters or periodic arrays to take advantage of the unique electromagnetic couplings that emerge from such arrangements. However, achieving unique and complex assemblies remains a challenging task. In this talk, I will demonstrate how fluid-fluid interfaces can be used to self-assemble ligand-functionalized NPs into exotic 1D and 2D architectures by harnessing the three-way competition between particle-particle interactions, particle-fluid surface energy, and fluid-fluid surface tension. I will begin by demonstrating via molecular dynamics simulations the interfacial assembly of binary systems of spherical NPs into open clusters, quasi-linear strings and networks, and layered structures [1]. Next, I will show how Monte Carlo optimization combined with analytical modeling of interfacial and interparticle interactions can be used to quickly map out the full repertoire of 2D NP superlattices achievable through this interfacial assembly approach [2]. I will also show how this approach can be extended to shaped NPs, where a range of periodic porous superlattices may be assembled from polymer-grafted nanocubes by controlling their orientation at the interface [3]. Lastly, I will discuss the development of multibody potential via a machine learning approach to elucidate the role of multibody effects in the self-assembly of polymer-grafted NPs [4]. Overall, our results suggest that the interfacial assembly approach could be a versatile platform for fabricating 1D and 2D colloidal assemblies of tunable structure and properties.

Growth Habits and Phonon Modes of Nanoparticle Superlattices QianChen; University of Illinois at Urbana-Champaign, United States

Growth habits of nanoparticle superlattices dictate major design parameters (for example, symmetry, morphology and surface structure) of crystalline materials and consequently their applications. Using liquid-phase TEM, we show that nanoparticles can follow four different growth habits during self-assembly as governed by nanoparticle interaction and mass transport, leading to distinct surface morphologies. Meanwhile, lattice relaxations at equilibrium are originated from nanoscopic springs and phonon vibrations, which we are able to map and quantify for the first time using single particle tracking and lattice dynamics theory for topologically-engineered nanoparticle superlattices. Our work paves the way for engineering geometries for applications of mechanical metamaterials.

10:45 AM SF02.06.06
Controlling Coulomb Interactions Among Nanoparticles to Achieve Novel Assembly and Crystallization BinayP. Nayak[1,2], HonghuZhang[3], WeiBu[4], BenjaminM. Ocko[3], AlexTravesset[1,2], DavidVaknin[1,2], SuryaK. Mallapragada[1,2] and WenjieWang[2]; [1]Iowa State University of Science and Technology, United States; [2]Ames National Laboratory, United States; [3]Brookhaven National Laboratory, United States; [4]The University of Chicago, United States

Controlling interactions among nanoparticles is paramount to achieving assemblies vital to technologies seeking to exploit their novel collective properties. Although various techniques have been advanced, robust ones are necessary for upscaling nanoparticle assembly and crystallization. Here, we explore the self-assembly of binary nanoparticle superlattices (BNSLs) at a vapor/liquid interface by grafting gold nanoparticles (AuNPs) with end-charge-polyethylene glycol (PEG). The grafting PEG terminates with either COOH (negatively charged) or NH_2 (positively charged) end groups. Lowering the pH increases the positive charge of NH_2 (to form NH_3^+) and decreases the negative charge of COO^- (to form COOH). Such control facilitates the formation of various two- and three-dimensional ionic-like superstructures of oppositely charged binary constituents either at the vapor/liquid interfaces or in bulk. Unlike traditional ionic crystals, this approach enables manipulation of the relative surface charge between the two constituents. We demonstrate this approach by using surface-sensitive synchrotron-based X-ray diffraction at grazing angles of incidence (GISAXS), X-ray reflectivity (XR), and SAXS, and establish the formation of distinct checker-board square and hexagonal lattice structures also by varying the molar ratios of the constituents. The main results of our study are summarized as follows: 1) For 1:1, 2:1, and 1:4 mixing ratios (-COOH: NH_2 terminated-PEG), a checker-board square lattice structure is formed at various pH values. 2) For the 2:1 mixing ratio, lowering the pH transforms the structure from a checker-board structure to a hexagonal superstructure. 3) In the case of extremely low pH, whereas the NH2 terminated nanoparticles are water soluble, the -COOH terminated forms a single-particle hexagonal structure similar to neutral PEG-grafted AuNPs at the vapor/liquid interface. Our results confront zeta-potential measurements that determine the total charge of each particle. This qualitatively allows for a quick prediction of outcome structures based on pH and the molar mixing ratios. SAXS measurements show executive super-ionic structures in bulk consistent with interfacial observations.

Work at Ames National Laboratory is supported by US Department of Energy and Basic Sciences (DOE) DE- AC02-07CH11358, and at NSLS-II, BNL, by DOE DE-SC0012704 and at NSF's ChemMat CARS by NSF/CHE-1834750.

11:00 AM SF02.06.07
Self-Assembly of Atomically Aligned Nanoparticle Superlattices from Pt–Fe_3O_4 Heterodimer Nanoparticles ShengsongYang[1], R.A. LaCour[2], Yi-YuCai[1], YugangZhang[3], CherieR. Kagan[1], SharonGlotzer[2] and Christopher B.Murray[1]; [1]University of Pennsylvania, United States; [2]University of Michigan–Ann Arbor, United States; [3]Brookhaven National Laboratory, United States

Multicomponent nanoparticle superlattices (SLs) promise the integration of nanoparticles (NPs) with remarkable electronic, magnetic, and optical properties into a single structure. Here, we demonstrate that heterodimers consisting of two conjoined NPs can self-assemble into novel multicomponent SLs with a high degree of alignment between the atomic lattices of individual NPs, which has been theorized to lead to a wide variety of remarkable properties. Specifically, by using simulations and experiments, we show that heterodimers composed of larger Fe_3O_4 domains decorated with a Pt domain at one vertex can self-assemble into an SL with long-range atomic alignment between the Fe_3O_4 domains of different NPs across the SL. The SLs show an unanticipated decreased coercivity relative to nonassembled NPs. In situ scattering of the self-assembly reveals a two-stage mechanism of self-assembly: translational ordering between NPs develops before atomic alignment. Our experiments and simulation indicate that atomic alignment requires selective epitaxial growth of the smaller domain during heterodimer synthesis and specific size ratios of the heterodimer domains as opposed to specific chemical composition. This composition independence makes the self-assembly principles elucidated here applicable to the future preparation of multicomponent materials with fine structural control.

11:15 AM SF02.06.08
Capillary-Wave Theory for Phase-Separated Active Brownian Particles AhmadOmar and LukeLangford; University of California, Berkeley, United States

Nonequilibrium phase transitions are now routinely observed in natural and synthetic systems. Purely repulsive model systems such as active Brownian particles (ABPs) have been demonstrated to phase separate into dense and dilute phases despite being homogeneous at equilibrium. The interface dividing such phase separations has been the subject of puzzling observations, including negative surface tension and qualitative agreement with equilibrium capillary-wave theory (CWT). Here, we begin from microscopic particle dynamics and systematically derive a mesoscopic Langevin equation for the interface dividing phase separated ABPs. Doing so allows us to calculate an interfacial tension distinct from the negative mechanical surface tension. In addition, we find a nonequilibrium analogy to CWT and identify the conditions at which this theory qualitatively agrees with the equilibrium case.

SESSION SF02.07: Macromolecular Crystallization and Assembly

1:30 PM *SF02.07.01
Directed Self-Assembly of Diblock, Multiblock, Bottlebrush and Rod-Coil Copolymers CarolineA. Ross; Massachusetts Institute of Technology, United States

Block copolymer microphase separation, driven by the chemical incompatibility between the blocks, leads to periodic patterns of spheres, cylinders, gyroids, lamellae and other structures with periods of a few nm and above. The microphase separation of thin films of block copolymers can be directed by topographical or chemical substrate features, leading to well-ordered patterns with long range order and/or non-bulk morphologies. This directed self-assembly (DSA) process offers compelling opportunities for the generation of dense patterns with small period which are useful in nanofabrication and nanolithography. The utility of DSA can be enhanced by expanding the range of possible microdomain geometries available, and by developing methods to direct their self-assembly in the out-of-plane direction to make three dimensional structures.

We will describe morphologies created by Si-containing triblock terpolymers, rod-coil copolymers, and bottlebrush copolymers, including zigzags, bends, junctions, tiling patterns and hierarchical structures with two independently tunable periods. As an example, a Janus bottlebrush triblock terpolymer yields layers made up of meshes of one block in a matrix of a second block, separated by layers of a third block. The meshes have sub-20 nm period and various angles, and can be aligned in topographical substrate features. Sequential self-assembly can produce three dimensional structures, including orthogonal mesh patterns, by assembling one block copolymer on another. We also describe metal infiltration of block copolymers by immersion in an acid solution of a metal salt, which locks the self-assembled structure, and reversibility of the metallization by immersion in a solution of a complexing agent, unlocking the structure so that it can evolve in response to annealing. We use in situ grazing incidence small angle x-ray scattering to reveal details of the self-assembly process during thermal or solvent vapor annealing. Combinations of novel polymers, templating approaches, and processing techniques yield an extensive array of rectilinear and 3D pattern geometries that can expand current nanofabrication capabilities.

2:00 PM SF02.07.02
Mapping the Phase Behavior of Block Copolymer Supramolecular Thin Films using Solvent Vapor Absorption – Desorption Isotherms NayanatharaHendeniya, CadenChittick, KaitlynHillery, ShaghayeghAbtahi and BoyceChang; Iowa State University of Science and Technology, United States

The self-assembly of block copolymers has been widely studied over decades as a potential platform in a plethora of nanotechnological applications. Recently, significant attention has been drawn to the self-assembly of BCP-based supramolecules rather than traditional BCPs, as a more efficient method of tuning the morphologies. While the self-assembly of supramolecules is governed by the competition between minimizing the enthalpy of mixing between the blocks and maximizing the conformational entropy, tuning of morphologies and kinetic behavior are heavily influenced by molecular architecture and processing. Solvent vapor annealing is a versatile processive pathway to obtain heavily periodic self-assemblies from high χ block copolymers and supramolecules. However, little evidence is found regarding the kinetic behavior of the order-disorder transition of such assemblies during controlled solvent vapor annealing. Adsorption–desorption isotherm is a method of characterizing host-guest interactions in porous materials. A similar approach can be used to understand the interactions between polymer

chains and solvent vapor molecules. The present study is focused on understanding the kinetic factors that influence the morphological evolution using characteristic absorption–desorption behavior of cylinder–forming polystyrene – block – poly (4 – vinyl pyridine) block copolymer combined with pentadecylphenol (PS – b – P4VP(PDP)) during solvent vapor annealing. We identify the transition points from kinetically trapped initial phase segregation to periodic horizontal cylindrical structures with long-range order using absorption–desorption isotherms. We further investigate the tunability of grain coarsening and macroscopic film dewetting under continuous flow solvent vapor annealing. Atomic Force Microscopy (AFM) is used to characterize surface morphological evolution. Using Grazing Incidence Small Angle X-ray Scattering (GISAXS), the periodicity (D0) and grain size are quantitatively analyzed.

2:15 PM SF02.07.03
Surface Crystallization of Molecular Crystals by Exsolution from Poly(ethylene) BryanErriah[1], AlexanderShtukenberg[1], ReeseAronin[1], DerikMcCarthy[1], LeilaniSmith[1], PetrBrazda[2], MichaelD. Ward[1] and BartKahr[1]; [1]New York University, United States; [2]The Czech Academy of Sciences, Czechia

The properties of synthetic polymers are often tuned with additives. Whilst most additives, like plasticizers, are non-migratory, some are migratory, like lubricants. Blooming and/or bleeding refers to phenomena in which additives in a polymer migrate to its surface; this is a common phenomenon that is important for several industries including food packaging and pharmaceutics, medicine, art, and the production of long-lasting insecticidal bed nets.
Many long-lasting insecticidal bed nets for protection against disease vectors are made of poly(ethylene) fibers in which the insecticide is embedded at the time of manufacture. Insecticide molecules diffuse from within the supersaturated polymers to surfaces and become bioavailable to insects, in most cases eventually crystallizing. Recent studies have revealed that contact insecticides can be highly polymorphic. Moreover, insecticidal activity is polymorph dependent, with forms having higher crystal free energy yielding faster insect knockdown and mortality. Consequently, the crystallographic characterization of insecticide crystals that emerge from fibers is critical to understanding net function and improving net performance. Structural characterization of insecticide crystals on bed net fiber surfaces, let alone their polymorphs, has been elusive owing to the minute size of the crystals that by necessity grow in and on threads, however.
Here we describe surface crystallization of several molecules by phase separation from extruded poly(ethylene) fibers including ROY, paracetamol, flufenamic acid, benzamide, benzil, deltamethrin, alpha-cypermethrin, lambda-cyhalothrin and chlorfenapyr. In general, solutes diffuse from the polymer matrix and form amorphous droplets on the surface. With time the system may undergo substantial evolution from droplet coalescence to metastable crystal growth, to recrystallizing as more thermodynamically stable forms, a demonstration of Ostwald's Rule of Stages. In general, crystallization on the surface of poly(ethylene) resembles growth from vapor phase and is often limited by diffusion mass transport. With the highly polymorphous compound ROY (5-methyl-2-[(2-nitrophenyl)-amino]thiophene-3-carbonitrile) as a proxy for insecticide crystallization, we investigated blooming kinetics and crystallization on the surface of melt-extruded, and cold-drawn poly(ethylene) fibers that had been impregnated with ROY. The blooming rates, tracked from the time of extrusion, were determined by UV-vis spectroscopy after successive washes. Six crystalline polymorphs (of the 14 known) were observed on poly(ethylene) fiber surfaces, and they were identified and characterized by Raman microscopy, scanning electron microscopy, and 3D electron diffraction (3D ED). We show both polymorph control and particle size/morphology control. These observations reveal that the crystallization and phase behavior of polymorphs emerging from poly(ethylene) fibers is complex, dynamic, and tuneable. Furthermore, the demonstration that 3D ED can characterize the minute crystals grown on fibers promises a pathway to bed net crystallography and subsequent optimization of bed net performance.

High Throughput Platform to Meet Covarying Materials Manufacturing Design Criteria for Block Copolymer Nanolithography PaulF. Nealey; University of Chicago, United States

Methodologies and tools for the accelerated discovery and design of materials for use in manufacturing have been transformed over the past decade through the combination and integration of experiment, theory, and computation. Here we build on the integration of experiment and molecular simulation to specify design rules for block copolymer (BCP) materials, for use in the directed self-assembly (DSA) of ultra-high resolution lithographic patterns for semiconductor manufacturing, and report on a high throughput synthesis and characterization platform for discovery and subsequent optimization of BCP materials for this application over a range of pattern dimensions. The design rules are agnostic to specific polymer chemistries and are derived from equilibrium (thermodynamic) and non-equilibrium (dynamic) predictive physics-based models that were validated by comparison to one of a kind quantitative experiments using the only BCP material and DSA process that have been successfully implemented in an industry-relevant format, at one serendipitously-found pattern dimension, and interrogated by state-of-the-art inspection tools so as to be known to satisfy manufacturing constraints. In a departure from conventional materials development, multiple co-varying properties must be simultaneously optimized in the BCP materials, and materials of different chemistry and composition must be developed for each pattern dimension over the desired range. A key advance to develop a family of different materials to realize these objectives is the design and implementation of a high throughput discovery-oriented synthesis and characterization platform using interchangeable polymer components to explore a large and complex parameter space to find possible combinations of components that satisfy the design rules at different pattern dimensions. The large data sets acquired from the high throughput methodologies then allow rapid convergence on the synthesis of BCP materials for specific objectives in the application space.

4:00 PM SF02.07.05
Assembly of Sequence-Defined Peptoids into Crystalline Nanomaterials as Biomimetic Catalysts Chun-LongChen[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

While natural enzymes, including lignin peroxidase, phosphotriesterase, and carbonic anhydrase, are promising for various applications, such as lignin depolymerization, degradation of toxic organophosphates, and accelerated CO_2 precipitation, there are numerous key technical barriers to prevent their practical applications, because they often suffer from low stability and high cost. To circumvent these barriers, researchers have started to develop synthetic materials as enzyme mimetics with enhanced stability for various purposes. Despite tremendous efforts made in this area, constructing highly efficient and robust enzyme mimetics with natural enzyme-like flexibility in tuning active sites and microenvironments remains a grand challenge.

In this presentation, we will report our recent progress in developing peptoid-based crystalline nanomaterials as highly robust and programmable catalysts for a variety of applications. Peptoids are one of the most advanced classes of sequence-defined synthetic foldamers that bridge the properties of proteins and polymers. [1-4] While exhibiting protein- and peptide-like molecular recognition, peptoids offer unique opportunities for controlled synthesis of hierarchically-structured crystalline nanomaterials[1,5-7] exclusively through side-chain chemistry due to the lack of backbone hydrogen bond donors. Because of highly tunable features and robustness of these peptoid-based crystalline nanomaterials, they provide an ideal platform to mimic nature enzymes by offering high surface area, programmable microenvironments, and other unique advantages. For example, comparing to a typical lignin peroxidase which contains one active site per enzyme molecule, peptoid-based crystalline nanotube catalysts can accommodate a high-density of active sites to achieve a significantly enhanced catalytic activity in lignin depolymerization. [8] Moreover, due to their high chemical and thermal stability, these peptoid-based catalysts can be operated at a variety of conditions, such as at elevated reaction temperature and broad pH range which nature enzymes denature.

Reconfigurable Multi-Component Assemblies Built from DNA Origami Voxels MinhTri Luu[1], JonathanBerengut[2] and ShelleyWickham[1]; [1]University of Sydney, Australia; [2]University of New South Wales, Australia

DNA origami is a robust nanofabrication method that enables the biomimetic self-assembly of diverse nanostructures with nanoscale addressability and reconfiguration. Hierarchical assembly of DNA origami components into larger assemblies offers a pathway to create larger or more complex structures. However, challenges remain in achieving structural diversity, rigidity, and programmable reconfiguration. Here we present a universal and robust DNA origami building block to support 2D and 3D hierarchical assembly that combines rigid DNA barrel monomers with rigid connections. The building block is modular and contains 14 directional binding interfaces in 3D, each with multiple DNA strands that can hybridise with connector strands to create rigid connections within hierarchical assemblies.

We demonstrate the use of DNA barrel monomers as modular voxels to build diverse multi-component assemblies with intricate custom features and addressable components for potential materials patterning. DNA strand displacement reactions are used to switch connections between flexible and rigid states, enabling rapid and reversible shape transformations of assemblies with high yield. Additionally, we explore strategies to improve the yield of hierarchical assembly of DNA origami. Inspired by protein assembly, we investigate multi-step folding pathways. Initially, we assemble individual DNA origami building blocks into a flexible linear chain of linked DNA origami. We then fold these chains into more compact structures in several steps, resulting in improved yields for certain pathways. We envision that DNA origami chains could be integrated with scalable assembly methods to build new materials with rapid and high-yield reconfiguration.

Peptide Self-Assembly: From Fibrillation to Crystallization MingdongM. Dong; University of Aarhus, Denmark

Amyloid self-assembly is a complex phenomenon with implications in both degenerative human disorders and materials science. In this context, various structures such as amyloid fibers, particles, and crystals exist, with crystal amyloids being the most stable energetically. However, achieving control over amyloid assembly and reversibly manipulating the crystallization process pose significant challenges. This study aims to explore the reversible formation of macroscopic crystals by examining the effects of temperature, pH, ionic strength, and solvents. Furthermore, in situ microscopy will be utilized to investigate the dynamic process of amyloid disassembly. The reversibility of self-assembly under external stimuli provides valuable insights into the mechanisms of amyloid formation, emphasizing the importance of considering the influence of external factors on crystal formation. Ultimately, the investigation of reversible amyloid crystallization holds promise for the development of innovative strategies in biomaterial design.

SESSION SF02.08: Poster Session II
Session Chairs: Chun-Long Chen and Shuai Zhang
Wednesday Afternoon, November29, 2023
Hynes, Level 1, Hall A

8:00 PM SF02.08.01
Bio-Inspired Physical Unclonable Function Labels Fabricated by Self-Assembly Processes Su EonLee[1], JunhyunPark[1], Jang HwanKim[2] and Bong HoonKim[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]LG Chem Ltd., Korea (the Republic of)

The demand for robust verification and recognition techniques is increasing because of the evolution of Internet of Things (IoT) and wireless data storage systems. Although authentications with software systems are prevalent, they are susceptible to external threats like hacking and electronic interference. For these reasons, verification methods with hardware systems using physical unclonable functions (PUFs) have been interested in applying wireless interconnection devices and network-based data servers. The validation process using PUFs relies on the electrical and optical signals generated from micropatterns or randomly oscillating signals in electronic devices, and the verification of these encrypted signatures typically depends on complex and time-consuming measurement instruments.

In this poster, we introduce bio-inspired PUF labels fabricated by self-assembly processes. BCP self-assembly forms randomly oriented nanopatterns (i.e., fingerprint-like lamellar structures) as small as 5 nm across the broad area because of the thermodynamical microphase separation. We fabricate the multi-layered nanopatterns from the randomly oriented BCP templates by stacking a thin layer of the metallic lamella structures *via* the transfer printing process on non-planar and flexible surfaces for wearable or soft electronic devices. As the purpose of the verification systems, we produce multiple independent keys, utilizing electrical resistance, optical dichroism, or Raman signals for high-security rates and fast scan speeds.

The multiple-layered fingerprint-like nanoscale PUF labels respond to the electrical potentials and polarized visible light, which can generate non-deterministic keys by physically measuring the electrical resistance, optical dichroism, and Raman scattering. We decrypt the respective or integrated signal according to the purpose with scan speeds of ~10 μs (resistance), ~1 μs (birefringence), ~100 ms (Raman scattering), and ~1 ms (Integrated methods). Moreover, we can form PUF labels on paper bills, deformable transparent polymer substrates, human wrists, human hair, ant bodies, and microbacteria by a transfer printing process, which provides ultra-high security rates, simultaneously rapid validation speeds, and universal application to the PUF labels.

In conclusion, we show randomly oriented BCP nanopatterns applied to the PUF labels with robust and secure properties and meaningful encoding abilities, which offer unpredictable signals for identification, utilizing electrical and optical response with fast scan time. Our approach reduces the critical dimensions of PUF labels, has the potential to be a versatile platform for advanced authentication systems, and can be used for discreet miniature identifiers on various surfaces or integrated multikey authentication systems. Integrating PUFs seamlessly with essential validation tools is the next valuable step, enabling versatile applications, including hardware-based on-demand cryptographic key generation.

8:00 PM SF02.08.02
Multiphase Silk Assembly for Two-Dimensional Composite ChenyangShi and JamesJ. De Yoreo; PNNL, United States

Early insights into native silk fibroin (SF) architecture suggested that its unique structures and properties are determined by its multiscale assembly and the evolution of its secondary structure. Yet the pathways of assembly and the relationship to that evolution are poorly understood. Here we investigate SF self-assembly at using in situ AFM, photo-induced force microscopy. (PiFM), and molecular dynamics. To do so, we assemble the silk at the interface between water and highly ordered pyrolytic graphite (HOPG). We find that SF grows heteroepitaxially on HOPG into highly ordered, monolayer-thick 2D nanocrystals consisting of 1D lamellae that exhibit β-sheet secondary structure. Molecular dynamics simulations show that the lamellae strongly prefer the armchair orientation of HOPG and polar packing to form a bilayer. As the SF concentration increases, SF assembles into multi-layers via two pathways that can occur concomitantly. One is a non-classical pathway by which a disordered metastable film forms on top of the lamellae monolayer and gradually converts into the lamellae structure of SF β-sheet nanocrystals. The second is a classical layer-by-layer pathway by which new lamellae grow homoepitaxially on the underlying 2D lamellae nanocrystals without any evidence of an intermediate state. These new findings fill in the missing pieces of the puzzle showing how SF structure evolves at the liquid-solid interface and provides inspiration for the design of heterogeneous 2D SF composites.

Effects of Crystallization on Micromechanical Behavior of Polyethylene Nanocomposites MasonMartell, LindaS. Schadler, DavidPunihaole and FredericSansoz; University of Vermont, United States

The addition of small amounts of nanofillers to a polymer matrix has been shown to impart significant changes in mechanical, dielectric, and optical properties. A common challenge in creating these polymer nanocomposites (PNCs) is controlling the dispersion of the nanofillers. Recent work has demonstrated methods to control dispersion and organization of spherical nanoparticles (NPs) in compatible matrices. At sufficiently slow crystallization rates in semicrystalline polymers, the NPs organize in the amorphous regions of the growing spherulites. PNCs with organized NPs have been shown to exhibit improved bulk mechanical properties, but the micromechanical behavior underpinning these has not been fully explored. In this study, in-situ Raman spectroscopy was performed on polyethylene samples under tensile load to explore differences in micromechanical behavior between neat, filled but unorganized PNCs, and PNCs with crystallization-induced particle organization. Crystallization of each sample was characterized in DSC, and organization of PNC samples confirmed by SAXS and TEM. Results show that the addition of fillers leads to a significant change in the distribution of load between the crystalline and amorphous phase. Shift is only apparent in samples that undergo necking (high strain), consistent with previous work on neat polyethylene.

Self-Assembled Tetrapod Molecules on Graphite Form Nanopockets with Attractive Force Distribution Studied by 3D Scanning AFM MoeOgasawara, MasayukiMorimoto and HitoshiAsakawa; Kanazawa University, Japan

The precise design of molecular architectures through molecular self-assembly on solid substrates is a promising approach for developing next-generation materials and their functions. The molecular architecture having nanopockets that can capture target molecules with high selectivity and affinity has immense potential for use in sensing devices and separation materials with molecular recognition functions. Toward the design and construction of molecular architecture with nanopockets, we have been exploring molecular building blocks having three-dimensional (3D) extended structures. Furthermore, we have developed a molecular-scale analytical technique based on atomic-resolution atomic force microscopy in liquid.
For the applications of molecular nanopockets, not only nanoscale surface structures such as molecular orientation, but also the recognition mechanism of how guest molecules and host nanospaces interact is an important research topic. However, the lack of a measurement method for interaction forces in 3D nanospace has made it difficult to improve the understanding of the recognition mechanism. We have developed a 3D scanning atomic force microscope (3D-AFM) that can visualize hydration structures and surface fluctuation structures at the solid-liquid interface with sub-nanometer resolution. Conventional AFMs scan the tip only in the XY direction, but 3D-AFM scans the tip in the Z direction in addition to the XY direction, making it possible to obtain 3D force distribution information. Combined with the frequency shift detection method, 3D-AFM can also detect the interaction force acting on the tip at the picoNewton (pN) level. Based on this principle and performance, we believe that 3D-AFM technology can be applied as an analysis tool for "interaction force measurement" as well as "structural measurement."
We have performed direct visualization with 3D-AFM of the characteristic interaction force in 3D nanospaces at the self-assembled molecules/water interface. Two types of tetrakis(4-ethynylphenyl)methane (TEPM) derivatives with oligo(ethyleneglycol) (EG_n) chain (EG_2-TEPM, EG_4-TEPM) were used as the building blocks and these TEPM derivatives form self-

assembled monolayers on graphite. In the monolayers, there are hydrophobic nanopockets (diameter: approx. 1.7 nm) surrounded by the aromatic structure of the TEPM derivatives. We performed 3D-AFM measurement at the self-assembled monolayers/water interface. As a result, characteristic localized attractive interaction was visualized only at the EG_2-TEPM monolayer/water interface, and analysis of the 3D-AFM images suggests that the attractive interaction forces originate from the nanopockets and that the nanopockets of EG_2-TEPM are slightly smaller than those of EG_4-TEPM. The number of hydrogen bonds forming the water molecule network and the water molecule density are reduced in restricted spaces, such as inside the EG_2-TEPM nanopockets, compared to the bulk water. The visualized attractive interaction forces seem to originate from the water molecule behavior in the nanopockets. Our results demonstrate that the 3D-AFM technique has the capability of visualizing the characteristic interaction forces at the single molecule level, suggesting future contributions to the elucidation of the molecular recognition mechanisms and the design of novel nanodevices.

Low Temp Heterogeneous Integration of Ultra-Thin-Silicon Interposer via Transfer Printing and Laser Bonding UhyeonKim, SeungbeomKim, JunhyungKim, AghaA. Jan and SeokKim; Pohang University of Science and Technology, Korea (the Republic of)

Interposer-based 2.5D heterogeneous integration packaging is being used as a key technology for next-generation semiconductor miniaturization that will lead "Beyond Moore." However, traditional wafer bonding techniques and flip chip processes have limitations in handling very thin silicon interposers (<30μm) that can be easily deformed. In this study, we developed a process of stably transferring and bonding ultra-thin silicon interposer with high accuracy using transfer printing technology through Shape Memory Polymer (SMP) stamp and laser heating.

The ultra-thin silicon interposer is designed as a transferable ink of Micro-Lego technology. Copper TSV (Through-Silicon Via) and Cu-Sn solder bump were formed on silicon on insulation (SOI) wafers with predefined thickness, and an independent ultra-thin interposer with a thickness of 15μm was prepared by separating the Box Layer. The interposer was accurately and stably transferred to the receiver substrate by and Shape Memory Polymer (SMP) stamp. At this time, the stamp is made by Shape Memory Polymer that can selectively transfer through heat deformation. Thereafter, the laser was irradiated to the interposer and coupled using a low-temperature bonding (~230°C) method suitable for the Cu-Sn eutectic condition. The interposer bonding was successful after finding the low-temperature bonding conditions according to the variables of laser power, time, and metal layer thickness to be used in the semiconductor post-process. The bonded interposer was characterized by FIB, IV curves, etc... This ultra-thin integration technology has advantages such as low-temperature bonding, low signal loss in channels, and low heat generation, so high-performance low-power packaging can be expected.

8:00 PM SF02.08.06

Effect of Au-Ag Bimetallic Seed in Controlling the Morphology of TiO_2 Nanowire ZhinaRazaghi and Guo-zhenZhu; University of Manitoba, Canada

The recently developed Vapor-Adsorbate-Solid method has demonstrated success in producing single-crystalline rutile TiO_2 nanowires that extend over tens of microns. This approach involves the adsorption and transfer of TiO_2 vapor species of the substrate along the surface of gold (Au) seed nanoparticles to the nanowire's growth front. Using different seed nanoparticles with gold-silver (Au-Ag) composition led to a change in the nanowire morphology, transitioning from bead-like <110>TiO_2 shapes to prismatic <111>TiO_2 shapes. This transformation was attributed to the unexpected Ag-rich segregation at the growth front, influencing nanowire shape and growth direction upon contact [1,2]. However, the exact mechanism behind how Ag segregation affects nanowire growth direction remains unclear.

To address this, the first step is to pinpoint the precise location of Ag-rich segregation at the growth front and understand its impact on nanowire shape. In this regard, a three-dimensional configuration of Ag-rich segregation was reconstructed using multiple Energy-Dispersive X-ray Spectroscopy (EDX) maps at various zone axes, including <3-15>, <1-11>, <1-12>, and <2-13>, for individual nanowires. The FEI TALOS F200X Transmission Electron Microscope (TEM) operating at 200 kV was utilized for this purpose. The results show that Ag-rich segregation primarily occurs at the hexagonal cross-section along the edges of {1-10} and {0-11} facets, which inhibits the formation of a rhombus cross-section, a component of the bead-like nanowire shape [3]. As a result, the preferred nanowire cross-section becomes hexagonal, leading to the formation of prismatic nanowires.

To decouple how Au and Ag interact with absorption species (TiO_x), X-ray Absorption Spectroscopy (XAS) was employed. Using specialized experimental settings, such as Grazing Incident X-ray Absorption Fine Structure (GI-XAFS), we enhanced the detection of weak interface signals collected at the Canadian Light Source (CLS) Hard X-ray Micro-Analysis Beamline. We analyzed X-ray adsorption spectra at the Au L3-edge and Ag K-edge for nanowires with varying shapes and growth orientations. Different atomic models were proposed for Ag-rich and Au-rich regions, with compositions of 30 at. % Au and 15 at. % Ag, respectively, determined from EDX measurements. These models explored Ag-to-Au replacement configurations with crystal parameter adjustments. Theoretical X-ray Absorption Near Edge Structure (XANES) spectra were computed using FDMNES, and Linear Combination Fitting (LCF) aligned experimental XANES spectra with theoretical models to estimate contributions of Au and Ag species. Additionally, ongoing Extended X-ray Absorption Fine Structure (EXAFS) analysis aims to validate bonding interactions by quantifying the local environment of Au and Ag species, including bond lengths and coordination numbers.

Initial findings suggest the existence of metallic Au, metallic silver Ag, an alloy of Au and Ag, Au combined with Ti, Ag combined with Ti, and Ag bonded to oxygen (Ag-O), while no evidence of Au bonding with oxygen (Au-O) was observed. These results suggest that the existence of Ag-rich segregations may lead to distinct adsorption and mass transfer characteristics compared to Au. Currently, we are investigating the precise mechanism by which Ag segregation influences growth direction using a combination of experimental techniques, including ex-situ and in-situ electron microscopy. Consequently, we anticipate that this ongoing investigation will shed light on how the composition of the seed material can be manipulated to control the morphology of TiO2 nanowires.

Water Condensation on Microstructured Superhydrophobic Surfaces MariiaS. Kiseleva and RobinH. Ras; Aalto University, Finland

Water condensation on solid surface is a phase change phenomenon where water undergo transition from vapor into liquid phase. In the initial stage of condensation process water droplets are nucleating on the surface defects or contaminants. These nucleated droplets then grow and coalesce with each other. The surface topography and coating properties play crucial roles in the nucleation and growth dynamic of the droplets. It was shown recently that superhydrophobic surfaces with densely packed sharp nanoconical features have a unique ability to repel condensing microdroplets [1,2]. When droplets coalesce on such surfaces, they can spontaneously jump away from the surface due to the release of excess surface energy. In this study, we employed in-situ optical, confocal, and environmental electron microscopies to investigate the dynamics of droplet growth and jumping during the condensation process on superhydrophobic surface with microscale conical features. Microstructured surface design was chosen due to simpler and more scalable manufacturing process. We prepared surfaces with ‘sparse’ arrays of tall cones (cone height h≈4 μm, base diameter d≈1 μm, opening angle β<18°) separated by 2 μm spacing arranged in hexagonal and squarer lattice. The advantage of ‘sparse’ arrangement is that light can be reflected from the flat area between bases of adjacent cones. Adjusting the focus plane in high-resolution optical microscope we were able to visualize the contact area between microdroplet and surface.

We showed previously that on the surface with square array of cones the macroscopic water drop is not sinking into the conical structures[3]. However, we showed that condensing microdroplets are in full contact with structure, i.e., in Wenzel state. As a result, condensing droplets are unable to jump. In contrast, on the surface with hexagonal array of cones droplets only partially wet the substrate, i.e., droplets are in partial Cassie state. Partial Cassie state enables active jumping upon coalescence of two or more droplets with radii exceeding 10 μm. Although the difference between square and hexagonal packing is very subtle, we discovered a critical transitional regime of condensing microdroplets that ranges from fully wetted (Wenzel) to partially wetted (partial Cassie) state.

Tuning Semi-Crystalline Polymer Thin Film Structure via Substrate Nano-Geometry Modulation RobertaRuffino, GiovanniLi Destri and GiovanniMarletta; University of Catania, Italy

The ability to create ultra-thin functional polymer films with controlled nano-crystallinity structure for large-scale integration is at the focus of numerous experimental and theoretical works. [1-3] The main goal is to control and manipulate the assembly of building blocks to obtain structures with desired characteristics and unique properties. The geometric constraints imposed by the nanometric thickness and interfacial interactions affect the self-assembly process and, in turn, their behaviour. [4,5] In addition, non-planar substrates, such as nano-curved substrates, can further complicate the resultant structure as already observed for block copolymer thin films. [6,7] The combination of geometric effects, i.e. surface curvature, with surface free energy (SFE) may allow more finely controlled self-assemblies. To this end, we have developed a novel approach to prepare substrates with controlled nano-curvature and surface-free-energy (SFE), to be used to investigate how geometric and energetic factors affect the self-assembly of polymeric thin films. [8,9] In particular, by employing a semi-crystalline model polymer, namely poly-3-

hexyltiphen (P3HT), it was observed that the crystals follow the surface curvature only in the presence of an energetic gain.[8]
Here, from the structural characterization via synchrotron radiation grazing incidence X-ray diffraction (GIXRD) and the morphological characterization via atomic force microscopy (AFM), we will demonstrate a non-conformal coverage, after the polymer equilibration, showing that the crystallization strongly depends on the surface curvature. The results suggest the polymer accumulation in the interstices between the particles for the lowest curvature, leading to an in-plane crystal growth. The increase in curvature improves the nucleation probability, leading to shorter crystals on both interstices and curved portions. Moreover, we demonstrate that the crystalline fraction is strongly curvature-dependent, as the crystallization only occurs when the distance between two neighbour particles is higher than the lamellar folding period. Finally, the in-situ structural characterization during thermal cooling shows a variation in the crystallization temperature (Tc) as a function of the substrate geometry, with a decrease in the onset of the crystallization with respect to the flat substrate. These results highlight the role played by the substrate in the crystallization process, suggesting that the geometric factors affect the crystalline structure itself, with the formation of distorted crystals following the surface curvature. The reported work provides a novel and easy method to modulate the structure of polymer films by exploiting geometric distortion and interfacial interactions with possible effects on the functional properties of the polymer film. This correlation sheds more light on how these factors influence the polymer film crystallization and could allow the determination of the crystallization enthalpy and its related loss when a nanometric strain is applied. A deeper understanding of this behaviour could pave the way for the development of finely tailored crystalline structures via control of the substrate geometry and energy.

Spray Deposited Block Copolymer Thin Films with Solvent Evaporation Controlled Domain Orientation SemihCetindag, BeatriceBellini, RuipengLi, EstherTsai and GregoryDoerk; Brookhaven National Laboratory, United States

With their ability to self-assemble spontaneously into well-defined nanoscale morphologies, block copolymer (BCP) thin films are a versatile platform to fabricate functional nanomaterials such as lithographic nanopatterns, nanoporous membranes and optical metasurfaces. An important yet unsolved challenge to wider deployment of BCPs in nanofabrication, however, is combining the desired precise control of BCP assembly with scalable deposition techniques that are applicable to large-area, curved and flexible substrates for high-volume manufacturing. Ultrasonic spraying is a scalable, non-batch casting method with minimal wasted polymer, yet its use in thin film BCP assembly has not been investigated.

Here, we show that the latent orientation (vertical *vs.* horizontal) of well-ordered cylindrical domains in spray-deposited, optically-smooth thin films of polystyrene-block-poly(4-vinylpyridine) (PS-*b*-P4VP) can be controlled by regulating solvent evaporation kinetics. Faster evaporation during deposition facilitates assembly of vertically oriented cylinders spanning the entire film thickness (100-300 nm) upon subsequent solvent vapor annealing. In comparison, slow solvent evaporation induces assembly of horizontal cylinders, imposing an additional energy barrier for reorientation to vertical cylinders during solvent vapor annealing. Using in-situ characterization by synchrotron grazing-incidence small-angle X-ray scattering (GISAXS), we identify the relevant timescale for polymer vitrification which determines latent cylinder orientation. This dependency on solvent evaporation kinetics is exploited to control cylinder orientation in multiple ways, including substrate heating, forced convection, and solvent formulation. To highlight the scalability and utility of the spray casting technique, an exemplar application using spray deposited self-assembled patterns on curved surfaces will also be described.

Funding: This research was conducted at the Center for Functional Nanomaterials (CFN) and the National Synchrotron Light Source II (NSLS-II), which are U.S. Department of Energy (DOE) Office of Science User Facilities, at Brookhaven National Laboratory under Contract No. DE-SC0012704. Controlling Structural Changes in 2D Magnets using *In Situ* Microscopy and Machine Learning TechniquesJulianKlein and FrancesM. Ross; Massachusetts Institute of Technology, United States

Electron beam patterning raises exciting prospects for modifying the crystal structure and hence physical properties of 2D materials, and has been explored for several 2D materials in single or few-layer form. Here we examine the opportunities arising from patterning thicker, more robust crystals of 2D semiconducting magnets, intriguing materials in which the local ordering of spins determines both the magnetic properties and the optical response. CrSBr is one such material, having layers with alternating magnetic moment and a structure in which Cr atoms located in their own columns are separated by columns of mixed S and Br atoms. For 10-50nm thick multilayer crystals, we find that broad-area irradiation by electrons reorganizes CrSBr into a new structure, which is also van der Waals-bonded but with a layer orientation and calculated magnetization that are rotated by 90º from the initial direction. Further structural changes can be generated if we irradiate the structure along rows of Cr atoms to open local gaps, changing the calculated interaction between magnetic atoms. Extending to the ultimate objective of controlling the position of individual Cr columns requires the use of machine learning techniques to track column positions, direct the beam and evaluate whether the desired modification has been achieved. We will describe strategies for achieving this goal and for understanding the process by which the Cr atoms are rearranged. We conclude by discussing correlative techniques to measure the optical and magnetic properties of the modified material, and the more general opportunities arising from patterned recrystallization of multilayer van der Waals bonded magnetic materials for spin-based and optical quantum devices.

9:00 AM SF02.09.02
Mechanism and Kinetics of Topochemical Etching for Synthesis of 2D MXenes from Layered MAX Phases MarkAnayee, Ruocun (John)Wang, StefanoIppolito, MikhailShekhirev and YuryGogotsi; Drexel University, United States

MXenes represent a rapidly growing family of 2D transition metal carbides and/or nitrides, which exhibit unique combinations of properties, including metallic conductivity, hydrophilic surface chemistry, redox-active surface, and plasmonic behavior that make them attractive as electrodes for pseudocapacitive energy storage to coatings for electromagnetic interference shielding, transparent conducting displays for optoelectronics, conductive yarns for functional textiles, implantable electrodes for medicine, and many other applications.

MXenes are typically derived via selective etching of atomically thick ‘A’ layers from precursor layered MAX phases using HF-based aqueous etchants. However, the chemical etching process is only somewhat optimized for one composition, and is nonetheless often slow, with low-yield, and results in defects in the materials. Thus, understanding the fundamental mechanism and kinetics of the etching reaction is needed to rationally explore etching of yet-to-be synthesized MXene compositions and optimize etching of existing MXene compositions. Despite their importance, such studies have been challenging because of the atomic thickness of the A-element layers being etched and the aggressive etchants that hinder in situ studies.

Here, we spatially track the etching front in 3D (using analytical setups for tracking byproduct gas evolution), 2D (using cross-sectional imaging of partially etched particles), and 1D (using in situ optical microscopy and profilometry of single particles). Thus, we show the role of surface oxide and binary carbide impurities on the nucleation of etching, and we discovered a layer-by-layer growth process for the etching front. From kinetic modeling, we show that etching varies from reaction-limited to diffusion-limited for various MAX compositions. Overall, our work enables rational high-throughput optimization of synthesis for all MXene compositions, scaling up synthesis towards industrial levels, and tailored synthesis for specific applications.

9:15 AM *SF02.09.03
Dynamics of Advanced Low-Dimensional Materials by Low-Voltage Atomic-Scale TEM Experiments UteA. Kaiser; University of Ulm, Germany

To create next generation functional low-dimensional materials, it is a growing demand in materials sciences to understand their formation mechanisms as well as their structural and electronic properties at the atomic or molecular scale. Some of the most challenging tasks nowadays are related to energy storage, nano-catalysts or battery materials.
A unique type of transmission electron microscopes operating at electron energies between 80keV and 20keV was developed, which allows to undercut most of the materials knock-on damage thresholds and enables sub-Angstroem resolution in an 4000x4000 pixels sized image, single-shoot image down to 40keV by correcting not only geometrical but also the chromatic aberration of the imaging lens [1-3]. This instrument is used for the in-situ studies presented here. Before we discuss several in-situ TEM experiments, we develop a detailed understanding of the electron beam - 2D specimen interactions: By density functional theory molecular dynamics we show that excitations in the electronic system can form vacancies through ballistic energy transfer at electron energies, which are much lower than the knock-on threshold for the ground state. We propose a two-step vacancy formation process as combination of elastic and inelastic events, evaluated also by an U-net-based fully convolution neural network (FCN) [4].
Based on this knowledge, we discuss the dynamics of properties of point, line and extended defects in various transition metal - dichalcogenides and –phosphor dichalcogenides [5-8]. Optical measurements are performed independent of the TEM experiment. To relate optical and TEM results we demonstrate proof-of-principle experiments in which we transfer electron-exposed defect-characterized TMD flakes from a TEM grid to arbitrary substrates and relate the subsequently performed photoluminescence and transport signals to the defect structure [9].
Furthermore, we present in-situ studies of a miniaturized electrochemical cell, where reversibly single-crystalline bilayer graphene is lithiated and delithiated in controlled manner using an electrochemical gate confined to a device protrusion [10] and report on the Li crystal nucleation and growth during lithiation and Li-O formation and amorphization during delithiation. We generate further incapsulated metal-atom-dimers within single-walled carbon nanotubes and observe the dynamics of single metallic bond formation by exact measurements of the interatomic distance [11].
At the end we show that the approaches of graphene encapsulation and lowering the electron accelerating voltage (here from 300kV to 120kV) can be successfully applied for imaging 2D organic materials at the molecular level [12-14].

Surface Dynamics of Atomically Controlled Electrodes for Clean Energy MagaliLingenfelder; EPFL, Switzerland

Our society faces a critical challenge in shifting from a reliance on carbon-based energy to sustainable renewable sources. A key step towards achieving clean energy lies in developing efficient catalysts that can convert chemical energy into electricity or use electrons to generate chemical energy.

In our research group, we tackle these challenges by creating customized materials that draw inspiration from nature (biomimicry) and combine principles from interfacial chemistry and surface physics. For this presentation, I focus on the process of photosynthesis as inspiration for the design, characterization, and dynamic nature of functional interfaces that drive energy conversion processes such as CO_2 electroreduction and water splitting on the surface of Earth-abundant materials.

I will also discuss the application of cutting-edge scanning probe microscopy and Raman spectroscopy under electrochemical conditions, which allows us to visualize dynamic processes at the nanoscale (*operando* imaging). Additionally, I will highlight our use of unconventional strategies that leverage the assembly of chiral molecular layers and two-dimensional materials to enhance electrocatalytic conversion processes. (References : Nanoletters, 2021, 21, 2059; Nature Comm., 2022, 13, 3356, IJC 62, 11, 2022).

Interfacial Liquid Water on Graphite, Graphene and 2D Materials RicardoGarcia; Consejo Superior de Investigaciones Científicas, Spain

Solid-water interfaces have a prominent role in a variety of fields such as surface science, geochemistry, electrochemistry, energy storage or molecular and cell biology. Liquids near a solid surface form an interfacial layer where the molecular structure is different from that of the bulk. Yet the molecular-scale understanding of the interactions of liquid water with solid interfaces is unsatisfactory for the lack of high-spatial resolution methods. Here I will present an AFM-based method that provides atomic-scale resolution images of solid-liquid interfaces.

The presentation is divided in three sections. The first section is an introduction to the relevance of solid-liquid interfaces. The second section, presents the features and capabilities of 3D-AFM [1-3] to image with atomic resolution the **three-dimensional** interfacial structure of surfaces immersed in aqueous solutions. The third section reports the structure of interfacial water layers on different **2D materials** from graphene to a few layer MoS_2 ; from hexagonal boron nitride to a few layer WSe_2. Those interfaces are characterized by the existence of a 2 nm thick region above the solid surface where the liquid density oscillates [4-8]. The distances between adjacent layers for graphene, few-layer MoS_2, h-BN and pentacene are ~0.50 nm. This value is larger than the one predicted and measured for water density oscillations (~0.30 nm). The experiments demonstrate that on extended **hydrophobic surfaces water** molecules are **expelled** from the vicinity of the surface and replaced by several molecular-size hydrophobic layers.

Modeling and Experimental Analysis of Vertical and Lateral Growth of 2D Mo2C Crystals via Chemical Vapor Deposition GoknurCambaz Buke[1], OmerCaylan[2] and TarikOgurtani[3]; [1]TOBB ETU, Turkey; [2]Massachusetts Institute of Technology, United States; [3]Middle East Technical University, Turkey

This study investigates the growth of Mo2C crystals through Chemical Vapor Deposition (CVD) on Cu substrates. The research combines theoretical and experimental approaches to examine both the vertical and lateral growth of Mo2C crystals. A physico-mathematical model is developed, incorporating bulk and surface diffusivities, as well as solubility gradients for Mo2C crystal growth. Nonlinear flow equations are used to predict Mo2C crystal growth rates in vertical and lateral directions within the Mo-, Cu-, Mo2C layer framework. The model correlates the height and diameter of the Mo2C crystals with the thickness of the copper layer and time, which is then validated through experiments and imaging techniques such as SEM and AFM. The results highlight the significant influence of the copper layer thickness on the height of Mo2C crystals, while its impact on the lateral dimensions is less critical. The study goes beyond enhancing Mo2C crystal growth and explores the synthesis of tailored Mo2C crystals for specific applications. The developed forward model provides a platform for further advancements and exploration of related material analogs.

Interface and Interlayer Dynamics in 2-D MnO2 via *In-Situ* CharacterizationScottT. Misture; Alfred University, United States

Supercapacitor electrodes can be prepared from MnO2 nanosheets exfoliated from highly crystalline powder particles and subsequently flocculated to form porous solid electrodes. Restacking of the 2-D nanosheets in packets of ~5 layers affords high surface area electrodes with highly flexible interlayer spaces for electrochemical activity. The talk centers on the application in-situ and in-operando studies using high energy X-ray diffraction, X-ray pair distribution functions, EXAFS/XANES and Raman spectroscopy. We show that linking electrochemical measurements to local structure characterization results enables us to understand the mechanisms by which charging occurs in supercapacitor electrodes. The data show that the re-stacked 2-D nanosheets go through a phase transition during charge/discharge wherein the interlayer chemistry alters the interlayer stacking in a subtle but detectable manner. The presence vs. absence of interlayer water and electrochemically active ions including Na, K or Rb define the interlayer stacking. Using a combined approach that tracks the Mn oxidation state, the local structures (via PDF and Raman) and charge/discharge electron exchange forms a clear picture of the physical mechanisms at play, including mechanisms of capacity fade.

SESSION SF02.10: Materials Surfaces II

Epitaxial and Interfacial Crystallization of Metal Halide Perovskites and Their Heterostructures SongJin; University of Wisconsin--Madison, United States

Metal halide perovskites are inexpensive semiconductor materials promising for high performance solar cells and light emitting diodes (LEDs) because they are easy to synthesize and tolerant of defects. We developed new methods for synthesizing nanostructures of both three-dimensional (3D) perovskites and two-dimensional (2D) Ruddlesden–Popper (RP) layered perovskites, including vapor phase epitaxial growth on crystalline inorganic substrates and general solution growth of 2D RP perovskite nanosheets at the air-water interface. More chemically unstable and less soluble 2D perovskites could also be crystallized at the interface of aqueous-nonaqueous solutions. We further create novel and arbitrary heterostructures, such as 2D/3D perovskite, vertical and lateral 2D heterostructures, with high quality interface and tunable band alignments. Various structural characterization and time-resolved spectroscopic methods have been employed to collaboratively study the carrier transfer mechanisms between these well-defined heterostructures of 2D and 3D perovskites. Fundamental understanding of the factors controlling the carrier transfer mechanisms in heterostructures of halide perovskites is crucial for guiding the synthetic strategies to improve properties and device applications.

2:00 PM SF02.10.02
Filament-Induced Crystallization of TiN/HfO_x/TiN Film in Neuromorphic Devices AlexandreFoucher[1], BaomingWang[2], TeodorTodorov[3], JohnRozen[3] and FrancesM. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Nanjing University, China; [3]IBM T.J. Watson Research Center, United States

HfO_x films are increasingly under scrutiny for applications in resistive random-access memory (ReRAM) devices. HfO_x-based structures have a fast-switching speed, excellent stability, and can be easily integrated in complex devices. However, changes in crystal structure when current and voltage are applied are not well understood and are crucial to guide the rational design of HfO_x-based devices. To this end, a TiN/HfO_x/TiN stack implemented in nanodevices was studied with *in situ* scanning transmission electron microscopy (STEM). We observed crystallization of the initially amorphous HfO_x films and grain growth of crystals during repeating switching with increasing applied current and voltage. The formation and growth of crystalline region could then correlate to changes in measured conductance on the sample studied with in situ STEM. *In situ* electron energy loss spectroscopy (EELS) showed the depletion in oxygen of crystalline phases compared to the initial amorphous HfO_x phase. We suggest that this is due to the displacement of oxygen vacancies that concentrate in the crystalline grains and is the cause of the neuromorphic properties of the HfO_x film. Oxygen migration toward the TiN/HfO_x interface and the importance of crystallization at the interfaces are also discussed. We aim to use this atomistic understanding of crystallization and structural changes of HfO_x in TiN/HfO_x/TiN to guide the rational design of multilayered materials for electronic applications.

2:15 PM SF02.10.03
In-*Operando* Optical Tracking of Vacancy Induced Phase Change in Few-nm Thick Ferroelectric HZOAtifJan, SunilTaper and GiulianaDi Martino; University of Cambridge, United Kingdom

Ferroelectric random-access memories (FeRAM) switching is achieved by ferroelectric switching of dipoles. FeRAMs offer low-energy and faster switching as compared to conventional memory circuitry. They excel in terms of power consumption and low voltage operation, when stacked against current-driven contenders. Unfortunately, FeRAMs have been restricted to niche markets due to their limited CMOS-compatibility and severe scaling issues of the complex ferroelectric perovskite systems. However, the discovery of ferroelectricity in binary oxides gave an impetus for development of universal memory concept, which may lead to a significant breakthrough in the development of memory devices. Binary oxides generally do not suffer from a “dead layer effect”, which makes non-binary oxides, such as perovskites, ineffective for thin film technology. Moreover, high coercive fields inside binary oxides give them a considerable resilience toward internal depolarization of the ferroelectricity, crucial to achieve scalability as well as overcome the widespread reliability disadvantages of FE material. The underlying reasons for the stable ferroelectricity and distinct switching of FE domains inside binary oxides at an atomic level are poorly understood. Moreover, non-idealities seen upon continuous electronic switching cycles like wake-up and fatigue introduce uncertainties in device performance and endurance. In this work, we present the first proof of the underlying reasons for these non-idealities with cycle-to-cycle tracking of morphology changes in few-nm thick binary oxide ferroelectric ultra-thin films.
This work presents the first proof of the underlying reasons for these non-idealities with cycle-to-cycle tracking of morphology changes in few-nm thick binary oxide ferroelectric ultra-thin films. With our Nanoparticle-on-Mirror (NPoM) geometry, we capture for the first time both migration of <1% oxygen ions and material phase change in just 5nm-thick binary oxide ferroelectric films when under continuous electronic switching, and therefore track in real-time and in-operando the nanoscale kinetics of wake-up and fatigue in ferroelectric ultrathin memories. We use in-situ electrical and optical characterizations like darkfield scattering, photoluminescence and Raman spectroscopy to understand the nano-kinetics of the atomic level switching. The tracking of vacancy migration and phase change with the above-mentioned techniques combined with density functional theory (DFT) and finite-difference time-domain (FDTD) simulations provide the first insights into the morphological changes in ultra-thin binary oxide films [1].

Denoising Total Scattering Data using Compressive Sensing NiklasB. Thompson and JamesWeng; Argonne National Laboratory, United States

Total X-ray scattering measurements performed with high-energy incident photons (> 50 keV), complemented by real-space analysis via the pair distribution function (PDF), is an indispensable tool in determining the local atomic structure of amorphous and nanoscale materials. While the application of PDF analysis to bulk systems is a mature field, there is burgeoning interest in extending its domain of application to more complex sample environments, such as thin films and dilute solutions, with an eye toward *in operando* measurements under realistic operating conditions. In this setting, the scattering signal originating from the material of interest is typically overwhelmed by the background signal (*e.g.*, from the substrate beneath a thin film, or the solvent in a dilute solution). The successful separation of the intrinsically weak signal of the desired material from the background thus depends on collecting raw data with a high signal-to-noise ratio (SNR), a central challenge in flux-limited X-ray scattering measurements on disordered systems.

Ideally, this challenge can be addressed by simply increasing the measurement time or incident X-ray flux. However, this can result in both radiation damage—altering the structure of the native sample—and limits the time resolution of total X-ray scattering in *operando* settings. Inspired by recent developments in compressive sensing, we have developed a means of signal denoising based on the responses of many “virtual detectors”, using a single real measurement from an area detector. The technique relies on the sparsity of real scattering images in an appropriate transformation basis, rendering the true signal separable from the (necessarily) non-sparse noise. Our purely computational approach allows the resolution of noisy signals which cannot be easily measured using current detectors without modification of the existing hardware. Based on experiments with both simulations and real data, the resulting virtual measurements behave as though they were independent measurements; by averaging over the virtual measurements, the actual SNR can thus be improved. Effectively, this turns one measurement into an arbitrary number of repeated measurements, thereby allowing for measurements of disordered materials susceptible to radiation damage and rapid kinetic experiments that are otherwise difficult to perform.

Bits to Atoms and Atoms to Bits: Atomic Fabrication in Electron Microscopy SergeiV. Kalinin[1], MarcBellemare[2], AaronCourville[2], JesseFarebrother[2,3], MaxSchwarzer[2], PabloS. Castro[3], JoshuaGreaves[3], MaximZiatdinov[4], AyanaGhosh[4], IgorMordatch[3] and KevinRoccapriore[4]; [1]University of Tennessee, Knoxville, United States; [2]MILA, Canada; [3]Google Deep Mind, United States; [4]Oak Ridge National Laboratory, United States

The last note left by Richard Feynman stated "*What I cannot create, I do not understand*." Building solid state quantum computers, creating nanorobots, and designing new classes of biological molecules and catalysts alike requires the capability to manipulate and assemble matter atom by atom, probe the resulting structures, and connecting them to macroscopic world. Until now, the only viable approach for atomic fabrication was the Scanning Tunneling Microscopy, often integrated with the bespoke surface science techniques. Over the last decade, it has been shown that electron beams in Scanning Transmission Electron Microscopy can be used not only to probe structure and electronic properties of materials on atomic level, but also to modify materials on the atomic level. Harnessing electron beam changes for direct atomic fabrication however requires synergy between machine learning methods and microscope control. In this presentation, I will illustrate the progression of automated electron microscopy from real-time data analysis to physics discovery to atomic manipulations. Here, the applications of classical deep learning methods in streaming image analysis are strongly affected by the out of distribution drift effects, and the approaches to minimize though are discussed. The robust approach for real-time analysis of the scanning transmission electron microscopy (STEM) data streams, based on the ensemble learning and iterative training (ELIT) of deep convolutional neural networks, is implemented on an operational microscope, enabling the exploration of the dynamics of specific atomic configurations under electron beam irradiation via an automated experiment in STEM. Combined with beam control, this approach allows studying beam effects on selected atomic groups and chemical bonds in a fully automated mode. We demonstrate atomically precise engineering of single vacancy lines in transition metal dichalcogenides and the creation and identification of topological defects in graphene. The ELIT-based approach opens the pathway toward the direct on-the-fly analysis of the STEM data and engendering real-time feedback schemes for probing electron beam chemistry, atomic manipulation, and atom by atom assembly. We further illustrate how deep kernel learning (DKL) methods allow to realize both the exploration of complex systems towards the discovery of structure-property relationship, and enable automated experiment targeting physics (rather than simple spatial feature) discovery. The latter is illustrated via experimental discovery of the edge plasmons in STEM/EELS. Finally, we demonstarte the use of the reinforcement learnign for real-time control of atomic motion. Jointly, these developments open the pathway for creation and characterization of designed defect configurations and artificial molecules in 2D materials.

4:00 PM SF02.10.06
Compositional and Structural Analysis of Iron Phosphate Conversion Coatings by Synchrotron Soft X-Ray Spectroscopy KokiItamoto[1], KakeruNinomiya[1,1,1], HidekazuFukushi[2], HideyukiTaguchi[2], KeiichiNakajima[2], EiUchiyama[2], YusukeMiyazawa[2], MikuAndo[2], SotaFukushima[2] and MaikoNishibori[1,1,1]; [1]Tohoku University, Japan; [2]Nihon Parkerizing Co. Ltd., Japan

Conversion coating, which precipitates on the surface of a metal material through a chemical reaction, prevents rust and improves coating adhesion. A typical treatment is the phosphate conversion coating treatment, which forms a coating containing phosphate. The iron phosphate conversion coating for steel materials is generally used because of its low-cost and low-sludge generation, although its rust prevention performance is inferior to other treatments. In this treatment, the Fe^{2+} is eluted from the surface of the steel by etching, which is immediately oxidized to Fe^{3+} by dissolved oxygen. Then, Fe^{3+} reacts with OH^- and $H_2PO_4^-$ in the treatment solution to precipitate a coating composed of Fe_2O_3 and $FePO_4$ [1]. Therefore, it is essential to understand the dissolution and precipitation reactions of Fe that occur at the interface between the steel and the treatment solution to improve the properties of the coating film. We have previously observed changes in the film structure with film thickness (deposition amount) by X-ray photoelectron spectroscopy and scanning electron microscopy. As a result, it was found that the film is composed of nm-sized particles generated by nucleation and aggregation and that the main component of the coating is $FePO_4$, regardless of the deposition amount[2]. This differs from the component ratio (Fe_2O_3:$FePO_4$ = 7:3) reported in a previous study [1]. In this study, we attempted to quantitatively analyze the chemical states of the constituent elements by X-ray emission spectroscopy, which is capable of element-selective state separation, to clarify the ratio of coating components according to the deposition amount in more detail.
The coatings that completely coated the steel surface comprised approximately 90 % $FePO_4$ and 10% Fe_2O_3. On the other hand, coatings with less than 80 % coverage were found to contain little Fe_2O_3 and 20 % FeO. Therefore, a part of Fe^{2+} eluted from the steel surface precipitates as a coating component without oxidizing. In addition, the amount of P content in the coating obtained by X-ray fluorescence analysis was used as the deposition amount of $FePO_4$, and the deposition amount of each component was calculated based on the component ratios obtained. The amount of $FePO_4$ kept increasing with reaction time. On the other hand, the total deposition of iron oxide components increased up to 80 % coverage and remained almost constant thereafter. Therefore, the deposition reaction of the coating may vary with the coverage. These results suggests that the iron phosphate conversion coating is deposited by a reaction path different from the conventionally considered steel/treatment solution interface reaction.

***In-Situ* Diffraction-Based Characterization on the Topotactic Reduction of Nickelate Thin Films**WenzhengWei[1], KidaeShin[1], HawoongHong[2], YeongjaeShin[1], RobertF. Klie[3], ArashdeepS. Thind[3], YingjieYang[3], FrederickWalker[1] and CharlesAhn[1]; [1]Yale University, United States; [2]Argonne National Laboratory, United States; [3]University of Illinois at Chicago, United States

Square-planar nickelates are a novel class of superconductors, which promise to help unveil aspects about the nature of superconductivity in oxide materials. Their synthesis consists of the growth of a perovskite precursor followed by a topotactic reduction to remove apical oxygen ions. The common reduction process involves annealing in vacuum with CaH_2 powder. This *ex-situ* process is less easily amenable to *in-situ* measurements of the dynamics of square-planar nickelate formation.
To address this challenge, we develop an *in-situ* process via the deposition of metallic aluminum in ultra-high vacuum (UHV), and we demonstrate the reduction process by reducing $NdNiO_3$ thin films grown using molecular beam epitaxy (MBE). During reduction we characterize the atomic and electronic structure of this class of square planar nickelates with the *operando* X-ray diffraction facility at beamline 33 ID-E in Argonne National Lab using crystal truncation rod (CTR) and diffraction-based X-ray absorption near edge structure (dXANES). By characterizing the $NdNiO_{3-x}$ thin films dynamically during the reduction process, we show that the Ni valence and $NdNiO_{3-x}$ lattice constant can be precisely controlled at each step of the Al deposition process, while maintaining the film's epitaxy and surface morphology. The metal reduction method and *in-situ* characterization of the reaction stages is straightforward and broadly applicable to oxide reduction.
Work at Yale University was supported by the US DOE, Office of Science, Office of Basic Energy Sciences under award no. DE-SC0019211.

4:30 PM *SF02.10.08
Manipulating the Assembly and Electronic Structures of 2D Materials at the Interfaces JunLiu; University of Washington, United States

This presentation will highlight our effort to develop innovative approaches to control the assembly and electronic structures of two-dimensional (2D) nanostructured materials. Several synthetic strategies will be discussed in which interfacial energies are manipulated using functional groups on the substrate, the solvation structure, nanoscale confinement in ordered surfactant templates, the strain energy between the crystal, and the substrate and electrochemical potentials. Substrate- or interface-controlled solution synthesis is used as the platform for nucleation and assembly. Several classes of materials are investigated: (1) 2D nanosheets formed by metal oxides and metals, (2) metal chalcogenides and dichalcogenides, and (3) organic/inorganic hybrid crystals. Furthermore, a new technique is developed based on quantum capacitance measurement to provide information about the position of defect energy levels with respect to conduction and valence band edges, and the position of the Fermi level. This measurement is used to capture the evolution of the density of states (DOC) during solution synthesis and electrochemical processes. The conduction and valence band edges, defect energy levels, and features inside the conduction band are revealed in real time and under ambient conditions. The band structures and defects are correlated to the electrocatalytic properties of the 2D crystals.

SESSION SF02.11: (Bio)Mineralization

8:30 AM *SF02.11.01
Designing Interfaces Between Inorganic Crystals and *De Novo* ProteinsHarleyPyles[1,2], FatimaDavila-Hernandez[1], BiaoJin[3], AmijaiSaragovi[1], ShuaiZhang[3], SakshiSchmid[3], LiliLiu[3], JingshanDu[3], JamesJ. De Yoreo[3] and DavidBaker[1]; [1]Institute for Protein Design - University of Washington, United States; [2]University of Washington, United States; [3]Pacific Northwest

National Laboratory, United States

Hybrid materials composed of biomacromolecules and inorganic crystals have exceptional properties and fulfill critical functional requirements of the organisms that produce them. These biominerals are known to contain proteins that play roles in controlling the crystal polymorph, shape, size, and organization of the mineral constituents. However, the structural details of protein-inorganic interfaces inside biominerals remain largely unknown and are challenging to study because native biomineralization proteins are often intrinsically disordered and function within complex multi-component systems. Designing well-structured de novo proteins with surfaces that form favorable interactions with inorganic crystals has allowed us to study both how these interfaces promote adsorption and assembly of proteins on existing minerals, and how the proteins template mineral growth.
Previously, we have shown that designed helical repeat proteins (DHR) with a periodic array of side chains lattice matched to the mica surface absorbed and assembled into 2D structures at the mica-water interface. The structure of the interfacial assemblies could be modulated by adding protein-protein interfaces in addition to the protein-mica interface. The size, regularity, and stable rod-like shape of these proteins has enabled further study on the effects of solvent and electrolytes on biomolecules at the solid liquid interface and mapping of the angular energy landscape of adsorbed proteins.
Recently, we have shown that specific DHRs that contain designed periodic arrays of negatively charged carboxylate containing side chains promote the direct nucleation of the calcite polymorph of calcium carbonate (CaCO3). This bypasses the formation of vaterite which is seen in the absence of protein, in the presence of bovine serum albumin control protein, and in the presence of a DHR with a similar surface but a different distance between adjacent repeats. Mutational analysis of a protein that promotes calcite formation indicates that activity depends on sidechain stereochemistry and is not driven by charge alone. The calcite nucleating proteins also altered the post-nucleation growth mechanism from classical growth to oriented particle attachment, a mechanism often seen in natural biomineralization processes.
Currently, we are working with a new designed library of over 6.5K de novo repeat proteins displayed on the surface of yeast. These proteins have a variety of topologies and have diverse chemical groups arranged in periodic and aperiodic arrays on their surfaces. We are using a high throughput flow-cytometry (FC) assay to screen for proteins that promote the strong adsorption of inorganic nanoparticles to the yeast cells displaying them. Nanoparticle binding proteins have been selected from the library and expressed in E coli, purified, and biochemically characterized, and we are studying their effects on the growth of these materials from ionic precursors and on metallic substrates.
Overall, our research shows the potential of de novo protein design as a powerful tool for studying and manipulating the interfaces between genetically encoded proteins and inorganic crystals, offering exciting prospects for biomimetic materials synthesis.

9:00 AM SF02.11.02
Sulfated Chitosan Derivatives Modulate the Kinetics of $CaCO_3$ Nucleation by a Systematic Relationship to Interfacial Energy Barrier BrennaM. Knight[1,1,1], RonnieMondal[1], NicholasPietra[1], BradyA. Hall[1], KevinJ. Edgar[1,1,1], ValerieVaissier Welborn[1,1], LouisA. Madsen[1,1], JamesJ. De Yoreo[2,3] and PatriciaM. Dove[1,1,1]; [1]Virginia Tech, United States; [2]Pacific Northwest National Laboratory, United States; [3]University of Washington, United States

Organisms use functionalized macromolecules at sites of biomineralization to nucleate and grow diverse $CaCO_3$-organic composites as skeletal structures. Acidic groups (COO^-, SO_3^-, PO_4^{3-}) are known to impact $CaCO_3$ mineralization but systematic relationships have not been ascertained. Establishing the kinetic and thermodynamic bases for mineralization are fundamental to understanding and replicating control on crystal nucleation and growth in these settings. Of particular importance is how macromolecules in the organic matrix regulate when and where crystals grow. Thus, discerning how functional groups moderate the crystallization of sparingly soluble salts is of first order importance.
Using complimentary experimental and theoretical approaches, we first synthesize a series of tailored and characterized chitosan derivatives that present variable degrees of sulfation ($DS(SO_3^-) = 0.1 - 0.8$) and sulfate regiopositions (C_2N- or $C_{3,6}O$-). Chitosan provides a simple model for macromolecules in the organic matrix that allows us to measure the dependence of calcite nucleation rate on sulfate density and to determine how this group modulates the energy barrier to crystallization. By quantifying the rate of $CaCO_3$ nucleation onto these materials over a range of supersaturations using established methods, we show rates increase with supersaturation as predicted by classical nucleation theory (CNT). Rates of nucleation onto materials with increasing $DS(SO_3^-)$ exhibit a stronger dependence on supersaturation, indicating a higher energy barrier to nucleation. Fitting the CNT model to the data, we demonstrate the interfacial energy barrier (γ_{net}) to calcite nucleation correlates with sulfate density by a systematic dependence that is independent of sulfate regioposition.
We propose that sulfate density creates an increasingly hydrophilic, negatively charged environment at the polysaccharide-water interface to increase γ_{net} through reductions in $\gamma_{substrate\text{-}water}$. Such an environment would also promote Ca^{2+} interactions with sulfate, possibly at the expense of carbonate.
To test this idea, we conduct a molecular dynamics (MD) study of sulfated chitosan chains that also have varying degrees and positions of sulfation. Each type of polymer is placed in a simulation cell populated with water, $NaHCO_3$, and $CaCl_2$. Polymer equilibrium conformation is first established on GROMACS using a non-polarizable forcefield, following which molecular dynamics simulations are run under a polarizable AMOEBA force field. The trajectory obtained is used to calculate the time-averaged radial distribution functions (RDFs) to ascertain proximity between atoms of interest.
As predicted, the MD simulations show the average S-Ca distance decreases with $DS(SO_3^-)$, indicating stronger Ca-S interactions in the increasingly hydrophilic environment. This is supported by a reduction in the average hydration number of Ca^{2+} in the N-sulfated and O-sulfated environments of 12.5% and 25%, respectively, compared to the bulk value (8) and by the significantly higher water density about SO_3^- groups compared to uncharged substituents. The findings from these combined experimental and theoretical methodologies suggest the potential to design biomaterials with localized regions of high/local activity and control crystal placement at near-molecular resolution for advanced applications.

9:15 AM SF02.11.03
Spatially Controlled Supersaturation of Calcium Phosphate for Controlled Crystal Nucleation and Self-Healing Precipitates MohsinJ. Qazi, RenaFukuda and NateJ. Cira; Cornell University, United States

Crystal nucleation and growth are widely studied phenomena due to their relevance to a range of disciplines including material science, process engineering, and biology. In order to obtain desirable crystal forms or crystallization dynamics, it is essential to tune parameters like nucleation time, nucleation rate, and growth rate. Supersaturation of material in the crystallizing solution is the first step in the crystallization process, and impacts all these parameters, hence controlling supersaturation is crucial to controlling the overall process of crystallization (1). Some common methods to achieve supersaturation include subjecting a solution to: evaporation, cooling (for materials with temperature-dependent solubility), the addition of antisolvents, and pH change (for materials with pH-dependent solubility). These methods typically result in supersaturation within the primary solution. However, in some systems such as biomineralization or studies probing nucleation dynamics, nucleation is required at specific locations, often outside the region where the primary solution composition can be easily actively controlled. This motivates the development of strategies to create localized supersaturated conditions.
In this study, we present a straightforward approach that enables spatially controlled deposition of precipitated material between two primary solutions (2). Our experimental setup focuses on calcium phosphate (CAP) as a prototypical system, taking advantage of its pH-dependent solubility. By connecting two saturated solutions at different pHs using a gel that allows ion diffusion, we establish a concentration gradient along the gel. The diffusion and reaction of H^+ and OH^- create a characteristic pH profile along the length of the gel, causing the diffusing calcium and phosphate to become supersaturated and precipitate. Over time, the precipitated band grows denser and forms a barrier that restricts further transport through the gel. We show how this band spontaneously recovers from perturbation, automatically resealing any damage. In addition to experiments, we perform quantitative analysis taking into consideration the diffusion dynamics of all the relevant ions, chemical equilibria, and reaction parameters, to predict the location of the precipitated bands. This work provides a simple physical strategy for creating self-healing precipitates that may be useful in civil engineering, restorative dentistry, and enhancing our understanding of mineral deposit formation in the abiotic and living world.

Nucleation and Growth of Minerals on Self-Assembled Monolayers VeselinaMarinova, StephenYeandel, VittoriaFantauzzo, ColinFreeman and JohnH. Harding; University of Sheffield, United Kingdom

Minerals are frequently grown in water-based systems in both nature (biomineralisation) and industry. The water may stabilise the interface and potentially hinder or aid the flow of ions to the interface and their attachment. The behaviour of water at these growing interfaces is therefore very important as it will often govern the growth dynamics. Self-assembled monolayers (SAMs) have long been used as substrates and/or templates for the growth of minerals [1] and as model systems for biomineralisation [2]. These organic systems provide arrays of organised head groups that can be functionalised and positioned to generate patterns and specific charge densities. How the water and ions within the solution organise at this interface is very important if we are to understand the nucleation and subsequent growth of minerals at this interface.

We explore a range of models to obtain surface ion concentrations from the simple Gouy-Chapman approximation to the Poisson-Boltzmann equation through to full solutions of the Grahame equation [3,4] including the effects of speciation and changes in activity as a function of local species concentrations. Explicit all atom simulations [5,6] are used to examine the organisation and distribution of ions at these interfaces. Use of a constant chemical potential ensemble [7] allows us to examine the effects of different ionic concentrations using atomistic simulations and so compare results with those obtained using the continuum Poisson-Boltzmann approaches.

We find that certain defects in the SAM structure, which we refer to as active defects, can impair ionic surface diffusion, as well as affect the diffusion of ions in close proximity to the surface feature in question. Our findings suggest that this effect can allow such topological features to promote ion clustering and increase local ionic concentration at specific surface sites. The work reported here shows how the presence of small atomic-scale defects can affect the role of a surface in the process of heterogeneous nucleation. We discuss the importance of SAM structures and the solution conditions at the interface on the efficacy of these monolayers as nucleating agents.

Molecular Interaction Forces at Mineral-Electrolyte Interfaces: Insights from AFM Spectroscopy FriederMugele; University of Twente, Netherlands

Colloidal self-assembly and aggregation are controlled by molecular scale interaction forces across (sub)nanometric films of an ambient fluid, often thin water layers of variable salt content and pH. In this lecture, I will give an overview over insights that we have gained using *in situ* Atomic Force Microscopy (AFM) measurements on the structure of the electric double layer and the resulting nano-scale interaction forces. I will discuss aspects of ion adsorption, hydration, and electrostatic forces for a variety of systems ranging from clay minerals to semi-conducting nanoparticles. In particular, I will illustrate the potential of operando-AFM for the characterization of photocatalytically active materials with a specific focus on facet-dependent surface charges and their role for the separation of photogenerated charge carriers.

10:45 AM SF02.11.06
Revealing the Molecular Forces that Stabilize Surface Precipitates of Hydroxides by Three-Dimensional Atomic Force Microscopy MingyiZhang[1], BenjaminA. Legg[1], YounjinMin[2] and JamesJ. De Yoreo[1,3]; [1]Pacific Northwest National Laboratory, United States; [2]University of California, Riverside, United States; [3]University of Washington, United States

Surface charging of solid-liquid interfaces plays a critical role in various chemical processes, such as ion adsorption, particle aggregation, crystal nucleation and growth. Recent work indicates that surface charging can drive the formation of complex laterally ordered surface structures. However, the properties of the resulting heterogenous charge distributions (and their associated electrical double layer structure) are still poorly understood. Modern atomic probe microscopy offers a promising tool for investigating the behaviors at heterogeneously charged surfaces. In situ high speed atomic force microscopy enables directly imaging of the motion of surface adsorbates at molecular scales; while three-dimensional fast force mapping (3D FFM) allows us to track the tip-sample interaction forces above the surface, aiding in the interpretation of surface charging phenomena through DLVO theory.

Here, the adsorption behaviors of multivalent cations (Mg^{2+} and Al^{3+}) on muscovite mica has been studied by atomic force microscopy across a range of pH values. At mild pH values, two-dimensional hydroxide films form whose morphology depends on the ion type. For the divalent Mg-hydroxide, it tends to form monolayered large continuous film. For the trivalent Al-hydroxide, it forms monolayered films with a persistent network of gaps, combining positively charged hydroxide islands and negatively charged bare mica regions, which is inconsistent with the prediction of the classical crystal growth model; at even higher pH values, multi-layered gibbsite film growth has been observed, with the upper layers exhibiting similar behavior to Mg hydroxide films that form large continuous sheets. At low pH conditions, it is feasible to image individual ions and clusters and see how the adsorbate populations change with pH. At a pH immediately preceding film nucleation, these ions reveal complex lateral ordering that are controlled by the interplay between ion/ion interactions and ion/substrate interactions.

The links between ion-ordering, film structure, and local surface charge were investigated by using 3D FFM and complementary streaming potential measurements. The results indicate that the coverage and structure of the surface precipitates are strongly influenced by the charged substrate. Also, Al-hydroxide films are more strongly charged than Mg-hydroxide films, supporting the hypothesis that the hydroxide nanostructure is stabilized by electrostatic interactions between positively charged film and negatively charged substrate. The work exemplifies the importance of surface charge in crystal nucleation, while also offering valuable insights on how electric fields can be utilized to control crystallization processes.

The Impact of Local Structure and Dynamics on the Free Energy of Aqueous Mineral Interfaces StephenYeandel, VeselinaMarinova, EmmaArmstrong, ColinFreeman and JohnH. Harding; The University of Sheffield, United Kingdom

The strong interactions between mineral ions and water molecules can profoundly alter the structure and properties of water molecules at aqueous interfaces[1]. Strong ordering produces density fluctuations, particularly for very flat interfaces (such as mica and calcite)[2]. Diffusion rates of water molecules are greatly reduced from the bulk, leading to the hypothesis that ice-like structure is present. The water often stabilises the mineral surface and configurational interfacial energies obtained from classical molecular dynamics simulations are used to interpret this, even though this ignores entropic effects. Our new methods for calculating interfacial free energies[3], based on using Einstein crystals as a reference state, demonstrate that these effects contribute significantly to the thermodynamics of these interfaces and cannot be ignored.

In this work we examine the aqueous surfaces of calcium sulphate (gypsum, bassanite) and calcium carbonate (calcite, aragonite). We explore the structure and dynamics of water at these interfaces and quantify the enthalpic and entropic contributions to the total free energy. New insights into the competing growth mechanisms of different polymorphs may also be obtained[4]. We will also discuss effects due to the presence of solute ions close to the interface which can alter the activity of interfacial water, induce electrical space charge layers or change the relative stability of different surfaces by disrupting the ordering of the solvent. Our simulations will examine the potential mechanisms of attachment at these surfaces and how the interfacial energy and solution affects these growth processes.

Modeling of Interfacial Growth and Structural Processes and Dynamics of sII Gas Hydrate Systems using Molecular Dynamics and Geometric Techniques SamuelMathews, AndreGuerra, PhillipServio and AlejandroD. Rey; McGill University, Canada

Gas hydrates are inclusion compounds comprising a backbone of water molecules that enclose guest molecules in separate cages. Each volume of hydrate contains 160 volume equivalents of gas. Initially, large scale gas hydrate research was centered around the flow assurance problems they cause in the extraction and transportation of petroleum and its derivatives. Naturally occurring gas hydrates are also studied to satisfy global energy demand: estimates put the total energetic capacity of hydrate reserves at twice that of other fossil fuel reserves combined. Their potential use in the removal of carbon from the atmosphere, carbon capture and storage, and for energy exploitation makes gas hydrates a prime candidate for climate change mitigation research. Characterizing the interfacial properties of a material that requires intense formation conditions and sublimates rapidly in standard atmosphere is experimentally challenging. Controlling sample purity and system homogeneity is often difficult in devices designed to measure interfacial properties. It is also costly to properly clean apparatus after using additives to study new ones. Finally, rapidly testing different guest molecules, external pressures, surface effects, and extracting meaningful, fundamental information about the atomic and molecular interfacial behaviors is nearly impossible without critical sample disruption. This work uses molecular dynamics as implemented in the Large-scale Atomic/Molecular Massively Parallel Simulator to characterize the temperature and pressure effects on the interfacial tension, energy of interfaces, and growth rate of natural gas hydrates to overcome the complexity of experimentally understanding their performance in extreme environments and prove that theoretical modeling, prediction, and advanced characterization techniques can explain the structural and transport properties that govern hydrate in engineering applications. This project studies the impact of the surface coverings and additives on surface energy, attachment strength, and creation of new nucleation sites in sII gas, and examines the thermal transport across the hydrate/water, hydrate/gas, and hydrate/ice interfaces by calculating the thermal conductivity across the interface. This project also uses geometric analysis techniques to understand the dynamic behavior of the crystalline interfaces, including what specific polyhedral faces tend to face the melting phase and what type of pre-melting dynamics and interfacial thicknesses exist in these systems. It is essential to understand the underlying mechanisms occurring at the molecular level and the nanoscopic behaviors leading to macroscopic properties, thereby clarifying behaviors and phenomena that dominate potential applications of these structures. Our work has shown that there is excellent agreement between sI methane hydrates and experimental values, as well as for sII natural gas hydrates. The hydrates nucleate preferentially with film-shaped

nucleation, then cap-shaped, lens-shaped, and homogeneous nucleation. We have confirmed the presence of a novel pre-melting layer at the interface between the structures. We have been able to produce temperature and pressure correlations of surface tension for engineering applications. The excess entropy, adsorption, radial pair distribution function, and charge distribution at the interface were calculated to confirm our findings. The molecular dipole at the interface indicates novel organization of molecules that affects further nucleation and governs the use of surface coverings and additives to control behavior. The interfacial thickness has been characterized to show interface expansion and contraction at certain conditions, as well as showing the fine atomic phenomena that are at play in controlling macroscale properties.

Towards a Holistic Chemistry of Metal-Organic Framework Formation HamishH. Yeung; University of Birmingham, United Kingdom

Metal–organic frameworks (MOFs) have established themselves as fantastic materials for fundamental studies and potential applications alike, owing to the almost limitless possibilities that different combinations of metal ion-based nodes and organic linkers offer. Synthesis is typically simple, in the sense that new MOFs can be discovered in one-pot reactions close to ambient conditions within a matter of minutes or hours. However, behind such simplicity lies a great lack of understanding of how MOFs form and why particular phases crystallise under different conditions or even under (seemingly) the same conditions.

Our group has been working to better understand MOF formation using model systems such as the canonical zeolitic imidazolate framework (ZIF) family of MOFs. Although topologically similar to zeolites, relatively few ZIFs have been discovered compared to their inorganic counterparts. Better understanding of the chemistry that underpins self-assembly of metal ions and linkers into ZIFs would enable us to create materials, for example with new topologies or with more precisely positioned functionalities for improved performance in separations, sensing, gas storage and other applications.

A combination of systematic studies, in-situ monitoring and kinetic modelling has enabled us to develop a chemical understanding of phase behaviour, crystallisation rates, particle sizes and reaction yields in two particular hybrid systems: lithium tartrates[1] and zeolitic imidazolate frameworks.[2] This presentation will describe some of our ongoing work in the area, looking into synthetically relevant parameters such as reagent concentration, solvent and pH, and more complex systems such as mixed-metal[3] and core-shell[4] particles.

11:30 AM *SF03.01.03
Inelastic Neutron Scattering Applied to Porous Materials AnibalJ. Ramirez-Cuesta; Oak Ridge National Laboratory, United States

Neutron scattering is uncommon and rare because there are only a handful of places worldwide where it is possible to perform the required experiments. The Spallation Neutron Source at ORNL in East Tennessee is the most advanced pulsed neutron source. The interaction of neutrons with the nuclei provides unique information on light elements (like hydrogen). It distinguishes between neighboring elements and isotopes, complementing X-ray capabilities and photon-based techniques.
In the case of Inelastic Neutron Scattering (INS), the technique is the neutron analog of Raman and infrared spectroscopies. Instead of using photons as the probing beam, a neutron beam illuminates the sample.
The penetrating power of neutrons means that with the adequate selection of materials, it is possible to build sample environments that can manage extreme conditions in pressure and temperature without the need for optically transparent windows—giving the technique much versatility. Gas handling experiments are trivial. The main disadvantages of INS are: that measurements usually require cryogenic temperatures, the neutron fluxes are low when compared with photons, and accessing neutron scattering facilities is challenging.
Atomistic computer modeling, particularly DFT, molecular dynamics, etc., is routinely used to interpret and analyze experimental results. The interplay of atomistic modeling and experimental data is unique and allows access to a precious insight into the mechanistic interpretation of the data.
Porous materials have space voids where it is possible to adsorb molecules. Traping these molecules to "store" them or sometimes react chemically is used in many applications.
This paper will present examples of INS spectroscopy applied to small molecule adsorption on porous materials, from zeolites to metal-organic frameworks, highlighting the unique information the technique provides and how computer models are essential to interpret the data.

SESSION SF03.02: MOFs and Porous Systems II

Computational-Aided Development of MOF Sorbents and Membranes for Molecular Adsorption/Separation GuillaumeMaurin; Université Montpellier, France

Metal-Organic Frameworks (MOFs) are an emerging class of porous solids for the selective capture of contaminants in a wide range of applications. The number of crystal structures is growing exponentially and they cannot be all tested experimentally for a given application. Computational High-throughput screening is therefore required to narrow down the best sorbents. This lecture will deliver our latest achievements in this field with typical illustrations. In another perspective, Mixed matrix membranes (MMMs) incorporating MOFs into polymeric matrices show promising properties for several key gas separation processes. Understanding of the MOF/polymer interface and gas transport through the MMMs is of utmost importance. Here, we selected a series of MOFs as fillers in conjunction with both rigid and flexible polymers and we deployed our in-house computational strategy to construct MOF/Polymer atomistic models and assess their thermodynamic and dynamic adsorption properties. This computational screening revealed that the distinct characteristic of polymer backbones and MOF surfaces results in different interfacial pore structuring. We evidenced that not only size but also shape of the interfacial pore region has eminent effects on the gas transport properties of the MMMs with respect to a selected range of molecules. This conclusion is an important step toward the rational design of MMMs with the optimal interfacial pore size/shape to achieve the best performance for molecular separation

1:45 PM SF03.02.02
(111)-Oriented Thin Film Fabrication of Metal–Organic Framework HKUST-1 on Insulating Glass Substrates by Combining Vacuum Deposition and Solvent Vapor Annealing ShuntaIwamoto[1], RyoNakayama[2], SeoungminChon[1], RyotaShimizu[2] and TaroHitosugi[2]; [1]Tokyo Institute of Technology, Japan; [2]The University of Tokyo, Japan

Metal–organic frameworks (MOFs) are crystalline porous materials composed of metal ions and organic ligands. Many reports have described the synthesis of oriented MOF films with high crystallinity and flatness by liquid-phase processes such as layer-by-layer method. Liquid-phase methods often require modification of the substrate surface with self-assembled monolayers, and there is a risk of corrosion and contamination of the interface by the solution. By contrast, synthesis by physical vapor deposition is suitable to prevent the degradation caused by solvents and is advantageous for the fabrication of well-defined interfaces and easy patterning for further device fabrication. Until now, oriented thin films of two-dimensional MOFs were fabricated on insulating substrates by physical vapor deposition[1]. However, the oriented three-dimensional MOF films have only been synthesized on metal surfaces[2], and never on insulating substrates by physical vapor deposition.

In this study, we report the fabrication of (111)-oriented thin films of a three-dimensional-MOF HKUST-1[3] ($[Cu_3(BTC)_2]$, BTC = 1,3,5-benzenetricarboxylate) on insulating glass substrates by combining vacuum deposition and annealing in acetic acid vapor. HKUST-1 is expected for device applications because of the tunability in ionic and electronic conductivities by introducing molecules into the pores. We utilized two-step processes for the HKUST-1 thin film fabrication. First, trimesic acid and copper(II) acetate thin films were deposited on the glass substrates as a precursor. Second, post-deposition annealing was performed in air and an acetic acid atmosphere. While the thin film annealed in air showed no peaks corresponding to HKUST-1 in the out-of-plane X-ray diffraction (XRD) pattern, the thin film annealed in acetic acid vapor showed 111, 222, and 333 diffractions, indicating (111)-oriented HKUST-1 films were successfully synthesized on the glass substrate. These results suggest that annealing with the acetic acid vapor facilitates the precursor diffusion and the solid-phase reaction to form HKUST-1 crystals.

Using MOF Bullets and Compressed Gases to Control the Release of DNA, Proteins and Lipid Nanoparticles into Plants and Skin JeremiahJ. Gassensmith; University of Texas-Dallas, United States

The demand for effective and specific drug delivery systems has driven the popularity of protein, DNA, liposome, and RNA-based drugs in clinical applications. However, their administration through injections poses challenges, such as the need for skilled medical personnel and the generation of biohazardous waste. This lecture will present an innovative approach to achieve controlled delivery of these biomolecules and lipid-based nanoparticles using Zeolitic-Imidazolate Framework-8 (ZIF-8) as a carrier. By encapsulating the biomolecules within ZIF-8, we demonstrate their stability in powder formulations and introduce a low-cost, gas-powered "MOF-Jet" delivery system for inoculating living animal and plant tissues.

Our investigations reveal that the release profiles of the encapsulated biomolecules can be modulated by selecting an appropriate carrier gas for the MOF-Jet. Utilizing carbon dioxide (CO_2) creates a transient and weakly acidic local environment, resulting in near-instantaneous release through ZIF-8 dissolution. On the other hand, employing air as the carrier gas allows for the slow biodegradation of ZIF-8, enabling a week-long release of the biomolecules. This pioneering study establishes the first example of controlled-biolistic delivery of biomolecules using ZIF-8, providing a powerful tool for fundamental and applied science research.

In addition to biomolecules, we explore the application of biolistic delivery as an alternative route for liposome and lipid nanoparticle delivery. Using this same methodology, I will discuss how we can deliver fragile liposomes into the skin using ZIF-8 as a protective nano-sized shell. The rigid and crystalline coating of ZIF-8 shields the liposomes from thermal and shear stresses, ensuring the preservation of cargo integrity and facilitating lyophilized powder formulation for room-temperature storage. By encapsulating liposomes in ZIF-8, we demonstrate enhanced mechanical protection, allowing for effective penetration into the skin. Through our experiments, we successfully coat liposomes with ZIF-8, ensuring the preservation of surface charges and enabling easy removal of the protective coating without causing damage to the encapsulated material. Furthermore, the protective coating prevents cargo leakage and facilitates efficient penetration of liposomes into agarose tissue models and porcine skin tissue.

This lecture presents an innovative approach to achieve controlled delivery of biomolecules, liposomes, and lipid nanoparticles using Zeolitic-Imidazolate Framework-8 (ZIF-8) as a carrier. By encapsulating the biomolecules within ZIF-8, their stability in powder formulations is demonstrated, and a gas-powered "MOF-Jet" delivery system is introduced for inoculating living tissues. The rigid and crystalline coating of ZIF-8 preserves cargo integrity and enables effective penetration, demonstrating its potential for improving drug delivery strategies.

Thermally Accelerated Alkali-Proton Exchange by Molten Long Chain Fatty Acids Toward Ceramic Electrochemical Cells AkihiroIshii, DaisukeKume, ItaruOikawa and HitoshiTakamura; Tohoku University, Japan

Ceramics with high proton conductivity and stability are essential for efficient electrochemical cells, such as fuel cells and electrolyzers. Protonic ceramics that exhibit 1) high proton conductivity at intermediate temperatures (300–600°C), 2) high chemical stability against CO_2, H_2O, and electrode materials, and 3) no practical difficulties for synthesis, are especially of interest for practical applications. Currently, two well-known classes of the protonic ceramics exist: solid oxyacids that exhibit high proton conductivity but decompose at relatively low

temperatures (≈ 200°C) as being dehydrated (e.g. $CsHSO_4$ derivatives), and perovskite-type refractories that are stable even in dehydrated state but show high conductivity only at high temperatures above 600°C (e.g. $BaZrO_3$-$BaCeO_3$ derivatives). Although efforts to develop thermostable oxyacids and perovskite-type refractories showing high conductivity at the intermediate temperatures have been energetically continued, the protonic ceramics meeting the three properties required for the electrochemical applications have not been developed.

As a new class of protonic ceramics, alkali-proton-exchanged ceramics have been gradually gained attention, and some ceramics in this class (e.g. $Li_{13.9}Sr_{0.1}Zn(GeO_4)_4$ and $Li_{2.5}Sr_{0.75}Zr_{1.25}(PO_4)_3$) have been suggested to show high proton conductivity and stability. Compared to the perovskite-type materials, the ceramics in this class are believed to exhibit less current leakage by electron holes under high oxygen potential due to donor doping and the incorporation of protons through means other than oxygen vacancy hydration. However, proton conductivities of the alkali-proton exchanged ceramics have consistently been observed for only a very limited number of systems, such as β/β"-alumina and $Li_5La_3M_2O_{12}$ (M = Nb, Ta, Sn). This is considered to be due to the difficulty of exchanging alkali for protons throughout dense ceramic bodies by a traditional ion-exchange techniques, which involve immersing the alkali ceramics into aqueous acid solutions. The use of water limits alkali-proton exchange processing temperatures to below 100°C, thereby restricting the thermal acceleration of mass diffusion, and usually, only porous or powder-form alkali ceramics are applied.

To overcome this challenge, here, we propose a new but simple method to synthesize the dense alkali-proton-exchanged ceramics using molten long chain fatty acids heated above 100°C. A homemade reaction vessel were developed for stable, uniform, and efficient ion exchange using fatty acids at high temperatures. A case study on Al-stabilized cubic garnet-type $Li_7La_3Zr_2O_{12}$ (LLZ) shows that the alkali-proton exchange occurs more than 300 µm deep throughout LLZ dense bodies under optimum conditions, and 91 % exchange can be achieved with only 8 h of treatment. The conductivity of the proton-exchanged LLZ and its potential for the applications will be discussed with DFT calculations.

Smart and Programmable Crystalline Sponges for Separations OmarK. Farha; Northwestern University, United States

This talk will focus on metal–organic frameworks (MOFs) from basic research to implementation and commercialization. MOFs are a class of porous, crystalline materials composed of metal-based nodes and organic ligands that self-assemble into multi-dimensional lattices. In contrast to conventional porous materials such as zeolites and activated carbon, an abundantly diverse set of molecular building blocks allows for the realization of MOFs with a broad range of properties. We have developed an extensive understanding of how the physical architecture and chemical properties of MOFs affect material performance in applications such as separations of hydrocarbons.

3:45 PM *SF03.02.06
MOFs for Indoor Contaminants Capture and Detection—A Combined Experimental-Computational Strategy SabineDevautour-Vinot[1], PedroBrantuas[1], PaulIacomi[1], EzgiGulcay[1,2], GuillaumeRioland[2] and GuillaumeMaurin[1]; [1]ICGM, France; [2]CNES, France

Volatile organic compounds (VOCs) are recognized by the World Health Organization (WHO) as one of the major pollutants contributing to the deterioration of indoor air quality. They are generated from construction and finishing materials (paints, wallpapers, floor covering, glue…), burning processes, cleaning and preservation substances. Their emissions, even at low concentration levels in indoor air, pose threats to both human health and sensitive machinery. Therefore, the detection and abatement of airborne contaminants traces (ppb to ppm) is an ongoing challenge for maintaining a clean and safe environment in living and working places, but also in regulated spaces, such as clean rooms, spacecraft or satellites.

In this context, porous solids like MOFs (Metal-organic Frameworks) appear as promising materials due their tailorable chemical and physical properties and highly porous structures, acting as sorption media for direct air capture of contaminants,[1] or as components in electronic devices designed for monitoring concentration of contaminants.[2] Nevertheless, given the large number of synthesizable frameworks [3] the choice of a material to target a specific contaminant is more often than not a question of serendipity.[4]

To overcome this limitation, a hand-in-hand computational/experimental approach is herein devised for screening and identifying the best MOFs for the adsorption of specific VOCs contaminants. This method combines high-throughput molecular simulations to identify key promising materials, followed by advanced adsorption experiments at very low contaminant concentrations and sensing tests. We further detail several classes of MOF materials which were identified through this approach that are applicable to the capture and/or the detection of contaminants of interest in the aerospace domain, including aromatics and more challenging substances such as siloxanes and phthalates.[5]

4:15 PM SF03.02.07
Defects and Nonlinear Infrared Intensity Behavior in UiO-67 Metal Organic Frameworks RyanP. McDonnell[1,2], Venkata Swaroopa DattaDevulapalli[2], Tae HoonChoi[3], LauraMcDonnell[2], IsabellaGoodenough[2], PrasenjitDas[3], NathanielL. Rosi[3], J.K. Johnson[3] and EricBorguet[2]; [1]University of Wisconsin–Madison, United States; [2]Temple University, United States; [3]University of Pittsburgh, United States

A major interest in the use of Metal Organic Frameworks (MOFs) is the simultaneous capture and destruction of toxic chemicals and chemical warfare agents. Catalysis typically occurs at defect sites in the MOF crystallite. An unexplored avenue for defect formation in UiO-67 MOFs is through temperature activation. Herein, we use a combination of Fourier transform infrared spectroscopy and density functional theory (DFT) techniques to understand the impact of thermal activation on the concentration and strength of Lewis acid defects (Zr^{4+} sites) in UiO-67. Ultra-high vacuum methods are employed to eliminate atmospheric contaminants. We devise a new method to allow vibrationally active probe molecules to diffuse through the MOF and preferentially adsorb to internal sites, providing insight into the structure and properties of internal MOF sites. Through the use of CD_3CN, whose ν(CN) mode is Stark active, and DFT calculations, we assign the presence of three distinct Lewis acid sites which evolve as a function of pretreatment temperature. Following dehydroxylation at 623 K, the Lewis acidity of the MOF appears to increase in both concentration and strength through the loss of capping groups. We additionally show that following CD_3CN diffusion into UiO-67, the intensities of the ν(CD) and ν(CN) modes depict nonlinear intensity behavior, complicating the interpretation of diffusion kinetics through UiO-67. Through DFT calculations, we observe that hydrogen bonding of CD_3CN to μ_3-OH groups in UiO-67 significantly decreases the transition dipole moment of the ν(CD) modes, while increasing that of the ν(CN) mode. These results highlight the importance of careful infrared spectra interpretation, as well as the propensity for thermal activation to increase the density and strength of Lewis acid sites.

4:30 PM SF03.02.08
Photocatalytically Active Metal Organic Frameworks for Toxic Chemical Degradation GwendolynHouser[1], AbigailBugg[1], EmmalinePendleton[1], SamrathSingh[1], AnnKulisiewicz[2], JaredDecoste[2], BryanLagasse[1] and ChiNguyen[1]; [1]United States Military Academy, United States; [2]U.S. Army Combat Capabilities Development Command - Chemical Biological Center, United States

Metal Organic Frameworks (MOFs) are incredibly versatile porous materials capable of degrading many toxic chemicals. By incorporating organic linker molecules that are photocatalytically active into the MOF it is possible to achieve multiple pathways of degradation. Pyrene based linker molecules, such as 1,3,6,8-tetrakis (para-benzoic acid) pyrene (TBAPy) are photocatalytically active when exposed to ultraviolet light and produce singlet oxygen in solution. The highly reactive singlet oxygen molecules then react with toxic species in solution and degrade them into less toxic molecules. This work focuses on determining the efficiency of the photocatalysis reaction for degrading toxic and persistent chemicals, such as pesticides in aqueous solutions.

4:45 PM SF03.02.09
Long-Term and Selective Release of Agrochemicals Supported in Porous Materials RaffaeleRicco; Asian Institute of Technology, Thailand

Agrochemicals (e.g., fertilizers, pesticides, growth hormones, etc.) are essential to meet the global need for food, both quantitatively and qualitatively, but their unsafe, unselective, and repeated administration pose environmental, health, and economical threats. Researchers are looking into ways to increase agricultural production, simulataneously aiming at the reduction of pesticide wastes. In this regard, delivery methods based on Metal-Organic Frameworks (MOFs) are recently gaining consideration in agricultural applications. Previous studies have already been performed on Cu-based MOFs (e.g., HKUST-1) as delivery agents in the agricultural sector. Moreover, the use of Copper salts is already established (e.g., $CuSO_4$ as fungicide), and it is also an essential element for plants, therefore showing a dual nature of nutrients and pesticides.
This communication reports the fabrication of HKUST-1 via a convenient one-step procedure involving the utilization of basic copper carbonate (BCC), a natural component of the minerals

malachite or azurite, with and without guest species like fertilizers (e.g., Urea), growth regulators (e.g., Gibrerelic Acid), insecticides (e.g., Imidacloprid), and fungicides (e.g., Mancozeb and Propineb). The encapsulation capacities and long term release profile of the aforementioned guest@HKUST-1 systems under different simulated soil parameters of pH, temperature, and salinity, as well as exposure to environmental conditions, are also evaluated.

SESSION SF03.03: Poster Session I

8:00 PM SF03.03.01
Medium-Range Order Structure Controls Thermal Stability of Pores in Zeolitic Imidazolate Frameworks RasmusChristensen, YossiBleile, SørenS. Sørensen, ChristopheBiscio, LisbethFajstrup and MortenM. Smedskjaer; Aalborg University, Denmark

Metal-organic framework (MOF) glasses have multiple potential applications as they combine advantages of traditional glasses with those of MOFs. The melt-quenching process used to form MOF glasses typically leads to a significant decrease in porosity, but the structural origin of this thermally-induced pore collapse remains largely unknown. Here, we study the melting process of three zeolitic imidazolate frameworks (ZIFs), namely ZIF-4, ZIF-62, and ZIF-76, using ab initio molecular dynamics (MD) simulations. By analyzing the MD data using topological data analysis, we show that while the three ZIF systems exhibit similar short-range order structural changes upon heating, they exhibit significant differences in their medium-range order structure. Specifically, ZIF-76 retains more of its medium-range order structures in the liquid state compared to the other glass-forming ZIF systems, which allows it to remain more porous than ZIF-4 and ZIF-62. As such, our results may aid in understanding what structural features govern the ability to maintain porosity in the melt-quenched glassy state.

Insight into The Barocaloric Potential of Fumarate-Based MOFs: A Computational Study of Dynamic Disorder Chi Cheng (Cecilia)Hong, ClaireHobday and AntoniaMey; University of Edinburgh, United Kingdom

As the effects of climate change become more apparent in the form of rising global temperatures, the necessity for temperature control become more significant.[1] Current refrigerants operate by undergoing continuous cycles through a vapour-liquid phase change. However, these liquids have a high global warming potential with potencies exceeding 2000 times of that of CO_2 when evaporated during disposal.[2] A greener alternative is a solid-state approach via barocaloric materials which exhibit large adiabatic temperature and isothermal entropy changes upon compression and decompression cycles.[3] Several classes of materials have shown potential for the barocaloric effect such as plastic crystals but to compete with the efficiencies of current refrigerants, the magnitude of pressure required must be reduced.[4]

Metal-organic frameworks (MOFs) are porous, periodic, and crystalline materials that are highly modular due to the many metal and linker combinations possible. Though largely studied for their adsorption properties, several MOFs have been reported to exhibit a *breathing effect* where large volume changes were observed as a result of pressurising the MOFs with and without guest molecules.[5] Hence, they have been recognised as potential barocaloric materials with the most well-known being MIL-53(Al) which has 1,4-benzenedicarboxylates (BDC) as the linkers reporting a colossal entropy change of 311 $J\ K^{-1}\ kg^{-1}$ under 16 bar of carbon dioxide gas.[6] The ability to accommedate large volumes changes has been assoisated with the inherent flexibilities within the ligand that acts as the linker, therefore, this work turns to fumarate linkers which are dicarboxylates like the BDC with a torsional double bond in the centre. Studies on the barocaloric performance of an aluminium-centred fumarate MOF was found to exceed that of the BDC-analogue, making this family of MOFs ideal candidates for further investigation.[7]

This research aims to develop further understanding towards fumarate-based MOFs, in particular, the gallium analogue to the fumarate-linked MIL-53(Al) and determine whether they exhibit the barocaloric effect by first using *ab initio* that can act as a benchmark for future studies. Using machine learning potentials, a classical force field can be derived from the *ab initio* data which in turn eases the cost and greatly increase the data output. Studying the correlation between structural changes, thermodynamic properties, and the dynamics of the MOFs at varied pressures and temperatures, determines the barocaloric potential which will ease future research in the discovery of novel barocaloric materials.

Rational Synthesis of Zeolites from Single-Source Molecular Precursor with Secondary Building Unit-Like Core Structure AkiraImaizumi, YurikaOhnishi, ArisaShimamura, AkinoriHonda and Ho-CholChang; Chuo University, Japan

Zeolite is an important material widely used in ion exchangers, adsorbents, and gas separation membranes. Many aluminosilicate zeolites have been synthesized by hydrothermal, solvothermal, and solid-phase methods using monomeric or polymeric Al and Si sources, such as alkoxides, fly ash, and kaolinite, in the presence of acids, bases, and structure-directing agents. In recent years, topotactic reactions have been developed to expand the structure from a two-dimensional layered precursor to a three-dimensional structure, and methods to design the structure of the target aluminosilicate have been developed, such as synthesis in which the position of Al atoms in the zeolite can be controlled by additives. Since control of the composition and structure of the target aluminosilicate is expected to enable control of functions, further development of rational structure construction methods based on the composition and structure of the starting materials is an urgent task. Therefore, the use of structurally and compositionally well-defined molecular precursors (MPs) would be reasonable starting materials by connecting their core frameworks. In this presentation, we demonstrated in detail the synthesis of aluminosilicate using molecules with secondary building unit (SBU) -like core structure as MP. Hydrothermal reactions of SBU-like MP without additives gave no insoluble product. On the other hand, the hydrothermal reactions of SBU-like MP with alkali metal cation afforded the zeolite that can be constructed by the core structure of the MP. It should be noteworthy that the hydrothermal reactions using separated Al and Si sources at the same Si/Al ratio, alkali metal cation content, and temperature resulted in several zeolites which could not be constructed by linking the MP core structure. These zeolites are known to be thermodynamically more stable than the zeolite synthesized by the SBU-like MP, and form at higher temperature and higher base-content conditions. These results suggest that the structure of the starting materials has an important influence on the construction of the product structure, and that the resulting structure is constructed through a kinetic process different from conventional methods. The use of MPs is expected to be a novel and promising method for rationally construction of inorganic material, and obtain structures that cannot be constructed by using conventional precursors.

Pushing Lithium-Sulfur Batteries Towards Practical Operation Through Cathode-Electrolyte Interplay and Interlayer Development ChenZhao and GuiliangXu; Argonne National Laboratory, United States

The practical application of lithium-sulfur (Li-S) batteries is still hindered by the sharp capacity fading and sluggish cathode redox kinetics. Although tremendous efforts have been devoted to inhibiting the polysulfide shuttling and enhancing the cathode kinetics, the unsatisfactory cell performance under high areal S loading and lean electrolyte conditions remains unsolved. To subsequently enhance the Li-S cell performance under practical operation conditions, we proposed several unconventional approaches including ordered macroporous S host with double-end binding sites [1], highly fluorinated ether-based electrolyte development[2], and versatile free-standing interlayer design[3]. Different from the conventional strategy merely focusing on limiting the polysulfide shuttling, our cathode design combined with electrolyte modification can effectively limit the flooding of polysulfide while enhancing the cathode redox through catalytic sites. Meanwhile, the robust solid-electrolyte interface as induced by highly fluorinated ether-based electrolyte and the regulated Li^+ flux through applying lithiophilic interlayer can prevent the continuous Li metal corrosion and enable stable Li striping/platting behavior. As a result, the Li-S cell performance under high areal S loading (>6.0 mg cm^{-2}), low E/S ratio (4 µL mg^{-1}), wide temperature range (0 – 55 °C), and thin Li metal foil (40 µm) is greatly enhanced through our proposed strategies. In addition, with the assistance of advanced in/ex-situ synchrotron characterizations, mechanism investigations of the S redox behavior in different electrolytes are conducted.

Low-Temperature Chiral Crystal Structure and Superconductivity in $(Pt_{0.2}Ir_{0.8})_3Zr_5$YutoWatanabe[1], HirotoArima[1], AichiYamashita[1], AkiraMiura[2], ChikakoMoriyoshi[3], YosukeGoto[4], Chul-HoLee[4], RyujiHigashinaka[1], HidetomoUsui[5] and YoshikazuMizuguchi[1]; [1]Tokyo Metropolitan University, Japan; [2]Hokkaido University, Japan; [3]Hiroshima University, Japan; [4]National Institute of Advanced Industrial Science and Technology, Japan; [5]Shimane University, Japan

Non-centrosymmetric superconductors, which do not have an inversion center, have been studied due to their unusual physical properties. $CePt_3Si$, $CeRhSi_3$, and $CeIrSi_3$ are well-known Ce-based non-centrosymmetric superconductor systems, which show extremely high upper critical field ($\mu_0 H_{c2}$) due to the antisymmetric spin-orbit coupling (ASOC) caused by lacking an inversion center even with a low superconducting transition temperature (T_c). Therefore, superconductors with a chiral space group have recently been a hot issue. In this presentation, we report a new superconductor $(Pt_{0.2}Ir_{0.8})_3Zr_5$ with a chiral space group of $P6_122$. We performed the synchrotron X-ray diffraction and revealed that $(Pt_{0.2}Ir_{0.8})_3Zr_5$ undergoes a structural transition from the non-chiral ($P6_3/mcm$) to the chiral ($P6_122$) space group at low temperatures. We observed bulk superconductivity with T_c = 2.2 K through specific heat measurement. The normalized electronic specific heat jump $\Delta C_{el}/\gamma T_c$ (γ is the electronic specific heat coefficient.) was estimated to be 1.49. This value is close to 1.43, which is the expected value in the weak-coupling BCS model. Furthermore, the normalized superconducting gap energy $2\Delta(0)/k_BT_c$ (k_B is the Boltzmann constant.) was estimated to be 2.96, which is also close to the 3.53 expected value in the weak-coupling BCS model. We observed the linear behavior of $\ln(C_{el}(T)/\gamma T_c)$ as a function of T_c/T at low temperatures, which means the superconducting gap structure of $(Pt_{0.2}Ir_{0.8})_3Zr_5$ is explained with an *s*-wave gap. From these experimental results, we confirmed that $(Pt_{0.2}Ir_{0.8})_3Zr_5$ superconductor obeys to weak-coupling BCS model with an *s*-wave gap. The $\mu_0 H_{c2}$ of $(Pt_{0.2}Ir_{0.8})_3Zr_5$ was estimated from specific heat under various magnetic fields. The estimated value of $\mu_0 H_{c2}$ at 0 K is $\mu_0 H_{c2}(0)$ = 2.59 T, which is an intermediate value between the orbital pair breaking limit $\mu_0 H_{orb}$ = 1.33 T and the Pauli-Clogston limit $\mu_0 H_P$ = 4.08 T. Although $(Pt_{0.2}Ir_{0.8})_3Zr_5$ belongs to the non-centrosymmetric crystal structure, its $\mu_0 H_{c2}$ is not larger than the Pauli-Clogston limit, which is different from the case of $CePt_3Si$, $CeRhSi_3$, and $CeIrSi_3$. This indicates that the dominant mechanism determining the $\mu_0 H_{c2}$ of $(Pt_{0.2}Ir_{0.8})_3Zr_5$ is the orbital pair breaking limit, and its ASOC effect is not significant. A similar phenomenon was observed in other non-centrosymmetric superconductors, for example, La*MP* (*M* = Ir and Rh; *P* = P and As) and $Mg_{10}Ir_{19}B_{16}$. The crystal structure and elemental composition could be important factors in the strength of the ASOC effect.

Superconductivity in In-Doped $AgPbBiTe_3$ Compounds Synthesized by High-Pressure Synthesis TakahiroSawahara[1], HirotoArima[1], TakayoshiKatase[2], AichiYamashita[1], RyujiHigashinaka[1] and YoshikazuMizuguchi[1]; [1]Tokyo Metropolitan University, Japan; [2]Tokyo Institute of Technology, Japan

NaCl-type metal tellurides (*M*Te), such as SnTe, PbTe, and InTe, have been widely studied due to their unique physical properties as topological insulators, thermoelectric materials, and superconductors. SnTe, which is a topological crystalline insulator, shows superconductivity upon carrier doping, and In-doped SnTe has been studied as a candidate material in which topological superconductivity emerges. Therefore, further development of new NaCl-type *M*Te superconductors is expected to expand material variation. In this study, we used alloying technique to design new *M*Te superconductors. In our previous report, in SnTe, we revealed that the partial substitution of Sn^{2+} site by $(Ag_{0.5}Bi_{0.5})^{2+}$ results in systematic lattice contraction while preserving the crystal-structure type and the total valence state. From first principles band calculations, a band inversion is predicted, suggesting the possibility of topologically preserved electronic state in the system. Furthermore, $AgSnBiTe_3$ also shows superconductivity by In-doping. Similarly, PbTe, which is a thermoelectric material, shows superconductivity by In-doping. From the analogy between SnTe and PbTe, we considered that $AgPbBiTe_3$ could be synthesized and will exhibit superconductivity.
We investigated the In-doping effects on the structural and physical properties in $AgPbBiTe_3$. Polycrystalline samples of $(AgPbBi)_{(1-x)/3}In_xTe$ (x = 0–0.5) were synthesized by high-pressure synthesis, and we conformed the NaCl-type structure by powder X-ray diffraction. In occupies the *M* site for all the compositions. From magnetic susceptibility measurements, superconductivity was observed for x = 0.2–0.5, and the highest transition temperature was 2.8 K for x = 0.4. For x = 0.4, the emergence of bulk superconductivity was confirmed by specific heat measurement. In the presentation, we will show the superconducting properties of $(AgPbBi)_{(1-x)/3}In_xTe$ and discuss the In-valence state of In-doped *M*Te with a NaCl-type structure.

Unleashing the Potential of Lanthanide-Doped Oxyfluoride Materials for Efficient Green Upconversion and Their Promising Applications. SonaliMohanty, MirijamLederer, SimonaPremcheska, HannesRijckaert, KlaartjeDe Buysser, ElsBruneel, AndreSkirtach, KristofVan Hecke and AnnaM. Kaczmarek; Ghent University, Belgium

The quest for highly efficient upconversion (UC) materials has led to the development of fluoride hosts with low phonon energies, minimizing nonradiative transitions. Among them, $NaYF_4$ doped with Yb^{3+} and Er^{3+} has emerged as a top performer. However, its limited thermal stability hinders its application in certain fields. On the other hand, oxide hosts offer improved stability but suffer from lower UC efficiencies due to higher phonon energies. Hence, the prospect of developing host materials that combine the robustness of oxides with the high upconversion efficiencies of fluorides remains an intriguing avenue of exploration.
Herein, we present a novel approach wherein we successfully synthesize lanthanide-doped oxyfluoride particles. This is achieved through the growth of a $NaYF_4$:Yb^{3+},Er^{3+} layer around SiO_2 spherical particles, followed by a high-temperature annealing process, yielding SiO_2@YOF:Yb^{3+},Er^{3+} particles. Our primary focus was to exploit these materials as Boltzmann type luminescence thermometers within the physiological range. Nonetheless, we encounter a noteworthy challenge concerning the limited emission observed in the green spectral region of these particles. To address this limitation, we have investigated the effects of introducing various metal ion co-dopants (Gd^{3+}, Li^+, or Mn^{2+}) into the SiO_2@YOF:Yb^{3+},Er^{3+} particles. Specifically, we analyze the overall emission intensity and the green to red ratio under 975 nm laser excitation. Beyond their role as ratiometric thermometers, our investigation uncovers the remarkable potential of these materials as carriers for drug delivery applications, following the conversion of SiO_2@YOF:Yb^{3+},Er^{3+} particles into hollow YOF:Yb^{3+},Er^{3+} structures, and their evaluation in terms of toxicity towards NHDFs. The investigation highlights the previously unexplored aspects of improving the green upconversion luminescence in YOF:Yb^{3+},Er^{3+} and its potential biomedical applications.

8:00 PM SF03.03.08
Surfactant-Templated Green Synthesis of Porosity-Tailored Silica Nanoparticles for Lithium-Ion Battery and 5G Communication Applications YeongjeLee, SanghyeokBae, Seok JinHong and SunhoJeong; Kyung Hee University, Korea (the Republic of)

In a recent decade, silica nanoparticles have received a significant attention owing to their distinctive chemical/physical properties and potentials in newly emerging applications including 5G communication and lithium-ion battery applications. In this study, we propose an environmentally friendly methodology of synthesizing highly functioning silica nanoparticles with characteristic porous structures. The surfactant-templated sol-gel emulsion method enables to adjust the dimension of monodispersed silica nanoparticles and to form dual porous (micro- and meso-porous) internal structures. The composite films, in which the dual porous silica nanoparticles are hybridized with polyimide polymeric resins, exhibit remarkably low dielectric properties, demonstrating their potential as a substrate material for 5G communication applications. By inducing a carbothermal reduction reaction, we can control the stoichiometric ratio of porous silica nanoparticles. This leads to a facile creation of porous SiO_x/carbon nanocomposites applicable to anode materials for lithium ion batteries. The resulting nanocomposites showed an excellent cycling stability (~100 % after 500 cycles at 0.5 A g^{-1}) and rate capability (554 mAh g^{-1} at 2 A g^{-1}), and a high capacity (1330 mAh g^{-1} at 0.1 A g^{-1}). Our findings affirm the feasibility of porous structure-designable silica nanoparticles for both 5G communication and battery applications. It would open up new possibilities for meeting the unique requirements across various fields through a simple synthesis method.

8:00 PM SF03.03.09
Crystallographic Structural Control of Manganese Dioxide Nanomaterials for Battery Applications SanghyeokBae, YeongjeLee, Seok JinHong and SunhoJeong; Kyung Hee University, Korea (the Republic of)

Recently, manganese oxides have received tremendous attention as active materials for various types of energy storage devices, owing to their cost-effectiveness and excellent electrochemical performances.
In particular, manganese dioxide can be used as an anode material for lithium-ion batteries and a cathode material for aqueous zinc-ion batteries. The MnO_6 octahedral building units are assembled into tunnel and layered structures, with a formation of variety types of crystallographic structures. The common synthetic method for synthesizing manganese dioxide particles is a hydrothermal reaction. However, in this synthetic method, it is highly demanding to control precisely the crystal structures of manganese dioxides, because of an everlasting heating/cooling time during the hydrothermal reaction.
Herein, we report an ultrafast annealing process for controlling sophisticatedly the crystallographic structures of manganese oxide nanoparticles.
By controlling the heating rate up to a given temperature and the cooling rate down to a room temperature, the oxidation states and the crystal structures are adjusted correspondingly depending on ultrafast annealing processing parameters. It will be confirmed that the crystalline structures are controllable precisely in manganese oxide nanoparticles, unlike the case of conventional hydrothermal reaction-based synthetic method. The resulting manganese oxide nanoparticles are incorporated inside unstacked 2D carbon materials, allowing for a formation of nanocomposite electrode materials. In this study, for understanding better the electrochemical reaction mechanisms in manganese oxide materials, the manganese oxide-based nanocomposites

with different crystalline structures will be evaluated and analyzed comparatively as anode materials for lithium ion batteries and cathode materials for zinc ion batteries.

8:00 PM SF03.03.10
The Synthesis of Layerded Hexagonal Structure Type of SnS_2@rGO as High-Performance Anodes for Lithium-Ion Batteries HyerinYoo[1], WonbinNam[1], YoonMyung[2], Chan WoongNa[2] and JaewonChoi[1]; [1]Gyeongsang National University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

SnS_2-based materials have garnered considerable attention as a highly promising anode material for lithium-ion batteries due to their unique two-dimensional layered structure, impressive theoretical capacity, and alloy metal properties. However SnS_2 suffer from low cycle life stability, inadequate electronic conductivity, and large volume expansion during the charge/discharge process.
One suggested solution is introducing carbonaceous materials, such as reduced graphene oxide (rGO). These can improve the electrochemical performances of metal sulfides, such as cycle stability and rate capability by their high electronic conductivity. This study comprehensively analyzed the as-synthesized SnS_2 and SnS_2@rGO composites using SEM, XRD, XPS, and TEM techniques. Furthermore, Ex-situ X-ray diffraction tests showed that the SnS_2@rGO nanocomposite electrode primarily operates via an anodic mechanism for SIBs. The SnS_2@rGO nanocomposite demonstrated enhanced cycling stability and discharge capacity, as evidenced by electrochemical testing (500 mAh/g at 542 mA/g after 300 cycles; 317.9 mAh/g at 100 mA/g after 600 cycles). Meaningful enough, the construction of composites using SnS_2 and SnS_2@rGO represents a promising strategy for improving the electrochemical performance of LIBs. Also, the CV curves at various scan rates are evaluated to investigate the electrochemical reaction kinetics of the SnS_2@rGO, and this process is mainly controlled by capacitive behavior. This work demonstrates the potential of SnS_2@rGO nanocomposite as anode materials for LIBs and enhances our understanding of electrochemical storage mechanisms. This research will facilitate the development of diverse energy storage materials based on SnS_2.

8:00 PM SF03.03.11
Synthesis and Characterization of MnS Nanoparticles Supported by Reduced Graphene Oxide as Anode for Lithium-Ion Batteries WonbinNam[1], HyerinYoo[1], Chan WoongNa[2], YoonMyung[2] and JaewonChoi[1]; [1]Gyeongsang National University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

Transition-metal sulfides have attracted significant attention as anodes for rechargeable batteries due to their high theoretical capacities, low cost, and eco-friendliness. For lithium-ion battery applications, Manganese sulfide (MnS) possesses a high theoretical capacity (616 mAh/g) by way of a conversion reaction. Nevertheless, problems are still associated with low cycle stability caused by volume expansion and poor electronic conductivity. This work prepared MnS nanoparticles embedded in reduced graphene oxide (rGO) using the one-pot method. The rGO behaves as an electronic conductor and buffers the volume change of MnS nanoparticles during lithiation and delithiation. The as-prepared MnS and MnS@rGO powders were characterized by scanning electron microscope (SEM), transmission electron microscope (TEM), X-ray diffraction (XRD), and X-ray photoelectron spectroscopy (XPS). The MnS nanoparticles have a size of around 40 nm, and the particles are uniformly distributed on the rGO. The MnS@rGO nanocomposite exhibited enhanced electronic conductivity and a significantly improved discharge capacity of 624 mAh/g after 100 cycles, compared with bare MnS nanoparticles, at a high current density of 500 mA/g. Thus, we propose that MnS@rGO composites represent a promising alternative for anode materials in lithium-ion batteries (LIBs).

8:00 PM SF03.03.12
Effect of UV Irradiation on Sol-Gel for Metal-Oxide Devices GiyoongChung[1,2], TaeEunHa[1], Eun KyungJo[1], Jeong HyunAhn[1] and Yong-SangKim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of)

We have investigated the effect of UV irradiation on Sol-Gel for amorphous metal-oxide semiconductors (AOS). Organic chemical-induced defects (e.g., voids, holes, organic residues) cause instability of solution-processed amorphous indium-gallium-zinc oxide (a-IGZO) thin-film transistors (TFTs). Hydroxyl radicals is strong oxidant that eliminate organic compounds. In this regard, we expose glass petri dish containing In-Zn-O sol-gel mixture to UV prior to spin-coating to deposit a-IZO film having less defects. Hydroxyl radicals are generated in sol-gel by irradiating UV through O_3/UV process, which is confirmed using potassium iodine (KI)/ultraviolet-visible (UV-vis) spectroscopy analysis. The intensity of the absorbance peak with wavelength of 290 nm and 350 nm increases as the UV irradiation time increases. These results indicates that a simple method of UV irradiation on Sol-Gel generates hydroxyl radicals and provides a decrease of organic chemical-induced defects effectively.

8:00 PM SF03.03.13
Improved Photocatalytic Efficiency of Nb_2O_5-Based Semiconductors Through Cu and Fe Nanoparticles Depositions for CO_2 Photoconversion FranciscoG. Nogueira[1], Ana LuizaA. Faria[1], JulianaA. Torres[2], LucasRibeiro[1], HigorA. Centurion[3], CaueRibeiro[2] and RenatoV. Goncalves[3]; [1]Federal University of São Carlos, Brazil; [2]Brazilian Agricultural Research Corporation, Brazil; [3]University of São Paulo, Brazil

In recent decades, the demand for energy has significantly increased due to population and industrial growth. However, a considerable portion of the energy consumed is derived from the combustion of fossil fuels, resulting in the emission of substantial quantities of gases that have the potential to contribute to global warming. Among these gases, carbon dioxide (CO_2) stands out, as one of the main causes of the greenhouse effect. Thus, the need to develop new economic and energetically viable technologies for energy production through clean and sustainable routes is fundamental. Among these technologies, one can highlight the CO_2 photoconversion process (“artificial photosynthesis”) into value-added products. However, currently, available semiconductors often exhibit a high recombination rate of their photogenerated electron/hole pairs, thereby compromising the effectiveness of the process. Thus, to improve the photocatalytic efficiency, this study aimed to develop semiconductors based on niobium pentoxide (Nb_2O_5) modified with iron (Fe) or copper (Cu) for photoreduction of CO_2, aiming to increase the photocatalytic efficiency of the material through of the reduction in the recombination rate of the photogenerated electron/hole pairs and enhancing light absorption in the visible region. For this purpose, Nb_2O_5-based semiconductors were synthesized using the oxidizing peroxide method with hydrothermal treatment. The Fe or Cu nanoparticles were deposited using the magnetron sputtering method, as this technique enables the deposition of highly pure nanoparticles. The incorporation of Fe or Cu nanoparticles onto the surface of Nb2O5 led to an effective decrease in the recombination rate of the photogenerated electron-hole pairs. This improvement can be attributed to the formation of heterostructures between the materials, which facilitated the greater spatial separation of the photogenerated charges. Consequently, there was a remarkable increase in the photoconversion of CO_2. In addition, scanning electron microscopy and high-resolution transmission electron microscopy analyses were performed to evaluate the morphology and structure of the photocatalysts. The SEM images indicate that the deposition of Fe and Cu does not significantly alter the morphology of the materials, where irregular spherical grains can be observed, Furthermore, the mapping images show a good distribution of Fe and Cu elements deposited by magnetron sputtering. Photoluminescence spectroscopy analysis was used to evaluate the recombination rate and lifetime of the photogenerated electron/hole pairs. All samples showed luminescence emission peaks at 455 nm and 472 nm, which may be related to surface defects in the samples. The luminescence emission peak at 446 nm can be attributed to free excitons at the band edge. The samples with nanoparticles on their surface showed a reduction in luminescence emission intensity. This decrease in intensity is directly associated with the reduction of photogenerated charge recombination and an increase in the "lifetime" of the photogenerated electron/hole pairs. This enhancement in charge lifetime is due to charge sharing between the metal and niobium oxide, leading to an extension of the lifetime of charges. Materials modified with Fe showed high production of carbon monoxide (CO) (356.6 µmol/g). Furthermore, the calcination of the Nb2O5 semiconductor and its modification with Fe favored the production of methane (5.13 µmol/g), methanol (75.78 µmol/g), and acetic acid (69.07 µmol/g). On the other hand, Cu-modified materials increased methane (52.5 µmol/g) and methanol (628.01 µmol/g) production compared to Nb_2O_5 and Fe-modified catalysts. The higher conversion efficiency for Cu-modified materials is related to the ability of Cu to trap photogenerated electrons in the Nb_2O_5 conduction band.

8:00 PM SF03.03.14
High Pyroelectricity of the Freestanding $BaTiO_3$ Nanomembrane Around Room Temperature SunokKim[1,2], SangmoonHan[1], Justin S.Kim[1], YuanMeng[1], ZhihaoXu[1], DonghwanKim[2,2] and SanghoonBae[1]; [1]Washington University in St. Louis, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Pyroelectricity is the temperature fluctuation (temporal temperature gradient) response of the spontaneous polarization in pyroelectric materials, where the high pyroelectricity is mainly observed around curie temperature. Mainly, $Ba_xSr_{1-x}TiO_3$ is mainly adopted to implement the giant pyroelectricity thanks to their Curie temperature as low as 30 degree Celsius. However, they have low polarization levels and large thermal noise owing to their low crystal quality and paraelectric centrosymmetric state. Ferroelectric and single-crystalline $BaTiO_3$ (BTO) are outstanding materials thanks to the high polarization change rate around Curie temperature, but it has a high Curie temperature as high as 120 degree Celsius.
In this paper, we demonstrate the high pyroelectricity for room temperature operation by using a freestanding BTO nanomembrane grown by PLD . For room temperature operation, we systemically decreased the Curie temperature by reducing the BTO thickness from 100 nm to 30 nm. At a 100-nm freestanding BTO nanomembrane, the Curie temperature was measured to be 110 degree Celsius, which is slightly lower than the conventional BTO on the host substrate. At the 30-nm freestanding BTO nanomembrane, the Curie temperature is decreased to 90 degree Celsius, which is the lowest value than those of previously reported results in the BTO-based pyroelectricity field. This result is attributed to the compressive strain of the freestanding BTO film. As the thickness of the BTO film decreases, the internal strain of the freestanding BTO increase, restricting the ion movement in crystalline. That restrict causes deflection of the ions, which enables high pyroelectricity of freestanding BTO around room temperature. Thanks to the low Curie temperature, the pyroelectricity around 25 to 60 degree Celsius is calculated to be 360 $\mu C/m^2K$ at 100-nm freestanding BTO, which is a much-improved result than those of previous works. The freestanding BTO nanomembrane and thickness-dependent pyroelectricity control reported in this work will be a core technology and building block for highly efficient thermal-based devices without any cooling system.

8:00 PM SF03.03.15

Optimizing CO_2 Photoreduction in Freestanding Silver Bismuth Iodide/Nanocellulose Films Through Incident Light Modulation and Integration of Gold Nanoparticles Ting-HanLin[1], Yin-HsuanChang[1], Yi-JingLu[1], Kai-ChiHsiao[1], Jia-MaoChang[1], Ying-HanLiao[1], Kun-MuLee[1,2] and Ming-ChungWu[1,2]; [1]Chang Gung University, Taiwan; [2]Chang Gung Memorial Hospital at Linkou, Taiwan

The rise in CO_2 emissions is one of the primary causes of global warming and climate change. To counteract this, researchers are dedicated to transforming CO_2 into valuable fuels using solar energy to facilitate the reduction of CO_2 into carbon-based fuels, a mechanism that mimics photosynthesis. Particulate photocatalysts are an attractive option for this process due to their easy fabrication and varied material configurations. Further, immobilizing these onto composite polymers improves their reusability and practicality. In this study, we fabricated a novel freestanding photocatalyst composite film by immobilizing Ag_3BiI_6 (SBI) onto a nanocellulose (CNF) transparent film using a sequential process involving noble metal nanoparticle solutions and thermal evaporation of BiI_3. The process of fabricating the SBI/CNF composite film unfolds in two distinct stages. During the initial stage, we prepare the Au NPs, Ag NPs, and a mixture of Au NPs and Ag NPs, each loaded onto a CNF film. This is achieved by applying a 0.05wt% CNF hydrogel to a hydrophilic membrane filter using suction filtration. Au, Ag, and Au-Ag mixtures are subsequently added, generating the Au/CNF, Ag/CNF, and Ag-Au/CNF films respectively. For ease of film detachment, they are briefly immersed in acetone, followed by a vacuum drying phase. The outcome of this process is a set of freestanding and flexible films. The second stage begins with affixing these prepared films to the upper surface of a glass dish, while BiI_3 is positioned at the bottom of the dish. The assembly is heated to a temperature of 200ºC for a span of 30 min, enabling the thermal evaporation deposition of BiI_3 onto the films. The BiI_3-infused films are then transferred into an oven for thermal annealing at varying temperatures, facilitating the creation of SBI. The effect of the sequence and composition of Au and SBI/CNF on the morphology, optical property, and CO_2 photoreduction performance was also investigated. The resulting SBI-Au/CNF film exhibited the highest photocatalytic activity for CO_2 reduction, achieving a CO yield of 31.96 μmol/g●h with high stability for long-term photocatalytic reactions lasting 72 h. The stability of SBI-Au/CNF was also demonstrated in long-term reaction conditions, showing stable reactivity for CO_2 reduction. This work highlights the potential of immobilized Ag_3BiI_6 materials and induced nanoparticles in improving light management, and provides versatile roles for metal nanoparticles in designing high-performance photocatalyst platforms for CO_2 reduction.

Incorporating Acidic Functional Groups into Metal-Organic Frameworks via Click Chemistry for Efficient Ammonia Storage Dae WonKim and Chang SeopHong; Korea University, Korea (the Republic of)

Despite extensive research on ammonia adsorbents for storage purposes, the development of adsorbents with both high ammonia capacity and efficient regeneration processes has been limited. Enhancing ammonia capacity in adsorbents can be achieved by decorating material pores with acidic groups that interact with ammonia. However, incorporating acidic functional groups into metal-organic frameworks poses challenges due to the need for high structural stability for C-C bond formation through post-synthetic modification. Alternatively, ligands decorated with acidic groups can be used, but this alters the framework structure as the acidic groups tend to coordinate with metals during synthesis. In this study, we introduce Ni_acryl_TMA (TMA = thiomallic acid), a metal-organic framework functionalized with acidic groups through bridging ligand exchange and following ene-thiol click reaction. Our findings reveal an outstanding gravimetric ammonia capacity of 23.5 mmol g^{-1} and an unprecedented ammonia storage density of 0.39g cm^{-3} at 1 bar and 298 K, accompanied by facile regeneration. The ammonia storage properties and adsorption mechanism were thoroughly characterized using various techniques including ammonia isotherms, NH_3-temperature-programmed desorption curves, NH_3 breakthrough curves, in-situ FT-IR, and DFT calculations. The synthesis details and comprehensive properties will be presented in the poster.

Synthesis of Unconventional 2H Pt Facets via Wet-Chemical Epitaxial Growth and Crystal Structure-Dependent Catalytic Behaviors of Pt in the Selective Hydrogenation Reaction LongZheng and YeChen; The Chinese University of Hong Kong, China

Pt-based nanocatalysts are promising heterogeneous catalysts in hydrogenation reactions. However, it remains a great challenge to achieve high chemoselectivity for high-value intermediates and avoid over-hydrogenation when substrates contain multiple competing functional groups. Numerous efforts have been made to improve the chemoselectivity of Pt-based nanocatalysts in hydrogenation, including tuning their size, composition, and surface ligands. However, to the best of our knowledge, the effect of crystal structure of Pt on hydrogenation reactions has not been investigated because it is still difficult to synthesize Pt nanocrystals with high-purity metastable phases with well-defined facets. In this work, we develop a novel hexagonal close-packed (2H) Pt-based nanocatalyst exposed with well-defined unconventional 2H Pt facets via epitaxial growth and reveal the crystal structure-dependent catalytic performance of Pt in hydrogenation reactions. Moreover, our distinctive epitaxial growth strategy could also be used to synthesize 2H/face-centered cubic (3C) heterophase Au and Ag shells. Impressively, the 2H Pt shell exhibits remarkably high catalytic selectivity toward the high-value intermediate and excellent durability, superior to conventional 3C Pt counterpart with nearly-same morphologies and identical surface ligand. This work not only provides a general strategy for crystal structure-controlled epitaxial growth of noble metal-based heterogeneous catalysts, but also demonstrates crystal structure-dependent catalytic behaviors of Pt in heterogeneous selective hydrogenation.

8:00 PM SF03.03.18
Valence Stability of Cations and the Formation of Perovskite Type ABO_3 Oxides KripasindhuSardar[1], SatoruKaneko[2,3], MamoruYoshimoto[3] and MasahiroYoshimura[1]; [1]National Cheng Kung University, Taiwan; [2]KISTEC, Japan; [3]Tokyo Institute of Technology, Japan

The analysis of the Madelung electrostatic potential and the lattice site potential of ABO_3 compounds (with many combinations of A and B) have been employed for building a set of criteria for the formation of perovskite structure type oxides ABO_3 by Yoshimura *et al.* [1,2,3]. Thus, oxides of A and B can be reacted to prepare perovskite structure type ABO_3compounds if: (i) B ion is smaller than A ion, (ii) valence of B ion is larger or equal to A ion and (iii) sum of the valences of A and B ion is six (including mixed valence situation $A'_{1-x}A''_x$ or $B'_{1-y}B''_y$). Furthermore, an in depth analysis show that the valence stability originates from the gain of lattice site potential.

Why many solid state compounds would crystallize into perovskite structure type ABX_3? Historically, the answer to this question has been attempted from ion-packing & tolerance factor consideration by Goldschmidt in 1926[4]. Even now, the stability of perovskite structure type ABO_3 oxides is mainly assessed in terms of the geometric parameters such as tolerance factor, and structure-field map [5, 6]. However, it can be argued that the stability is more related to thermodynamic energy therefore, originate from thermodynamic principles rather than numerical geometrical parameters. The crystal chemistry and thermodynamic energy of ionic solids are reflected into Madelung electrostatic potential as shown by Van Gool and Piken in 1969 [7]. However, M. Yoshimura demonstrated "The valence stability using lattice site-potential" in perovskite structure type ABO_3 oxides for the first time in 1974 [1].

Herein, the freely available software VESTA[8] has been used to calculate the lattice site potentials and Madelung electrostatic potential directly from the known crystal structures. Thereby, some fundamental aspects of synthesis, stability and properties of perovskite structure type ABO_3 oxides have been addressed. It is hoped that this work will contribute to the designing, synthesis, structures and properties of inorganic solid state materials to overcome the challenges of tomorrow.

Nanoparticle Conversion Chemistry: A Toolbox for Multimetallic Nanostructures NabojitKar, MaximilianMcCoy, JoshuaWolfe and SaraSkrabalak; Indiana University Bloomington, United States

The synthesis of multimetallic nanoparticles (NPs) with size- and shape-control has been studied over the last several decades due to their applications in catalysis, plasmonics, solar cells, electronics, and even as theranostics. To synthesize multimetallic NPs with precision, NP conversion strategies are appealing, where NPs of a desired shape, size, and phase can be synthesized from an easily accessible NP starting material. The NP starting point (reactants) serves as a compositional and morphological template to control the composition and morphology of the product NPs. For example, architecturally complex PdCu-Au NPs were synthesized through galvanic replacement between PdCu NPs and $AuCl_2^-$ (Au^{1+}) and $AuCl_4^-$ (Au^{3+}), allowing for the role of reaction stoichiometry on NP architecture. Here, the role of reaction stoichiometry is shown to direct the overall architecture of multimetallic PdCuAu nanostructures. Similarly, thermal diffusion is another tool from the NP conversion strategy toward synthesizing monodisperse high entropy alloy (HEA) NPs from core@shell NPs. These NPs, consisting of 5 or more metals in a single phase are an exciting class of NPs because of their unlimited compositions, superior stability, and potential for high catalytic activity. Even though significant progress, a more generalizable pathway to control the composition of HEA NPs while maintaining monodispersity is still desirable in the science community. The retrosynthetic principles to synthesize

HEA NPs were established by studying a library of core@shell systems, outlining that metal precursors that have a high reduction potential (Ered) relative to other constituent metals in the seed should be incorporated in the core of the core@shell NPs. Similarly, metal precursors that have a much lower Ered than the other constituent metals in the seed, should go in the shell. Metals that are adverse to alloy phase formation or have poor wettability should go in the core of the core@shell NPs. Importantly, the obtained core@shell NPs were transformed into monodisperse HEA NPs through thermal annealing, demonstrating the generality of the approach. These NP conversion strategies exhibit a remarkable level of modularity, thereby offering a versatile approach to obtain a wide range of compositions and architectures for multimetallic NP.

The Synthesis of Mixed Metal High Entropy Oxybromides ($Sr_xBa_{1-x}BiO_2Br$) for Photocatalytic Degradation of Tetracycline Antibiotic ChakgridNoomak and NumponInsin; Department of Chemistry, Faculty of Science, Chulalongkorn University, Thailand

Nowadays, antibiotic contamination in aquatic environments, especially tetracycline (TC), can cause toxicity to human health. There are several strategies that have been used to remove this contaminant. In the past few decades, photocatalysis has attracted considerable attention as a method to remove pollutants in wastewater because of its high oxidation activity, stability, and non-toxicity. Recently, high entropy materials (HEM), which are new materials that contain five or more elements, have been applied in various applications. It has been proven that HEMs with multielement can provide good structural stability. However, the application of HEMs in the field of photocatalytic has rarely been reported. Therefore, it is interesting to construct HEMs to be used as photocatalysts. In this work, we designed and fabricated a mixed metal high entropy oxybromide ($Sr_xBa_{1-x}BiO_2Br$), a novel photocatalyst that contains five elements in the structure, by incorporating metals (Sr and Ba) into bismuth oxybromide material (BiOBr) to enhance their stability and photocatalytic activity toward degradation of tetracycline antibiotic (TC). The BiOBr was synthesized using a simple solvothermal method before BiOBr mixed with metal acetate (ratio 1:1) were calcined at 700 ^oC for 8 hours to construct a mixed metal high entropy oxybromide. The properties of the synthesized photocatalysts were characterized by XRD, SEM, EDX, TGA and surface area analysis. The photocatalytic activity of catalysts was evaluated by the photocatalytic degradation of tetracycline antibiotic (TC) under visible light. The results illustrated that the photodegradation efficiency for $Sr_{0.75}Ba_{0.25}BiO_2Br$ was higher than monomeric materials, which was 1.3 times and 1.6 times higher than that of $SrBiO_2Br$ and $BaBiO_2Br$, respectively. Moreover, it can maintain high efficiency despite using multiple cycles. These observations imply that a mixed metal high entropy oxybromide has high activity and stability. This study demonstrates a new approach for developing photocatalysts which are more effective and stable.

8:00 PM SF03.03.21

Exceptional Thermochemical Stability of Graphene/N-Polar GaN for Remote Epitaxy for Exfoliation and Device Fabrication JoonghoonChoi and Young JoonHong; Sejong Univeristy, Korea (the Republic of)

Graphene (Gr) has drawn great attention as an epitaxial template for production of single-crystalline, freestanding semiconductor membranes through remote epitaxy. This emerging epitaxy facilitates the growth of single-crystalline epi-layer membranes, whose crystallographic properties follow to that of the underlying wafer across a Gr gap layer.[1] The lattice transparency of Gr allows the overlying layer to resemble the crystallinity of the mother substrate while permitting the effortless release of the grown film using sticky tape- and/or metal stressor-assisted exfoliation techniques, a result of non-chemical bonds at the interface.[1,2] Notably, the mother substrate can be reused for other subsequent epitaxial growths, given the damage- and contamination-free exfoliation, which is contrast to the damage and performance degradation caused by laser/chemical lift-off. Various material systems, such as compound semiconductors, complex oxides, halide perovskites, etc., have been extensively studied for remote epitaxy.[3] However, metal–organic vapor deposition (MOCVD)-based GaN remote homoepitaxy remains unaccomplished due to the poor thermochemical stability of graphene/Ga-polar GaN substrates.[4] III–nitrides (i.e., GaN, AlN, and AlGaN) are conventionally grown using MOCVD at high temperatures under a hydrogen atmosphere for commercial purposes. However, the harsh conditions required for MOCVD growth of III–nitride potentially lead to thermochemical decomposition of graphene and underlying substrate, making it difficult to take the full advantages of remote epitaxy. Thus, the remote homoepitaxy of GaN and successful exfoliation of GaN overlayer have remained as challenges.

In this presentation, we report the N-polar remote homoepitaxy of GaN using single-layer graphene (SLG). MOCVD yields N-polar micro-crystals (μCs) and Ga-polar thin films are yielded on graphene-coated N- and Ga-polar substrates, respectively. However, only the μCs overlayer is gently separated from the mother substrate via the adhesive tape-assisted exfoliation method, confirming the successful remote homoepitaxy. We investigate the stability of GaN substrates of Ga- and N-polarity for remote epitaxy and demonstrate only the SLG-coated N-polar GaN substrates allow the remote epitaxy. The N-polar remote homoepitaxy is confirmed by Raman spectroscopy, electron microscopy analyses, and overlayer delamination tests. The successful remote epitaxy is contingent on SLG's stability, correlated with the decomposition of GaN substrates. Complementary molecular dynamics (MD) simulations and annealing experiments confirm that the thermochemical stability of graphene is dependent on the polarity of GaN due to varying hydrogen reaction behaviors at high temperatures. Our findings elucidate why graphene's thermochemical stability varies depending on substrate polarity and present an opportunity to prepare N-polar GaN that is releasable from the substrate through MOCVD-based remote epitaxy. Lastly, we apply the successful N-polar remote homoepitaxy of μCs to grow flexible light-emitting diodes (LEDs), consisting of p–n junction μCs with InGaN heterostructures for fabricating deformable LEDs.

Hollow Ruthenium Nanoparticles for Photothermal and Colorimetric Detection of Cholesterol Se HwaCheon, Su JeongLee, Han BeenLee, Chang HyeonHa, Do HyeonKim and Gi hunSeong; Hanyang University, Korea (the Republic of)

The development of porous metal nanoparticles is a standout field due to their unique mechanical, chemical, and thermal properties. Hollow nanoparticles, one of the porous nanoparticles, have better activity compared to solid nanoparticles due to their high surface-to-ratio, low density, and facilitated transfer of reactants. As a result, hollow nanoparticles can be used in various fields such as electrochemical analysis, drug-delivery systems, and lithium-ion batteries. These nanoparticles can be synthesized using methods such as chemical etching, the Kirkendall effect, and the galvanic replacement reaction (GRR). Among these methods, GRR is the most commonly used approach due to its several benefits, including a single reaction process and easy surface modification. This method enables the deposition of desired metal ions on the surface of sacrificial metal, allowing for the synthesis of hollow nanoparticles with very thin shells in a short time. To the best of our knowledge, there have been few studies that apply hollow nanoparticles as chemical catalysts.
Cholesterol is one of the lipid molecules in the human body as well as a component of the cell membrane of animal cells. It plays a crucial role in the synthesis of biomolecules like vitamin D and steroid hormones. However, abnormal cholesterol levels can lead to various diseases, including high blood pressure, hyperlipidemia, arteriosclerosis, and cardiovascular issues. Therefore, accurate determination of cholesterol levels is vital for early diagnosis of these conditions.
In this study, we successfully synthesized hollow ruthenium nanoparticles (HRNs) that mimic the activity of horseradish peroxidase (HRP), a natural peroxidase. The HRNs were synthesized using GRR, where nickel (Ni) was used as a sacrificial template. The transmission electron microscopy (TEM) images clearly revealed the distinct hollow structure of the HRNs, with an average diameter of approximately 40 nm and a shell thickness of 3 nm. Notably, the HRNs exhibited superior catalytic activity compared to HRP. This enhanced activity can be attributed to the presence of the hollow structure, which provides a large surface area with abundant active sites.
The synthesized HRNs were utilized in the colorimetric and photothermal detection of cholesterol, employing 2,2′-azino-di-(3-ethylbenzthiazoline sulfonic acid) (ABTS) as a substrate. Cholesterol was oxidized by cholesterol oxidase, resulting in the generation of H_2O_2. The HRNs acted as catalysts for the oxidation of ABTS in the presence of H_2O_2, leading to the production of oxidized ABTS ($ABTS_{ox}$). $ABTS_{ox}$ served as a substrate for both colorimetric and photothermal detection, as it exhibits strong absorbance in both the visible and near-infrared (NIR) regions. The oxidation of ABTS caused a change in color from transparent to green, with absorbance peaks observed at wavelengths of 405 nm and 418 nm. Additionally, $ABTS_{ox}$ could be excited by absorbing NIR laser light at 808 nm, emitting energy in the form of heat. Consequently, the difference in solution temperature before and after laser irradiation was found to be proportional to the cholesterol concentration. The colorimetric and photothermal detection methods displayed good linearity within a concentration range of 80 μM to 10 mM, with a limit of detection values of 12.3 μM and 54.4 μM, respectively. These results demonstrate that HRNs can serve as effective alternatives to natural enzymes in the sensitive detection of cholesterol. Moreover, the hollow structure of HRNs offers advantages such as enhanced properties with abundant active sites and easy surface modification, making HRNs applicable to various fields in the future.

8:00 PM SF03.03.23

Enhanced Microwave Heating Properties and Gas Decomposition Efficiency of Polymer-Derived SiC Fibers via Multi-Metal Doping YoungJinShim[1,2], KwangYounCho[1], HyukJunLee[1,2], SangHyunJoo[1], YoungKeunJeong[2] and Young JunJoo[1]; [1]Korea Institute of Ceramic Engineering & Technology, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

Polymer-derived SiC fibers are one of the most effective materials for high-temperature microwave absorption due to its low manufacturing temperature, ease of processing, and good

oxidation resistance at high temperatures. Also, by adding specific additives at the polymer stage, polymer-derived SiC materials can achieve desired properties such as the modulation of thermal stability, mechanical strength, electrical characteristics, and chemical stability to meet specific application requirements. In particular, the use of metal organic compounds can enables to acquire specific catalytic properties.
In previous research, we confirmed the microwave heating mechanism of SiC fibers fabricated using polycarbosilane. In this study, SiC fibers doped with Fe and Ti were fabricated through the electrospinning process and exhibited a relatively small diameter and enhance the efficiency of NO_x, SO_x, and methane gas decomposition under microwave. The data demonstrated that multi-metal doped SiC fibers generated high-temperature heat under microwave, resulting in the decomposition of methane gas. Moreover, the presence of the rutile phase of TiO_2 in the fibers exhibited catalytic properties at high temperatures facilitating the decomposition of NO_x gas.
The structural analysis via FE-SEM and XRD revealed that multi-metal doped SiC fibers with a predominant rutile phase of TiO_2 exhibited enhanced NO_x gas decomposition under microwaves, attributed to the catalytic activity of TiO_2, as compared to their polymer-derived SiC fiber. Furthermore, the fibers with small diameter formed through electrospinning and the doping of Fe improve the absorption performance of microwaves, leading to excellent heat generation characteristics. The residual Fe content in the SiC fiber was about 0.5wt% and showed higher microwave heating efficiency than the SiC fiber without Fe doping. we have confirmed that the superior heat generation characteristics exhibited in the microwave gas decomposition system effectively promote methane gas decomposition.

8:00 PM SF03.03.24
Tunable Synthesis of Nanostructured Materials for Energy Storage in Pressure and Temperature Controlled Chamber via Photonic Curing NajmaKhatoon, BinodSubedi, MichaelJohnson and DouglasB. Chrisey; Tulane University, United States

Nanoparticles and nanostructured materials stand out from their bulk counterpart because of their high surface-to-volume ratio, and novel chemical, electrical, magnetic, and optical properties. Interestingly, these properties can be tuned by controlling size, shape, and phase of nanoparticles (NPs). Gas-phase and vapor-phase synthesis of nanoparticles (NPs) are among several synthesis techniques employed for NPs synthesis. In conventional NPs synthesis techniques, there is enough time to achieve thermodynamic equilibrium, however on quenching NPs before they reach equilibrium state, metastable states of NPs can be trapped. As such, the high quenching rate for NPs synthesis is a promising way to produce unique nanostructured morphologies. We used pulsed photonic curing (quenching rate ~ 10^3°C/msec) to achieve this goal. Photonic curing is a unique technique to process materials using xenon flash lamp light (wavelength ranging from 250 nm – 1200 nm). The maximum calculated temperature reaches ~1100 C during post pulsed photonic curing process. In this work, we designed a special chamber to incorporate photonic curing with gas-phase and vapor phase synthesis simultaneously. The chamber we designed can treat the material with photonic processing in argon or forming gas (N_2/H_2) environment under variable pressures (vacuum – 3.5 bar). High temperatures and high pressures in pulsed photonic curing can lead to novel transformation of precursors in vapor phase. The nucleation and growth during the processing depends on pressure, temperature and thus on the mean free path of the gas molecules. We processed organometallic transition metal oxide (MnCo) precursor under 1 atm to 3.5 atm, the mean free path varied from 1.14 x 10^{-18} µm to 1.76 x 10^{-16} µm during the process. Results showed that there is less rGO conversion when MnCo treated under argon gas environment. The chamber is also capable of treating 2D layered material with less rate of oxidation. Results showed a significant decrease in oxidation of MXenes (Ti_3C_2) under argon gas environment which is desired for enhanced electrochemical properties.

8:00 PM SF03.03.25
Symmetry Breaking in $NaMnO_2$: Exploring the Interplay Between Strain and Magnetism in Novel Quantum Materials EuanBassey[1], RaphaëleClement[1,2] and AntonVan der Ven[2]; [1]Materials Science Laboratory, United States; [2]University of California, Santa Barbara, United States

Spatially anisotropic magnetic systems are a playground for the modern physicist and materials scientist: excitations of the ground state, if sufficiently long-lived, may be manipulated for use in quantum computing applications, while external stimuli such as stress, temperature and applied magnetic field strength can modulate the magnetic properties of the system. Perhaps one of the most widely studied anisotropic systems to date is α-$NaMnO_2$, a layered, antiferromagnetic triangular lattice of space group $C2/m$.[1–5] On cooling from 300 K, it undergoes both crystallographic—from a monoclinic $C2/m$ phase to a triclinic P phase below 30 K[3]—and magnetic—from a paramagnetic (T > 45 K) to an antiferromagnetic state (T_N = 22 K), *via* an incommensurate phase (45 < T < 22 K)—symmetry breaking transformations.[2] The interplay between the crystallographic and magnetic symmetry breaking phase transformations, however, remains unclear: does strain encourage magnetic ordering, or does magnetic exchange control strain? For the first time, we explore the interplay between magnetic exchange interactions and strain *via* a density functional theory cluster expansion method. We compute the energy landscape for α-$NaMnO_2$ over a range of strained and magnetic states; determine the exchange interaction constants as a function of strain; and obtain the magnetic susceptibility and spin correlation lengths as a function of temperature, while comparing against experimental data. This methodology can be extended to a plethora of anisotropic systems of interest to the wider materials science community.

8:00 PM SF03.03.26
Nanometer-Thick Co Doped MoO_3 Films and Full-Device with Enhanced Electrochromic Properties YusufTutel[1], Mete BatuhanDurukan[1], SerifeHacioglu[2], UmranC. Baskose[1], EdaCevik[1], LeventToppare[1] and HusnuE. Unalan[1]; [1]Middle East Technical University, Turkey; [2]Iskenderun Teknik University, Turkey

In the past decades, transition metal oxides have received noteworthy attention due to their unique properties to be used in applications like electronics, optoelectronics, electrochemistry, sensors, and catalysis. Among them, molybdenum trioxide (MoO_3) showed promising thermal, chemical and electrochromic properties with good chemical and physical stability. Moreover, the electrochromic properties of MoO_3 may simply be tuned via doping. However, the production of uniform, crack-free and stable MoO_3 thin films for electrochromic applications using conventional deposition techniques is still difficult, as it is necessary to achieve continuous cycle stability. Ultrasonic spray deposition (USD) method enables cost-effective deposition of thin films through wet chemistry, facilitating the appropriate incorporation of various dopant atoms to improve material properties. Moreover, this method allows high material utilization, mass-production and is vacuum free. In this work, MoO_3 and Co doped MoO_3 (MoO_3:Co) thin films were deposited onto pre-heated indium tin oxide (ITO)/glass substrates using USD method. As-deposited thin films were then annealed to crystallize. The addition of Co dopant atoms on the morphological, optical, electrochemical and electrochromic properties of MoO_3 thin films have been systematically investigated. Significant decrease in the crystallite sizes were observed upon Co doping. Likewise, the bandgap of MoO_3:Co thin films (3.42 eV) decreased slightly compared to bare MoO_3 thin films (3.49 eV). According to the XPS results, bare MoO_3 exhibits a predominance of Mo^{6+}, however, a minor reduction in these charges to +5 is observed due to the Co doping effect in MoO_3:Co films which causes an increase in electrocatalytic activity. Addition of Co dopant atoms to MoO_3 thin film electrodes resulted in improved maximum transmittance change in the colored and bleached states compared to bare MoO_3 thin film electrodes. Furthermore, it was observed that cyclic stability of the bare MoO_3 thin film electrodes decreased with increasing cycle numbers. In contrast, the MoO_3:Co electrodes showed significantly higher capacitance retention of 92%, indicating superior cyclic stability and improved performance compared to the bare MoO_3 electrodes. In the light of these enhancements, electrochromic full-device was fabricated with MoO_3:Co and NiO thin film electrodes using organic ($LiClO_4$/PC/PMMA) gel electrolyte. Full device showed 23% maximum transmittance change with excellent cyclic stability (around 99% capacitance retention). Especially with device engineering, electrochromic full device stability has been increased by using inorganic thin films and organic gel electrolyte. Our results indicated that USD method is highly suitable for the deposition of functional MoO_3:Co thin films for electrochromic smart windows and full-devices.

New Oxide Glass Cathode Materials for Sustainable and High-Energy Density Lithium Batteries TaosGuyot, JuliaAgullo, DamienPerret, LoicSimonin and SébastienMartinet; Commissariat à L'énergie Atomique et Aux Energies Alternatives (CEA), France

As energy concerns grow and the society needs more sustainable and renewable energy sources, the ability to effectively store and retrieve energy is paramount. Currently, rechargeable lithium-ion batteries (LIB) seem to be one of the best alternatives to reduce our dependency on fossil fuels. LIB are made of cathodes materials based on polycrystalline oxides or polyanion compounds[1]. However, some of them have their performance limited by their crystalline structure where other compounds suffer from irreversible phase changes against cycling[2]. To overcome these key shortcomings, implement glasses or glass-ceramics as cathode materials seems to be an interesting approach. Glasses have a structure composed of more free volume,

which can accept a large amount of lithium[3] and easily accommodate structural changes upon lithium ions extraction/insertion[4]. Furthermore, glass production is scalable and commercially easier to implement than most of synthesis processes of conventional cathodes materials.
In this study, various types of oxide glasses have been investigated as promising cathode materials for sustainable and high energy density lithium batteries. The influence of the nature of the transition metal (Fe, Mn, …) and the polyanion (PO_4, BO_3, SiO_4) on the microstructural and electrical properties of the as-prepared glasses were examined. Electronic and ionic conductivities were measured by Electrochemical Impedance Spectroscopy (EIS). The electrochemical properties in terms of specific capacity, redox potentials vs Li^+/Li, first cycle capacity loss, coulombic and energy efficiencies of these materials were investigated in coin-cell by Galvanostatic Cycling (GC). Finally, to elucidate the reaction mechanisms of the electrochemical processes involved in these materials, X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) at room temperature were coupled and performed on the as-prepared glasses and on ex-situ (after cycling) materials at different electrochemical states of charge. This new study will bring significant elements to optimize both the glass composition and its elaboration conditions to obtain high performance cathode materials without critical materials.

CO_2 Capture from Flue Gas by MOFs MohammadWahiduzzaman[1], SabineDevautour-Vinot[2] and GuillaumeMaurin[2]; [1]CNRS, France; [2]Université Montpellier, France

In light of the current environmental situation, reduction of anthropogenic CO_2 emissions from carbon-intensive industries like power plants, cement, steel, or petrochemical industries become one of the most pressing issues to combat global warming. Shifting towards a low-carbon economy requires cost-effective carbon capture utilization or sequestration (CCUS) technology to be developed. Currently utilized amine-based absorption-regeneration process suffers from high energy penalties for solvent regeneration. In this regard, adsorption-based processes are considered promising alternatives for CCUS. Metal-organic frameworks (MOFs) are a widely studied class of porous adsorbents that offer tremendous potential, owing to their large CO_2 adsorption capacity and/or high CO_2 affinity. However, the performances of MOF-based CCUS technologies have not been fully evaluated in real industrial conditions. For example, the industrial flue gas contains CO_2, N_2, H_2O, and traces of other contaminants, such as H_2S, SO_2, and NOx, which compete for different adsorption sites or might impact the stability of the adsorbent materials. Therefore, it is crucial to understand the competitive adsorption of the various components of the flue gas. From an experimental standpoint, such study is tedious and time consuming while molecular simulations provide a quicker route to understand their adsorption behavior and plausible degradation at the microscopic level. In this presentation, I will outline a systematic joint computational/experimental approach to evaluate the stability and CO_2 capture performance of a series of MOFs in the presence of various impurities within the framework of MOF4AIR, a multidisciplinary H2020 EU project. A more detailed analysis will be provided for a few top-tier MOFs that were selected for large-scale deployment in the industrial post-combustion capture process.

Choline based Plastic Crystals as Barocalorics: Insights from *Ab Initio* Molecular DynamicsShivaniGrover, JoshuaLevinsky and ClaireHobday; University of Edinburgh, United Kingdom

Conventional refrigeration technologies based on vapour-compression cycles of greenhouse gases pose a serious threat to the environment and lack scalability to small sizes. Materials with large solid-state caloric effects induced by external field (mechanical, electric or magnetic field) are needed for the development of eco-friendly, energy efficient solid-state refrigeration technologies.[1]
The refrigeration capacity is associated with a large isothermal entropy change and/or with a large adiabatic temperature change, induced by external stimuli such as mechanical pressure (barocaloric effect) or electric field (electrocaloric effect) or magnetic field (magnetocaloric effect), effects that are enhanced near phase transitions. To this end, organic-inorganic plastic crystals offer new interesting opportunities for the solid-state cooling applications.[2] Thus far, plastic crystals are the only known class of caloric materials which exhibit entropy changes on par with current commercial refrigerants and therefore require further investigation and development.

In this work, we explore the potential of choline-based plastic crystals, $(C_5H_{14}NO)_2MCl_4$ where M= Co, Zn, Cu, as promising barocaloric materials due to a large entropy change (~100 $JK^{-1}Kg^{-1}$) associated with the symmetry-breaking order-disorder phase transition. Using methods of ab initio molecular dynamics as implemented in CP2K, we provide insights into the local structure such as choline disorder and tumbling of $CoCl_4$ tetrahedra observed in this system. This is quantified by calculating the Co-Cl vector autocorrelation functions and its vibrational contribution to entropy change, which is dominated by the soft Co-Cl vibrational modes. The choline disorder is quantified by calculating the diffusivity of choline in the two phases. Our model is validated with our experimental study, thus providing a complete understanding of the interplay between dynamic and disordering effects in choline based plastic crystals.

Optimizing Room-Temperature Electrochemical (De)Fluorination of $CsMnFeF_6$ using Differential Electrochemical Mass Spectrometry JessicaAndrews and BrentMelot; University of Southern California, United States

While research on cation intercalation has thrived and resulted in real-world applications, like Li-ion batteries, anionic intercalation is largely understudied. Energy storage based on anionic intercalation is extremely promising as anionic charge carriers, like fluoride, provide a new frontier to explore for the development of high energy density, rechargeable batteries. Thus far, F-ion batteries are mostly limited to conversion-based systems, in which redox reactions at the electrodes form entirely new products, typically with drastically different structures. Although these reactions are reversible, they often incur large volume changes that lead to poor cycling stability. More recently, all-solid-state cells that leverage fluoride-ion intercalation, in which the host material may experience structure changes but broadly maintains its original topology, have been reported. These systems show improved reversibility, but the solid electrolyte suffers from poor room-temperature fluoride conductivity, requiring high operating temperatures and limiting any practical use. Recent liquid electrolyte advancements include salt/solvent combinations that exhibit large stability windows and significant fluoride mobility at room temperature, presenting an avenue to overcome barriers limiting research on fluoride (de)intercalation.

We previously reported electrochemical fluorination of ReO_3, wherein ReO_3 cycled vs. Cu at room temperature using a liquid electrolyte, *n*-tetrabutylammonium fluoride (TBAF) dissolved in THF, exhibits irreversible insertion of 0.5 equiv. of fluoride. Although Cu provides a consistent reference potential, it cannot be reduced, calling the counter-reaction into question. Differential electrochemical mass spectrometry (DEMS) measurements were employed to monitor the evolution of H_2, O_2, F_2, and CO_2 gases during electrochemical cycling, and only H_2 evolved in substantial quantities. Therefore, the counter-reaction is presumed to be the hydrogen evolution reaction (HER) from electrolyte attack.

Following this work, we reported the reversible (de)fluorination of the defect pyrochlore $CsMnFeF_6$ at room temperature using TBAF. Unlike ReO_3, approximately 1 fluoride ion can be reversibly (de)inserted into $CsMnFeF_6$ for 10 galvanostatic cycles, after which the capacity begins to fade. $CsMnFeF_6$ is cycled against a Bi/BiF_3 composite counter electrode to incorporate a species that can be reduced in the counter electrode and because M/MF_x composite electrodes are more stable over long-term cycling compared to MF_x alone, although they still impose the limitations of conversion-based electrochemistry on the cell. We extensively characterized the structural impact of fluoride (de)insertion on $CsMnFeF_6$. *Ex situ* diffraction shows expansion and contraction of the cubic $CsMnFeF_6$ lattice on insertion and removal, respectively, during the first 2 cycles. New reflections intensify in the diffraction from cycle 3, corresponding to a topotactic transformation of pyrochlore $CsMnFeF_6$ into an orthorhombic polytype that continues to reversibly cycle fluoride ions. The capacity does not fade immediately after the

transformation, suggesting the observed decrease is likely due to limitations of the Bi/BiF_3 counter electrode or a decomposition of the TBAF electrolyte.

We will present our work building and using a DEMS set up to study gas evolution during $CsMnFeF_6$ cycling in TBAF with various counter electrodes. Our DEMS studies aim to answer two key questions: Is HER the dominant counter-reaction in F-ion batteries when organic, liquid electrolytes are used? If HER dominates and proceeds via electrolyte attack, is cycling lifetime limited by the amount of electrolyte? In other words, *in situ* gas analysis will be used to identify the counter-reactions occurring in cells containing organic, liquid electrolytes to uncover which cell component(s) might be impeding cycling lifetimes and begin to optimize room-temperature F-ion battery performance.

8:15 AM SF03:04.02
Ti_2C, A Bicontinuous 3D Electride MatthewLanetti, NhiHuynh and ScottWarren; University of North Carolina, United States

Electrides are ionic crystals in which electrons act as anions in periodic lattice positions stabilized by an adjacent framework of cations. These unconventional solids offer desirable properties and have been explored in applications including battery electrodes and catalysis. In all experimentally realized electrides, the continuity of the electride sites have been observed to be non-continuous (0D), continuous in one dimension (1D), or continuous in two dimensions (2D). Here, we identify Ti_2C as among the first synthesized topologically three-dimensional (3D) electrides. We propose that Ti_2C consists of two bicontinuous structures: a 3D anionic electron gas contained within a 3D lattice of atoms. The atomic and electron gas structures are both diamond cubic (Fd3m) and extend throughout 3D space. We experimentally synthesize this material and demonstrate, using both theory and experiment, that it contains a continuous 3D pathway of anionic electrons. The anionic electron sites in electrides can be exchanged with traditional anions, giving electrides utility in ion storage. We demonstrate that the 3D network of anionic electrons in Ti_2C is capable of taking up hydrogen as hydride at relatively low temperature. This research suggests that 3D electrides may exhibit superior ion storage performance over 2D electrides which have fewer dimensions for ion insertion. We show that Ti_2C is the first member of a novel type of topological electride where anionic electron gas is confined within a 3D form, bicontinuous with a symmetrical 3D atomic framework.

Designing Battery Electrode Architectures Across Length Scales SarbajitBanerjee; Texas A&M University, United States

The design and operation of rechargeable batteries is predicated on orchestrating flows of mass, charge, and energy across multiple interfaces. Understanding such flows requires knowledge of atomistic and mesoscale diffusion pathways and the coupling of ion transport with electron conduction. Using multiple polymorphs of V_2O_5 as model systems, I will discuss our efforts to develop an Ångstrom-level view of diffusion pathways. Topochemical single-crystal-to-single-crystal transformations provide an atomistic perspective of how diffusion pathways are altered by modification of V—O connectivity, pre-intercalation, and high degrees of lithiation. Recently devised multi-step synthetic schemes enable the positioning of Li-ions across four distinct interstitial sites of a V_2O_5 insertion host and allow for deterministic redirection of Li-ion flows through strategic positioning of transition-metal ions.
At higher length scales, scanning transmission X-ray microscopy and ptychography imaging provide a means of mapping the accumulative results of atomic scale inhomogeneities at mesoscale dimensions and further enable tracing of stress gradients across individual particles. I will discuss strategies for the mitigation of diffusion impediments and degradation mechanisms based on controlling the coupling of chemistry, geometry, and mechanics. Some of these strategies include (a) utilization of Riemannian manifolds as a geometric design principle for electrode architectures; (b) atomistic design of polymorphs with well-defined diffusion pathways that provide frustrated coordination; and (c) site-selective modification as a means of tuning lattice incommensurability between lithiated and unlithiated phases.
This research was funded by the National Science Foundation under DMR 1809866.

9:00 AM *SF03:04.04
NASICON-Based Materials, The Perfect Match for The Next Generation of Batteries?Jean-NoelChotard[1,2], PieremanueleCanepa[3], VincentSeznec[1,2], EunikeMahayoni[1,2], AaronTieu Jue Kang[3], KritiKriti[1,2], SunkyuPark[1,2] and ChristianMasquelier[1,2]; [1]University of Picardie Jules Verne, France; [2]RS2E, FR CNRS, France; [3]National University of Singapore, Singapore

NASICON-based materials have a regain interest in the last decade. Firstly known for their high ionic conductivity (hence the name : NA SuperIonic CONductor) [1], their chemical versatility allow them to be used as electrode materials (anode or cathode) as well as as coating materials for different battery technologies (Li-ion, Na-ion, multivalent-ions and all-solid-state batteries) by tuning its composition [2-4]. Indeed, the NASICON crystal structure of general formula AxMM'(XO4)3, allows a wide range of chemical substitutions. The Alkali "A" atom can either be Li^+/Na^+/K+, and the M/M' sites can basically be filled with any combination of 3d or 4d transition metals.
Among them, the vanadium phosphate $Na_3V_2(PO_4)_3$ (NVP) is of particular interest because of its fantastic rate capacity and thermal stability, with a theoretical capacity of 117.6 mAh/g at 3.4 V vs. Na/Na^+ by the V^{3+}/V^{4+} redox couple yielding an energy density of 396 Wh/kg [4]. Because of the wide oxidation range of Vanadium, NVP can be used either as an anode or a cathode.
NASICON materials have also proven to be among the best solid electrolyte material for sodium All-Solid-State-Batteries (ASSBs). As an example, $Na_{3.4}Zr_2Si_{2.4}P_{0.6}O_{12}$ attains ionic conductivity as high as 10 mS/cm [5-6] with 3D diffusion path.
Because of those electrochemical properties, their chemical stability and compatibility, NASICON-type are perfectly matching for building All-Solid-State-Batteries.
In this presentation, we will discuss the astonishing diversity of the crystal chemistry of the NASICON materials (both as electrode or electrolyte) mostly studied through operando X-Ray Diffraction as well as its use in ASSBs.

9:30 AM SF03:04.05
Reducing Voltage Hysteresis in Li-Rich Sulfide Cathodes by Tuning the Metal-Ligand Covalency XiaotongLi[1], Seong ShikKim[1], MichelleQian[1], EshaanPatheria[1], JessicaAndrews[2], ColinMorrell[1], BrentC. Melot[2] and KimberlyA. See[1]; [1]California Institute of Technology, United States; [2]University of Southern California, United States

Multielectron redox can be achieved by leveraging the redox activity of anion sublattice (anion redox) in addition to the transition metal, to significantly increase the capacity of cathode materials. Li-rich sulfides are promising cathode candidates for anion redox since they operate at voltages within the electrolyte stability window and sustain the high capacity. Most of the anion-redox based cathode materials still face the problem of slow kinetics and large voltage hysteresis. One of the ways to solve this problem is to increase the covalency of the metal-ligand bonds. By substituting Mn into the electrochemically inert $Li_{1.33}Ti_{0.67}S_2$ (Li_2TiS_3), the anion redox can be activated in the $Li_{1.33-2y/3}Ti_{0.67-y/3}Mn_yS_2$ (y = 0 – 0.5) series and the voltage hysteresis is significantly reduced. The y = 0.3 phase also exhibits excellent rate and cycling performance, which shows fast kinetics for anion redox, because the energy of Mn *d* states is located in between the Ti *d* and S *p* states, bridging the energy gap and increasing the metal-ligand bond covalency. X-ray absorption spectroscopy shows that both the cation and anion redox processes contribute to the charge compensation. This work provides insights on how to design cathode materials with anion redox to achieve fast kinetics and low voltage hysteresis.

Disordered Rocksalt Cathodes: Linking Composition, Structural Stability and Performance RaphaëleClement; University of California, United States

Rechargeable batteries have transformed our daily lives through portable electronics, and hold the key to a low carbon future. While they dominate the electric vehicle market, current Li-ion chemistries are approaching their theoretical limit in terms of energy density. Remarkably, despite significant effort over decades, we continue to rely on a limited subset of Li-ion battery materials — most commercial cathodes are derivatives of $LiCoO_2$ developed in 1980 — that cannot meet our ever-growing need for energy storage. In recent years, disordered rocksalt oxides, with mixing of the transition metal and Li species on the face-centered cubic cation sublattice, have emerged as more sustainable and higher energy density cathodes than the standard layered oxides. In this talk, I will present the links established between the composition, structure and electrochemical properties of such systems obtained by combining paramagnetic solid-state NMR, first principles calculations, and complementary tools. I will also introduce a new, rapid and energy-efficient synthesis procedure to obtain disordered rock salt cathodes, and emphasize the importance of ^{7}Li/^{19}F solid-state NMR to determine the true composition of such systems and establish robust materials design rules.

10:45 AM *SF03:04.07

Understanding Chemical and Structural Organization in Disordered Rocksalt Oxides for Li-Ion Batteries MeganM. Butala; University of Florida, United States

An attractive feature of Li-excess disordered rocksalt oxide electrodes is their high chemical versatility compared to commercial Li-ion battery cathode materials. With this chemical versatility, this emerging class of energy storage materials could alleviate current reliance on expensive or geographically-concentrated materials, and prevent similar dependence in the future. To realize the promise of disordered rocksalt oxide cathodes, however, requires overcoming seemingly inherent ionic transport limitations that, even in relatively high-performing compositions, require sub-micron-sized particles and careful incorporation of conductive carbon additives.

A challenge to realizing their promise is that the same compositional versatility that makes disordered rocksalt oxides so compelling, which is associated with atomic structure and nanometer-scale complexity. Broad sampling of chemical space has led to new empirical understanding of structure-property relationships, especially between the size and charge of constituent cations and short-range chemical ordering.

We report a detailed investigation of a narrow range of composition space to understand the key characteristics of cation features on hierarchical chemical and structural organization. To do so, we combine average and local structure characterization methods and propose a conceptual framework to reconcile the hierarchical chemical and structural features, including crystal structure, local distortions, short-range order, and nanoscale chemical segregation.

11:15 AM SF03:04.08
Phase Segregation and Nanoconfined Fluid O_2 in an Oxygen Redox Battery Cathode KitMcColl[1,2], SamuelW. Coles[1,2], PezhmanZarabadi-Poor[3,2], BenjaminJ. Morgan[1,2] and SaifulIslam[3,2]; [1]University of Bath, United Kingdom; [2]Faraday Institution, United Kingdom; [3]University of Oxford, United Kingdom

Next-generation, sustainable high energy density batteries require high-capacity cathodes composed of Earth-abundant elements. Lithium and manganese rich oxide cathodes are leading candidates because they achieve high capacity from a combination of transition metal and oxygen redox.[1] O-redox, however, is accompanied by structural changes that cause a large loss of energy density.[2] To apply O-redox cathodes in practical devices, these structural changes must be understood and prevented. These structural changes are exceedingly difficult to characterise for both experimental and computational modelling,[3] which has led to uncertainties and ambiguities in the mechanisms of O-redox in battery cathodes.

The characterisation of O-redox behaviour is particularly challenging for computational modelling. Because O-redox cathodes undergo atomic rearrangements during cycling, cathode structures after the early stages of the first charge are not known *a priori* and must be solved *in silico*. For computational modelling studies to make credible predictions of O-redox behaviour, both the kinetics and thermodynamics of structural rearrangements must be considered. Modelling schemes that predict O-redox behaviour from structures that i) form via kinetically inaccessible pathways, ii) are kinetically unstable or iii) are far from the thermodynamic ground state, can produce unrealistic descriptions of O-redox. Furthermore, cycled O-redox cathodes exhibit crystallographic site disorder and nanoscale structural changes, such as the formation of nanovoids. Computational modelling using DFT, however, cannot directly investigate disorder and nanoscale structures, meaning that additional modelling methods are required to provide a complete picture of O-redox behaviour.

Here, we use a computational strategy that directly addresses these kinetic and thermodynamic factors. To identify kinetically viable atomic-scale rearrangements during the first charge, we have used long-timescale ab initio molecular dynamics (AIMD). In parallel, to account for disorder and nanoscale structural changes produced after many cycles, we have developed a DFT-derived cluster-expansion model of oxygen-redox, which we have used to perform large-scale Monte Carlo simulations. This approach allows us to efficiently search the vast configurational space for thermodynamically low-energy structures at the top of charge, and to conduct this search in structures containing ~50,000 atoms, so that nanoscale structural rearrangements can be examined.

We apply this strategy to high-capacity O2-layered $Li_{1.2-x}Mn_{0.8}O_2$, which is an exemplar system for understanding Li-rich oxide cathodes. We identify a kinetically viable O-redox mechanism, in which the formation of interlayer superoxide and peroxide intermediates drives out-of-plane Mn migration, resulting in O_2 molecules forming within the bulk structure. The thermodynamic ground-state structure at the top of charge exhibits phase segregation into a two-phase mixture of MnO_2 and O_2. Bulk O_2 molecules are confined within nanometre-sized Mn-deficient voids that form a connected, percolating network. These O_2 molecules have a nanoconfined supercritical fluid character and can potentially diffuse through the network of voids, providing a mechanistic link between bulk O_2 formation and surface O_2 loss.[4]

11:30 AM SF03:04.09
Completely Passive Capture of Carbon Dioxide from Air HsinhanTsai[1,2], JianZeng[2,1], Tae HwanLim[2], MattherDods[1], ZitingZhu[1,2], HannesAlberts[2,3], AdrianHuang[1,2], MengshanYe[1], HiroyasuFurukawa[1,2], HannaBreunig[2], RaviPrasher[2,1], SeanLubner[4,2] and JeffreyLong[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]ETH Zurich, Switzerland; [4]Boston University, United States

In addition to reducing greenhouse gas emissions, it is now imperative that we implement direct air capture (DAC) of CO_2 from the atmosphere at a scale of hundreds of giga metric tons before the year 2100 to avoid catastrophic climate change[1,2]. Development of a viable DAC technology is still limited by the high cost[3] and high energy consumption[4,5]that result from a low adsorbent capture capacity, requirements for expensive, cumbersome infrastructure, and widespread societal acceptance challenges[6,7]. In this work, we aim to address all three of these challenges and have designed and demonstrated a completely passive DAC device with a projected net CO_2 capture cost as low as 80 \$ t_{CO2}^{-1}, lower than the 'Carbon Negative Shot' 2030 goal (100 \$ t_{CO2}^{-1})[8] and potentially profitable at 100 \$ t_{CO2}^{-1} with the 45Q carbon tax credit. The modular design and passive operation of the system should enable deployment across broad geographic regions far from infrastructure centers, thereby enabling a distributed, self-powered solution to the problem of removing dilute CO_2 from the atmosphere. It further combines low-cost solar-thermal and low-risk photovoltaic technologies, facilitating installation at different scales in any corner of the world with abundant solar resources.

11:45 AM SF03:04.10
Improved Cycle Life and Determination of Li Ion Transport Parameters in Doped Ni-Rich NMC Cathodes for Lithium Ion Batteries EthanWilliams[1,2], DavidBurnett[1,2] and EmmaKendrick[1,2]; [1]University of Birmingham, United Kingdom; [2]Faraday Institute, United Kingdom

Ni-rich Li-ion cathode materials like NMC-9.5.5 ($LiNi_{0.9}Mn_{0.05}Co_{0.05}O_2$) are of interest due to their higher energy density and limited cobalt content, aiding the transition away from questionably sourced critical raw materials, when compared to materials like NMC111 - 622. This has the advantage of reducing production costs while maintaining a high working voltage and capacity. However, the high nickel content of these materials can be detrimental due to disorder introduced by Li+/Ni2+ cation mixing, lithium residuals, and irreversible phase changes during operation resulting in significant capacity fade during cycling. Similarly, the different synthesis methods and treatments drastically affect the morphological, structural, and electrochemical properties
We present a structural and electrochemical study of NMC-9.5.5 prepared at scale via a hydroxide coprecipitation synthesis in a 5 L continuous stirred reactor tank (CSTR). In this work, bulk doping and co-doping with two metal cations are investigated with a simple and scalable method to achieve mixed metal and mixed valence doped NMC-9.5.5 with the aim to further improve cycle life and stability. Additionally, the effect of bulk doping on the thermodynamic and kinetic properties of the cathode material are investigated in both half-cells and full-cells (paired against a graphite electrode) using galvanostatic intermittent titration technique (GITT), intermittent current interruption (ICI), and electrical impedance spectroscopy (EIS), where a 3-electrode configuration is used to elucidate the individual electrode potentials and stoichiometries.
The bulk doping of the transition metal layer was found to significantly reduce the capacity fade in the NMC-9.5.5, increasing the capacity retention after 100 cycles from 78% in the undoped material to 92% and 89% in the doped and co-doped NMC-9.5.5 half-cells. The mixed metal co-doped material was also effective in delivering a higher specific capacity than the baseline throughout the full cycling range. The improved cycling performance can be understood by the inspection of the differential capacity plots, which show a suppression of the H2-H3 irreversible phase transition in the doped material and stabilisation of this peak to a higher voltage compared to the baseline. The effect of doping on the structural stabilisation is similarly reflected in the XRD characterisation, in which the introduction of the metal cation acts to constrain the detrimental Li+/Ni2+ cation mixing due to a widening of the transition metal channel. This is also supported by the EXAFS characterisation that indicate the dopants may act to stabilise the local Ni environment. These structural changes appear to be further beneficial in facilitating improved Li ion transport properties in the doped material as evidenced by the lower charge transfer resistances during cycling and increased diffusion coefficient.
This research illustrates the high capacity performance of low cobalt cathode materials and as suchthus reducing the reliance on critical materials, as well as the ability to produce Ni-rich cathode material at large scale and further stabilise its cycle life by simple structural engineering. Improved materials manufacturing processes will enable a greater understanding of the

synthesis process and enable more sustainable methods of synthesis. There are also benefits for cell makers with improvement in processability and additional stabilisation knowledge for battery manufacturers, as well as the consumers that benefit from longer driving ranges and battery life in their EV's.

Exploiting Surprising Phase Behavior in Superprotonic Solid Acid Compounds to Enhance Functionality LouisS. Wang, GraceXiong and SossinaM. Haile; Northwestern University, United States

Creation of novel proton-conducting electrolytes with a combination of desirable properties, including negligible electronic conductivity, chemical stability, and processability, in addition to the prerequisite of high proton conductivity, has taken on increased urgency as the world turns to hydrogen as a clean energy carrier. Superprotonic solid acids, in particular phosphates in this group, hold technological potential as components in fuel cells and other electrochemical devices. In such materials, orientational disorder of polyanion groups in high temperature phases facilitates rapid proton transport. Superprotonic solid acids include CsH_2PO_4, $CsHSO_4$, and $Rb_3H(SeO_4)_2$. Device development approaches have largely focused on CsH_2PO_4 because of its stability under both oxygen and hydrogen. Traditional chemical modification routes for improving transport properties, such as replacing Cs^+ with Rb^+ to influence proton mobility or replacing $(HPO_4)^{2-}$ with $(SO_4)^-$ to influence both mobility and carrier concentrations, appear to have been exhausted without generating technologically relevant outcomes. Here we describe an unexpected chemical lever for tuning properties, specifically, modifying the alkali cation : polyanion ratio. Remarkably, we find that the CsCl structure-type adopted by CsH_2PO_4 and RbH_2PO_4 in their respective high-temperature, superprotonic phases, can support large concentrations of both cation and polyanion vacancies, charged balanced by adjustments to the overall proton concentration. The material stoichometries are described by $A_{1-x}H_{2+x}PO_4$ (with cation site vacancies) and $AH_{2-3y}(PO_4)_{1-y}$ (with polyanion site vacancies), where A is Cs^+ or Rb^+. Additionally, in the Cs-poor region of chemical space relative to CsH_2PO_4, we discover a new solid acid of fixed composition $Cs_7(H_4PO_4)(H_2PO_4)_8$. Thus, stoichiometry control emerges as a new approach to designing superprotonic electrolytes.

Evolving Structural Pathways in Next-Generation Lithium- and Sodium-Ion Battery Materials Revealed by Pair Distribution Function Analysis PhoebeAllan; University of Birmingham, United Kingdom

The need for battery technologies with higher energy densities and improved sustainability has motivated a large body of research into new potential electrode materials for rechargeable lithium- and sodium-ion batteries. However, in many cases, characterising the lithium/sodium-ion (de)insertion mechanisms of these new materials presents significant challenges to conventional crystallographic analysis, as disordered or nano-sized phases may form, some of which may be metastable and exist only within the battery. Here, I will present our recent work detailing how pair distribution function (PDF) analysis - a total scattering technique which is sensitive to both local and long-range structure – has been applied in situ to give highly consistent data sets from which subtle changes to local structure during electrochemical cycling can be resolved. PDF data is analysed alongside complementary methods such as x-ray diffraction, solid-state nuclear magnetic resonance, x-ray absorption spectroscopy and theoretical calculations to gain insight into a range of potential new electrode materials, including disordered rock salt cathodes, lithium-ion conversion anodes and alloying anodes for sodium-ion batteries. In particular, my focus will be on systems where the lithiation/sodiation mechanisms evolve upon electrochemical cycling, forming nanostructures which differ significantly from the initial electrode structure. I will discuss the impact of these evolving structural pathways on the physical properties and how these structural insights may aid future electrode material discovery and design.

Resolving the Influence of Structural Water on Li-Ion Diffusion in Pyrochlore Iron Hydroxy Fluoride Cathodes JulianF. Baumgärtner[1,2], MichaelWörle[1], KostiantynKravchyk[1,2] and MaksymV. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Lithium-ion batteries composed of cost-effective cathode materials exhibit substantial potential for large-scale stationary storage of electricity. Iron (III) fluorides are appealing low-cost energy storage materials due to the virtually unlimited supply of the constituting elements and high energy densities.[1] The pyrochlore modification is of particular interest because its 3D interconnected channels may potentially enable fast Li-ion diffusion.[2] However, the prohibitively high cost of synthesis and cathode architecture currently prevent their commercial use in low-cost Li-ion batteries. Moreover, amorphization upon prolonged cycling makes structural characterization of the Li-ion intercalation behavior challenging. Inspired by the synthesis of porous materials, such as metal organic frameworks, zeolithes and Prussian blue analogues, which often employ dissolved precursor building blocks that condense into the desired porous structure in the presence of a suitable templating agent, we reasoned that a similar approach could be used to synthesize the pyrochlore type structure at ambient conditions.
Herein, we extend this synthetic paradigm to access pyrochlore iron (III) hydroxy fluoride (Pyr-IHF) from soluble iron (III) fluoride precursors.[3] This facile dissolution-precipitation synthesis of Pyr-IHF allows the production at low costs (10-20 \$ kg^{-1}), competitive with Lithium iron phosphate. Guided by *operando* X-ray diffraction experiments, we selectively vary the solvent content inside the channels of Pyr-IHF by heat-treatment to study the effect of structural water on the Li-ion diffusion within the channels of Pyr-IHF. Rate capability tests of Pyr-IHF cathodes of different solvent content confirm this hypothesis, thereby providing the first experimental evidence for Li-ion diffusion occurring through the 3D channels of Pyr-IHF. Without the need for elaborate cathode designs, we demonstrate outstanding capacity retention of >80% after 600 cycles at high current densities of 1 A g^{-1}.

Pressure Driven Phase Transitions: A Look into the Future of Solid-State Refrigeration ClaireL. Hobday; University of Edinburgh, United Kingdom

Heating and cooling processes are responsible for 78% of the UK's environmentally damaging fluorinated gas emissions, primarily due to the employment of hydrofluorocarbon (HFC)-based refrigerant gases. [1] Such compounds are being phased out due to their devastating environmental impact, notably very high global warming potentials (GWP) (~2000 times that of CO_2). This has created a major technological and scientific challenge to find new types of refrigeration materials which are made from sustainable resources, have increased efficiency and are environmentally friendly throughout their entire lifecycle. There is now a strong focus on developing solid-state materials, which are easier to recycle, that demonstrate caloric effects. These have been shown to out-perform vapour compression technology in domestic refrigeration, additionally resulting in lower energy costs. [2] Caloric effects rely on the reversible thermal response of solids to an externally applied field (magnetic or electric field, or hydrostatic pressure) to give rise to magnetocaloric (MC), electrocaloric (EC) or barocaloric (BC) materials.

This talk focusses on understanding the barocaloric effect via study of order-disorder transitions in organic ionic plastic crystals (OIPCs). OIPCs provide a rich parameter space in which to explore the tunability of the BC effect experimentally. This class of materials are comprised completely of ions and at room temperature are solids with significant disorder in the crystal lattice. [3] The disorder comes from the rotational, translational and conformational motions which allows them to flow under stress and increases their conductivity, which has rendered them desirable solid-state electrolytes that can be used in batteries, fuel cells and solar cells. [4] OIPC's inherent order-disorder phase change properties are ideal as potential candidates for BC refrigerants; however, little is known about how to maximise their ionic conductivity, ability to flow and change phase.

In this work combined we explore the expansive chemical parameter space of ionic plastic crystals via a combined simulation and experimental approach. By employing pressure- and temperature-dependent single crystal/powder diffraction and differential scanning calorimetry experiments, we can understand structurally and thermally how these materials behave and by ion substitution, we demonstrate the ability to tune the transition temperature, isothermal entropy change, ΔS, and the barocaloric coefficient, dT/dP. Molecular dynamics simulations provide complementary information into the atomistic details of the complex landscape of the phase behaviour of these materials. Together, the results of this work can be used to inform the design of future solid-state refrigerants.

Barocaloric Hybrid Organic-Inorganic Salts for Green Refrigeration RichardJ. Dixey[1], ShurongYuan[1], BernetE. Meijer[1], NareshC. Osti[2], AnthonyE. Phillips[1] and HelenC. Walker[3]; [1]Queen Mary University London, United Kingdom; [2]Oak Ridge National Laboratory, United States; [3]Rutherford Appleton Laboratory, United Kingdom

Barocalorics are materials that undergo a solid-solid phase transition between high and low entropy phases, which can be driven by pressure to form the basis of a refrigeration cycle. As solids they are less prone to leaking and causing environmental damage than traditional haloalkane vapour-compression refrigerants.

We recently reported the molecular mechanism underlying the entropy change in the canonical plastic crystal adamantane, showing in the process that this material is an excellent low-temperature barocaloric [1]. We are now extending this approach to orientationally disordered crystals more widely; an obvious extension is to salts, where Coulomb as well as van der Waals interactions are significant.

Based on this approach, we have discovered a new family of hybrid organic-inorganic barocalorics: quinuclidinium salts, in which the near-spherical quinculidinium cation packs with inorganic counteranions into structures analagous to the alkali halides. The quinuclidinium ion is an excellent component for high-entropy phases since it strikes a fine balance between spherical geometry and anisotropy: its quasi-spherical shape promotes vibrational entropy arising from molecular libration, while the deviation from perfect spherical symmetry generates configurational entropy.

We have studied seven quinculidinium salts (with counterions Cl, Br, I, NO_3, BF_4, PF_6 and IO_4) by crystallography and high-pressure differential scanning calorimetry. These materials show solid-solid phase transitions between 290 and 340 K, entropy changes of up to 164 J/K.kg, and barocaloric coefficients dT/dP of up to 60 K/kbar, making them "colossal" barocalorics [2]. We show that chemically and physically simple changes in the inorganic counterion lead, for instance by changes in the hydrogen-bonding network, to subtle differences in the resulting materials' barocaloric properties.

A Low-Carbon Strategy to Synthesize Cobalt-Free Cathode Materials of Lithium-Ion Batteries JiananZhang, ChuweiZhang, MaanasaBhat and SiliDeng; Massachusetts Institute of Technology, United States

Given the high uncertainty of cobalt supply and related ethical concerns, the development of cobalt-free cathode materials has become an urgent priority for lithium-ion battery industry. Nevertheless, manufacturing cobalt-free cathode materials involves energy-intensive processes such as long-time high-temperature lithiation, which significantly contributes to the carbon footprint of cathode material production. As such, establishing low-carbon manufacturing strategies is crucial to improve the sustainability of energy storage applications, including electric vehicles and renewable energy grid storage. In this study, we propose a low-carbon technique, termed Flame-Assisted Spray Pyrolysis (FASP), characterized by its reduced synthesis time and utilization of hydrogen as an energy source. The FASP method demonstrated its efficacy in synthesizing cobalt-free cathode materials, particularly layered structure nickel-rich cathode materials. Using an inexpensive aqueous solution of metal nitrates as a precursor, FASP saves a significant amount of time and energy by reducing the calcination process from over 20 hours to just 40 minutes. Furthermore, with hydrogen as a supplementary fuel, FASP further mitigates carbon emissions compared to traditional heating methods.
Comparison with long-time calcinated samples in full cells using graphite as the anode confirms that the electrochemical performance of the newly synthesized cobalt-free cathode materials is maintained. This work also investigated the detailed material formation mechanism through X-ray diffraction and transmission electron microscopy. We found that uniform lithium distribution in the as-synthesized material prior to calcination was the key to shortening lithium diffusion, fastening layered structure formation, and preventing impurity phases. Furthermore, inhibiting the generation of hard-to-decompose lithium compounds, particularly lithium carbonate, was also critical in ensuring the desired electrochemical performance of fast-calcinated samples. Moreover, emission analysis shows that the carbon emission could be reduced by more than 30% with this novel synthesis route. The current work underscores the potential for FASP to significantly contribute to a low-carbon future in the manufacturing of cobalt-free lithium-ion batteries.

A Co-Free Li-Rich Layered Oxide Cathode without Voltage Decay for High Energy Solid-State Batteries YangRen; City University of Hong Kong, Hong Kong

Due to high specific capacity at low cost, Li- and Mn-rich layered oxides (LMRs) are very promising cathode materials for next generation batteries. However, these materials suffer severe voltage decay due to the unstable Li_2MnO_3 honeycomb structure, which has plagued its practical application for decades. Recently, we have designed and successfully synthesized a novel honeycomb structure for LMRs, where the honeycomb structure in the Li_2MnO_3 component is partially capped to strengthen its stability. This capped-honeycomb structure is persistent after high-voltage cycling and prevents TM migration and oxygen loss. As a result, the designed LMR material exhibits no voltage decay upon cycling, which is ideal for use in high energy solid-state battery.

Crystal Structure-Derived Intrinsic Principles for Low Thermal Conductivity in High Performance Thermoelectric Materials TakaoMori[1,2]; [1]National Institute for Materials Science, Japan; [2]University of Tsukuba, Japan

Development of thermoelectric (TE) materials & devices is important, for energy saving via waste heat power generation [1], and as dynamic power sources for IoT sensors, etc. [2]. There are traditional tradeoffs between the key physical properties which hinder to attain high TE performance. We are systematically developing principles which can circumvent the tradeoffs, namely to enhance Seebeck coefficient, and selectively lower thermal conductivity, in order to lead to viable materials and devices [3 and references therein].
In addition to various nanostructurings, crystal structure-derived mechanisms have been found to engender intrinsic low thermal conductivity. Materials informatics approach led to identification of a material catalogue with low thermal conductivity, with a simple crystallographic parameter as an effective descriptor [4]. Particular transition metal doping into SnTe was shown to lead to softening of the lattice, and a dramatic reduction of thermal conductivity largely exceeding the contribution from phonon scattering [5]. Minor amount of Cu doping into the interstitial site of Mg_3Sb_2-type compound led to large reduction of the phonon velocity and high performance rivalling the long time champion bismuth telluride [6]. Finally, the heterogeneous bonding in mixed anion compounds was shown to result in exceptional low thermal conductivity [7]. I will analyze these methods and ways for further TE enhancement. Support from JST Mirai Large-Scale Program (JPMJMI19A1) and collaborators are acknowledged.

Gas Phase Synthesis of Inorganic Nanomaterials on the Pilot Plant Scale MartinUnderberg, MathiasSpree, FrederikKunze, TimHuelser and SophieM. Schnurre; Institut für Umwelt & Energie, Technik & Analytik e. V. (IUTA), Germany

key applications for nanomaterials within rapidly developing markets. The production of nano scaled materials from gaseous precursors in the gas phase is a so called bottom-up method, the advantages of this synthesis route are process control, high purity products and the opportunity to design a continuous process. Generally, the highly specific properties of particulate systems are directly correlated with the size of each particle and applications often require highly defined properties.
In this work we provide an overview of our combustion, thermal decomposition and plasma assisted material synthesis on the pilot plant scale. Furthermore, direct transfer of these materials

into processable dispersions using wet electro precipitator technology will be presented.
The combustion based flame spray synthesis is a widely used in lab scale for the synthesis of nanomaterials, but has not reached industrial scale yet. Here, we present the generation of particles using easily available metal nitrates and demonstrate their conversion into defined nanoparticles in a spray flame. The composition of the particles can be adjusted and range from single metal oxides like titania to complex lanthanum strontium manganite (LSM or LSMO) perovskite particles with defined metal ratios. The particles are typically used in catalysis applications like hydrogen generation in electrolysis or the decomposition of versatile oxide components. We will demonstrate oxygen evolution ratio measurements on these materials.
Thermal decomposition is used for the generation of pure silicon material, which is a candidate for battery application. The decomposition of silane (SiH4) in a nitrogen/hydrogen atmosphere leads to the formation of highly crystalline material, which can be doped on demand. Production rates of up to 1kg/h material can be achieved using this method. Battery performance of silicon based materials has been evaluated and reveals promising results for future applications.
The plasma based system decomposes precursors at higher temperatures (T > 2000K) into atoms and subsequent nucleation leads to particle formation, while a steep temperature gradient helps to obtain nanomaterial with designed characteristics.
We report on the formation of graphene, since it offers high potential to improve a wide range of energy applications. It is well known that the combination of high production rates and material with defined properties is a major challenge in graphene synthesis. To address this, we performed eco-friendly continuous gas- phase synthesis of graphene on a pilot plant scale using easily available ethanol as precursor material. For this purpose, ethanol is evaporated and subsequently fed through an argon-hydrogen plasma generated by microwave radiation. The graphene powder is ex-situ analyzed by scanning and transmission electron microscopy as well as RAMAN spectroscopy, which reveals the typical signal of graphene with low defects. Results reveal that a throughput of 200 g/h of ethanol and low plasma energy supports the formation of graphene structures and, therefore, paves the way for energy efficient synthesis.

Fluorophlogopite (Mg-Mica) as a Novel Material for Enhanced Triboelectric Nanogenerators MinKyeongKim[1], WoojongKim[2], SoohongLee[1], JinpyoHong[2,2] and JohnHong[1]; [1]Kookmin University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Wearable electronics have gained significant interest in various applications, including healthcare monitoring, human-machine interfaces, and portable devices. The development of large-area wearable energy devices that can efficiently harvest biomechanical energy is crucial for sustainable and efficient applications. Triboelectric nanogenerators (TENGs) have demonstrated excellent potential in capturing biomechanical energy by converting mechanical energy into electrical energy. However, enhancing the output performance, flexibility, stretchability, and sensitivity of TENGs requires the exploration of new materials and device designs.
Mica, a raw clay mineral composed of layered silicates, has been identified as one of the most promising inorganic non-metal triboelectric materials due to its abundant availability and low friction coefficient. While previous studies have primarily focused on investigating the triboelectric properties of muscovite, this study introduces fluorophlogopite (Mg-mica), an artificially synthesized mica, as a novel material for TENG applications. Fluorophlogopite has not been previously utilized in TENG applications but has been studied as a dielectric material for capacitors due to its high dielectric constant. The fabricated TENG device using Mg-mica as the friction layer exhibited more than a twofold increase in output voltage compared to conventional mica-based TENGs.
Kelvin Probe Force Microscopy (KPFM) measurements were performed to validate the higher surface potential of Mg-mica compared to muscovite. The results indicated that the composition of metallic substances replacing silicon within the mica structure significantly influences the overall output voltage of mica. Additionally, output power measurements from the Mg-Mica-TENG demonstrated an open circuit voltage of 130V, a short circuit current of 6μA, and a maximum power density of 151mW/cm^2. These findings highlight the potential of Mg-mica as a promising material for the development of high-performance TENGs. Further research and exploration of different types of mica can lead to the discovery of more efficient and effective triboelectric devices.

Functionalization of Magnetite (Fe_3O_4) Nanoparticles with Cyclodextrin via Polydopamine Coating for Ciprofloxacin Remediation AgnesPholosi, OlayinkaEmmanuel, SaheedO. Sanni and SamsonAkpotu; Vaal University of Technology, South Africa

Superparamagnetic iron oxide nanoparticles are promising materials in emerging pollutants remediation due to their biocompatibility and easy surface modification. However, challenges of oxidation, agglomeration and surface defects still impair their commercial application. As such, a benign and green approach is a proposed strategy to overcome the limitations. In this study, magnetic nanocomposite was synthesized by coating magnetite with silica (SiO_2) using the modified stober route. The synthesized Fe_3O_4-SiO_2 was polymerized with dopamine in a basic solution to obtain Fe_3O_4-SiO_2-PDA followed by functionalization with β-cyclodextrin. The successful synthesis of Fe_3O_4-SiO_2-PDA-CD nanocomposite was confirmed through scanning electron microscopy (SEM), transmission electron microscopy (TEM), Fourier transform infrared (FTIR), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and vibrating sample magnetometry (VSM). Batch adsorption studies were conducted to investigate if the synthesized nanocomposite could adsorb ciprofloxacin from an aqueous solution. Functionalization of magnetite with polydopamine and cyclodextrin led to improvement in surface characteristics and incorporation of relevant functional groups. VSM results showed that magnetite retained its magnetic properties after incorporation of PDA and CD. Morphological and structural analysis showed the presence of iron, carbon, oxygen, and nitrogen with spherically shaped nanoparticles with average particle size of 12.02 nm. Maximum adsorption was achieved at pH 7 and equilibrium time was reached before 30 min. The adsorption kinetics suited pseudo second order model equilibrium data fitted Langmuir isotherm. The results indicate that the Fe_3O_4-SiO_2-PDA-CD is most efficient and could be applied over wide concentration ranges and temperature, and therefore, would be potentially feasible for the removal of ciprofloxacin and other emerging pollutants from wastewater.

8:00 PM SF03.06.03
Water Adsorption Inside Microporous CPO-27 Metal-Organic Frameworks MarvinKloß, ChristianWeinberger and MichaelTiemann; University of Paderborn, Germany

Metal-organic frameworks (MOFs) with open metal sites (i.e., vacated coordination sites) are particularly interesting for adsorption of guest molecules, especially water. One example is CPO-27 (M2(dhtp), dhtp = dihydroxyterephthalate) [1], also known as MOF-74 [2]. It is even more fascinating due to the variety of bivalent metal cations that can be used to synthesize this framework.

A detailed investigation of the hydration and dehydration of this series of MOFs revealed that water molecules inside the pores can be divided into three different types [3]: Primary water molecules coordinate to the metal (i.e., they occupy the open metal sites), secondary water molecules interact with primary ones via hydrogen bonding, and tertiary water molecules interact (only) with secondary ones. It was found that the interaction of water molecules with the framework is governed by the choice of the respective metal.

We present a comprehensive study of water inside the pores of a series of CPO-27(M) materials (M = Co, Cu, Mg, Mn, Ni, Zn). For this purpose, we carried out water sorption analysis and performed IR spectroscopic studies of water-loaded samples. We observe a strong impact of the respective metal on the incipient water uptake (i.e., adsorption in the low-pressure region). Furthermore, the metal center not only governs the interaction with the coordinated (primary) water molecules but has also an impact on the interaction with the secondary and tertiary water molecules. By humidity- and temperature-resolved DRIFT spectroscopic studies and by thermogravimetric analysis (TGA) we further investigate the dehydration behavior in some detail.

Lithiophilic Montmorillonite as a Robust Substrate for Uniform Lithium Deposition and Enhanced Electrochemical Performance BoNie and HongtaoSun; Penn State University, United States

Lithium metal is a highly promising anode material due to its exceptional theoretical capacity and low redox potential. However, issues such as uneven lithium deposition and uncontrolled volume expansion during cycling lead to cracks on the solid electrolyte interface (SEI), resulting in electrolyte consumption and dendrite growth. These challenges impede the commercial development of lithium metal batteries by causing poor performance, low Coulombic efficiency (CE), and safety concerns.

In this study, we investigate the potential of lithiophilic montmorillonite (MMT), a two-dimensional interlayered phyllosilicate material, as a robust substrate for achieving uniform lithium deposition and enhancing electrochemical performance. MMT possesses an interlamellar structure with an octahedron layer of aluminum oxygen sandwiched between two tetrahedron layers of silicon oxygen. This interlayered structure provides pathways for the transportation of exchangeable cations, including Li^+, Na^+, K^+, and Ca^{2+}. We focus on lithiophilic MMT as it exhibits a strong affinity for lithium ions.
By utilizing MMT as a substrate, we demonstrated the maintenance of uniform lithium deposition, which promotes enhanced electrochemical performance. The interlayered MMT structure facilitates fast diffusion channels for lithium ions and provides sufficient space to accommodate volume expansion, effectively leading to a dendrite-free lithium surface. To validate the stability of the lithium deposition process, we conducted in situ optical microscopy analysis and utilized COMSOL Multiphysics simulations. Our results showcase the effectiveness of MMT@Cu as an electrode material, achieving an average Coulombic efficiency of 99% over 700 cycles at a current density of 2 mA cm^{-2} with a lithium areal capacity of 1 mAh cm^{-2}. Additionally, the symmetric cell incorporating MMT@Cu demonstrates an extended lifespan of 20,000 minutes at 1 mA cm^{-2} for a 1 mAh cm^{-2} capacity. This work presents a novel strategy for suppressing dendrite growth and ensuring high-performance lithium metal batteries. The utilization of lithiophilic MMT as a substrate for uniform lithium deposition holds great promise in overcoming the challenges associated with lithium metal anodes, paving the way for the development of advanced lithium metal batteries with improved performance and safety.

8:00 PM SF03.06.05
Tubular Carbon Nanofibers with $MnCr_{2-x}Rh_xO_4$ Nanostructures Driven by Electrospinning and Its Application for Oxygen Evolution Reaction Catalysis JuheeYang, Myung HwaKim, YejinKim and Hee AhOh; Ewha Womans University, Korea (the Republic of)

As a result of development based on fossil fuels to this day, various environmental problems are being highlighted as a side effect. As part of the solution, one of the notable methods is the development of hydrogen energy through water decomposition. The OER, one of the half reactions of water splitting, does not occur thermodynamically well, so a catalyst to activate it is needed. Precious metals such as Ru, Ir, and Rh used as existing catalysts are expensive due to their scarcity. Therefore, it is essential to develop a cheaper and more efficient catalyst that can replace them.
We introduce facile synthesis of $MnCr_{2-x}Rh_xO_4$ nanostructures on carbon nanofiber (CNF) driven by electrospinning process. We expect that the partial introduction of Rh^{3+} ions into spinel B sites instead of Cr^{3+} ions could effectively perturb the electronic structure of the original $MnCr_2O_4$ nanostructures, resulting in the enhancement of the electrocatalytic activity for oxygen evolution reaction with beneficial effects of a high conductivity and specific surface area of CNF backbone. In this study, the shapes and compositions for $MnCr_{2-x}Rh_xO_4$ nanostructures on carbon nanofiber (CNF) in various synthetic conditions are carefully confirmed using the Scanning Electron Microscope (SEM), Energy Dispersive Spectroscope (EDS), and X-ray Diffraction (XRD). Furthermore, electrochemical performances for $MnCr_{2-x}Rh_xO_4$ nanostructures on carbon nanofiber (CNF) are performed to explore the electrocatalytic activity of oxygen evolution reaction reaction.

8:00 PM SF03.06.06
Advanced Output Performances of Thermoelectric Generator via Poled Ferroelectric Ceramics Ji YoungPark and Jeong MinBaik; Sungkyunkwan University, Korea (the Republic of)

Toward free-fuel energy society, the sustainable and renewable energy sources are necessary. There are various energy sources for that, however, each source has lots of problems to overcome. Thermoelectric generator (TEG) is a promising device for energy harvesting, which produces electric energy via the Seebeck effect. Due to the growing demands for electricity and the associated energy crisis, the importance of TEG also has been increased to solve environmental concerns. However, low energy conversion efficiency and stability still remain as the main challenges of TEG. To address these limitations, the recent work demonstrated the optimized Bi_2Te_3 ink-based TEG with charged triboelectric materials to enhance the output voltages by contact electrification. Although the output power was increased, the retention time was still short to applicate. Herein, we propose TEG with a Cu/p-type BiSbTe/Au/Cr/SiO_2/Si in which poled ferroelectric materials are attached at the cold zone. When the poled ferroelectric materials are attached at the back of TEG, the remanent polarization increases charge mobility permanently, inducing charges created on the TEG. The output voltage of TEG coupled with $BaTiO_3$ ceramic is 4 mV when the temperature difference is 10 K, which is up to 2 times higher than the output voltage of conventional TEG. In addition, when the $BaTiO_3$-added Pb(Ni,Nb)O_3-PbZrO_3-PbTiO_3 ceramic is coupled with TEG, the maximum output voltage was over 4 mV under the temperature difference of 10 K, which is 2 times increased compared to conventional TEG. This approach provides broad applications of TEG and will achieve practical uses by increasing output performance and retention time without material modification.

8:00 PM SF03.06.07
Facile Synthesis and Morphological Analysis of Si-Zr-C-O Fiber Felts with High-Thermal Resistance Young JunJoo, Young JunShim, HyukJunLee and KwangYounCho; KICET, Korea (the Republic of)

Silicon carbide (SiC) fibers with excellent oxidation resistance, high tensile strength, elastic modulus at high temperature are mainly used as a reinforcing material for ceramic matrix composites (CMCs). The polymer-derived SiC fibers are generally manufactured by the processes of melt-spinning, curing, and pyrolysis using polycarbosilane (PCS) as a ceramic precursor. The polymer-derived SiC fibers can be largely divided into amorphous SiC fibers and polycrystalline SiC fibers depending on the oxidation resistance temperature, and various manufacturing methods have been studied to fabricate high-performance polycrystalline SiC fibers. PCS for the spinning is mainly synthesized in autoclave and modified with organometallic compounds by reflux system. These methods showed good polymerization results, such as increases in molecular weight and ceramic yield due to the reaction between PCS and the zirconium source. However, there is a disadvantage that it requires a lot of time with specific equipment. Therefore, in the present study, a zirconium-added PCS solution for electrospinning was prepared by simple and easy blending method. In this studies, Si-Zr-C-O fiber mats were easily and simply fabricated via combination of solution blend and electrospinning methods. The various analyses were performed to verified that the blending method had the same effect as the autoclave or reflux methods.
In this study, Si-Zr-C-O fiber mats were easily and simply fabricated via combination of solution blend and electrospinning methods. The various analyses were performed to verified that the blending method had the same effect as the autoclave or reflux methods. Also, the zirconium added SiC fiber felts were heat-treated at 1500°C or 1600°C for 1 h in an Ar atmosphere to investigate thermal-degradation behaviors. Si-Zr-C-O fiber felts retained blackness and flexibility, whereas SiC fiber felts were thermal-degraded and discolored to gray. Moreover, the results confirmed that the growth of crystalline size (approximately calculated via XRD analysis) was significantly inhibited by the presence of zirconium. Therefore, zirconium acetylacetonate as a zirconium source was cross-linked with the PCS structure via the blending method and its role for heat resistance was exhibited at high temperature.

8:00 PM SF03.06.08
Electronic Structure of Ce-Containing Oxides by X-Ray Absorption Spectroscopy MaikoNishibori[1], KakeruNinomiya[1], HirotoTsuji[1], HinanoTabara[2], ShuheiYamaguchi[2], AkiraYoko[1], HidenoriYahiro[2] and TadafumiAdschiri[1]; [1]Tohoku University, Japan; [2]Ehime University, Japan

The valence change of cations constituting metal oxides plays an important role in the chemical and electronic properties of functional materials. Among them, Ce exhibits high oxygen storage capacity, oxygen mobility, and oxidation catalytic activity due to its ability to oscillate between Ce^{4+}/Ce^{3+} valence while maintaining a nearly constant ionic radius [1]. The Ce electronic state depends on the complex interaction between localized 4f electrons and the oxygen and vacancy orbitals [2], directly related to the material functionality. In this study, X-ray absorption spectroscopy was performed on CeO_2 nanoparticles (NPs) [3] to discuss the correlation between Ce local structure and electronic state.
The correlation between Ce-O bonding distance and Ce valence was investigated using CeO_2 with different particle sizes. In the Ce L_3-edge, although the Ce^{3+} increased slightly with decreasing grain size, the X-ray absorption fine structure (XAFS) spectral shape was nearly constant, suggesting that the CeO_2 state was maintained. On the other hand, in the Ce $M_{5,4}$-edge, the XAFS spectral shape changes significantly with grain size, and the peak intensity of Ce_{3+} remarkedly increases as the grain size decreases. This indicates that the electrons are localized in the Ce4f orbitals. Here, we investigated the O-Ce interaction from O K-edge XAFS spectra measurements. The O2p-Ce5d,eg and O2p-Ce5d,t2g peaks broadened with decreasing grain size. This suggests that the local structure of the CeO_8 hexahedron is disordered. On the other hand, the O2p-Ce4f peak intensity decreased significantly with grain size. This implies a decrease in the interaction between O2p and Ce4f orbitals. These results suggest that lattice expansion and distortion of CeO_2 may localize electrons in the Ce4f orbitals.
This research was partially supported by JSPS Grant-in-Aid for Scientific Research Grant Number 21H05010 and JP22H01764.

Single-Phase $CrVO_4$ and Rh-Doped $CrVO_4$ Nanostructures for Efficient Electrocatalytic Performance in Oxygen Evolution Reaction YejinKim, Myung HwaKim, Hee AhOh and JuheeYang; Ewha Womans University, Korea (the Republic of)

In recent years, research on hydrogen(H_2) as sustainable energy source has been widely conducted to deal with deteriorating energy problems. Water splitting is promising way to produce pollution-free H_2. However, overall efficiency of water splitting is restricted by sluggish kinetics of oxygen evolution reaction (OER), so effective catalyst is required. Noble metals have been widely studied as efficient OER catalyst, but their scarcity and high cost hinder sustainable water splitting. Therefore, it is necessary to devise an OER catalyst material which is cost-efficient and shows high catalytic activity toward OER. In this work, thus, we report facile formation of single-phase $CrVO_4$ and Rh-doped $CrVO_4$ nanostructures via simple acid-base titration

followed by thermal annealing process at various temperature and atmosphere conditions. Synthesized $CrVO_4$ nanostructures were then characterized by using Field Emission Scanning Electron Microscope (FE-SEM), Energy Dispersive Spectroscopy (EDS), X-ray Diffraction (XRD), Transmission Electron Microscope (TEM), X-ray Photoelectron Spectroscopy (XPS), micro-Raman spectroscopy. Electrochemical measurements are also conducted to confirm the effectiveness of $CrVO_4$ based nanostructures as an OER catalyst.

Two-Dimensional (2D) Assembly of Binary Shaped Nanoparticles BinWang and AndreaR. Tao; University of California, San Diego, United States

Programmable assembly of binary nanoparticles on the two-dimensional (2D) scale offers nanomaterials a variety of structures and properties that are difficult to attain via conventional means. Despite significant computational progress in the prediction and discovery of assembly phases for binary nanoparticle mixtures, experimental realizations are still lacking. We prepared the binary assembly of nanoparticles with two different shapes: silver nanocubes (AgNC) and gold nanospheres (AuNS). By varying the surface chemistries and composition ratios of AgNC and AuNS building blocks, we were able to access a variety of assembly behaviors and correlate them to different phases predicted in 'phase diagrams' by theory. This work bridges the gap between computational and experimental efforts and represents progress in understanding the assembly behavior of binary shaped building blocks.

Magnetic Nanoparticles in Biofilm Disruption: A Promising Approach to Combat Marine Fouling PayelBiswas and IreneAndreu Blanco; University of Rhode Island, United States

Marine biofilms, which are formed by the growth of various organisms, can negatively affect underwater surfaces such as boat hulls and bridge foundations. They can lead to increased fuel consumption, corrosion, and damage to the substrate, resulting in extra costs for biofilm removal procedures. Removing bacterial biofilms early on can prevent the attachment of harmful macro-organisms. This project proposes using magnetic nanoparticles (MNPs) to remove marine biofilms under alternating magnetic fields. Spherical iron oxide MNPs of 20 nm diameter were synthesized by the polyol method and their morphology, crystallinity and magnetic properties were evaluated by electron microscopy, X-ray diffraction and static and dynamic magnetometry. The MNPs are magnetite with a size close to the superparamagnetic/ferromagnetic transition at room temperature and present a saturation magnetization close to that of bulk magnetite. The synthesized MNPs were coated with a biocompatible layer of silicon dioxide via a sol-gel method and polyethyleneimine, a positively charged polymer with antimicrobial properties. The integrity of these coatings were verified and quantified using transmission electron microscopy, Z-potential measurements, and thermogravimetric analysis. The MNPs were internalized within *C. marina* biofilms and placed under alternating magnetic fields. Several high-frequency alternating magnetic fields, in the hundreds of kHz range, were tested. This frequency range is designed to promote MNP heating for our MNP morphology and composition. The morphology of the biofilm and viability of the bacteria before and after alternating magnetic field treatment were evaluated by fluorescence microscopy. The study will investigate the most effective MNP treatment regime and the effects of mechanical or thermal excitation on biofilm and bacterial physiology. The proposed research has the potential to provide a new and effective approach to addressing the problem of marine biofilms and could be used to treat biofilm caused by antibiotic resistant bacteria strains.

8:00 PM SF03.06.12
The Electrochemical Versatility of Manganese and Molybdenum-Based Materials Towards Rechargeable Aqueous Zinc Batteries JasonKuang[1], LeiWang[2,1], ShanYan[2,1], EstherS. Takeuchi[1,2], AmyMarschilok[1,2] and KennethJ. Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

As the demand for energy increases, large-scale energy storage systems will be required. Rechargeable aqueous zinc battery (RAZB) systems are promising systems for large-scale electrochemical energy storage especially due to the appropriate reduction potential and low cost of zinc and inherently safer operation from the non-flammable aqueous electrolyte. Further, with appropriate materials selection, there is opportunity for high specific capacity. Specifically, the oxide and sulfide analogs of manganese and molybdenum-based positive electrode materials are appealing for RAZBs, as they are low cost and environmentally friendly, and can be produced through scalable synthesis methods. The electrochemical versatility of Mn- and Mo-based materials as redox-active materials and catalysts in RAZBs will be highlighted in this presentation, including materials synthesis, electrode preparation, characterization, and electrochemistry results.

Production of Transparent Ceramics Based on YAG: Ce (Y3-xCexAl5O12) for use as X-Rays Detectors using Colloidal Process DaniloB. Janes[1,2], TarcísioMicheli Perfecto[1], IgorBarbosa da Cruz[1], ViníciusFortes Carvalho[1], IçamiraCosta Nogueira[1] and EdsonR. Leite[1]; [1]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil; [2]Federal University of Sao Carlos (UFSCAR), Brazil

Scintillators play a central role in modern engineering as converters of high-energy ionizing radiation (such as X-rays) into visible light, being one of the main components of radiation detectors. To meet the high demand for these components, in combination with the development of new materials and techniques for the production of increasingly efficient scintillators, a series of research has been carried out in recent decades. Yttrium Aluminum Garnet (YAG) is a material that stands out in different fields of scintillation. To produce transparent ceramics scintillators, in this work, Ce-doped YAG nanoparticles were prepared by the co-precipitation method, followed by calcination at 1100 °C. To achieve the desired microstructure and transparency for the final application of the material, conformation, and sintering were tailored to achieve the best parameters for obtaining such properties. Seeking to achieve a high green density through a colloidal process, using the pressure slip casting method, the concentration of solids in the colloidal suspension was a key parameter, as well as the colloidal stability and pressure applied during the slip casting. The final densities obtained for the different parameters were measured and compared. In this way, the purpose of this work is to present a methodology for the production of transparent ceramics scintillator by pressure slip casting method, seeking to reach the final properties necessary for use in the Sirius fourth generation Synchrotron, located at the National Center for Research in Energy and Materials (CNPEM) in Brazil.

Modulation of Electrical and Thermal Properties of Niobium Oxide by Alternating Oxygen and Hydrogen Plasma in Atomic Layer Deposition YunhaJung[1], SettasitChaikasetsin[1], HeungdongKwon[1], EunjooJung[2], Hyun sooHan[1], WoosungPark[2] and FritzPrinz[1]; [1]Stanford University, United States; [2]Sogang University, Korea (the Republic of)

Transition metal oxide films are a key material for various applications, such as neuromorphic devices, electrochemical energy systems, and optical systems. The material characteristics significantly vary with its stoichiometry between metal to oxygen due to its polymorphic nature. Despite much of previous work on conventional transition metal oxide, the impact of oxidation state on both electrical and thermal properties has been left underexplored. In this work, we modulate the stoichiometry of the metal oxide via alternating oxygen and hydrogen plasma during atomic layer deposition. We use niobium oxide as a sample material, demonstrating tunable electrical and thermal properties. Through systematic material characterization and electrical measurements, we find that the dielectric constant of niobium oxide is enhanced with increased electronic polarizability. Using the optical pump-probe method, the thermal properties are found to be tuned with the stoichiometry of niobium oxide.

Phase Transition, Tuned Ferroelectric, Pyroelectric and Electromechanical Properties in Hafnia Thick Films JalajaMa and PavanNukala; Centre for Nanoscience and Engineering (Cense), Indian Institute of Science (IISC), India

The unconventional ferroelectric behaviour in hafnia-based systems, particularly at nanoscale dimensions, holds great potential for advancements in nanoelectronics due to their Si compatibility, reduced toxicity, and simple chemical structure. However, there is ongoing debate regarding the precise mechanism of polarization switching in these films and the ferroelectricity in hafnia is considered to be originating from the orthorhombic crystal structure. The ferroelectric orthorhombic structure in hafnia can be stabilized by means of doping, process temperature, film thickness, choice of electrode and particle size. The stable phase in bulk Hafnia is monoclinic, and the orthorhombic phase is only stable to a few nanometre thicknesses.
Our study presents the ferroelectric, pyroelectric and electromechanical properties of 40 nm thick La-doped HfO_2 films prepared using a wet chemical method. We investigate the influence of process temperature, film thickness, and dopant concentration on achieving the desired orthorhombic phase. The films exhibit a polycrystalline structure with saturated polarization hysteresis loops, a remanent polarization value of approximately 27 $\mu C/cm^2$, and a 1.2 MV/cm coercive field value. Dielectric parameters are determined through C-V measurements, while the hysteretic

piezo response is measured using a Radiant hi tester, revealing an effective d_{33} value of around 10 pm/V for the La-doped hafnia films. The phase transitions originating from the defect dynamics in Hafnia are not well explored and we report a ferroelectric to non-ferroelectric phase transition around 140K. Our findings demonstrate the potential of the wet chemical method for fabricating La-doped HfO_2 films with desirable ferroelectric and electromechanical properties, even at larger film thicknesses (40 nm).

8:00 PM SF03.06.16

Gas-Solid Phase Reaction-Driven CO_2 Reduction : Exploring the Photocatalytic Potential of Silver-Bismuth-Iodide Rudorffite Jia-MaoChang[1], Ting-HanLin[1], Yin-HsuanChang[1], Kai-ChiHisao[1] and Ming-ChungWu[1,2]; [1]Chang Gung University, Taiwan; [2]Chang Gung Memorial Hospital, Taiwan

In recent decades, researchers have been striving to tackle climate change originated from global warming and searching a solution for CO_2 reduction. Photocatalytic CO_2 reduction is a promising solution to balance reduction greenhouse gas and creating energy sources. However, the main challenges of photocatalysts for CO_2 reduction are their wide band gaps and short lifetime of photo-induced electron-hole pairs. That not only limits their visible-light absorption but also inhibits the transportation of electron-hole pairs for catalytic reactions. Silver bismuth iodide rudorffite materials (SBI) having a relatively lower band gap, < 1.8 eV, and high absorption coefficient are selected for photocatalytic CO_2 reduction. Herein, we synthesize various SBI photocatalysts including $AgBi_2I_7$, $AgBiI_4$, Ag_2BiI_5, and Ag_3BiI_6 through a gas-solid phase strategy. Owing to the different crystal structures, SBI photocatalysts perform photocatalytic activity differently. To realize the correlation between crystal structure of SBI and photocatalytic activity, X-ray diffractometer (XRD), X-ray photoelectron spectroscopy (XPS), X-ray absorption spectroscopy (XAS), and photo-assisted Kelvin Probe Force Microscopy (Photo-assisted KPFM) are used to frame the mechanism of their photocatalytic CO_2 reduction. Through gas-solid phase reaction, the crystal structures of SBI productions can be easily manipulated by controlling the stoichiometry of their reactants, silver iodide and bismuth iodide. For Ag-rich compositions, Ag/Bi ratio ≥1, the SBI photocatalyst tends to crystalize in a hexagonal structure. The partial Ag ions are delocalized in the lattice and occupy the vacant tetrahedral sites between AgI_6 and BiI_6 octahedrons. That results in the formation of AgI secondary phase. On the other hand, Bi-rich composition, Ag/Bi ratio <1, prefers to form a cubic structure. Bi ions tend to partially substitute the central site cation, Ag, of AgI_6 octahedron. To insight the speculation above, XPS and XAS were applied to realize the electronic structure, valence state changes, and atomic environment surrounding Ag atoms in SBI materials. In terms of the Ag-rich components, they all exhibit a high density of uncoordinated silver, strong Ag-I bonding, and short bond length between Ag and I. The photocatalytic CO_2 reduction rate shows a significant relative to increasing the ratio of silver in SBI photocatalysts, Ag_3BiI_6 > Ag_2BiI_5 > $AgBiI_4$ > $AgBi_2I_7$. The same tendency of photocatalytic activity and electron configuration of SBI materials points out that the metallic Ag in SBI photocatalysts is the active sites for CO_2 photoreduction. Among the SBI materials, Ag_3BiI_6 shows the highest photocatalytic activity, achieving average CO and CH_4 production rates of 0.23 and 0.10 $\mu mol \bullet g^{-1}h^{-1}$. Furthermore, the results of Photo-assisted KPFM reveals the photo-induced potential change, contact potential difference (CPD), of SBI materials under different LED light sources including UV at 365 nm, blue at 470 nm, green at 530 nm, and red at 656 nm. The highest CPD of Ag_3BiI_6 validates that the photocatalytic CO_2 reduction rate is proportional to the evolution of CPD. The high CPD can be ascribed to the effective electron-hole pair separation that are originated from active Ag sites. The effective separation rate of electron-hole pairs promotes the photocatalytic CO_2 reduction activity. In summary, our study sheds the light in the curial role of SBI crystal structure in photocatalytic CO_2 reduction. By validating the active sites within SBI and unraveling its photocatalytic mechanism, we offer a promising solution to address the challenges of environmental pollution and the increasing demand for sustainable energy. The insights gained from our research pave the way for further advancements in the field of photocatalysis and contribute to the development of efficient and environmentally friendly CO_2 reduction technologies.

8:00 PM SF03.06.17

Exploring Photo-Piezocatalysis in Heterostructured Barium Titanate and Titanium Dioxide: Insights from Photo-Triggered Contact Potential Differences Ting-HanLin, Jia-MaoChang, Kai-ChiHisao, Kun-MuLee and Ming-ChungWu; Chang Gung University, Taiwan

Pollutants perpetually generated by various industries intensify the burden on the environment and progressively damage our living spaces. The combination of photocatalysis and piezocatalysis presents an intriguing technique for achieving pollutant degradation and potential in versatility and energy efficiency. However, the significance influence of catalysis reaction is sufficient electron-hole pairs to generate the reactive radicals. The piezocatalyts, triggered by mechanical strain and stress possesses a spontaneous polarization field of ferroelectric bodies on charge transport, and attract external charge on the interface. The effective modulation of the catalyst dielectric properties and the internal static electric field, improve the piezoelectric-induced catalytic performace. In this study, we synthesized a nanosized photo-piezocatalyst by incorporating titanium dioxide (TiO_2) with barium titanate ($BaTiO_3$) using an in situ hydrothermal method. Utilizing the spontaneous polarization of $BaTiO_3$ under strain to form a built-in electric field and high voltage coefficient, this promotes the separation of electron-hole pairs and enhances photocatalytic activity. As the reaction temperature increased, $BaTiO_3$ gradually grew onto the TiO_2 nanoparticle, promoting a phase transition in the crystal structure. At a critical temperature of 120°C, both the primary crystalline structures of $BaTiO_3$ and TiO_2 coexisted, revealing a heterostructure evident in microstructure observation. When compared to pristine TiO_2 and $BaTiO_3$, the $BaTiO_3$-TiO_2 photo-piezocatalyst demonstrated superior degradation activity towards methyl orange dye under both illumination and ultrasonic vibration. This resulted in a reaction rate constant of 0.01326 min^{-1}. It also proves that the incorporation of photocataylsyt and peizocatalyst is beneficial for the overall activities. To further explore strain-induced polarization in the photo-piezocatalyst, we employed Raman spectroscopy and noted a significant change in the typical phonon mode (E(LO + TO) + B1(309.0 cm-1)) for $BaTiO_3$ following compression. This suggests that lattice compression in BaTiO3 reduces the vibration of oxygen atoms and alters the dipole properties in the $BaTiO_3$-TiO_2 photo-piezocatalyst. To understand the enhancement mechanism of photo-assisted piezocatalysis, we used an innovative photo-induced in-situ Kelvin probe analyzer to measure the contact potential difference (CPD) of the material. The generation of electron-hole pairs through photo-assisted excitation of photosensitive materials causes a shift in the Fermi energy band, yielding a greater surface potential difference, indicating increased photosensitive properties.Tests on the optimal $BaTiO_3$-TiO_2 photo-piezocatalyst revealed that the change in CPD of $BaTiO_3$-TiO_2 exhibits a delayed behavior under continuous UV LED illumination in both short-term and long-term illumination switch tests. We infer that the hysteresis of CPD could be caused by photo-induced charge driven by TiO_2, which reduces the polarization of $BaTiO_3$. This phenomenon likely contributes to interfacial charge migration under photo and ultrasonic vibration, possibly extending the charge life and maintaining a sufficient surface charge concentration for radical generation. Consequently, the overall piezoelectric and photocatalytic characteristics are significantly improved. The photo-peizocatalyst is expected to be applied in cyclic wastewater treatment in the future, using the surface local stress generated by water flow to achieve the goal of degrading pollutants.

8:00 PM SF03.06.18

Synthesis, Modification and Characterization of $BaBiO_3$ Thin Films EdvinT Berhane, SpencerDoyle, CharlesBrooks and JuliaMundy; Harvard University, United States

The perovskite $BaBiO_3$ exhibits superconductivity around 30 K when doped with potassium on the A-site. This is the highest observed transition temperature for an oxide superconductor without copper. $BaBiO_3$ is also predicted to be a large-bandgap topological insulator when electron-doped. However, the topological insulator state has not been realized experimentally thus far. Here we synthesize high-quality phase-pure thin-films of $BaBiO_3$ on strontium titanate substrates using reactive-oxide molecular beam epitaxy. We study various dopings and post-growth modifications focused around achieving a superconducting or topological insulator state. X-ray diffraction, atomic force microscopy, and x-ray photoemission spectroscopy are used to characterize the quality and content of our films.

8:00 PM SF03.06.19

Growth and Characterization of N-Doped VO2 Thin Films for the Thermochromic and Smart Windows by the Mist Chemical Vapor Deposition TaiseiKano, YutaArata, HiroyukiNishinaka and MasahiroYoshimoto; Kyoto Institute of Technology, Japan

Vanadium dioxide (VO_2) has attracted considerable attention after F. J. Morin reported that it exhibits a metal-insulator transition(MIT) at around 67°C [1]. The MITs of VO_2 have been demonstrated to occur by various stimuli, such as heating, applying voltage, and light, and to be used for smart windows, to absorb and reflect infrared(IR)-region light at a high temperature to prevent it from entering inside the room. To apply the smart windows using the MIT derived from the heat, the transition temperature is higher than the expected temperature operated around 30°C. Therefore, experiments and theoretical calculations have been conducted to decrease the MIT temperature of VO_2 thin films by incorporating other elements, such as N, F, and Mo. In previous report, N-doped VO_2 thin films were deposited by reactive pulsed laser deposition (PLD) and the MIT temperature decreased at 50°C [2]; however, further investigations are necessary to decrease at 30°C. On the other hand, J.G. Lu et al. reported that mist CVD allowed to dope N into oxide thin films [3]. Furthermore, our group demonstrated that VO_2 thin films were deposited by mist CVD on synthetic mica substrates and showed a tunable MIT temperature through bending stress. In this study, we doped nitrogen(N) into VO_2 thin films to decrease the transition temperature by mist CVD and investigated the impact of N into thin films on the MIT temperatures.

First, N-dope VO_2 thin films were grown on a synthetic mica substrate with a SnO_2 buffer layer to control the VO_2 orientations. X-ray diffraction 2θ-ω analysis revealed peaks of the VO_2(010) plane and the buffer layer SnO_2(100) plane in the undoped and N-doped samples in the temperature range from 425°C to 500°C. Furthermore, SIMS revealed that N concentration in the VO_2 thin film was approximately $10^{20}cm^{-3}$ at the growth temperature of 425°C. Thus, we successfully grew N-doped VO_2 epitaxial thin films by mist CVD.

Temperature-resistance characteristics were measured of the VO_2 thin films to investigate their electrical properties and MIT temperatures. For undoped samples, the transition temperature slightly decreases with decreasing growth temperature, consistent with the results by Matamura et al. [4]. On the other hand, N-doped VO_2 thin films exhibited a decrease of the transition temperature, and the MIT temperature of VO_2 thin films at the growth temperature of 425°C was 30°C. This indicates that the VO_2 thin film blocks the IR light from entering the room above the 30°C using as the thermochromic and smart windows. This result is lower than the transition temperature of 50°C reported using PLD.

The transmittance of the N-doped VO_2 thin films was investigated as varying the measurement temperatures. Similarly to the electrical properties, the N-doped VO_2 thin film grown at 425°C showed the transition at around 30°C. These results pave the way for the thermochromic and the smart windows applications that can help address future energy problems.

Bulk Alumina Glasses and Glass-Ceramics with Multiple Stabilizers AngshumanGupta, AnuMohan and AshutoshS. Gandhi; Indian Institute of Technology Bombay, India

Alumina rare-earth oxide glasses have unique properties, including high chemical resistance, high hardness, and a high refractive index in the IR region, with potential applications in optical devices. Alumina (Al_2O_3) alone cannot be obtained as bulk glass, although it can act as a network former. Alumina can form glasses when alloyed with calcia, zirconia, and other rare-earth oxides. It has been observed that the glass-forming ability and short-range ordering are enhanced if the size difference of the constituent cations is large. Having excellent optical and mechanical properties, the development of alumina based glasses is hampered by their high melting points and the high cooling rates required to obtain the glassy structure. Several studies have been conducted to obtain alumina-based glasses using splat quenching, aerodynamic levitation, and flame spraying; limiting the size to thin films, ribbons, fibers, and small spheres. Obtaining bulk alumina glasses is challenging because of their limited thermal stability against crystallization. Chemical synthesis techniques, including co-precipitation, sol-gel, spray pyrolysis, and solution combustion synthesis (SCS), provide alternate routes to obtain glassy powders. In the present work glassy powders were obtained by utilizing SCS process, because it is simple, fast and cheap. Compositional space for Al_2O_3 based glasses was explored by varying the amounts of different stabilizers such as CaO, Gd_2O_3, La_2O_3, TiO_2, Y_2O_3, Yb_2O_3, ZnO, ZrO_2. The stabilizers were chosen based on their efficacy in stabilizing the glassy state. Compositions were designed by varying alumina content from 60-80 mol% and rest in four to eight stabilizers in equimolar ratio. The amorphous phase stability and crystallization sequence of the synthesized powders were investigated. A few compositions showing higher glass phase stability were selected for the densification studies. Sintering of calcined powders was carried out under pressureless, vacuum, and hot press sintering conditions. First time, extensive densification was observed under free sintering and vacuum sintering conditions without undergoing crystallization. This study opens up the opportunity to obtain bulk dense alumina glasses.
Being metastable, a glassy phase always has the driving force for crystallization. Bulk dense glasses can act as precursors for nanostructured ceramics as the crystallization is carried out at low temperatures so that the nucleation rate is much greater than the growth rate. Crystallization of bulk alumina glasses into nanocrystalline oxides was carried out by suitable thermal treatment with and without applied pressure. X-ray line broadening and HRTEM images were used to find the sizes of nano-crystals. Microstructural characterization was carried out on these nanocrystalline glass-ceramics, in addition to basic mechanical property evaluation. Precession electron diffraction (PED) analysis was carried out on crystallized glasses, for phase mapping and crystallite orientation mapping.
Structural modification taking place during consolidation were studied by ^{27}Al MAS NMR and X-ray absorption spectroscopy (XAS). ^{27}Al MAS NMR was utilized to probe the local structural units around Al cations and clearly indicated the presence of AlO_x units (x = 4, 5, 6) in the calcined powder. The relative abundances of different Al sites, isotropic chemical shift (δ_{iso}), and average quadrupolar coupling constant ($<|Q_C|>$) fitting parameters were extracted using a simple Czjzek model. Extended X-ray absorption fine structure (EXAFS) was used to probe the local structural changes around different stabilizing cations. EXAFS studies indicated that the local structure around the stabilizing ions remains unaffected during pressureless sintering. Characterization by NMR spectroscopy suggests that structural changes/relaxation during densification originate from the short-range collective rearrangement of AlO_x polyhedra.

8:00 PM SF03.06.21
Fabrication of Nanostructure on Waste Glass from End-Of-Life Vehicles by NaOH Leaching TatsumiNaganuma[1], ToshihiroKuzuya[1], HisayoshiMatsushima[2], KenSawada[1], NaoyaSawaguchi[1] and AkiraSato[3]; [1]Muroran Institute of Technology, Japan; [2]Hokkaido University, Japan; [3]MATEC Inc, Japan

We have investigated upcycling of waste glass from end-of-life vehicles. The waste glass contains various additives such as Ce, Ti, and other transition metals for UV-cut and coloring. Furthermore, alkaline earth metals were added to adjust the mechanical and chemical properties of the glass. These additives would better be used to fabricate upcycling glasses with novel functions. Therefore, we investigated the facile alkaline leaching to fabricate the nanostructure of these additives' oxides.
Front and front door glass were recovered from end-of-life vehicles and pulverized into glass cullets. XRF analysis indicated that the glass cullet contained Ce, Fe, and alkaline earth metals. Glass cullets were heated at 1673K for 3 h. The glass melt was quenched on the steel plate and formed into a plate shape. Then, the as-quenched glass was annealed at 873 K for 2 h and cooled for 24 h to ambient temperature. Glass samples were cut to 7.5× 7.5mm^2 with a diamond cutter and mechanically polished to obtain a mirror finish. And then, the polished glass was annealed at 873K near the glass softening point for 24h. After annealing, the glass surface was polished again with 3 to 4 μm diamond paste. The glass samples were immersed in 1.0 mol/L NaOH solution for 1 or 8 days to etch Si atoms on the surface selectively. The morphology of the nanostructure formed on the surface was observed using an atomic force microscope (AFM) and a scanning electron microscope (SEM). A treated glass sample was thinned by a focused ion beam (FIB) to observe the distribution of elements near the glass surface using a STEM-EDX. The chemical state of the element on the glass surface was analyzed by XPS.
AFM images indicated a significant surface morphological change between before and after etching. In the 1-day-etched glass, nano-sized precipitates were observed. After 8 days, the micrometer-order precipitates were also observed. XPS wide spectra indicated that the peak intensities of the Fe-2p, Ca-2p, Mg-2p, and Ce-3d relatively increased. The Ce-3d peak structure suggests that the Ce ion took the tetravalent state. STEM-EDX images revealed a thin film of approximately 25 nm thickness containing Fe, Ca, and Ce on the sample surface. This result is consistent with the XPS results. Furthermore, STEM and TEM images revealed nanosized cavities under the thin film of additives.
NaOH reacts with SiO_2 to form soluble $Na_2O(SiO_2)_x$. On the other hand, cerium hydroxide, calcium hydroxide, magnesium hydroxide, and iron hydroxide are deposited on the surface due to their low solubility products of 2.0×10^{-48}($Ce(OH)_4$), 5.02×10^{-6}($Ca(OH)_2$), 5.61×10^{-12}($Mg(OH)_2$), 2.79×10^{-39}($Fe(OH)_3$), respectively. As the leaching reaction proceeded, an insoluble hydroxide film formed and grew on the glass surface. Then, the leaching reaction proceeded through this thin film. As a result of this reaction process, the cavities were considered to be formed under this thin film. Because alkali earth metals and cerium exhibit strong interactions with phosphoric acid, a glass surface enriched with these elements is expected to be a strong candidate for antimicrobial and phosphoric acid recovery materials.

8:00 PM SF03.06.22
Thermoelectric Properties of P-Doped and B-Doped Polycrystalline Silicon Thin Films KeisukeShibata[1], ShinyaKato[2], MasashiKurosawa[1], KazuhiroGotoh[1,3,4], SatoruMiyamoto[1], TakashiItoh[1], NoritakaUsami[1,5] and YasuyoshiKurokawa[1]; [1]Nagoya University, Japan; [2]Nagoya Institute of Technology, Japan; [3]Niigata University, Japan; [4]Interdisciplinary Research Center for Carbon-Neutral Technologies, Niigata University, Japan; [5]Institutes of Innovation for Future Society, Nagoya University, Japan

Thermoelectric power generation (TEG) is one of the ambient energy sources and a clean power generation method that directly converts heat, an unutilized energy source, into electrical energy. TEG modules are safe, maintenance-free, and can be expected to be used over the long term because they can be operated with a simple structure that has no driving parts.
Silicon (Si) is the 2nd most abundant materials in the Earth’s crust and is relatively cheap and non-toxic. However, its high thermal conductivity κ is a bottleneck for usage as a TE material. Many silicon-based next-generation TE materials have been investigated to reduce κ and improve the Seebeck coefficient *S*. In TE materials, a structure called PGEC that behaves like a glass for the phonons responsible for thermal conduction and like a crystal for the carriers responsible for electrical conduction is considered suitable. One of the strategies to decrease high κ by phonon-scattering and maintain high electrical conductivity σ is nanostructure by developing polycrystalline Si (poly-Si) from amorphous Si (a-Si).
This study focused on the annealing process of P-doped and B-doped a-Si thin films prepared by plasma-enhanced chemical vapor deposition (PECVD). In PECVD, it is easy to control a doping concentration at the high doping level, since PECVD is a non-equilibrium process. Moreover, the effective κ of thin films can be decreased by reducing the thickness due to the influence of interfacial thermal resistance and surface phonon scattering. After post-annealing, TE properties of P-doped or B-doped poly-Si thin films were measured from room temperature to 873 K.
P-doped or B-doped hydrogenated a-Si (a-Si:H) thin films were prepared on a quartz substrate by PECVD. After deposition, the samples were annealed at 1173 K for 30 minutes under a forming gas atmosphere (N_2: 97%, H_2: 3%). The σ, the *S*, and thermal diffusivity were evaluated under an Ar atmosphere using a TE property measurement system. The κ was estimated from the data of thermal diffusivity, density, and mass heat capacity of a-Si. From spectroscopic ellipsometry, the thicknesses of P-doped and B-doped poly-Si thin films were estimated to be 480 and 440 nm, respectively. In Raman scattering spectra, the peaks derived from the crystalline silicon phase did not appear in both samples. a sharp peak due to the crystalline silicon phase was observed at 514 cm^{-1} for both samples. Crystal volume fractions of P-doped and B-doped thin films were estimated to be 0.32 and 0.51, respectively. The *S* for both types tended to increase with increasing temperature up to -231 μV/K and 301 μV/K. The σ tended to decrease for P-doped and increase for B-doped with increasing temperature. On the other hand, the κ was not changed with temperature and was lower by about two orders of magnitude compared with that of bulk Si. In the case of P-doped poly-Si, the dimensionless figure of merit *ZT* exceeded unity around 573 K, and *ZT* = 1.92 was obtained around 873 K. This *ZT* value is relatively high compared with Si-based TE materials previously reported. This may be due to the high σ of 629 S/cm with a doping concentration of ~10^{21} cm^{-3} and the low κ of 1.51 W·m^{-1}·K^{-1} at 873 K. The increase in crystallinity enhances dopant activation, leading to the increase in carrier concentration, and also enhances carrier mobility. That is why high σ was obtained. Moreover, the low κ was obtained, which is as low as that of quartz. This may be due to the thermal interfacial resistance (R_{int}). When the thickness of the poly-Si thin film and the intrinsic κ of bulk Si at 873 K were assumed to be 480 nm and 38 W·m^{-1}·K^{-1}, the R_{int} was estimated to be 3.05×10^{-7} m^2·K·W^{-1}, which is in the range of previously reported R_{int} at a Si/SiO_2 interface, suggesting that the low κ is due to R_{int}. In the presentation, we will also provide the dependence of TE properties on crystal volume fraction and doping concentration.

8:00 PM SF03.06.23
Pulsed Laser Deposition of RuO_2 Thin Films for Cryogenic Temperature Measurements DenisAglagul and JianShi; Rensselaer Polytechnic Institute, United States

Ruthenium oxide (RuO_2) has a well-resolved temperature-resistivity response making it a compelling choice for cryogenic temperature measurement. In this work, we report the use of pulsed laser deposition to grow RuO_2 thin film on various substrates such as GaAs and Au. We characterize the crystallinity of as-grown and post-annealed films by x-ray diffraction. We evaluate its temperature sensitivity, as a function of deposition conditions such as pulse energy, growth temperature, oxygen partial pressure, and substrates, with electrical transport measurements from liquid helium temperature to room temperature. By growing RuO_2 film on our thermal-active samples, we evaluate the thermodynamic performance of the thermal-active devices.

8:00 PM SF03.06.24
Implementing a-IGZO Thin-Film Transistors on Thin Ceramic Substrates to Reduce Self-Heating Effects MeganNoga, ChristineMcGinn, SourabhPal, VikrantKumar, ReemAlshanbari, RajinderS. Deol, OliverA. Durnan and IoannisKymissis; Columbia University, United States

In recent years, amorphous indium gallium zinc oxide (a-IGZO) thin film transistors (TFTs) have proliferated in both small-scale research and industry products due to the metal oxide's beneficial properties. IGZO's optical transparency, high and tunable mobility, and relatively low cost has made it an appealing candidate for use in applications ranging from gas sensors to electronic backplane arrays. However, the stability of a-IGZO TFTs is limited by the degree to which such devices' electrical performance varies with changes in factors like operation temperature. For this reason, the reliability of a-IGZO TFTs can be improved by reducing the amount of self-heating that the transistors experience due to Joule heating and other effects. Previous investigations have focussed on mitigating the self-heating effect by altering the structure or driving conditions of the TFT itself. While TFT modifications, such as restricting the bias voltage and frequency or tuning the channel width, can reduce self-heating, methods of reducing device temperature that are independent of or work in conjunction with TFT structure and operation adjustments could be beneficial. For example, building TFTs on a substrate that significantly reduces self-heating would allow device optimization efforts to concentrate on other improvements, such as increasing mobility.
Recent work has shown that thin, thermally-conductive substrates can be used as passive heat-sinks for microLEDs. MicroLEDs built on 80 um-thin Corning Alumina Ribbon Ceramic demonstrated less self-heating and less external quantum efficiency (EQE) reduction compared to microLEDs built on standard glass substrates during both I-V speed curve and drive time tests. Additionally, the microLEDs built on the ceramic substrate outperformed those built on glass during destruction testing, exhibiting superior optical power outputs at higher driving currents [3]. While the mechanisms contributing to the self-heating of microLEDs are not identical to those affecting TFTs, heat-sinking a significant portion of the thermal energy generated by the Joule heating effect prior to the deterioration of electrical characteristics would improve TFT stability regardless of device structure or biasing conditions.
In this work, we explore ongoing efforts to reduce self-heating in a-IGZO TFTs by implementing them on thin ceramic substrates. The extent to which the devices are experiencing self-heating under standard and stressed biasing conditions is quantified by analyzing the current droop visible on the TFT I-V curves, corroborated using infrared thermal imaging techniques, and compared to the performance of identically-structured a-IGZO TFTs built on thicker glass substrates. Additionally, the degree to which the thickness of the ceramic substrate affects TFT stability is analyzed, and reliability improvements across different TFT structures, compositions, and operation environments are normalized to assess the extent to which ceramic heat-sinking could benefit a variety of metal oxide TFT applications.

8:00 PM SF03.06.25
Ultrathin Nanofibrillar Cu Sheet Covered with Directly Grown Lithiophobic CNT for Anode-Free Li-Metal Battery Anode Current Collectors InyeongYang, DongyeonWon, SukkyungKang and SanhaKim; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

Li-metal batteries (LMBs) are in the spotlight because of their low electrochemical potential and high energy density (3860 mAh/g) of Li-metal. However, low electrochemical reversibility and side reaction including SEI formation still remain as challenges. LMBs with excessive Li in the anode, thus having high N/P ratios, has been proposed to compensate the low reversibility and fast capacity loss, yet their energy density becomes even lower than that of Li-ion batteries when the N/P ratio is higher than 3. Therefore, to maximize the advantages of Li-metal while minimizing safety problems caused by Li, anode-free Li-metal batteries (AFLMBs) with N/P ratio = 0 is ideal.
In AFLMBs, unlike the conventional LMBs, the anode current collectors (CCs) are not completely covered by Li. In addition, only limited amount of Li is cycled. As a result, fast capacity loss and side reactions including galvanic corrosion at the anode arise as new challenges. In this research, we study the effect of three-dimensional surface structures in copper anode CCs in AFLMB, and suggest novel fabrication strategy to enhance the electrochemical reversibility of Li and minimizing side reactions. The nanofibrillar Cu network in a form of thin sheet is fabricated through a rearrangement process of Cu on the woven Cu wiremesh via electrochemical etching and electrodeposition. The electrodeposited nanofibers exhibit approximately 400 nm in diameter. We can control the nanofibrillar sheet thickness to be 15 μm in minimum, which equivalent to 8 μm thick Cu foils in mass per unit area, yet the surface area is yet significantly greater. In addition, an optimized thermal reduction treatment method is suggested to interconnect the Cu nanofibers, effectively increasing the electrical conductivity in nano-scale. We quantitatively evaluate the capacity loss, the charge transfer resistance, and the side reaction including galvanic corrosion according to the sheet thickness and surface treatment. By introduction of a rationally-designed ultrathin nanofibrillar sheet as the Cu CC, we experimentally confirm reductions in overpotential and in side reaction in AFLMB by 0.3 V, and 90%, respectively. Accordingly, the discharge capacity at the first cycle can be enhanced by 36%. Finally, we decorate the top of the three-dimensional anode CC with carbon nanotubes (CNTs), as a lithiophobic nanoporous layer. Multi-walled CNTs with diameter of ~10-20 nm are directly grown on the surface of Cu nanofibrillar sheet via thermal chemical vapor deposition. The top CNT layer can further enforce the growth of Li inside the nanofibriallar Cu CCs, and thereby maximizes the reversible Li cycling in AFLMBs.

8:00 PM SF03.06.26
Memory Effect of Surfaces: From Wetting to Electrification WilliamS. Wong[1,2]; [1]Aalto University, Finland; [2]Max Planck Institute for Polymer Research, Germany

The *"Memory Effect"* is often a phenomenon attributed to bulk materials, such as shape memory alloys or polymers. The resulting behaviors are often macroscopic and highly mechanical. When considering surfaces and interfaces, responses are often much more subtle in nature. Nonetheless, re-orientation of surface moieties such as oligomers, molecular groups, ions, and electrons can lead to macroscopically-detectable responses. In this work, we use water drops as the stimuli and the ambient environment (r.t.p.) for recovering the equilibrium condition.

In the first instance, we used a polydimethylsiloxane surface with minute amounts of uncrosslinked oligomers. Upon drop-wetting, the surface experiences increased lubricity due to the water-induced surface saturation of oligomeric moieties which decreases the contact angle hysteresis (and thus adhesion). The surface recovers its pristine behavior upon environmental equilibration. We model this contact memory behavior behind the use of first-order adaptation dynamics and demonstrate how they deviate from both traditional molecular kinetic and hydrodynamic theories (which do not account for adaptation).

In the second instance, we synthesized a multi-layered/composited surface. Firstly, a base hydrophobic layer (perfluoroalkylated or alkylated) is fabricated. Upon drop-wetting, it acquires a positive charge while the surface is negatively counter-charged. To dynamically flip the charge polarity (*i.e.* polarity reversal), the hydrophobic layer is then coated with a long-chained (C_{10}) multi-amine. The presence of the amine results in a redox response (ion transfer with $-NH_2$ as an H^+ acceptor) during drop-wetting. The long alkyl chain hinders molecular mobility, enabling a gradual real-time observable polarity reversal (within a few seconds). Therefore, depending on the drop-contact interval, the magnitude, and polarity of charge responses are now tunable, highlighting contact-memory behaviors. The surface recovers its pristine behavior upon environmental equilibration.

Layered Double Hydroxide/Boron Nitride Nanocomposite Membranes for Efficient Separation and Photodegradation of Water-Soluble DyesÁineCoogan[1], NataliaGarcia Domenech[1,2], DonaghMcGinley[1], TigranSimonian[1,1,1], AranRafferty[1], QuentinFedix[3], AmyDonlon[1], ValeriaNicolosi[1,1,1] and YuriiK. Gun'ko[1,1,2]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]University College Dublin, Ireland; [3]Institut Universitaire de Technologie Clermont-Auvergne, France

Increasing scarcity in access to clean, safe water is being fuelled by escalating industrialisation, rapid urbanisation and biodiversity loss, and the relentless forces of climate change. Therefore, the need for development of innovative and sustainable methods of water purification is of the utmost urgency. Nanofiltration is proving to be an increasingly attractive potential solution to this global issue.[1,2]
Previous reports of nanofiltration membranes using boron nitride (BN) and partially oxidised BN (BNOx) have demonstrated outstanding performance, achieving retentions of up to 100% for various water-soluble dyes which can be harmful to humans and aquatic life.[3,4] However, the main drawback of these membranes is their vulnerability to membrane fouling, meaning they must be disposed of after a single use. Consequently, innovative approaches to mitigate membrane fouling are crucial to ensure the long-term sustainability of current and future nanofiltration technologies. Herein, we report the development of novel high-performance nanofiltration membranes based on a recyclable CuAl-CO_3 LDH/BNOx nanocomposite. These membranes have demonstrated up to 100% retention of several water-soluble dyes (Evans blue, methyl orange, methylene blue and rhodamine B). Additionally, they exhibit excellent water flux, over 2 orders of magnitude higher than commercially available nanofiltration membranes. The incorporation of CuAl-CO_3 LDH photocatalyst within the nanocomposite membranes enables up to 91% visible-light-induced photodegradation of these dyes within 120 minutes using a household LED lamp.

This introduction of photocatalytic functionality into existing nanofiltration membranes offers a low-cost, innovative route to the mitigation of membrane fouling. Significantly, this work demonstrates the first instance of Evans blue degradation by a visible-light active LDH photocatalyst. Overall, we believe this work represents a significant advancement in the field of advanced nanofiltration technology, offering superior performance and enhanced sustainability.[5]

Potential Applications of Electrically Conductive Concrete DouglasX. Shattuck[1,2], ZoieZeng[3], ZachariasDaniel[4] and ArshKhan[5]; [1]St Joseph School Wakefield, United States; [2]National STEM Honor Society, United States; [3]Andover High School, United States; [4]Boston University Academy, United States; [5]Wilton High School, United States

Research Summary

Following in the footsteps of many[1,2,3], our objective was to investigate whether electrically conductive concrete could be used to de-ice roads[4], regulate surface temperature, or convert heat to energy in hot environments. Several 5cm^3 (2in^3) samples with embedded electrodes were fabricated. Concrete formulas containing conductive materials such as carbon fibers, iron powder, and steel wool were prepared [5,6,7]. Preliminary results indicate this technology has the potential to reduce the use of environmentally harmful chemicals, provide control surface temperature and produce energy in hot climates.

Electrically Conductive Concrete

Using a 12v DC power source and multimeter, current was measured between electrodes. Compressive strength was tested using a Rebound Hammer. Two concrete batches were prepared with 5% or 15% conductive material by volume. 5% Iron Powder and 15% Steel Wool were the most electrically efficient. The 15% Iron Powder samples lost compressive strength, shattered and were eliminated. The current was applied to all of the samples for two hours. Temperature was read using a commercially available infrared thermometer. The Iron Powder and Steel Wool samples averaged a 7° increase in temperature above room temperature.

Regulating Temperatures

Phase-changing materials (PCM) absorb or releases energy [8,9]. To investigate the rate of temperature change in concrete we cut paraffin wax, the PCM, into 1cm^3 cubes and added them to the concrete mixtures. We constructed a test chamber with electric heaters to heat our samples to approximately 180°. The initial temperature of the cured samples was ~73°. After 10 minutes the temperature of control samples rose 58° to 131°. The PCM concrete's temperature rose only 34° to 107°. From 10 to 30 minutes, the temperature of both samples rose at the same rate. After 40 minutes, the rate of change slowed and at 50 minutes all samples reached a constant temperature, around 185°. The temperature increase was delayed during the initial heating, presumably during the time the paraffin was absorbing the heat energy.

Thermal Energy

Seebeck, Peltier, and others developed thermoelectric generators to convert heat to electricity. [10,11,12]. To use the Seebeck Effect, we used 5% steel wool concrete, electric heaters, Sterno™, Peltier tiles, and a 40° ice-water bath. We heated 5cm^3 blocks indoors using electric heaters to 160° and outdoors using Sterno™ to 240°. After 80 minutes the heated concrete samples were placed on a Peltier tile attached to a multimeter, placed in a 5 mil aluminum cup and lowered into the bath. With the temperature difference of 120° between the indoor sample (160°) and the water, 1 volt was generated with a decay rate of -0.001 volts per 30 seconds. For the outdoor sample (240°) 1.3 volts were generated with the same decay rate.

Conclusion

In an era of concern for climate change and global warming we believe the formulation of concrete can be modified using inexpensive materials to reduce the use of harmful chemicals, change the rate at which pavement temperatures change, and collect solar radiation to generate electricity. The authors would like to thank Malden Catholic High School for their support on this project.

A Post-Synthetic Modification Strategy for Enhancing Pt Adsorption in MOF/Polymer Composites TillSchertenleib[1], VikramV. Karve[1], DragosStoian[2], MehrdadAsgari[3,1], OlgaTrukhina[1] and WendyL. Queen[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]European Synchrotron Radiation Facility, France; [3]University of Cambridge, United Kingdom

Growing polymers inside of porous supports, like metal-organic frameworks (MOFs), allows incoming guests to access the backbone of otherwise non-porous polymers, possibly boosting the number and/or strength of available adsorption sites inside the porous material. Given this, we have focused attention on the design of MOF-polymer composites for the recovery of targeted metals from liquid streams and shown that the separation performance of such composites is significantly higher than the sum of the individual MOF or polymer counterparts. Now, in an effort to further boost performance, we have devised a novel post-synthetic modification (PSM) strategy that allows one to graft metal-chelating functionality onto the polymer backbone, while inside MOF pores. For the proof of concept, polydopamine (PDA) was first grown inside of a MOF, Fe-BTC. Next, a small molecule, 2,3-dimercapto-1-propanol (DIP), was grafted to the PDA via a Michael addition. Notably, the DIP contains thiols that can chelate targeted soft metals, like platinum (Pt). After the PSM of the PDA, the Pt adsorption capacity of the composite is shown to reach a record value of 684 mg/g. More importantly, the Pt uptake is greatly enhanced at low Pt concentrations, owed to the high affinity of Pt towards the thiols. Techniques, including XPS and in-situ XAS, provide insight into the Pt adsorption/reduction process, which is clearly enhanced after the PDA modification with thiols. Last, it is shown that various thiols, beyond DIP, can be grafted to the Fe-BTC/PDA, demonstrating the versatility of the chemistry. It is hoped that this work will open up a pathway for the future design of other novel composites that are fine-tuned for the rapid, selective retrieval of high-value and/or critical metals from complex liquids.

Structure-Property Relationship of MOF Materials: Theoretical Aspects RodionBelosludov; Tohoku University, Japan

It has been established that the porous materials can be defined by type or by function, which determined from practical applications [1]. Thus, the realization of high efficient porous media for various applications such as gas adsorption and separation, drug delivery, molecular sensing, batteries and catalysis can based on the understanding of the chemical and physical changes of the targeted species after their adsorption as well as the design and synthesis of nanoporous compounds that can recognize these changes. The computational structure-property predictions play a significant role in modern design of porous solids because often experiments require theoretical interpretation and computing power has grown rapidly in the last decade. In collaboration with experimentalists, the concept using a designable regular MOF material could be applicable to a highly stable, selective adsorption system [2]. The CO_2 adsorption mechanism into $Mn_3(Hpdc)_2(pdc)_2$ and $Mg_3(Hpdc)_2(pdc)_2$ has been studied. It has been found that guest-guest interaction plays an important role in formation a stable CO_2 chain configuration inside framework channel. A very pronounced step observed in experimental adsorption isotherm has been explained by delaying of the chain formation that associated with low permeability of guests inside the $Mn_3(Hpdc)_2(pdc)_2$ pore [3].
Recently, the possibility of the formation of polymeric structures by visible light inside the metal-organic framework host (MFM-300(In)) has been studied using first-principles calculations. The adsorption of P_4 by the host has been modelled by filling this fragment stepwise with the phosphorus. At each step the system was fully optimized and its total energy was calculated. The geometry of P_4 molecules were found to be in agreement with the experimental structural data. It was confirmed that the optimal number of monomers and their configurations due to guest-host and guest-guest interactions are suitable to form polymer chain. The partial density of states have been calculated for the guest-free as well as with P_4 monomers and P_n-chains. The theoretical predictions are in agreement with the results of UV-Vis spectroscopy, supporting again the correctness of structure determination for the phosphorus adducts. The inclusion of these chains results in the formation of host-guest system with a narrow band gap, which can be used as a gas sensor and photocatalyst for the water purification.

8:15 AM SF03.07.02
Benchtop Room-Temperature Synthesis of High Performance Thermoelectrics KirillKovnir; Iowa State University, United States

Se-containing materials often synthesized by solution-assisted from toxic and expensive organo-Se precursors. We are reporting a facile alternative utilizing elemental Se which is cheap and non-toxic. Elemental Se reagent has a drawback of low solubility and reactivity resulting in sluggish kinetics at low temperatures. A process of elemental Se activation was developed resulting in stable solution of multiple Se species confirmed with ^{77}Se NMR studies, including R-Se-Se-R and never detected before “naked” Se_2^{2-}. Dynamic equilibrium between the produced Se species allow to perform reactions at wide temperature ranges including room temperature. The developed activated Se precursor allows us to produce Ag_2Se-based materials at room temperature thus avoiding the high-temperature polymorphic phase transitions during the synthesis. The produced materials exhibit flat, almost temperature-independent zT in the 300-400 K range with average zT’s exceeding 1.

Preparation and *Operando* Imaging of Pt-Bimetallic Oxygen Reduction Catalysts for Polymer Electrolyte Fuel CellMizukiTada; Nagoya University, Japan

Polymer electrolyte fuel cell (PEFC) is key for clean energy production using hydrogen for carbon-neutral society. Electrocatalysts with Pt have been used as efficient catalysts for both electrodes in membrane electrode assembly (MEA), which has a stacking structure of anotde catalyst layer, electrolyte membrane, and cathode catalyst layer. Under practical PEFC operating conditions with lots of water and fuels, various events proceed in MEA such as catalysis at both electrodes, surface redox reactions of Pt electrocatalysts, dissolution, migration, and aggregation of Pt electrocatalysts, water flooding, deactivation of electrocatalysts by air contaminants, formation of unfavorable radical species, and migration of radical scavenger. The optimization of reaction controls on electrocatalysts are essential for efficient PEFC performances. Compared to anode conditions, cathode reactions with oxygen often bring about degradation of cathode electrocatalysts and the developments of cathode catalysts with durable performances under PEFC operation conditions are still challenging.
In this paper, I present the preparation and electrochemical performances of Pt-bimetallic electrocatalysts for PEFC and operando imaging of electrocatalysts under PEFC working conditions. The use of hard X-rays enables to visualize these events inside MEA under PEFC operating conditions, and the recent examples of 3D imaging of PEFC MEA by operando XAFS-CT spectroimaging will be presented.

Rapid Joule Heating Synthesis of Oxide-Socketed High-Entropy Alloy Nanoparticles as CO_2 Conversion Catalysts JaewanAhn, SeyeonPark and Il-DooKim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Historically, strategies for lowering CO_2 emissions have centered on using alternative sources of energy and carbon-neutral fuels as a means of prevention. However, modern thinking has evolved to also include techniques that actively decrease and repurpose CO_2 from exhaust gases as a way to counteract carbon emissions.[1] In this context, the unconventional surface chemistry of high-entropy alloy nanoparticles (HEA-NPs), featuring many inter-elemental synergies, plays a critical role in facilitating key chemical processes such as transforming CO_2 into CO – a sustainable approach to mitigating environmental pollution.[2] To produce HEA-NPs in a systematic way, carbothermal shock synthesis has been recently proposed as a simple yet efficient synthetic method.[3] Nonetheless, the potential for particle aggregation and phase segregation in HEA-NPs during high-temperature operating conditions for CO_2 conversion presents ongoing challenges that hinder their practical application.
In this work, we present HEA-NP catalysts that are tightly sunk in an oxide overlayer for promoting the catalytic conversion of CO_2 with exceptional stability and performance.[4] We first demonstrated the controlled formation of conformal oxide overlayers on carbon nanofiber surfaces via a simple sol−gel method, which facilitated a large uptake of metal precursor ions and helped to decrease the reaction temperature required for nanoparticle formation. During the rapid thermal shock synthesis process, the oxide overlayer would also impede nanoparticle growth, resulting in uniformly distributed small HEA-NPs (2.37 ± 0.78 nm). Because the reducible oxide layer promotes the hydrogen spillover reaction and also strongly anchors the high-entropy alloy nanoparticles, these HEA-NPs demonstrated an ultra-stable catalytic performance involving >50% CO2 conversion with >97% selectivity to CO for >300 h without extensive agglomeration.
Through this work, we establish the rational design principles for the thermal shock synthesis of high-entropy alloy nanoparticles and offer a helpful mechanistic perspective on how the oxide overlayer impacts the nanoparticle synthesis behavior, providing a general platform for the designed synthesis of ultra-stable and high-performance catalysts that could be utilized for various industrially and environmentally relevant chemical processes.

Wet-Chemical Synthesis and Catalytic Properties of Metal Nanomaterials with Unconventional Crystal Phases YeChen; The Chinese University of Hong Kong, Hong Kong

Metal nanomaterials own excellent intrinsic catalytic activities, high conductivity and high stability. While traditional solution-based syntheses mostly focused on morphologies and compositions of the nanocrystals, we made some interesting discoveries on crystal phase controlled synthesis. Instead of getting the normal phase of face centered cubic (fcc) structure, we obtain noble metal nanomaterials in unusual crystal phases with high yield and productivity. These unconventional metastable phases are excellent substrates on which other catalytically active metals like Pd, Cu and Pt can be grown epitaxially. Further study on new metastable phases of these metals can lead to novel physical or chemical properties, such as an enhanced catalytic performances. It provides an alternative strategy of engineering crystal phases of metal nanomaterials via wet-chemical method and exploring their templating effects on various properties. In this presentation, our recent work on the wet-chemical synthesis of metal nanostructures with unconventional phases and their electrocatalytic properties are introduced. First, epitaxial growth of one-dimensional core-shell metal nanostructures with unconventional crystal phases, including 4H/fcc heterophase Au@Pd nanorods, Au@Cu nanomaterials with 4H and 4H/fcc phases, and Pd@Pt nanocrystals with 2H phase, is demonstrated. Then, phase dependence study of metal nanomaterials with novel crystal phases in different catalytic reactions is discussed.

Nanoporous Lanthanum Oxycarbonate Powders for Enhanced CO_2 Detection - From Nanopowders Elaboration to Microsensor Development SandrineBernardini, PaulRivas, CarineChassigneux and Marie-VanessaCoulet; CNRS-AMU, France

Indoor air quality is a major public health concern. The World Health Organization estimates the number of deaths caused by air pollution at around 4 million per year. In addition, the recent health crisis has highlighted the need for regular air renewal to reduce the spread of viruses. The measurement of carbon dioxide (CO_2) levels in indoor spaces is therefore an interesting indicator of how often the air needs to be renewed.

Among CO_2 sensors, chemoresistors have many advantages such as their good sensitivity and stability [1]. In this type of sensors, the detection phenomenon is based on the change in the electrical resistance as a function of the gas adsorption rate. In the quest to reduce cost and power consumption of these sensors, there is a need in reducing the size of these devices without losing in efficiency. To achieve this objective, new materials are being proposed including the development of inorganic nanoporous powders: since the detection is based on an adsorption phenomenon, increasing the surface area accessible to the gas should allow to improve the detection.

In this presentation, we will focus on lanthanum oxycarbonate ($La_2O_2CO_3$) for CO_2 detection. This compound has been recently proposed as sensitive layer for resistive microsensors [2]. Here, we propose a new elaboration method based on high-energy ball-milling [3]. We will present this method along with a detailed characterization of the obtained nanopowders in terms of morphology, porosity, structure and reactivity. It will be shown that mesoporous $La_2O_2CO_3$ nanopowders with tunable pore sizes and crystallographic structures can be synthesized.

The second part will be devoted to microsensor fabrication and performances. Optimisation of the nanopowder deposition method on microsensor interdigitated electrodes will be detailed. The performances of the microsensors in the presence of different concentrations of carbon dioxide (from 400 ppm to 5 000 ppm diluted) will be presented. The influence of the $La_2O_2CO_3$ porosity and crystallographic structure on microsensor performances will be discussed.

The Assembly of Polyoxometalate-Based Coordination Networks as a Route to Diverse and Modular Metal Oxide Materials AlinaSchimpf; University of California, San Diego, United States

The assembly of molecular building blocks offers a promising strategy in the development of metal oxide materials with tailored and emergent properties. We have developed a method for the assembly of the Preyssler polyoxoanion ($[NaP_5W_{30}O_{110}]^{14-}$) bridged with transition metal or lanthanide cations and demonstrated tunability of the architecture, connectivity, and void-volume via inclusion of additional cations. Inclusion of polymer during framework synthesis enables easy processing into gel and film form-factors. Additionally, the frameworks can be reversibly photochemically reduced to contain electron densities on the order of 10^{21} cm^{-3}, revealing their potential for electron-manipulation and charge-storage applications. This talk will discuss advancements in the synthesis of polyoxoanion-based extended solids as well as their structure–composition–property relationships.

10:45 AM *SF03.07.08
Ion Diffusion in Porous Crystalline Materials Dae-WoonLim; Yonsei University, Korea (the Republic of)

Solid-state proton conductors (SSPCs), which are a key component for the safety and efficiency of fuel cells, have received attention due to their broad application in electrochemical devices. In particular, porous metal-organic frameworks (MOFs) have been extensively studied as a new type of proton conductor due to their designability. During the past decade, proton-conductive MOFs have achieved high performance ($>10^{-2}$ S cm^{-1}), comparable to the conventional material, through various synthetic strategies. The veiled conduction mechanism has been elucidated through structural analysis and spectroscopy tools such as NMR, X-ray diffraction, and neutron scattering measurement.[1] Herein, we demonstrate a new strategy for high proton conductivity in MOF.[2,3] Specifically, we used MOF-74 for coordinative urea insertion through post-synthetic modification and assessed the priority factor on proton conduction between the void space and pore-surface modification. Furthermore, molecular dynamics study and DFT calculation provide a comprehensive understanding of the proton conduction pathway and mechanism.

Metastable Access to Kitaev Quantum Spin Liquid Candidates: A Chemistry Approach LucasPressley, BishnuPrasad Thapaliya, DarrenDriscoll, ColinSarkis, RaymondR. Unocic, JiaqiangYan, MichaelMcGuire and CraigBridges; Oak Ridge National Laboratory, United States

Since Alexei Kitaev proposed an exactly solvable model for spin ½ systems, there has been an influx of predicted and synthesized materials that would meet such requirements. These Kitaev quantum spin liquid (QSL) candidates are of particular interest for the realization of topological quantum computing due to their ability to host Majorana fermions in their QSL ground state. While many candidates have been investigated, no material has arrived as a clear winner for possessing a Kitaev QSL ground state. Here we will show through the chimie doucie approach the design of new metastable honeycomb compounds. We will show through chemical/electrochemical methods the stabilization of Pt^{5+} ($5d^5$) on a honeycomb lattice. Structural characterization shows a shift in the Na ion stacking like that seen in in deintercalation of Na-Ir-O systems, with XAS measurements confirming oxidation of Pt compared to the parent compound. Magnetization measurements show a transition from diamagnetic to paramagnetic behavior with no sign of magnetic ordering down to T=2 K. Curie-Weiss analysis gives us close to expected for j_{eff}=1/2. A comparison will be made in the chemical/electrochemical methods and their effect on Na/Li ordering. Future directions will be discussed in utilizing these chemical techniques for the design of QSL candidates as well as crystal growth.

Anion Ordering in Metal Chalcogenides: Design Rules for Predictive Synthesis AyatTassanov[1], HuijuLee[2], YiXia[2] and JamesHodges[1]; [1]The Pennsylvania State University, United States; [2]Portland State University, United States

Chemical alloying is a powerful tool for modifying the properties of materials used in thermoelectric applications. Here, a statistical distribution of atoms is only achievable if the sites where the mixing occurs are symmetrically and chemically identical. Adding complexity to the structure through the introduction of additional metals (ternary and quaternary compounds) will often result in systems with anion sites that have unique chemical environments and bond lengths. In principle, this can allow chemists to direct anions onto specific locations within the lattice, however, only a few literature reports have exploited this feature. Here, we present a library of new ordered chalcogenides that are synthesized in a predictive fashion using site-selective alloying. This includes a series of mixed-anion copper chalcogenides that have been prepared using solid-state methods including ACu_5Te_2S (A = Rb, Cs), which adopts the $CsAg_5Te_3$ structure type. ACu_5Se_3 has two unique anion sites and using site-selective substitutions, we are able to synthesize ACu_5Se_2S, ACu_5Te_2Se, and ACu_5Te_2S. To understand what drives ordering in these compounds, we derived a term called “switching energy” which explains ordering in metal chalcogenides using entropy and enthalpy contributions of mixing chalcogen anions on the unique Wyckoff positions within the parent structure. Both experiment and theory suggest that sulfotelluride (S-Te) analogs are generally more ordered than sulfoselenide (S-Se) analogs. DFT calculations suggest that this ordering phenomenon impacts the electronic and thermal transport properties of thermoelectric materials. We believe the synthetic techniques presented here can open the door to an expanded library of metal chalcogenides for energy-related applications.

SESSION SF03.08: Functional Materials II

2D Quantum Coordination Frameworks MatthewCliffe; University of Nottingham, United Kingdom

Coordination framework materials, where metal ions are connected by molecular ligands into extended networks, are modular: their components can be exchanged while retaining the overall structural topology. This modularity allows for design strategies that are challenging to realise in conventional atomic inorganic materials. In this talk I will discuss recent work from the Cliffe Group realising quantum properties in coordination frameworks, particularly with reference to neutron scattering studies of their properties.
In particular I focus on our work on 2D materials, including non-collinear magnetism in post-perovskite metal thiocyanates, single layer ferromagnetism in $Ni(NCS)_2$; and new routes to long-sought quantum phases such as topological *S*=2 Haldane phase.

From Porous Organic Cages to Porous Liquids: Translating Porosity from the Solid to Liquid State RebeccaGreenaway; Imperial College London, United Kingdom

The landscape of microporous materials is often dominated by crystalline, ordered materials. However, the development of microporosity in the liquid state is leading to an inherent change in the way applications of functional porosity are approached. Porous liquids combine the mobility of a liquid with the properties of a microporous solid, and fundamentally differ to conventional liquids in that they contain *permanent*, *empty*, accessible cavities. Four types of porous liquids have now been proposed: type I – neat molecular porous liquids; type II – solutions of molecular porous species in pore-excluded solvents; type III – dispersions of microporous solids in pore-excluded liquids; and type IV – neat meltable microporous extended frameworks. Like their solid counterparts, porous liquids are capable of both gas uptake and selectivity and demonstrate increased gas solubility compared to conventional liquids. However, this combination also means porous liquids offer unique properties and applications when compared to porous solids, such as the ability to be pumped around a continuous system, facilitating guest loading and unloading steps. Our recent work in the area, with a focus on translating porous organic cages - discrete shape-persistent molecules containing permanent molecular cavities accessible through windows – into different types of porous liquids using different strategies will be presented, alongside how we are attempting to streamline their discovery using a high-throughput workflow. The properties of the different porous liquids including gas uptake, guest selectivity, and controlled gas release, will also be discussed, touching on our recent work on incorporating a photoresponse into a porous liquid.

Local Distortions and Long-Range Polarity in Pyrochlore Oxides from Total Scattering GenevaLaurita; Bates College, United States

The pyrochlore structure exhibits myriad technologically relevant properties including superconductivity, ferroelectricity, and frustrated magnetism. There has been a wealth of research on the structural and compositional intricacies of these compounds. However, there exist few design principles in regard to the intentional manipulation of the chemistry and structure for desired functionality. Here we will describe drivers of polarity on the pyrochlore structure through a combination of structural, computational, and physical characterization techniques. The main focus will be on the use of total scattering to establish structure-property relationships in these systems.

4:00 PM *SF03.08.04
Chemical Pressure-Based Design Principles Toward Modular Intermetallic Phases DanielFredrickson; University of Wisconsin-Madison, United States

Intermetallic phases comprise a broad family of solid state compounds with rich diversity in both their crystal structures and physical properties. To fully harness this combination in the development of new materials, however, guidelines are needed for the synthesis of new compounds with desired structural features. In this presentation, we demonstrate how the DFT-Chemical Pressure (CP) analysis opens avenues toward this goal, with a focus on the creation of complex intermetallic structures that merge fragments of different parent structures in a modular fashion. We begin with σ phase and dodecagonal quasicrystal approximants as the products of Chemical Pressure-driven intergrowths of the simpler Cr_3Si and Al_3Zr_4 structure types, whose joining at shared layers of atoms is promoted by the favorable alignment of complementary CP features. Drawing lessons from these cases, we introduce the CP Interface Fragment Theory of modular solid state structures and illustrate its use in the interpretation and discovery of several new intermetallic structures. Through these case studies, the CP Interface Fragment approach will emerge as a framework for integrating theory, structural database screening, and synthesis toward the goal of materials design in intermetallics.

4:30 PM SF03.08.05
Local Structural Analysis of Transparent Conducting Anatase TiO_2 Films TomohitoSudare[1], ReiichiUeda[1], RyotaShimizu[1,2], RyoNakayama[1], NaoomiYamada[3] and TaroHitosugi[1,2]; [1]The University of Tokyo, Japan; [2]Tokyo Institute of Technology, Japan; [3]Chubu University, Japan

[Introduction] Niobium-doped anatase titanium dioxide ($Ti_{1-x}Nb_xO_2$: TNO) has gained much attention due to its transparent conducting properties. The resistivity, ρ, of TNO epitaxial thin films exhibit 2.3×10^{-4} Ω cm at 300 K and a high internal transmittance of ~97% in the visible region, comparable to Sn-doped In_2O_3 [1]. The conductivity of TNO is due to carrier doping by isostructural substitution of Nb for Ti sites. Interestingly, electron carriers are generated only when the deposition and post-deposition annealing are conducted in a reducing atmosphere [2]. On the other hand, when TNO thin film is annealed in an oxidizing atmosphere, the carrier electrons are killed and hence the film becomes highly resistive [3]. On this base, excess oxygen incorporated into the thin film presumably plays an important role, but experimental evidence of its presence has not been reported yet. Therefore, in this study, we aim to experimentally observe the local structural change of TNO before and after annealing in an oxidizing atmosphere and to reveal the carrier generation mechanism.
[Experimental Section] Radio-frequency magnetron sputtering was used to deposit conductive TNO epitaxial thin films. A $Ti_{0.94}Nb_{0.06}O_2$ ceramics was used as a target, and a $LaAlO_3$ (LAO) (100) single-crystal substrate was used. The film was grown at 400°C at O_2/ ($Ar + O_2$) flow rate ratio of 0.3% under a total pressure P_{tot} =1.0 Pa. Sputtering was conducted for 50 min to obtain a TNO thin film with a thickness of approximately 100 nm. The highly resistive TNO thin film was obtained by annealing the above sample at 400°C for 30 min in air. The crystal structure of both samples was characterized by X-ray diffraction (XRD) and the chemical state and local structure were analyzed by X-ray absorption fine structure (XAFS).
[Results and Discussion] XRD patterns of as-deposited films showed that (001) oriented anatase-type TNO epitaxial thin films were successfully grown on the LAO substrate. The as-prepared films were electrically conductive but turned to be insulative by annealing in air. At the same time, the color of the thin film changed from blue to colorless. Next, the radial distribution function around Nb atoms was obtained through Fourier transformation of the Nb *K*-edge XAFS spectra. As a result, multiple oxygen atoms with different Nb-O bond lengths were confirmed only in TNO after annealing treatment. the generation mechanism of electron carriers will be comprehensively discussed at the conference, along with the results of local structure analysis for Ti and O atoms.

4:45 PM SF03.08.06
Control of High Entropy Oxide Formation ColinFreeman[1], AliNasrallah[1], ThomasHooper[1], GeWang[2] and DerekSinclair[1]; [1]University of Sheffield, United Kingdom; [2]The University of Manchester, United Kingdom

Much of recent materials discovery has focused on "high entropy" systems with multiple components on the lattice sites. There has been excitement in both the metals and ceramics communities around new properties and the reduction of expensive and rare elements. The basic principle revolves around the use of multiple species that generate a high entropy of mixing that can counteract the enthalpic penalties associated with mixing different species. There are now a large number of examples of successfully produced compounds in a variety of crystal structures for both ceramic and metal systems. Despite the large amount of data now in the literature, our understanding of the mixing and formation of these materials is still relatively poor.

The perovskite lattice is a particularly exciting opportunity as mixing can be carried out on both the A or B site presenting a wealth of enthalpic and entropic possibilities to achieve a single-phase solid solution with a favourable Gibbs free energy. We use this crystal structure as a template to explore a range of factors that can control the formation of potential high entropy oxides. Using a combination of computational and experimental methods we interrogate the significance of various features including the tolerance factor, cation size variance, the decomposition rates of reactants, the stability of alternative products and the role of order on the lattice. By combining this information we are able to give insight to how these different features interplay and potential limit or aid the formation of high entropy oxides. We also comment on where the materials enter a high entropy, disordered state or where enthalpy plays a more significant role than might be expected. From our results, we offer thoughts on the differing rules governing the mixing processes in these perovskite phases.

5:00 PM SF03.08.07
Non-Classical Electrostrictors, Novel Type of Electromechanically Active Ceramics IgorLubomirsky; Weizmann Institute of Science, Israel

Electrostriction is a second order electromechanical response observable in all solid dielectrics. According to the scaling law presented more than two decades ago by Prof. R. Newnham (Penn State), the electrostriction polarization coefficient for a wide range of classical electrostrictors scales with the ratio of the elastic compliance to the dielectric constant.
In 2012, Gd-doped ceria, one of the most studied oxygen ion conducting ceramics, was reported to exhibit an unusually large electrostriction. This first report was followed by reports on non-classical electrostriction (NCES) in other aliovalent-doped ceria, on (Nb,Y)-stabilized cubic Bi_2O_3 and acceptor-doped, hydrated barium zirconate, suggesting that strong electrostriction may be an inherent property of superionics. At room temperature, these ceramics exhibit a longitudinal electrostriction strain coefficient $|M_{33}|>10^{-17}m^2/V^2$. However, with elastic modulus >80 GPa and dielectric constant <100, the experimental Q-coefficients of these ceramics are at least 100 times larger than values predicted by the classical scaling law. Of the three ceramics, aliovalent-doped ceria is the most studied. Below 1Hz, $|M_{33}|$ for 10mol% Sm- or Gd-doped ceria reaches 10^{-16} m^2/V^2 relaxing to $<10^{-18}$ m^2/V^2 above 100 Hz. Aliovalent lanthanide dopants with smaller ionic radii than that of Gd, such as Lu or Yb, raise $|M_{33}|$ at 100Hz to $\approx10^{-17}m^2/V^2$.
Acceptor-doped $BaZr_{1-x}X_xO_{3-x/2+\delta}H_{2\delta}$ proton-conducting ceramics, where X= Ga, Sc, In, Y or Eu, and $0.05 \leq x \leq 0.2$, exhibit non-classical electrostrictive strain for all dopants in both the dry and hydrated states: $|M_{33}|=(1\text{-}7)\bullet10^{-16}m^2/V^2$ below, and $\approx10^{-18}$-$10^{-17}m^2/V^2$ above, the Debye-type relaxation frequency. Hydration does not significantly affect M_{33}, but raises the relaxation frequency by a factor of 10 to 100, indicating that proton-based elastic dipoles can respond more quickly than those based on oxygen vacancies.
According to our current understanding, NCES emerges from electric field-induced rearrangement of highly polarizable elastic dipoles induced by point defects: oxygen vacancies or proton interstitials. In this model, elastic and dielectric properties are largely defined by the host lattice, while electrostrictive strain is controlled by the strength of the elastic dipoles. We suggest that non-classical electrostriction may be a common feature for crystalline dielectrics containing mobile point defects.

SESSION SF03.09: Poster Session III
Session Chairs: Craig Brown and Brent Melot

8:00 PM SF03.09.01
Role of Fermi Surface Nesting and Hidden Nesting in Controlling Kohn Anomalies in *α*-UraniumAdityaP. Roy[1], RanjanMittal[2] and DipanshuBansal[1]; [1]Indian Institute of Technology Bombay, India; [2]Bhabha Atomic Research Centre, India

Charge density wave (CDW), the periodic modulation in electrons charge distribution, is accompanied by a simultaneous symmetry lowering and a finite gap opening near the Fermi level (E_F) in low dimensional metals. The Fermi surface topology of such systems allows Fermi surface nesting (FSN), resulting in divergence of the imaginary part of electronic susceptibility ($Im\{\chi_0(\boldsymbol{q})\}$). The divergence in $Im\{\chi_0(\boldsymbol{q})\}$ is further carried over to the real part ($Re\{\chi_0(\boldsymbol{q})\}$) under specific scenarios that drives the electronic instability. Kohn extended the implications of electronic instability to the lattice explicitly showing anomalous phonon behavior at $\mathbf{q}_{CDW}$. A finite resolution of momentum transfer ($\mathbf{Q}$) in x-ray or neutron scattering experiments often fails to capture the Kohn anomalies owing to its localized nature in the *k*-space. Hence, such phenomena are challenging to realize in experiments.
In this work, we use comprehensive *ab-initio* simulations of electrons and phonons [1] and earlier inelastic neutron scattering (INS) measurements [2] to understand the governing mechanism of CDW instability in *α*-Uranium (*α*-U) that displays pronounced Kohn anomalies in multiple phonon branches. *α*-U undergoes CDW transition (T_{CDW} = 43 K) along with a symmetry lowering and unit-cell doubling along the a-axis. Initially, we capture the Kohn anomalies in multiple phonon branches. Subsequently, we map it to the electronic origin by calculating $Re\{\chi_0(\boldsymbol{q})\}$. The results display a diverging peak in $Re\{\chi_0(\boldsymbol{q})\}$ indicating electronic instability. Finally, we project the contribution of $Re\{\chi_0(\boldsymbol{q})\}$ in the entire *k*-space. The result highlights that besides the FSN features where contributions coincide with the Fermi surface, many *k*-points away from the Fermi surface also display a finite contribution to the divergence in $Re\{\chi_0(\boldsymbol{q})\}$. This phenomenon is called hidden nesting and manifests by the nesting of the electronic states above and below near E_F. Hence, our study demonstrates that the combined effect of FSN and hidden nesting drives the Kohn anomalies in multiple phonon branches and results in the CDW transition in *α*-U. Understanding such systems with coupled FSN and hidden nesting opens avenues to exploit electronic and lattice states of topological Weyl semimetals and superconductors.

Strong Trilinear Coupling of Phonon Instabilities Drives The Avalanche-Like Hybrid Improper Ferroelectric Transition in $SrBi_2Nb_2O_9$AdityaP. Roy[1], NainiBajaj[1], VasantSathe[2], SanjayMishra[3], RanjanMittal[3], ManhD. Le[4] and DipanshuBansal[1]; [1]Indian Institute of Technology Bombay, India; [2]UGC-DAE Consortium for Scientific Research, India; [3]Bhabha Atomic Research Centre, India; [4]ISIS Facility, India

Hybrid improper ferroelectrics (FEs) harbor spontaneous switchable polarization (*P*) below FE transition temperature (T_{FE}) owing to condensation of two unstable non-polar zone-boundary modes coupled to a stable polar zone-center mode. However, in Aurivillius family, besides two non-polar modes, the polar mode is also unstable. This instability of polar mode has significant implications on origin of *P*. Here, we investigate origin of *P* in Aurivillius family compound $SrBi_2Nb_2O_9$ [3]. Using group theory (GT) and *ab-initio* simulations using Landau's theory, we build an energy invariant polynomial as a function of the three unstable modes connecting paraelectric to FE phase. We find that trilinear coupling is strong enough to surpass positive biquadratic terms, allowing an *avalanche*-like simultaneous condensation of all three modes at T_{FE} instead of multi-step transitions at different temperatures. The magnitude of trilinear coupling term is nearly two to six times higher than in isostructural $SrBi_2Ta_2O_9$[2], where a double-step transition is favored. Using inelastic neutron scattering, we capture evolution of phonons from 5 – 1000 K. Extracted phonon density of states (DOS) is consistent with simulations and shows a predominant O atom vibration of NbO_6 octahedra. Similar to other hybrid improper FEs [4], we observe significant broadening even at 300 K. Despite a first-order transition, a clear discontinuity is not visible in phonon DOS across T_{FE} primarily due to a localized nature of these modes in the Brillouin zone. We identify and track the three distortions across T_{FE} using Raman spectroscopy. *T*-dependence of these modes are consistent with our theoretical prediction and previous Monte-Carlo simulations [5]. Our findings provide a better understanding of hybrid improper FEs and open avenues to understand role of chemical doping of Nb with Ta atom on trilinear coupling as recently shown in another hybrid improper FE, $Ca_{3-x}Sr_xTi_2O_7$ [4].

Radiatve Cooling and Light Enhancement of Transparent Crystalline Si Solar Cells KangminLee, JeonghwanPark and KwanyongSeo; UNIST, Korea (the Republic of)

A light-harvesting film is considered as a means to improve the power conversion efficiency (PCE) of solar cells. However, when a light-harvesting film is applied to transparent solar cells, it is difficult to maintain the transparency of transparent solar cells due to the high haze ratio of the film (>95%). In this study, we apply a light-harvesting film onto the selective area, which is the light absorption region of the c-Si transparent solar cells. As a result, the c-Si transparent solar cells with light-harvesting film exhibited a current density (J_{SC}) increase of 2.6

mA/cm^2 compared with the transparent solar cells without a light-harvesting film. Therefore, the best device showed a PCE of 15.8% at an average visible transmittance of 20%, while maintaining a low haze ratio (0.95%). Furthermore, the c-Si transparent solar cells with the light-harvesting film have the advantage of minimizing the PCE degradation depending on the angle of light incidence. In addition, the strategy also helped reduced the temperature increase through the radiative cooling effect.

Influence of The Local Environment on The Formation of Sulfur Vacancies in Calcium Lanthanum Sulfide CassidyAtkinson[1], AlexandrosKostogiannes[2], MatthewGuziewski[3], PamirAlpay[1], ParagBanerjee[2], RomainGaume[2] and KathleenRichardson[2]; [1]University of Connecticut, United States; [2]University of Central Florida, United States; [3]U.S. Army Research Laboratory, United States

Sulfur loss during the processing of calcium lanthanum sulfide has been shown to negatively impact the optical properties of the material. In order to better understand the phenomenon, density functional theory is used to determine the structural stability and formation likelihood of sulfur vacancies across several stoichiometries within the calcium lanthanum sulfide system. It was found that the local atomic environment surrounding defect sites plays a significant role in their formation energies and this was strongly related to the redistribution of charge. Using this information, a functional relationship to predict the sites that are most likely to lose sulfur was developed. Simulated diffraction patterns were compared to experimental work in order to determine the atomic structure present after processing. With this knowledge, it may be possible to better predict the effects of different processing approaches to minimize sulfur loss and potentially speed the material development process.

Atomic-Scale Structural Investigation on p-Type Copper Bismuthate for Photocathodes: Insights into Charge Hopping Conduction and Correlation with Crystal Defects Structure YounghwanLim, Hyun JoonJung and Sung-YoonChung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Metal oxides with p-type semiconducting properties have been actively investigated in the fields of semiconductor industry, gas sensors, and (photo)electrochemistry. Especially, Cu-based oxides have been considered as an adequate p-type semiconductor for energy applications due to their proper band-edge energies located near the electrochemical redox potentials. Copper Bismuthate, $CuBi_2O_4$, is one of the promising p-type oxides with appropriate band structures which depend on the crystal structures. The peculiar crystal structure of $CuBi_2O_4$, containing isolated $[CuO_4]$ planes aligned in the c-axis direction, has not been reported in other AB_2O_4-type materials which usually have spinel-like structures. Although a few studies have demonstrated the electrical and (electro)chemical properties, there is still a lack of demonstration on major defect structures of $CuBi_2O_4$, acting as a bottleneck for practical use. The investigation into the defect structure should be the first step to improve catalytic performance and modify the electronic structure suitable for other applications.
In this research, atomic-scale scanning transmission electron microscopy (STEM) combined with energy-dispersive X-ray spectroscopy (EDS) is employed to identify a noteworthy occurrence of antisite intermixing between copper and bismuth cations. The Bi_{Cu}-Cu_{Bi} intermixing is represented as a major type of defect existing in $CuBi_2O_4$. The local Cu 3d polaron states and the effects of point defects on electric conduction behavior are presented by utilizing density functional theory (DFT) calculations. A higher degree of intermixing leads to a greater activation energy and decreased electronic conductivity due to the possible electric conduction mechanism by the hopping of hole polarons. The hole-polaron hopping occurs in between isolated Cu atoms along the c-axis but it can be hindered by the Bi_{Cu} point defects. These results give insight into the significance of employing STEM-EDS analysis and DFT calculations, to identify point defects and to understand the electronic characteristics in complex oxides.

Nanoporous IGZO Thin Film Transistors for Visible-To-NIR Detection SrinivasGandla, AnamikaSen and SunkookKim; Sungkyunkwan University, Korea (the Republic of)

The amorphous metal oxide semiconductors (AMOSs) have revolutionized the transparent semiconductor industry due to their potential intrinsic material and electrical, and low-temperature processing attributes.[1] Among these is indium-gallium-zinc-oxide (IGZO), an important AMOS material that is known for its ability to form transparent thin films with desirable electrical characteristics, making it suitable for applications in flat panel display technology. The presence of gallium in the composition leads to controlled charge concentrations, thereby enabling high current I_{ON}/I_{OFF} ratios in thin film transistor (TFT) transfer characteristics.[2] Due to a lack of grain boundaries and overlapped isotropic spherical ns-orbitals, the TFT with this material exhibited high electron field-effect mobilities. Like most AMOS, IGZO is also a wide bandgap semiconductor of nearly 3-4 eV. With this bandgap, the material is applicable for image and optical sensing applications within the UV region of the spectrum.[3] However, its current limitations in detecting a broad spectrum of light prompted the exploration of enhancing its light detection range.
To address this, researchers have proposed a laminated approach by introducing secondary materials to the IGZO thin film. This approach involves adding materials with different optical properties to create a wider range of light absorption capabilities. These secondary materials include quantum dots, graphene dots, metal nanoparticles, and other thin films. The absorption of light by these added layers generates charge carriers that are then transferred to the IGZO channel, enabling extended light detection. Various strategies involving nanowires and heterojunctions with other materials have also been investigated to increase the subgap states within IGZO's bandgap, further enhancing its light detection capabilities.
Herein, a novel method to extend IGZO's light detection range using block copolymer lithography on a 4 inch wafer is demonstrated. This technique creates nanopores in the IGZO semiconducting channel, modifying the material's properties without altering its composition. The presence of these nanopores is confirmed through advanced microscopy and spectroscopy techniques. By introducing these nanopores, the subgap states within IGZO's bandgap can be controlled to a certain extent, influencing its light absorption properties. The fabricated nanoporous IGZO phototransistor can detect longer wavelengths of light up to 852 nm. The photoconducting and photogating effects related to specific wavelengths are discussed. These findings highlight the substantial promise of NP IGZO phototransistors for the future of large-scale optoelectronics.

Synthesis and Modification Methods for Electrode Materials of Secondary Batteries Based on the Decomposition Reaction of Ammonium Fluoride JinyoungChun[1], Il-SeopJang[1,2], Bo-YeSong[1,2] and Gun-HeePark[1,2]; [1]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

With the rapid growth of the electric vehicle (xEV) and energy storage system (ESS) industries, there are urgent needs for the development of high-performance secondary batteries based on advanced electrode materials. Electrode materials are key components that intrinsically determine the performance of secondary batteries. Therefore, in order to realize secondary batteries with high energy and power densities, the development of advanced electrode materials based on new approach is required.
In this study, using the decomposition reaction of ammonium fluoride (NH_4F), we developed metal fluoride (MF_x) cathode materials that exhibit high specific capacities based on conversion reactions. In addition, we found that this synthesis method could be applied to modify various electrode materials: (i) Improving electrochemical performance of silicon (Si) anodes by removing impurities and controlling the morphology of raw material. (ii) Improving rate capabilities of $Li_4Ti_5O_{12}$ (LTO) anodes through surface fluorination. (iii) Conversion of commercial lithium metal oxides into metal (M)/lithium fluoride (LiF) nanocomposites and their application to sacrificial cathode materials. Furthermore, the synthesis method in this study is simple and relatively safe. Therefore, it is expected that this study will provide new strategies for developing advanced electrode materials with high energy/power densities.

Catalyst Droplet-Based Puncturable Nanostructures for Mechano-Bactericidal Effect on Bioaerosols InaeLee, DongkyuKang, EunyoungJeon, SunghyunPark and JoonseokLee; Hanyang University, Korea (the Republic of)

Exposure to airborne contaminants and particulate matter causes serious public health risks, leading to the need for new technologies that effectively collect and inactivate airborne microorganisms. Typical nanomaterial-based filter membranes usually sterilize airborne microorganisms using photocatalysts, electrical stimulation, and thermal treatment, which are expensive and require additional devices and cumbersome manufacturing. In this study, we fabricated a puncturable nanostructured membrane for bioaerosol filtration and inactivation using a catalyst droplet-based solution-phase synthesis. The catalyst droplets are templates for in situ novel puncturable nanopillar growth on the membrane surface. The unique puncturable nanostructures featuring a nano-edge caused mechanical deformation of the bioaerosol collected on the filter surface without external stimulations. A puncturable nanostructured air filter (PNAF) is compared to a bare air filter and exhibits higher bioaerosol collection efficiencies (>98% and 89.3–95.7%, respectively). The amount of airborne *E. coli* collected on PNAF was up to 2.3 times higher than that of the bare air filter. Furthermore, after incubation, PNAF inhibited the growth and proliferation of deposited bacterial cells. The bioluminescence value and viable *E. coli* count in PNAF were 90.9% and 92.7% lower than those in the bare air filter. PNAF is tested under breathing conditions as part of a face mask, where it effectively captures and deactivates *E. coli* aerosols through a mechano-bactericidal effect, inhibiting bacterial proliferation and, finally, death. The nanostructures were maintained intact after further sterilization by heat and solvent, indicating a lower risk of secondary infection by the remaining viable bacteria or emission of nanomaterials. Thus, PNAF can be applied as an air purifier or face mask filter

for bioaerosol collection, presenting antibacterial effects without external stimulation. Puncturable nanostructures can be used as antimicrobial membranes and surfaces in many areas, such as medical diagnosis, food processing and hygiene facilities, and water quality management.

8:00 PM SF03.09.09
Development of Silicon-Gradient Block Copolymers as EUV Lithography Inorganic Pattern Masks JeehyunHong and Yeon SikJung; KAIST, Korea (the Republic of)

The production of finer patterns with enhanced qualities is more emphasized, owing to the elevated demand for device performance. The utilization of extreme-ultraviolet lithography (EUVL) as the next-generation lithographic technique has become increasingly prominent. Nevertheless, failures arising from the reduction of the thickness of photoresists and inherent stochastic defects intensified along with the reduction in the pattern sizes. The defects substantially compromise the productivity and performance of the devices. Directed self-assembly (DSA) of block copolymers became a viable solution to overcome the limitations of EUVL. The DSA process not only improves pattern roughness but also facilitates the production of finer patterns at increased throughputs. Still, integration of DSA into EUVL presents the following challenges including increased complexity of the process related to surface energy neutralization, limited etching selectivity for effective pattern transfer, and undefined polymerization methods constraining its application within production processes.
Here, novel block copolymers with organosilicon gradients, Poly(methyl methacrylate)-block-poly(((bis(trimethylsilyl)methyl)acetamide)-gradient-styrene) (PMMA-b-P(Si_2-g-S)) and Poly(methyl methacrylate)-block-poly((Polyhedral oligomerized silsesquioxanes)acetamide)-gradient-styrene) (PMMA-b-P(POSS-g-S), are presented. These BCPs were engineered to overcome the challenges of DSA based on the three pivotal design principles. First, the incorporation of gradient random copolymer blocks is leveraged to facilitate the generation of vertically aligned patterns, irrespective of substrate surface properties. Next, novel organosilicon polymers are introduced, serving as a robust mask for pattern transfer with high etch resistance. Third, by integrating a reactive polymer, a versatile block copolymer synthesis platform is established. This platform enables the generation of various block copolymers from a single reactive precursor block copolymer. Notably, synthesized PMMA-b-P(Si_2-g-S) and PMMA-b-P(POSS-g-S) block copolymers exhibit highly ordered, vertically aligned lamellar patterns on diverse surfaces. After undergoing directional alignment and selective etching procedures, the gradient organosilicon block demonstrates its effectiveness and robustness as a pattern transfer mask. This novel block copolymer system thus presents a promising platform for efficient pattern transfer, addressing the challenges associated with integrating DSA into EUVL.

3-D Mesoporous Architectures for Carbon-Conversion Photocatalysis: Block Copolymer-Templated Semiconductor Mesostructures Substantially Enhance Photocatalytic Dry Reforming of Methane WilliamMoore[1], ShusakuShoji[2], R.P. Thedford[1], FeiYu[1], LieihnTsaur[1], WilliamTait[1], M.S. Riasi[3], AniruddhaSaha[1], AustinReese[1], SolGruner[1], SadafSobhani[1], JinSuntivich[1] and UlrichWiesner[1]; [1]Cornell University, United States; [2]National Institute for Materials Science, Japan; [3]University of Cincinnati, United States

The recent discovery of low-temperature photocatalytic conversion of methane and carbon dioxide to syngas (photocatalytic dry reforming of methane; photo-DRM) transformed an expensive high-temperature process into an appealing sustainable process for carbon conversion. This simple reaction, which can proceed under illumination without external heating, could provide an alternative to crude oil for supplying the organic chemical precursors our modern world is built upon. While much attention has been paid to alternative photocatalyst support chemistries or exotic metallic promoters, the 3-D architecture of the semiconductor support itself has been largely overlooked. This has left a massively important variable space in photocatalyst support development largely unexplored.

By utilizing block-copolymer self-assembly templating of common semiconductor supports, we have studied TiO_2 and Ta_2O_5 photocatalyst supports in a range of architectures: from hexagonally packed cylinders to 3-D co-continuous gyroids to asymmetrically porous thin films. This mesoporosity provides enhanced activity across a wide range of volumetric flow rates, delivering record low-temperature performance beyond the expectations of enhanced surface area alone. Beyond surface area, the 3-D accessibility of co-continuous architectures greatly reduces tortuosity, leading to fast facile transport of reactive species through the structure.

Further, we developed novel TiO_2 thin film catalyst architecture derived from liquid filtration membranes that has a thin mesoporous top layer with macroporous support layer. This highly-active low-density membrane architecture delivers the highest reported activity per gram for low-temp photo-DRM to-date by supporting a thin active layer on a macroporous substructure, allowing rapid gas transport. These solution-based polymer processes for creating 3-D architectures are simple, low-cost and scalable routes to create world-class photocatalyst supports, applicable to a wide-range of gas-phase catalytic reactions.

8:00 PM SF03.09.12
Plasmonic Au/TiO_2 Composite Nanoparticles: Synthesis, Structural and Optical Characterization and Functional Performance in The Photocatalytic Reduction of CO_2 to CO PascalBuskens[1,2], FrancescSastre[1], ManXu[1], NicoleMeulendijks[1], Jonathanvan den Ham[1], JelleRohlfs[1], AnthonySanderse[1], RobertoHabets[1] and PauMartínez Molina[1]; [1]TNO, Netherlands; [2]Hasselt University, Belgium

Because of their localized surface plasmon resonance, metal nanoparticles are of interest for a broad variety of applications ranging from chemical and biological sensing to surface enhanced Raman spectroscopy and improved light extraction in LEDs. Here, we present the synthesis, structural and optical characterization of Au nanoparticles applied on TiO_2 for application as photocatalysts for the sunlight-powered reduction of CO_2 to CO.
The Au/TiO_2 composite nanoparticles were prepared by tailored deposition of $Au(OH)_3$ on the surface of 20 nm-sized anatase TiO_2 particles dispersed in water at a precisely controlled pH 9, and subsequent thermal anneal in an Ar:O_2 mixed atmosphere (80:20). The Au content was determined by Inductively Coupled Plasma-Atomic Emission Spectroscopy (ICP-AES) obtaining a value of 3.12% Au. The particle size distribution was determined using High-Angle Annular Dark Field Scanning Transmission Electron Microscopy (HAADF-STEM). The Au nanoparticles were randomly distributed on the surface of 20 nm-sized anatase nanoparticles, and their size followed a lognormal distribution with an average of 1.6 nm. The interplanar distance in the Au NP was 2.37 Å, corresponding to the (111) spacing. The (111) lattice planes were perfectly aligned with the (101) TiO_2 planes. The presence of Au and TiO_2 as sole crystalline materials was confirmed by XRD. The diffuse reflectance spectrum of the Au/TiO_2 powder displayed a broad minimum centered around 500 nm, which respresents the light absorption based on the plasmonic renonance of the Au nanoparticles. Since we intended to apply the Au/TiO_2 nanoparticles for photocatalysis, we also determined the light penetration depth (skin-depth) of the powder using UV-vis-NIR spectrophotometry. The resulting skin-depth was about 100 µm.
We applied the resulting Au/TiO_2 composite nanoparticles for the sunlight-powered reverse water gas shift reaction, i.e. the reaction of CO_2 and green H_2 to CO and H_2O. Whilst this reaction, which is endothermic (ΔH = 41.2 kJ/mol) and limited by equilibrium, requires temperatures above 600°C in conventional thermocatalysis, we achieved high production rate (7888 mmol/(m^2 h)) and CO selectivity (96.9%) at temperatures below 300°C using mildly concentrated sunlight (up to 14 kW per m^2) as sole and sustainable energy source. Reference experiments in dark at the same catalyst bed temperature yield more than 30% CH_4 as undesired side product. We proposed that the high selectivity of the catalyst could be attributed to promotion of CO desorption through charge transfer of plasmon generated charges, consequently avoiding further reduction of CO to unwanted CH_4.
The TiO_2 nanoparticles without Au show no CO production when illuminated with sunlight. Furthermore, removal of all light below 400 nm (above the anatase TiO_2 bandgap) resulted in no loss of activity and selectivity for Au/TiO_2, demonstrating the direct excitation of the semiconductor plays no role in this catalytic process. The rate of the reaction exponentially increased with the solar irradiance, demonstrating that in addition to the above mentioned plasmon-induced desorption of CO, also photothermal heating contributes to the process. Studies with differently sized Au nanoparticles revealed a linear relationship between the catalytic activity and the number of Au-TiO_2 contact points, and studies with Au nanoparticles supported on dielectric materials such as Al_2O_3 and SiO_2 yielded no catalytic activity. In combination, these phenomena suggest that charge carriers generated in the Au nanoparticles by its localized surface plasmon resonance are injected into the semiconductor over the Schottky barrier, which prolongs their lifetime and makes them available for participation in the catalytic conversion of CO_2 to CO. Ergo, TiO_2 is not a simple catalyst support, and both Au and TiO_2 are essential components of this catalyst which operate synergistically.

8:00 PM SF03.09.13
Defect Chemistry and Doping of Lead Phosphate Apatite $Pb_{10}(PO_4)_6O$MichaelToriyama[1], Cheng-WeiLee[2], G.J. Snyder[1] and PrashunGorai[2]; [1]Northwestern University, United States; [2]Colorado School of Mines, United States

It is claimed that copper (Cu) doping of lead phosphate apatite $Pb_{10}(PO_4)_6O$ causes volume contraction and, consequently, room-temperature superconductivity. Unsuccessful attempts to reproduce these claims have raised many questions about the reported composition, possible oxygen off-stoichiometry, and copper doping itself, among others. Additionally, unintentional incorporation of other elements (besides Cu) present in the initial reaction mixture has been speculated. Many of these questions are intimately related to the native defect chemistry and thermodynamic phase stability. We perform first-principles defect calculations to provide much needed insights into the defect chemistry and doping of $Pb_{10}(PO_4)_6O$. We find that Pb and O vacancies are the dominant defects that pin the Fermi energy in the mid-gap region consistent with an insulating behavior. Our defect calculations suggest the plausible existence of closely related Pb and O sub-stoichiometric phases; we predict one such stable phase. We predict moderate levels of Cu incorporation on the Pb site, which still results in insulating behavior that is consistent with single-crystal measurements. We also rule out interstitial Cu doping, but find that unintentional S incorporation is highly possible. Our findings emphasize the need for more careful characterization of the parent composition, and intentional and unintentional dopant incorporation in the structure.

8:00 PM SF03.09.14
High Tunability and Low Loss in Layered Perovskite Dielectrics through Intrinsic Elimination of Oxygen Vacancies HangfengZhang, HenryGiddens, TheoG. Saunders, NingLiu, VicenteAurallo-Peters, XinzhaoXu, MatteoPalma, MikeReece, IsaacAbrahams, HaixueYan and YangHao; Queen Mary University of London, United Kingdom

Dielectric materials with moderate dielectric permittivity, high tunability and low loss are critical in modern communication technology. However, high tunability is often associated with high loss and high dielectric permittivity. Here, a novel material, textured $Sr_2(Ta_{1-x}Nb_x)_2O_7$ (STN), with a layered perovskite structure, has been designed to break this correlation. These materials exhibit low dielectric loss associated with oxygen vacancy elimination through the creation of stacking faults in the layered structure, as evidenced by transmission electron microscopy. A modification of the Vendik model was used to fit the thermal dependence of their relative dielectric permittivity, which included an oxygen defect parameter as an indicator of the oxygen defect concentration. The high tunability is attributed to the presence of local polar nano-clusters just above the Curie point. A 2-step spark plasma sintering method was employed to prepare grain-oriented ceramics with optimised properties. A near optimum maximum tunability of 72% at room temperature was obtained for a textured $Sr_2Ta_{1.88}Nb_{0.12}O_7$ ceramic, with moderate dielectric permittivity (ε'~ 520) and a dielectric loss of less than 1%.

8:00 PM SF03.09.15

Wet-Chemistry: A Promising Route to Realize Highly Efficient Semiconductor-Based Photocatalysis HongPang[1], XianguangMeng[2], FumihikoIchihara[1], JinhuaYe[1], TakayoshiSasaki[1] and RenzhiMa[1]; [1]National Institute for Materials Science, Japan; [2]North China University of Science and Technology, China

Photocatalysis represents a promising approach to alleviate the environmental crisis and resources shortage. In principle, the semiconductors can be excited by appropriate photoenergy and generate the electron-hole pairs for the redox reactions on the surface. The highly efficient semiconductor-based photocatalysts are conventionally synthesized by solid-state methods. Or the photocatalysts were synthesized through the reactions with high temperature or pressure and dried into powder, which has to be redispersed well in water before carrying out the photocatalytic measurement. However, such synthetic process always meets the difficulty of uniform dispersion and the loss of surface reactivity. Our latest findings found the low-dimensional semiconductor photocatalysts prepared without drying process make it more efficient and facilely controllable in photocatalytic reactions. Furthermore, such method is flexible in modulating the surface chemistry and constructing robust platform for photocatalytic reactions. Here two examples will be presented:

With sufficiently high conduction band, ZnS is one of the typical photocatalysts for hydrogen evolution and CO_2 reduction. In our work, a series of ZnS-based nanocrystals with an average size of 3 nm were synthesized by mixing the precursor $ZnSO_4$ and Na_2S in water at room temperature. The as-synthesized nanocrystals were only rinsed with water and directly used in the subsequent photocatalytic experiments without any drying process. Such all-inorganic wet system showed an outstanding performance in the CO_2 conversion to formate with a high efficiency and selectivity. By simply changing the precursor composition and concentration, the ZnS systems could also be introduced dopants, cocatalysts and vacancies.

Molecularly nagatively-charged titanate monolayers are stably dispersed in aqueous solution but showed limited photocatalytic applications up to date. One of the drawbacks is the easy accumulation of metallic cocatalyst reaching to tens of nanometers by photodeposition that results in a fast recombination of charges. By exchanging the water with nucleophile solvents and reserving the outmost layer ligands, it is successful to realize the uniform dispersion of the ultrasmall metallic cocatalysts on the surface of the titanate monolayers. After rinsing the monolayers with pure water without drying process, a boosted photocatalytic activity can be achieved.

The presentation highlights the wet chemistry as a facile synthetic approach at ambient conditions, which greatly reduces the experimental time and efforts. The experiments disclose the importance of the wet surface and the possible loss of active sites and reactivity during drying process. The insights into the surface chemistry (large surface energy, rich active sites, tunable functional groups, etc.) may lay a significant groundwork for future investigations aiming at efficient photocatalytic systems.

8:00 PM SF03.09.16

Large-Scale Synthesis of 3D Nanonetworked Silica Film for Polymer-Free Drug-Eluting Stents EunyoungJeon, SuyeonKim, InaeLee, SunghyunPark and JoonseokLee; Hanyang University, Korea (the Republic of)

Self-expandable metallic stents (SEMSs) are interventional implants for treating esophageal strictures, and require additional drug therapeutics to suppress stent-induced tissue hyperplasia and restenosis. However, methods of loading drugs on SEMSs are challenging in terms of fabrication, mechanical stability, and therapeutic. There are several strategies to produce polymer-free drug-eluting stent (DES): top-down approaches such as patterning micro-pores via femtosecond laser beam etching, and bottom-up approaches such as decorating surfaces with nanomaterials (e.g., nanoparticles and nanowires). However, poor mechanical stability or peeling off of the coating materials, makes it difficult to observe therapeutic effects. we developed a large-scale, 3-dimensional, and flexible nanonetworked silica film (NSF) as a promising alternative drug carrier for polymer-free DESs. Here, using facile bottom-up synthesis, a 3-dimensional NSF is constructed to function as a drug carrier on the entire surface of the SEMS. Enlarged micelles as nanonetwork structure templates, are adhered to the surface via van der Waals interactions, and hydrolyzed silicates are assembled and deposited with the templates via electrostatic interactions. NSF is synthesized without defects, even on a large area and curved surface, with only 0.4% increase in thickness compared to the SEMS wire. Owing to the full range coating of nanonetwork structures, the NSF is fixed well on the surface and is flexible enough to withstand mechanical stress during dynamic expansion. NSF was grafted with octyltrimethoxysilane (OTMS) and hexadecyltrimethoxysilane (HDTMS) to induce surface hydrophobicity. 3-fold more sirolimus (approximately 30 $\mu g/cm^2$). Sirolimus can be loaded on NSF than on a polymer coating of the same thickness. The NSF stents show extremely slow elution compared to samples without NSF. The hydrophobic interaction and structural confinement of nanonetworks enable slow drug release even without polymers. Thus, NSF opens new avenues for manufacturing high-performance polymer-free drug-eluting stents and is a promising platform for drug delivery, protein adsorption, virus capture and generating flexible biosensors.

8:00 PM SF03.09.17

Signal-Amplifiable Porous Nanostructures for Detection of Infectious Viruses SunghyunPark, EunyoungJeon, InaeLee and JoonseokLee; Hanyang University, Korea (the Republic of)

Avian influenza virus (AIV) is the highly contagious and fatal viral disease that occurs among wild birds worldwide, mainly caused by influenza A virus. The proliferation of high pathogenicity AIVs, which requires massive killing, has a significant impact on the poultry industry and causes serious social and economic damages, therefore diagnosing AIV at early stage and prevent its spread is important. In addition to the large amount of enzyme required for signal amplification, it is important that the antibody is located on the outside of the particle to increase the accessibility to the antigen. The purpose of this study was to develop a size-selective biomolecule immobilization strategy that facilitates optimal porous silica nanoparticles (PSNPs) and conjugation system, which enables larger molecules (such as antibodies) to be conjugated to the outside of the nanoparticles, and smaller molecules (such as HRP) to be incorporated into its internal pores.
The rationally designed nanoprobe has been successfully adapted for chemiluminescent lateral flow stick immunoassay (CL-LFA). The detection limit of the CL-LFA using the signal-amplifiable nanoprobe for the nucleoprotein of the H3N2 virus was 5 pM. Sensitivity tests for low pathogenicity avian influenza H9N2, H1N1, and high pathogenicity avian influenza H5N9 viruses were conducted, and the detection limits of CL-LFA were found to be $10^{3.5}$ 50% egg infective dose (EID_{50})/mL, $10^{2.5}$ EID_{50}/mL, and 10^4 EID_{50}/mL, respectively, which is 20 to 100 times lower than that of a commercial AIV rapid test kit. Additionally, CL-LFA showed high sensitivity and specificity against 37 clinical samples. The signal-amplifiable probe used in this study may be a potential diagnostic probe with ultrahigh sensitivity for applications in the field of clinical diagnosis, which requires sensitive antigen detection as evidenced by enhanced signaling capacity and sensitivity of the LFAs.

8:00 PM SF03.09.18

The Influence of W-Doping on The Crystallization of VO2(M) within Hydrothermal Synthesis RobertoHabets[1], KimberlyTimmers[1], LucLeufkens[1], DanielMann[1], PascalBuskens[1,2] and AlishaChote[3]; [1]TNO, Netherlands; [2]UHasselt, Belgium; [3]Hogeschool Utrecht, Netherlands

30%-40% of a buildings operational energy consumption is due to heat loss or unwanted solar heat gain through windows [1]. To reduce the energy demand for heating and cooling simultaneously, a window has to adapt to changing requirements, which can be achieved via so called “smart windows”. Vanadium dioxide can be used as active material in smart windows to realize adaptive solar heat regulating properties. In its monoclinic form, the crystal displays thermochromic properties, changing electrical and optical properties based on its structural phase transition from monoclinic VO2 (M) to rutile VO2 (R) at 68 °C. For application purposes, the switching temperature can be lowered by introducing defects in the crystal structure via a dopant, like tungsten [2]. VO2 (M) can be synthesized from V2O5 using a reducing agent under hydrothermal conditions at mild temperatures [3]. However, due to the many existing non-thermochromic crystal phases of VO2, as well as the potential to be reduced to V(III) or oxidized to V(V), it is not trivial to synthesize highly pure and crystalline VO2 (M). The difficulty to realize mixing in hydrothermal batch reactors, placed in an oven, often leads to inhomogeneous products. Here we present a method to synthesize VO2(M) from V2O5 and oxalic acid, as reducing agent, via hydrothermal reaction. We introduce a new method to enable mixing of the reaction solution within a hydrothermal batch reactor, increasing homogeneity of the resulting crystalline VO2 (M). Furthermore, we investigate the influence of the W dopant on the crystallization of VO2 (M). We show that under established conditions VO2 tends to crystallize in the (A) and (B) phases, whereas with introduction of W a preferential crystallization in the (M) phase can be achieved. By optimizing the reaction conditions, we obtain highly crystalline and pure VO2 (M) particles at a lowered switching temperature.

Unveiling The Mechanistic Reaction Pathway of Selective Photocatalytic CO_2 Reduction AmrSabbah[1], Kuei-HsienChen[2] and Li-chyongChen[1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

The conversion of CO_2 into chemical fuels via photoreduction is regarded as one of the most effective methods of addressing the environmental greenhouse gas problem and the energy shortage. Creation of a suitable active and selective photocatalyst is the main goal of photocatalysis research. Meanwhile, better catalytic efficiency and controlled selective production yield can be achieved by developing photocatalysts, which can be facilitated by a deeper understanding of the chemical pathways. In this context, investigation of the reaction mechanism and understanding the nature of the active sites have recently attracted more attention. Thus, it is important, while challenging, to monitor reaction intermediates during the gas-phase photocatalytic CO_2 reduction reaction to achieve higher CO_2 conversion yield. In this perspective, we report a mechanistic insight for the photocatalytic CO_2 reduction over Two-dimensional $ZnIn_2S_4$ as an active model photocatalyst that exhibits promising photocatalytic performance with a high absorption coefficient under visible light. Our study combines in-situ FTIR investigation, physisorption measurements, operando XAS. We systematically probed the intermediate species (HCOO*, and CH_3O*) and established a co-feeding scheme to confirm the reaction pathway. The change in the oxidation state and the charge transfer behaviors were monitored for Zn, In, and S during the reaction coordinate to explore the active sites towards CO_2 molecules adsorption and activation. Finally, DFT calculations will be presented to prove the validity of the reaction mechanism.

Ceria-Based Materials for Catalytic Degradation of Ciprofloxacin in Water under Visible Light Irradiation AjitK. Dhanka; University of Delhi, India

Contamination of water by antibiotics poses a serious threat to environmental and human health. The antibiotics enter into water from domestic waste, hospital discharge, agrochemicals, veterinary medicines, human excretion, pharmaceuticals manufacturing, etc. When antibiotics get into water they make it more likely for bacteria to develop antimicrobial resistance - which is said by the WHO (World Health Organization) to be dangerous to humanity. Some of the antibiotics found in water affect microbes at concentrations below 10 µg/L. One among such antibiotic is ciprofloxacin (CIP). CIP is a synthetic fluoroquinolone antibiotic, widely used for treating microbial infections in human and animals. But CIP in water even at low concentrations, causes harmful effects to human and animal health such as vomiting, tremors, nausea, headache, diarrhea, nervousness, stomatitis, leucopenia, carcinogenic, pathogen resistance, chromosomal mutation, skin disorder and damage to the immune system. To encounter the problem of antibiotic contamination of water, researchers have developed various techniques for the degradation of antibiotics, such as catalytic degradation, physical adsorption, chemical oxidation and biodegradation. Among them, catalytic degradation is receiving significant attention. Therefore, in this work we present a simple chemical method to prepare Ag/CeO2 catalyst for visible light driven degradation of CIP in water. The catalyst has been characterized by UV-Vis, X-ray diffraction (XRD), Raman, Field emission scanning electron microscopy (FE-SEM), Transmission electron microscopy (TEM), Thermogravimetric Analysis (TGA) and Brunauer-Emmett-Teller (BET) techniques.

Suppression of Oxides Regrowth at Air-Interfaces in Superconducting Quantum Circuits using Self-Assembled Monolayers SaleemG. Rao[1,1], MohammedAlghadeer[1,2], ArchanBanerjee[3], AhmedHajr[3], HosseinFariborzi[4] and HusseinHussein[4]; [1]King Fahd University of Petroleum and Minerals, Saudi Arabia; [2]University of Oxford, United Kingdom; [3]University of California, Berkeley, United States; [4]King Abdullah University of Science and Technology, Saudi Arabia

Defects in materials at different interfaces in circuit quantum electrodynamics (cQED) systems contribute significantly to decoherence at single photon level and millikelvin temperature. Low loss design, materials, and dielectrics have been reported and orders of magnitude improvement in coherence time have been observed however, to achieve scalable architectures for quantum computing still we need order of magnitude improvement in the coherence time. Defects at air-interfaces are foremost regions of TLS and non-TLS losses and these losses cannot be ousted in conventional way, i.e. by depositing an inorganic passivating layer because such additional layers can worsen these interfaces. Defects at air-interfaces can be removed by etching however, their regrowth remains a problem. Chemisorption of molecular self-assembled monolayers (SAMs) on metals and oxides is a promising option to engineer the desired properties of such interfaces. SAMs on metal and semiconducting surfaces can suppress the growth of oxides and can enhance dielectric constant of the surfaces. All SAMs themselves have known chemical and electronic structure and SAMs binding end makes strong chemical bond with top atomic layer of the metal/semiconductor surface. Therefore, SAM can significantly reduce the interface defects in cQED architecture. Here, we used SAMs to stop the regrowth of oxide-defects, both at Niobium-air and substrate-air interfaces and to modify the dielectric constant of the interface and observed sustained improvement in quality factor of the superconducting co-planer waveguide (CPW) resonators. We observed order of magnitude improvement in Q_{TLS} due to SAMs compared to etched-clean CPW resonator surface, which clearly shows that SAMs not only suppresses the regrowth of oxide it also contributes in improvement of the quality factor. Quality factor measurements at millikelvin temperature and at single photon, XPS data and TEM images of SAM passivated air-interface sustenance our claim. Furthermore, SAM assembly is highly compatible with micro-/nano-fabrication processes, therefore these results will open new ways to improve the coherence time in cQED using different SAMs.

8:00 PM SF03.09.22
Oriented ZSM-5 Nanoarray Encapsulation Enabled Robust Monolithic Catalysts for CH_4 and CO_2 Conversion BinchaoZhao[1], ChunxiangZhu[1], YiweiYu[2], FangyuanLiu[1], JingyueLiu[2] and Pu-xianGao[1]; [1]University of Connecticut, United States; [2]The University of Arizona, United States

Stable and active catalysts are the key to catalytic reactions requiring harsh conditions with high temperatures (>600 °C) and moist content. However, it is challenging to maintain high activity when catalyst design strategies such as strong metal support interaction and physical encapsulation, are applied to improve stability due to a tradeoff in the reactivity sacrifice as a result[1–3]. Through rational design and manipulation[4,5], we have demonstrated a well-defined nanoarray hybrid monolithic catalyst which is composed of transitional metal oxide (Co_3O_4) nanoarray and the encapsulation layer of brush-like oriented ZSM-5 nanoarray, denoted as CC-HZA. The hybrid nanoarray catalysts have shown high thermal stability and excellent activity for catalytic processes under harsh conditions. CC-HZA demonstrates superior thermal stability and catalyst activity for high-temperature reactions such as methane oxidation, reverse water gas shift, and methane dry reforming reaction under both oxidative and reductive conditions at a high-temperature range (600-700 °C, 1 bar) with moist conditions. The internal and external ZSM-5 confinement is revealed for the Co_3O_4 nanoarray forest, playing a key role in the demonstrated superior stability. Besides the encapsulation effect, the oriented ZSM-5 nanoarray offers important merits including (1) improved CO selectivity for RWGS, (2) strong hydrophilicity of ZSM-5, endowing the excellent catalyst water resistance, and (3) oriented hierarchical nanoarray structure, offering fast transfer with high activity and less material usage. This work provides a new design of highly thermal stable monolithic catalysts, which allows highly stabilized non-noble nanometal and metal oxides catalysts for high-temperature applications.

Manipulating Ligand Binding Affinity in Allosteric Coordination Complexes through Inherent Ring Strain Design YimingHu, FionaY. Wang and ChadA. Mirkin; Northwestern University, United States

Organometallic complexes are highly versatile given that their binding affinities are sensitive to their chemical makeup and environment. Indeed, these differences in binding affinities can be leveraged with the use of hemilabile ligands to construct spatially responsive structures. However, modifying binding affinities usually involves adding specific electron groups to binding atoms, a process that is not only synthetically complex but also can limit the integration of other functional groups. One solution to this challenge is to use ring strain in cyclic compounds to act as a binding affinity modulator combined with a hemilabile coordination system. The Weak-Link Approach (WLA) is a particularly powerful hemilabile coordination system that contains chemical modularity by exploiting binding affinities with combinations of strong binders, weak binders, and metal nodes.

Here, we introduce a new WLA system by replacing an asymmetric P,S ligand with a symmetrical bis-carbene and explore the effects of ring strain on allosteric reactivity. By studying ligand displacement in 4- to 8-membered rings, a correlation between ring size and coordination reactivity is established. Adjusting the ring size proved to be an effective way to alter binding affinities without further complex chemical modifications. Moreover, we observed that increased ring strain also leads to changes in overall allosteric reactivity, and even reversing conventional coordination binding to prefer weaker binders vs stronger ones in highly strained 4-, 7-, and 8-membered cyclic systems. Overall, through careful selection of metal-binder coordination, and thus enthalpy, along with the formation energy associated within a strained ring-forming system, we precisely define a desired allosteric state. In sum, this work not only represents a paradigm shift in harnessing ring strain as a strategy for binding affinity manipulation, but also redefines our understanding of coordination dynamics in these systems.

8:00 PM SF03.09.24
Photocatalytic fuel cells: Fundamentals and applications HebertonWender; Federal University of Mato Grosso do Sul, Brazil

The global concerns surrounding the energy crisis and environmental pollution have recently escalated. Photocatalytic fuel cells (PFCs) emerge as promising energy conversion devices that harness solar energy. These PFCs utilize cost-effective semiconductor electrodes to spontaneously convert the chemical energy of renewable fuels or pollutants, alongside oxidants, into electricity. What sets PFCs apart is their amalgamation of photoelectrochemical and fuel cell concepts, offering dual benefits to address both environmental and energy challenges. The engineering concept behind PFCs is elegantly simple, relying solely on light as the driving force. Consequently, constructing affordable PFC devices becomes feasible, providing effective

solutions for local environmental pollution and low-power energy consumption devices. This work delves into essential definitions, working principles, and the theoretical underpinnings of PFCs. It also offers a practical tutorial on constructing these devices and conducting half-cell reaction tests to evaluate PFC performance. Furthermore, some recent application cases will be thoroughly discussed, with a primary focus on critically analyzing strategies to enhance the efficiency and stability of PFCs.

8:00 PM SF03.09.25
A Bias-Free Tandem Photoelectrochemical Cell of BiVO4 - CuO for Solar-Driven Water Splitting RenatoV. Goncalves, LucasG. Rabelo and WashingtonSanta Rosa; University of Sao Paulo, Brazil

Photoelectrochemical (PEC) water splitting has been considered as a promising technique for converting solar energy into clean and renewable hydrogen (H_2) fuel. Recently, Tandem PEC cells based on stable and low-cost metal oxides have attracted attention for generating green H_2 solely through water and solar energy. In this study, we synthesized $BiVO_4/FeNiO_x$ photoanodes and CuO photocathodes using magnetron sputtering deposition. These materials were integrated into a straightforward and cost-efficient Tandem PEC cell to facilitate oxygen and hydrogen evolution reactions (OER and HER), respectively. Notably, the $BiVO_4/FeNiO_x$ photoanode displayed remarkable PEC performance and demonstrated robust chemical stability in OER, achieving a high photocurrent density of +1.22 mA cm^{-2} and an impressive charge transfer efficiency of 96% at the water oxidation potential. The CuO photocathode displayed remarkable performance in the PEC process for the hydrogen evolution reaction. It initiated at a starting potential of 1.03 V vs. RHE and achieved a photocurrent density of approximately 0.4 mA cm^{-2} at +0.40 V vs. RHE. This outcome underscores the viability of employing these materials in a bias-free PEC cell. Additionally, we introduced a practical model based on classical band theory to assess the interfacial band alignment of photoelectrodes during PEC water splitting under operational conditions. Our energy band diagrams, simulated under illumination, illustrated that the photogenerated (electrons ad holes) in the $BiVO_4/FeNiO_x$ - CuO Tandem PEC film possessed sufficient energy to drive OER and HER without requiring external bias. Encouragingly, our novel $BiVO_4/FeNiO_x$ - CuO Tandem PEC device produced a stable operating photocurrent density of ~50 μA cm^{-2} under zero-bias illumination (AM 1.5G) for at least 1000 seconds, evidencing the occurrence of bias-free solar water splitting reactions.

SESSION SF03.10: Functional Materials III
Session Chairs: Craig Brown and Brent Melot

8:00 AM SF03.10.01
Synthesis of Hydride Materials at Moderate Pressures by Combining Pressure and Electrochemical Potential MgciniK. Phuthi[1], NishaGeng[2] and EvaZurek[2]; [1]University of Michigan, United States; [2]University at Buffalo, The State University of New York, United States

Hydride systems such as metal hydrides or doped ternary hydrides are interesting for their potential applications as high temperature superconductors and for hydrogen storage. Traditionally, these materials have been synthesized either by passing a pressurized hydrogen source over the material or electrochemically loading the material. We show that by combining the two methods, new phases are accessible and hydrides with higher hydrogen content are accessible at much lower pressures unsing less than 1V of applied potential while also suppressing hydrogen evolution which limits electrochemical loading. We present results for the Yttrium hydride system and explore the possibility of synthesizing the recently claimed high temperature superconducting material, Nitrogen doped Lutetium Hydride.

Single-step, Novel Synthesis of Carbonaceous Cobalt Spinel Ferrite Nanocomposites and a Study of Their Magnetic Properties Naveen NarasimhacharJoshi[1,2,3] and S. A.Shivashankar[1]; [1]Indian Institute of Science, India; [2]Indian Institute of Technology Kharagpur, India; [3]North Carolina State University, United States

Metal oxide/ carbon composites offer prospects as new, improved functional materials, as they would exploit the unique properties of both of their components. Such composites have promising applications in energy storage, catalysis, and as adsorbents; the addition of carbon overcomes the inherent poor electronic conductivity of most metal oxides while enhancing the specific surface area of the material. Among them, spinel ferrite composites are widely explored for their promising magnetic properties. However, the benefits of carbonaceous spinel ferrites are yet to be explored. Herein, we report the novel synthesis of carbon composites of cobalt ferrite by a simple, one-step, inert-ambient sealed-tube pyrolysis (STP) of a stoichiometric mixture of the ketoesterate complexes of the Co (II) and Fe (III) as precursors, and without the aid of any catalysts or any further heat treatment. We show that composites formed this way are homogeneous on a macroscopic scale, with interesting variations in the morphology of the carbon formed. The metal oxide composites so formed are characterized through various techniques and evaluated for their magnetic properties. The isothermal field-dependent magnetization plots indicate ferrimagnetic interactions with a saturation magnetization of 34 emu/g. Temperature-dependent magnetization plots does not show blocking temperature as a consequence of the well-saturated magnetic spins in the sample. A clear deviation in the field-cooled (FC) and zero-field cooled (ZFC) curves until above the room temperature indicates that the Curie temperature (T_c) of the sample is well above 300 K. As such, the T_c of the cobalt ferrite composite is found to be ~ 400 K, obtained by the extrapolation of fits to experimental data using modified Bloch's law. Thus, cobalt ferrite nanocomposite opens a new frontier for soft magnetic applications of spinel ferrite structures.

In-Plane Spin Dynamics and Complex Phase Spaces of Conducting Antiferromagnets DanielP. Shoemaker; University of Illinois at Urbana Champaign, United States

Recent demonstrations have shown that it may be possible to change the orientation of magnetic ordering (the Néel vector) of antiferromagnetic materials by applying electrical currents, even though the currents are not spin-polarized and the material has zero net magnetic moment. The candidate materials have ultrafast antiferromagnetic resonances and belong to centrosymmetric space groups with magnetic cations in non-centrosymmetric sites. Exemplary materials include tetragonal CuMnAs and tetragonal Mn_2Au. However, this seemingly straightforward goal is complicated by strong magnetostrictive interactions in CuMnAs and related materials that share the Cu_2Sb structure type, such as Fe_2As and Mn_2As. Understanding in-plane antiferromagnetism also leads to conceptual overlap with magnetic topological insulator candidates, such as $EuSn_2P_2$. We show how traditional crystal growth methods can access these complex phases and reveal new materials with unique structure types. Understanding the fundamental phenomena and engineering devices from these materials requires measuring energy scales with detailed torque magnetometry and transport measurements that set stringent requirements on sample size and quality.

Exploring Novel Nonbenzenoid π-Electron Systems Toward Unusual yet Stable Functional Materials AikoFukazawa; Kyoto University, Japan

Aromatic hydrocarbons and their heteroaromatic analogs are playing a dominant role in today's organic optoelectronic materials. On the other hand, nonbenzenoid hydrocarbons and relevant cross-conjugated π-electron systems exhibit attractive properties such as long-wavelength absorption and multistep redox properties, most of which are difficult to achieve with the benzenoid π-electron systems of similar molecular sizes. However, the difficulties in their synthesis, high reactivity, and lack of appropriate molecular design guidelines pose substantial obstacles to the utilization of these classes of compounds as basic frameworks for superior optoelectronic materials. To address the above-mentioned issues, we have been focusing on the molecular design based on the annulation of weakly aromatic (hetero)arenes on the nonbenzenoid hydrocarbons in a ring-fused manner. Furthermore, we have recently synthesized novel nonbenzenoid hydrocarbons that exhibit exceptional stability toward multi-electron reduction like C_{60} yet intense light absorption in the visible region. In this presentation, I will describe the overview and some of our recent studies based on this strategy.

9:30 AM SF03.10.05
Chemical Strategies to Induce Superconductivity in Rare-Earth Nickelate Thin Films AriTurkiewicz, GracePan, DanFerenc Segedin, NicoleK. Taylor, CharlesBrooks, JaradA. Mason and JuliaMundy; Harvard University, United States

Since the discovery of high-temperature superconductivity in copper oxides, there have been continued efforts to better understand the origins of the superconducting phase and to identify related materials families. Rare-earth nickelates, particularly Ruddlesden-Popper phases of the type $Ln_{n+1}Ni_nO_{2n+2}$, are a promising class of materials owing to the many shared properties of isoelectronic Ni^{1+} and Cu^{2+} cations. Recently, superconductivity was observed in thin films of the infinite layer ($n = \infty$) nickelate $Nd_{0.8}Sr_{0.2}NiO_2$ as well as in thin films of the five-layer ($n = 5$) phase $Nd_6Ni_5O_{12}$. Theoretical and experimental studies suggest that increased dimensional confinement of the nickelate layers will lead to more 'cuprate-like' superconductivity. The $n = 1$ phase Ln_2NiO_4 is therefore expected to display the highest degree of dimensional confinement with single layers of nickel oxide separated by blocking rare-earth oxide layers. Here, we describe efforts to synthesize thin films of the parent compound Ln_2NiO_4 through molecular beam epitaxy. We then explore different chemical strategies to tune the nickel valence of as-grown

films to induce superconductivity.

Developing High-Performance P-Channel TFTs—From Emerging Semiconductors to Amorphous AoLiu and HuihuiZhu; Northwestern University, United States

The development of high-performance p-channel thin-film transistors (TFTs) that can be made by cost-effective methods and can match with n-type metal oxide counterparts for the integration of complementary circuits has attracted great interest of the electronics community. Unfortunately, after decades of efforts, the achievement of high-performance p-channel TFTs is still a nearly-impossible technique challenge. In my talk, I will give a comprehensive overview of this research field[1] and introduce our recent progress in the fabrication of high-performance p-channel TFTs based on different semiconductors, including metal oxide,[7,8,] and chalcogenide.[9] The optimized devices show high hole mobilities of > 50 $cm^2 V^{-1} s^{-1}$ and high current on/off ratios over 10^8. At the end of my talk, I will introduce our recent breakthrough work on high-performance amorphous p-channel oxide TFTs, overcoming the technical challenges over the past decades.

Atomistic Polarization Textures JayakanthRavichandran; University of Southern California, United States

Topological defects such as vortices, and skyrmions have gained recent significant interest in solid state materials as ferroic materials (ferromagnets and ferroelectrics) have become a test bed to realize and control these nanoscale structures. Although this phenomenon is being investigated as a pathway to energy efficient information storage, broader applications in interaction of electromagnetic waves with such features are emerging. In the case of ferroelectrics, boundary condition engineering is used to achieve vortices, skyrmions, and merons in low dimensional epitaxial oxide heterostructures.
In this talk, I will introduce the notion that similar phenomenology but at the atomic scale can be achieved in charge density wave phases, especially nominally semiconducting chalcogenides. I will outline my group and other groups efforts in showing non-trivial toroidal polar topologies at the atomic level in chalcogenides with nominally empty conduction band with *d*-orbital character such as 1*T*-$TiSe_2$, Ta_2NiSe_5 and $BaTiS_3$. Specifically, we use X-ray single crystal diffraction as a probe for high quality single crystals of a quasi-1D hexagonal chalcogenide, $BaTiS_3$, to reveal complex polar topologies such as vortices, and head-to-head and tail-to-tail arrangement of dipoles. Recent experiments and theoretical studies on the stability and dynamics of these features will also be discussed. Lastly, I will outline how such platforms can broadly enable the search for materials with chiral optical materials and polarization sensitive light-matter interaction.

11:15 AM SF03.10.08
Jahn-Teller Distortion in Layered Nickel Oxides LiamNagle-Cocco[1], AnnalenaR. Genreith-Schriever[1], GeorgePhillips[1], JohnS. Evans[2], JamesM. Steele[1,1], JoshuaD. Bocarsly[1,1], AndrewGoodwin[3], ClareP. Grey[1] and SiânE. Dutton[1]; [1]University of Cambridge, United Kingdom; [2]Durham University, United Kingdom; [3]University of Oxford, United Kingdom

The Jahn-Teller (JT) distortion has been under intense scrutiny from the solid state chemistry community in recent years. For example, understanding the role of JT behavior and associated orbital ordering is crucial for understanding battery cathode behaviour with cycling, cuprate superconductivity, and colossal magnetoresistance. One interesting aspect of JT research which is not fully-resolved is the behaviour of the JT distortion with heating; in $LaMnO_3$, studies of local structure show an order-disorder transition at ~750 K, characterized by the persistence of JT-distorted octahedra even when the average structure does not exhibit JT distortion [1]. However, there are limited reports on other materials and it is not clear from the literature whether this behaviour is generalised or system-specific.

In this study, we have used a combination of variable-temperature and variable-pressure neutron/synchrotron diffraction, Pair Distribution Function (PDF) with large box modelling, EXAFS, nuclear magnetic resonance (NMR), and *ab initio* Molecular Dynamics on two d^7 layered nickel oxides ($LiNiO_2$ and $NaNiO_2$) to explore the JT behaviour, including orbital ordering and the nature of the JT transition. We will present our findings that the transition is displacive in $NaNiO_2$ rather than order-disorder, with ferro-orbital ordering at room temperature and the absence of Jahn-Teller-distorted octahedra at higher temperatures. This contrasts with the intra-plane anti-ferro-orbital and inter-plane ferro-orbital ordering at room-temperature and reported Potts model behaviour at higher temperature in $LaMnO_3$. We will also compare this to our findings for the orbital ordering in $LiNiO_2$, which has been a controversial subject for many years owing to its enigmatic behaviour [2,3].

11:30 AM SF03.10.09
Exploiting the Response of Lone Pair Electrons (LPEs) to Pressure: Synthesis of Mixed-Anion BiSF with In-Plane LPEs ChengchaoZhong[1,2], CédricTassel[1], DaichiKato[1], KantaOgawa[1,3], RyuAbe[1] and HiroshiKageyama[1]; [1]Kyoto University, Japan; [2]Ritsumeikan University, Japan; [3]Imperial College London, United Kingdom

While inorganic compounds such as oxides generally have high symmetry, compounds with the stereochemically active s^2 lone pair electrons (LPEs) of p-block cations tend to have lowered symmetry.[1,2] The LPEs in the electron-rich cations (e.g., Pb^{2+}, Sb^{3+} and Bi^{3+}), which are energetically stabilized by relativistic effects, cause electronic repulsion with the surrounding anions and displace the cation. Symmetry breaking by LPEs is valuable in functional materials, causing large spontaneous polarization in ferroelectrics $BiFeO_3$ (95 $\mu C/cm^2$)[3] and small thermal conduction in thermoelectric materials Pb*Q* (*Q* = S, Se, Te).[4] Recently, in-situ XRD has revealed that the stereochemical activity of LPEs is lost upon external pressure and reappears upon decompression.[5] Therefore, if the stereochemical activity of LPEs is controlled by external pressure at the synthesis process, the creation of novel structures can be expected.
In this study, a new mixed-anion compound BiSF has been synthesized using high-pressure synthesis. BiSF has a distorted PbFCl-type structure with LPEs oriented along intralayer direction, whereas those of previous layered compounds with PbFCl-type structures such as PbFCl and BiOF are oriented in the interlayer direction (Revised Lone Pair Model).[2] DFT calculations show that the stereochemical activity of LPEs is suppressed above 5 GPa, and a phase transition to a distortion-free PbFCl-type structure is observed. Since the synthesis of BiSF requires high-pressure conditions of 5 GPa, it is considered that a distortion-free structure is formed first under high-pressure synthesis at high temperatures, which stabilizes the metastable atmospheric pressure phase. Anisotropic lattice expansion of BiSF with respect to temperature was observed, and BiSF has a small band gap (1.89 eV). The *n*-type response and relatively high photocurrent were clearly observed under visible light irradiation, suggesting its potential application as a photoelectrode.

Distinguishing Isotropic and Anisotropic Signals in X-Ray Scattering Data using Machine Learning DanielleN. Alverson[1], DanielOlds[2] and MeganButala[1]; [1]University of Florida, United States; [2]Brookhaven National Laboratory, United States

Improving understanding of structure-property relationships is imperative for the advancement of electronic materials that are implemented in devices as thin films. Thin films for electronic applications, such as phase change, ovonic, and spintronic materials, are typically deposited on single-crystal Si substrates. While X-ray diffraction is commonly used to study electronic thin films, it cannot provide comprehensive atomic structure insights for amorphous and nanocrystalline films.

X-ray pair distribution function (PDF) analysis can access the relevant atomic structure details, and is derived from total X-ray scattering data encompassing both diffuse and elastic scattering. Traditionally, PDF measurements are performed for powder samples. PDF has been adapted to thin films by depositing them on amorphous substrates; amorphous substrates provide a means to separate the thin film and substrate scattering signals through subtraction.

Moving forward, the next progression of thin film PDF is its application to films on single-crystal substrates. Unfortunately, high-intensity anisotropic Bragg spots from single-crystal substrates saturate the detector images and overwhelm the thin film's isotropic (radially-symmetric) signal. The nature of this data precludes the use of the substrate subtraction processing method used for thin films on amorphous substrates.

To overcome this challenge, we are developing unsupervised machine learning methods that combine non-negative matrix factorization and hierarchical agglomerative clustering to isolate the thin film scattering signal. We are validating our approach using SimDat2D, a Python module we created to generate and process synthetic data representative of total scattering from thin films on single crystal substrates. We find our machine learning methods can separate the isotropic thin film signal of interest from the high-intensity single crystal Bragg spots by leveraging their symmetry differences, thus enabling profound structural insights in functional thin film materials.

By implementing these advancements in X-ray scattering data analysis, we seek to enhance the understanding of structure-property relationships in electronic materials, facilitating the development of more advanced thin-film devices.

SESSION SF03.11: Functional Materials IV

Chromatography Separation of Hydrogen Isotopes at Ambient Temperature using Dihydrogen Complexes ShinyTakaishi; Tohoku University, Japan

Hydron isotopes such as deuterium (D) and tritium (T) play important roles not only in the fundamental research but also in the industry. D has been used as NMR solvents, tracer, moderator in nuclear reactors, and silicon semiconductive devices. D and T are also used as the nuclear fusion reactors, which will be expected as a future energy supply. T is contaminated with water in the nuclear waste, and its removal will be beneficial from the viewpoint of environmental protection.
Natural abondance of D is 0.015 % (mainly in the sea water) and distillation process at 20 K is used to concentrate D to produce D_2 gas, which is energy-intensive process. Recently, quantum sieving has been extensively studied as a new technique of the hydrogen isotope separation. Beenakker and co-workers proposed the concept of kinetic quantum sieving (KQS), which utilize the difference of the diffusion rate in the small pore due to the thermal de Broglie wavelength between H and D. More recently, chemical affinity quantum sieving (CAQS) has been studied, which utilizes the difference of zero-point energy (ZPE) and resultant adsorption enthalpy (ΔH) among the hydrogen isotopes. Although CAQS potentially enables the hydrogen isotope separation at higher temperatures, the operating temperature was still below 200 K due to the small ΔH.
From the viewpoint of ΔH, metal-dihydrogen complex is one of the most appealing candidates for this target. The first metal-dihydrogen complex was reported by Kubas and coworkers in 1984, and hundreds of compounds were reported so far. In the metal-dihydrogen complexes, chemical bond is formed between metal and dihydrogen molecule, whereas H-H bond is kept albeit it is elongated and weakened. This can be regarded as an intermediate of physisorption and chemisorption, and therefore, moderate adsorption enthalpy and fast ad/desorption kinetics could be achieved. In spite of such advantages, there has rarely been studied on the hydrogen adsorption of the dihydrogen complexes in the solid state.
We have recently studied the hydrogen adsorption of solid-state dihydrogen complexes and found that ΔH of D_2 is significantly larger than that of H_2 in the most of dihydrogen complexes. In the presentation, we discuss the possible mechanisms of this phenomenon. In addition, we also report the demonstration of the separation of H_2 and D_2 using column chromatography at ambient temperature.

2:00 PM *SF03.11.02
Novel Inorganic-Organic Combined Complex Metal Hydrides for Energy-Related Applications HuiWu; National Institute of Standards and Technology, United States

With increasing concerns on global climate change, many efforts have been made to tackle this challenge. Development of clean energy such as hydrogen and electricity generated by renewable energy sources will simultaneously reduce the dependence on fossil fuel and emissions of greenhouse gases and pollutants. While for the existing anthropogenic carbon dioxide from combustion of fossil fuels, carbon capture and storage are widely acknowledged as a necessary carbon abatement strategy. Complex hydrides have been intensively studied as promising solid-state hydrogen-storage materials and electrolyte materials for battery applications. They recently have also attracted attention for their potential usage for CO_2 capture and conversion. In this talk, I am going to present our work on development of novel complex metal hydrides, particularly inorganic-organic combined complex hydride systems, with interesting relevant versatile properties for diverse applications such as hydrogen storage, ionic conduction, and CO_2 capture. The talk will focus on the structural studies of these materials. The rich information obtained from the structural analysis and its implications for hydrogen storage, ionic conduction, and CO_2 capture of the related hydrides will also be discussed.

2:30 PM SF03.11.03
Fast and Non-Equilibrium Uptake of Hydrogen by Pd Nanocrystals with Defects SiyuZhou, YifengShi and YounanXia; Georgia Institute of Technology, United States

The energy-storage technologies (*e.g.*, hydrogen storage in metals and electricity storage in batteries) rely on facile absorption and desorption of solute in storage materials. However, the sluggish kinetics of the absorption or desorption process could be an issue if there is a need to overcome extra kinetic barriers, such as nucleation of a second phase and growth through interface motion. Herein, we report that hydrogen absorption by Pd nanocrystals with defects can bypass the energy barriers associated with nucleation and growth of β-phase palladium hydride. Therefore, these Pd nanocrystals with defects absorb hydrogen at a speed that is three times as fast as Pd single-crystal nanocrystals. Moreover, the solubility of H in the Pd nanocrystals with defects is greatly increased, favoring the formation of PdH_x with metastable compositions. The as-obtained PdH_x nanocrystals show promising properties such as high catalytic activity toward formic acid oxidation (FAO).

Tailoring Linear Organic Molecules onto Inorganic Scaffolds TomceRuncevski; SMU, United States

The reactivity and functionality of organic molecules in the solid state are primarily governed by weak, non-covalent interactions, which pose challenges in terms of rational control. Furthermore, organic crystals often lack the necessary mechanical properties for the development of functional materials. These challenges can be overcome by utilizing inorganic scaffolds that incorporate functional groups capable of spatially organizing organic molecules. Conversely, the presence of molecules also influences the structure and properties of the scaffolds, often leading to improvements in their properties. In this context, we present three examples highlighting the synergy between organic molecules and inorganic scaffolds. Firstly, we demonstrate how metal-organic frameworks can be employed to store and stabilize 2-aminoethanethiol (cysteamine), a thiol-based drug, is prone to oxidation in its molecular form. By binding the thiol groups to open metal sites in MOF-74, we effectively protect the drug from oxidation and enable controlled release. Next, we explore how a slight modification of the organic molecule can significantly alter the properties of the MOF. Using ethylenedithiol instead of 2-aminoethanethiol introduces defects into the MOF structure, resulting in emergent properties like luminescence that are absent in the parent framework. Furthermore, we investigate other inorganic scaffolds, such as brucite layers, that can be interspersed with organic molecules. Incorporating sorbic acid within the layers of Co(OH)2 yields a new hybrid material with modified magnetic properties. Notably, this material serves as a platform for the synthesis of atomically-precise polymers from small organic monomers, such as an analogue of natural rubber. In summary, the combination of small organic molecules with inorganic scaffolds presents promising opportunities for tailoring and enhancing properties that can be used in the design of materials to overcome the challenges of tomorrow.

3:45 PM *SF03.11.05
A Dynamical View of Mechanochemical Reactions AdamA. Michalchuk; University of Birmingham, United Kingdom

Mechanochemical reactions – the ability to induce reactivity with mechanical force – offers an unparalleled opportunity for sustainable materials manufacture, removing solvent, reducing reaction times, and offering potential for highly scale-able reactions. Moreover, given the unconventional conditions of mechanochemical routes, they provide a route to synthesize materials that are otherwise impossible to make. Unfortunately, there remains very little understood about how mechanochemical processes occur, which greatly hinders their adoption by the wider community.[1]
In this light we have been developing new experimental strategies to follow mechanochemical reactions in situ and in real time.[2] This includes innovations in time-resolved *in situ* (TRIS) diffraction[3] and TRIS X-ray absorption spectroscopy.[4] To date, these methods have provided exciting new insight into reaction profiles under various conditions, and both phase and microstructural evolution of materials within mechanochemical reactors. To supplement this work, we are developing fundamental new theoretical models to describe mechanochemical reactions, with the aim to understand at the atomic scale how mechanical energy is able to induce chemistry in solid materials.[5] Together our experimental strategy to probe macroscopic dynamics of mechanochemical reactions, coupled with theoretical methods to probe microscopic dynamics, are providing unprecedented understanding of this potentially transformative technology.[6] Through this talk we will highlight both experimental and theoretical developments and their applications to understanding the reactivity of solids under mechanochemical conditions.

Chemistry of Nucleation: Mapping the Hydrothermal Chemistry of Tungsten Oxide Formation MikkelJuelsholt; University of Oxford, United Kingdom

The goal of materials science is to develop new materials with useful properties that can improve the world we live in. At the moment synthesising new materials rely almost solely on educated guesses and trial-and-error methods.[1,2] As materials become more and more complex, this approach becomes unsustainable because the number of possible synthetic parameters grows infinitely large.[1,2] Instead, we need to move to a rational synthesis approach where we design the synthesis of materials based on an in-depth knowledge of the chemistry governing the formation of solids.[1,2] However, we currently have little knowledge of the chemistry controlling the formation of a new phase.[1,2] To understand the chemistry of materials formation, it is necessary to investigate the chemical reaction as they happen using in situ methods.[2,3,4]
In this study, we use in situ total scattering with Pair Distribution Function (PDF) analysis to investigate the solvothermal synthesis of tungsten oxide nanoparticles. We show how the structure of the precursor at the moment just prior to nucleation can induce the formation of a metastable phase. We show how both solvent and temperature can also influence the precursor structure and induce the formation of a metastable phase. The tungsten oxide nanoparticles are synthesised from a solution of polyoxometalates, which are large polyanions composed of tungsten and oxygen. The use of *in situ* total scattering and PDF enables us to follow the entire reaction in one experiment and identify the different polyoxometalates formed as well as all formed solid phases. This enables us to map the hydrothermal chemistry of tungsten oxide as a function of pH, precursor and counterions and how they govern the formation of metastable phases.

4:30 PM SF03.11.07
Dynamical Changes for Exsolved Ni-Based Alloys from Lanthanide Perovskite Oxides SomchateWasantwisut, SohamShah and KandisL. Abdul-Aziz; University of California, Riverside, United States

Using in-situ exsolution of reducible transition metals from perovskite precursors allows for synthesizing strongly adhered nanoparticles that are thermally stable and homogeneous in size and shape. The perovskite oxides can reversibly exsolve transition-metal cations as nanoparticles under fluctuating reducing and oxidizing reaction conditions. The Abdul-Aziz laboratory has pioneered using perovskite oxide precursors to synthesize multimetallic nanoparticles. This presentation discusses the dynamic tracking of the formation and re-dissolution of NiFe and NiRu nanoparticles exsolved from $LaFeO_3$ and $LaNiO_3$, respectively. In situ X-ray absorption spectroscopy (XAS) along with ex-situ scanning transmission electron microscopy high-angle annular dark-field (STEM-HAADF) and energy-dispersive X-ray spectroscopy analysis of the parent perovskite oxide precursor, $LaFe_{0.8}Ni_{0.2}O_3$ and $LaNi_{0.8}Ru_{0.2}O_3$, as its structure forms bimetallic NiFe or NiRu nanoparticles in reductive environments. For NiFe formation, the $LaFe_{0.8}Ni_{0.2}O_3$ transforms to NiFe alloy supported on LaO_x-$LaFeO_x$ as corroborated by EXAFS and XANES analysis. The Ni emerges as nanoparticles at 268 °C, while most of the Fe emerges at 700 °C to form NiFe alloy nanoparticles[1]. For NiRu formation, the Ni starts to form nanoparticles at 280 °C, and Ru emerges at 200 °C where the formation of the NiRu nanoparticles occurs at ~300 °C. This presentation will discuss recent in situ spectroscopic work to address the existing materials’ chemistry challenges for controlled Ni-based bimetallic nanoparticle formation.

4:45 PM SF03.11.08
Rare Earth Oxide Superstructures Assembled via Surface Ligand Switching at High Temperature GraysonC. Johnson and SenZhang; University of Virginia, United States

Superstructures comprised of precisely controlled building blocks open opportunites in the rational design and manufacture of functional materials. However, there is a scarcity of synthetic techniques to facilitate the mass production of these materials. Here we present a scalable synthesis of superstructures assembled from atomically precise $Ce_{24}O_{28}(OH)_8$ and generalize the method to other rare-earth oxide nanoclusters. Combining operando small-angle X-ray scattering, *ex-situ* molecular and structural characterizations and molecular dynamics simulations, we provide a detailed description of the self-assembly mechanism. At high temperature, oleate ligands on the nanoclusters are replaced by benzoate supplied from chemical decomposition of the solvent. This benzoate, participating in pi-pi stacking interactions, drives the self assembly of the superstructures. Removing the benzoate with oleate again at room temperature controls superstructure disassembly into principle component nanoclusters that can be used for the synthesis of multicomponent superstructures, demonstrated up to 5 rare earth element componenets. The implementation of this synthetic approach, combined with an understanding of the mechanisms involved, offers exciting prospects for generating superstructures that are well-suited for materials applicable to electronics, plasmonics, magnetics, and catalysis.

SESSION SF03.12: Functional Materials V

Kinetics of Adsorption and Isotherm Models for Sustainable Zeolite Nano Resin for Water Decontamination RaghavDosi and Jordan C.Poler; UNC Charlotte, United States

Clinoptilolite, a ubiquitous zeolite mineral with aluminosilicates framework intertwined with cations (Na, K, Ca) is highly porous and has shown strong cation exchange affinity towards some

analytes. Our group has functionalized clinoptilolite grains with anion exchange polyelectrolyte into novel Zeolite Nano Resin (ZNR) which adsorbs toxic contaminants from drinking water. The targeted contaminants are PFOA and PFOS which are highly stable in nature and proposed as unsafe to environment by USEPA with interim lifetime health advisory level down to 0.004 parts per trillion. This study investigates various parameters such as kinetics of adsorption, thermodynamics, concentration of adsorbate and adsorption capacity of several ZNR materials. After comparing with the first order kinetics and Intraparticle diffusion mechanism, ZNR tends to follow pseudo second order chemisorption model with fast kinetics and maximum mass transfer capacity of 3.40 ± 0.04 mg/g. Adsorption isotherm experiments have been performed with initial concentration ranges from 200-2300 mg/L of fluorescein. The adsorption behavior has been explored with Langmuir and BET adsorption isotherm models fit on adsorption isotherm curves. Strong interaction between ZNR and fluorescein has been seen with Langmuir adsorption constant of 0.28 ± 0.1 L/mg and q_{max} of 4.28 ± 0.20 mg/g which will be optimized further. The grain size adsorption pattern has been explored by crushing the ZNR grains into smaller dimensions and comparing with full grain size (14 × 40 mm) adsorption isotherm curves. It has been found that the adsorption process is dominant on outside porosity of the framework. However, the elemental analysis by energy dispersive x-ray spectroscopy of half cut grain reveals that fluorescein content was able to reach the inner porous nanochannels of ZNR grains as well. Clinoptilolite undergoes dehydration and rehydration when exposed to water and heat for ZNR aqueous synthesis which was characterized by thermogravimetric analysis along with quantification of polymerization reaction. Kinetics of polymerization of clinoptilolite grains has been examined under 3 different reaction times for optimization. The optimized longest reaction of 118 hours exhibits maximum adsorption capacity. Thermodynamic parameters have been calculated with initial concentration of 1000 mg/L fluorescein at different temperatures. The adsorption capacity found to be maximum at room temperature which shows non-spontaneous process corroborated by positive ΔG as desired under the influence of hot and cold temperature. The high ΔH value also indicates the chemical adsorption where adsorbate molecules are held at the ZNR grain interface by chemical bonds or electrostatic force of attraction. The ΔS is also positive which means that there is randomness at the fluorescein-ZNR interface to reach the adsorption equilibrium. The fluorescein molecules are adsorbing and desorbing simultaneously after certain mass transfer. The equilibrium adsorption constant considered for thermodynamic results is only valid in the adsorption isotherm curve where Langmuir adsorption capacity is equal to the maximum adsorption capacity after the model fitting. Nevertheless, ZNR analyte adsorption seems not limited by only monolayer adsorption as per the isotherm curves. Preliminary studies for the regeneration of ZNR for controlled desorption reveals that approx. 1.5 mg of adsorbed analyte desorbs with just one iteration of 4 mL of 4M NaCl aqueous solution.

8:15 AM SF03.12.02
Formation Mechanisms of Hierarchical Porosity in Carbon Aerogel Mohd ShaharyarWani, BridgetDenzer, SehmusOzden and CraigArnold; Princeton University, United States

Carbon aerogels are highly porous and low-density materials exhibiting exceptional structural, electrical, electronic, and electrochemical properties offering a broad scope for applications such as energy storage, catalysis, water desalination/filtration, and more. The present approaches for synthesizing these materials are multi-step and non-sustainable. In contrast, we have recently developed a single-step, scalable, and green approach for synthesizing these hierarchically porous materials using a protein precursor method. The resulting structure shows porosity on multiple scales and exhibits beneficial properties in water filtration applications. In this presentation, we will discuss the detailed formation mechanisms of this complex architecture and explore the range of parameters associated with the precursor materials, focusing on the resulting structure-property relationships.

8:30 AM SF03.12.03
High-Entropy Perovskite Oxides with a Manganese-Based A-Site for Solar Thermochemical Hydrogen Production CijieLiu[1], DaweiZhang[2], WeiLi[1], JamieA. Trindell[3], KeithKing[3], SeanBishop[3], JoshuaSugar[3], AnthonyMcDaniel[3], AndrewSmith[3], PerlaSalinas[3], EricCoker[3], JoergNeuefeind[4], JianLuo[2,2] and XingboLiu[1]; [1]West Virginia University, United States; [2]University of California San Diego, United States; [3]Sandia National Laboratories, United States; [4]Oak Ridge National Laboratory, United States

We report a new series of A-site high entropy based on $(La_{2/3}Sr_{1/3})MnO_3$ as the parent perovskite for solar-driven thermochemical hydrogen (STCH), $(La_{1/6}\ Pr_{1/6}\ Nd_{1/6}\ Gd_{1/6}\ Sr_{1/6}\ Ba_{1/6})MnO_3$ (LPNGSB_Mn), which exhibits favorable thermodynamic and kinetic properties, along with exceptional phase stability and long-lasting cycling durability. Moreover, LPNGSB_Mn shows enhanced hydrogen production (~100 mmol mol oxide^{-1}) compared to the parent perovskite$(La_{2/3}Sr_{1/3})MnO_3$ (~68 mmol mol oxide^{-1}) in a short one-hour redox reaction. 50 cycles redox experiment demonstrates the extraordinary phase stability of LPNGSB_Mn. Notably, LPNGSB_Mn shows an outstanding balance between fast kinetics (7.992×10^{-5} cm s $^{-1}$) and desirable thermodynamics (enthalpy of reduction (ranging between 260 and 286 kJ (mol-O) $^{-1}$);entropy of reduction(ranging between 130 and 164 J (mol-O)$^{-1}$ K $^{-1}$)) along with excellent phase stability during the redox process. Meanwhile, the XPS and in-situ EELS results revealed that Mn is the only redox-active element in this oxide. In addition, the number of A-site elements in the oxide seems to correlate with H_2 production.

8:45 AM SF03.12.04
One-Step Manufacturing of Highly Adsorptive ZnO Thin Films for Gas Sensing Applications MaanasaBhat, JiananZhang, ChuweiZhang and SiliDeng; Massachusetts Institute of Technology, United States

Metal oxide gas sensors, key in pollution control and safety applications, promise significant potential for use in novel areas such as disease diagnostics, food safety, and disaster management. These sensors operate based on chemiresistivity, defined as change in resistance due to surface adsorption of gas molecules, and require high sensitivity and selectivity. A typical chemiresistive sensor consists of a metal oxide thin film supported on a sensor substrate attached to a resistance measurement device. The change in resistance occurring when the sensing film is exposed to the target gas is recorded as the sensor response. The sensor is said to be high performance if it has high sensitivity for low concentrations of target gas (< 1 ppm) and high selectivity for the target gas within a mixture of gases. The first step in the sensing mechanism of a chemiresistive sensor is the adsorption of oxygen and target gas molecules onto the surface of the thin film. Higher adsorption rate introduces more gas molecule and surface interactions leading to increased sensor response. Since gas adsorption is a surface phenomenon, the amount of gas adsorbed is dependent on the surface area and the morphology of the metal oxide thin film. Larger surface areas are preferred due to increased availability of adsorption sites on the surface. This makes nanostructured thin films ideal for sensing due to their high surface area to volume ratio. Among several transition metal oxide candidates, ZnO has been reported to show preferential adsorption of ammonia, acetone and isoprene which are important compounds for gas sensor-based disease diagnostics. The desired morphology for a high adsorption ZnO thin film is ultra-fine nanoparticles connected to form a porous film structure. Conventional methods for preparing these ZnO thin films are wet chemistry-based methods followed by annealing and doctor-blading or spin coating the particles onto the sensor substrate. These methods are generally time and energy intensive and sometimes fail to produce the desired film structure. Our work proposes a flame-based, one-step manufacturing process for the synthesis of ZnO thin films with a porous structure and ultra-fine (~10 nm) nanoparticles. Utilizing stretch-stabilized stagnation flame configuration, we deposit 8-10 nm sized ZnO particles directly onto a water-cooled sensor substrate, creating a granular film structure. By varying flame synthesis input parameters, we produce films of different thicknesses and BET surface areas, enabling us to gather adsorption isotherms for ammonia, acetone, and isoprene at varied operating temperatures. This data guides the identification of optimal input parameters for manufacturing a highly adsorptive ZnO thin film in a single step. The highly adsorptive sensor films synthesized using our method hold the potential to be incorporated into sensing devices for non-invasive disease diagnostics, promising a significant stride toward effective and efficient gas sensor development.

9:00 AM SF03.12.05
Topological Insulators for Thermoelectrics MichaelToriyama and G.J. Snyder; Northwestern University, United States

The rising energy demand and environmental concerns from conventional cooling systems, including those pertaining to refrigeration and air conditioning, poses significant challenges. Distributed thermoelectric cooling offers a viable solution, yet the low power conversion efficiencies necessitate new search and design strategies for improved thermoelectrics. Here, we show that topological insulators are a promising class of materials for next-generation thermoelectrics. We find that the band inversion strength is a key property of topological insulators connected to warping of the bulk electronic structure and, as a result, fundamentally influences the thermoelectric performance. The band inversion strength can be tuned by modulating orbital interactions through e.g. alloying or strain engineering. We evaluate the band inversion strengths of a large set of topological insulators, resulting in the prediction that NaCaBi is a particularly promising thermoelectric candidate. The study offers unique avenues for discovering and designing thermoelectric materials by capitalizing on the electronic structure topology.

9:15 AM SF03.12.06
Thermal and Electrical Transport Properties of Novel Metal Oxychalcogenides for Thermoelectrics JoeWillis[1], KatarinaBrlec[1], KieranB. Spooner[2] and DavidO. Scanlon[2]; [1]University College London, United Kingdom; [2]University of Birmingham, United Kingdom

Up to 50 % of global energy production is lost as waste heat.[1] Harvesting or recycling this energy could provide a new source of energy or increase the efficiency of extant operations, contributing to the green energy transition. High efficiency thermoelectric materials typically contain rare or toxic materials such as Pb, unsuitable for widespread use, so the discovery of nontoxic, earth-abundant but nevertheless efficient thermoelectrics are necessary to fulfil their potential.
Following the recent proposal of the mixed anion system $Y_2Ti_2O_5S_2$ as an n-type thermoelectric,[2] we investigate the electronic and thermal and transport properties of its family, the $Ln_2M_2O_5Ch_2$ oxychalcogenides (Ln = Sc, Y, La; M = Ti, Zr, Hf and Ch = S, Se, Te) as thermoelectrics. We first identify which materials are kinetically and thermodynamically stable, before demonstrating via band alignment they share a preference for n-type doping with $Y_2Ti_2O_5S_2$. We then assess the electronic transport properties using the momentum relaxation time approximation (MRTA) as implemented in AMSET[3] to identify the most effective candidates for which to calculate the lattice thermal conductivity, in order to assess their dimensionless figure of merit, ZT.

9:30 AM SF03.12.07
Giant Dielectric Permittivity in $Ca_3Co_4O_9$ Ceramics and Thin Films MohammadAl Thehaiban[1], SonyaHarizanova[2], BrunoRente[1], RadostinaStoyanova[2] and PeterK. Petrov[1]; [1]Imperial College London, United Kingdom; [2]IGIC-BAS, Bulgaria

$Ca_3Co_4O_9$ is a thermoelectric material representing the family of the so-called misfit layered oxides. It consists of a Ca_2CoO_3 layer, an insulating subsystem that maintains the charge supply for the conducting CoO2 layer, where Co^{3+} and Co^{4+} ions coexist. Recently, a giant dielectric permittivity was measured in $Ca_3Co_4O_9$ ceramic at room temperature.
In this work, we investigated and compared the structural and electrical properties of $Ca_3Co_4O_9$ (CCO) ceramics and thin films. The CCO thin films were produced from a stoichiometric, in-house made CCO ceramic by pulsed laser deposition (PLD) onto (100) oriented lanthanum aluminate ($LaAlO_3$) substrates. Both the CCO ceramics and thin films were subsequently characterised by X-ray diffraction (XRD). To evaluate the samples' dielectric properties, capacitor structures were formed. Their capacitance was measured and the corresponding permittivity was evaluated in a temperature range RT – 450 K.
For the CCO ceramics, the dielectric permittivity measured at room temperature was ~5,300, which corresponds well with the previously reported values. It was increasing monotonically with no maximum observed at temperatures up to 450 K, where the value was several tens of thousands. Similar behaviour of the capacitance as a function of the temperature with a maximum at 430K was measured for the thin film sample. Due to the small thickness of the layer, the error associated with the dielectric permittivity evaluation procedure is very high. Nevertheless, one could speculate that it is in a similar order of magnitude as those of the CCO ceramic.
The observed giant dielectric behaviour makes $Ca_3Co_4O_9$ an attractive material for applications like high-K dielectric layers, capacitors and thermoelectric converter devices.

9:45 AM SF03.12.08
Thermal Physics of RFe_4P_{12} (R = La, Ce, and Pr) Filled Skutterudites RafaelaF. Penacchio[1], SergioL. Morelhao[1], MiltonS. Torikachvili[2] and StefanW. Kycia[3]; [1]University of São Paulo, Brazil; [2]San Diego State University, United States; [3]University of Guelph, Canada

Phosphide skutterudites attracted much attention in the 2000s due to their potential application as thermoelectrical materials, but also for exhibiting interesting phenomena depending on the filler of its icosahedral cages: superconducting $LaFe_4P_{12}$ below 4.2 K, insulating $CeFe_4P_{12}$, antiferromagnetic $PrFe_4P_{12}$ below 6.4 K, and ferromagnetic $NdFe_4P_{12}$ below 1.9 K [1]. Experimental and theoretical investigations have sought insight into their unusual lattice dynamics, electronic structure with strongly correlated electrons, and thermoelectric performance [2-5]. However, most first-principles modeling has been performed at fixed temperatures - primarily considering the 0-K equilibrium structure, and there has yet to be a comprehensive and systematic computational study of the effect of temperature on these material properties. In this work, we report a comparative lattice-dynamics study of the temperature dependence of the properties of RFe_4P_{12} (R = La, Ce, and Pr), focusing mainly on phonon frequencies, thermal displacements, and electronic band structure. Calculations were performed within the quasiharmonic approximation using GGA for the exchange-correlation energy [6]. The results are compared against experimental data and other calculations, adding insight to the ongoing debate on the filled skutterudites and the role of filler-cage dynamics in the figure of merit ZT, which provides clear directions toward designing more efficient P-based skutterudites for thermoelectric applications.

Dictating Nanoparticle Architecture with Reaction Stoichiometry Using Galvanic Replacement NabojitKar[1], MaximilianMcCoy[1], XunZhan[1], JoshuaWolfe[1], ZhiyuWang[2] and SaraSkrabalak[1]; [1]Indiana University Bloomington, United States; [2]University of Illinois at Urbana-Champaign, United States

Galvanic replacement (GR) provides a simple and versatile route to engineer interesting multimetallic nanostructures, with examples such as nanoboxes, nanocages, nanoshells, nanorings, and heterodimers reported. In GR a solution containing cations of a more noble element is added to a dispersion of NPs of a less noble metal. The less noble metal NPs serve as sacrificial templates, from which some portion of the metal is oxidized and transferred into solution concurrently with the reduction and deposition of the more noble metal. The replacement of bimetallic templates by a more noble metal is less studied and can generate trimetallic nanostructures with different architectures. Here, the specific nanostructure depends on the reduction potentials of the participating metals, the stoichiometry of the GR reaction, and the reaction temperature. Interestingly, titrating NP templates with different cationic species of the same metal can lead to nanostructures with different morphologies and compositions. Herein, architecturally complex PdCu-Au NPs were synthesized through GR between PdCu NPs and $AuCl_2^-$ (Au^{1+}) and $AuCl_4^-$ (Au^{3+}), allowing for the role of reaction stoichiometry on NP architecture to be systematically studied. Interestingly, PdCu-Au heterostructures with multiple Au domains formed in the case of GR with $AuCl_2^-$ while only single Au domains (PdCu-Au Janus particles) were observed in the case of $AuCl_4^-$. Moreover, with an increase in $AuCl_2^-$ volume, the Au domain adopts a boat-like shape with PdCu positioned within the concavity (confirmed by tomographic reconstruction). These different NP architectures and their connection to reaction stoichiometry are consistent with Stranski–Krastanov (SK) growth, providing general guidelines on how the conditions of GR processes can be used to achieve multimetallic nanostructures with different defined architectures. Broadly, the stoichiometry of a GR reaction provides a synthetic lever to generate different architecturally complex NPs, with potential utility in chemical sensing, as theranostics, and in catalysis.

Chemically Tuning Interlayer Coupling and Coherent Light Generation in $AMTeO_6$ Triangular Magnets XudongHuai and ThaoTran; Clemson University, United States

2-D triangular magnets with broken spatial inversion symmetry can uniquely offer the precision and tunability needed to meet the demands of spin–photon architectures for the second quantum revolution. While the intralayer coupling (J_1) within 2-D triangular spin lattice has been studied, a largely unexplored question is how the interlayer ionic/covalent bonding influences the electronic structure and interlayer interaction (J_2) of the low-dimensional magnets. To address this, we created a new material $CaMnTeO_6$ and surveyed $AMTeO_6$ systems (A = s^0, s^2, and d^0 cations; M = Mn, Cr) materials, in which the S = 3/2 transition-metal ion M site forms a 2-D triangular lattice and separated by the A site. $CaMnTeO_6$ features an incommensurate magnetic ground state with AFM in the ab-plane and spiral FM along the c-axis. In addition, this new 2-D magnet exhibits nonlinear optical responses, a prerequisite for integrating spin–photon constructs. We supplemented the results of the structural and physical properties characterization with band structure and chemical bonding. In this talk, we will share our understanding of how the electronic structure of the A site affects the interlayer magnetic coupling of $AMTeO_6$ materials and their ability to generate coherent photons.

11:00 AM SF03.12.11
Spin and Valence Variation in Cobalt Doped Barium Strontium Titanate Ceramics AnumeetKaur[1,2] and ArkapravaDas[3]; [1]Guru Nanak Dev University, India; [2]Global Group of Institues, Amritsar, India; [3]Universite de Mons, Belgium

In the present decade, owing to half-metallic ferromagnetism, controlled 3d transition metal-doping based defect engineering in oxide perovskites attracts considerable attention in the pursuit ofspintronics. We have investigated the electronic structure of Co-doped barium strontium titanate ($Ba_{0.8}Sr_{0.2}Co_xTi_{1-x}O_3$ where x = 0, 0.1, 0.2) solid solutions. Structural, vibrational and microscopic properties indicate the cationic substitution of Co at the octahedral Ti position along with a displacive kind of tetragonal-to-cubic phase transformation. X-ray photoelectron spectroscopy evidences the reduction in the valence state from Co^{3+} to Co^{2+} and Ti K edge X-ray absorption spectroscopy endorses the higher lattice symmetry with increasing Co doping. Orbital hybridization triggered electron hopping between O 2p and Co e_g orbitals results in a spin fluctuation from the occupation $t_6^{2g}e^0_g$ for x = 0.1 to the occupation $t_6^{2g}e^1_g$ L for x = 0.20 (L

designates a hole in the O 2p shell) aligned state observed from density functional theory calculations. The dominating crystal field energy as compared to intra-atomic exchange (Hund) energy decides the spin-orbital degeneracy for the Co 3d orbital to induce spin fluctuations. The experimentally observed change in the Co oxidation state and its correspondence with theoretically observed half-metallicity brings out good compatibility between experimental observation and density functional theory (DFT) calculations. This compatibility proves its possibility to become a potential candidate for spin injection application in the field of spintronics.

11:15 AM SF03.12.12
Designing Stoichiometric Materials with Eu^{3+} for Dense, Optically Addressable Quantum Memory ZacharyRiedel, DonnyPearson, ElizabethGoldschmidt and DanielP. Shoemaker; University of Illinois at Urbana-Champaign, United States

Quantum memory built with stoichiometric rare-earth materials opposes conventional doped systems. Rather than containing ppm levels of weakly emitting, randomly distributed rare-earth dopants, stoichiometric compounds drastically increase concentrations while improving homogeneity. This, in theory, produces optical spectra with narrow inhomogeneous linewidths that can resolve hyperfine splits with hours-long coherence times, creating high densities of optically addressable rare-earth qubits. To explore how chemical factors influence stoichiometric materials' linewidth, we initially studied known compounds with large Eu^{3+} separation to avoid undesirable cation interactions. We grew single crystals of an environmentally stable metal-organic framework with a long optical lifetime and an oxide with coexisting polymorphs, isolating one polymorph for the first time. But we wanted to expand the limited list of compounds with large Eu^{3+} separation. Therefore, starting with known structures, we built 32 chemically diverse compounds using high probability Eu^{3+} and mononuclidic ion substitutions to create candidates with large separations and without linewidth broadening from isotopes. To guide our subsequent exploratory synthesis, we narrowed the candidates down to five with density functional theory stability calculations, which have rarely been used for lanthanide compounds. At least two of the predicted stable candidates, a fluoride and a phosphate, are synthesizable. Inhomogeneous linewidth studies will reveal how crystal quality and defect chemistry influence accessibility to the desirable, optically addressable Eu^{3+} transitions.

11:30 AM SF03.12.13
Understanding $NaNbO_3$-Based Ceramics with Enhanced Antiferroelectricity for High Energy-Storage Density Applications WoohyunHwang, KwangraeKim, SeunghyunV. Oh and AloysiusSoon; Yonsei University, Korea (the Republic of)

Lead-free antiferroelectric (AFE) ceramics have attracted increasing attention in recent years for its niche application in high-power capacitors owing to both environmental friendliness and high energy density. $NaNbO_3$ (NNO) is one of few lead-free perovskites with a AFE structure. But the polarization-electric field (*P-E*) double hysteresis loop was only observed in high-quality single crystals, while in most cases, it was found to possess a ferroelectric (FE) ordering [1,2]. To enhance the antiferroelectricity in NNO, a composition modification strategy by doping was proposed to stabilize the AFE phase effectively [3]. However, in the case of lead-free NNO-based ceramics, the doping effect on its antiferroelectricity is still very poorly understood. In this work, by using first-principles calculations, we will show that the AFE phase of pure NNO is stabilized in the solid-solution due to the decrease of its tolerance factor. A modification of the relative stability of the polar and nonpolar structures will be rationalized by the phase transition pathways for the switching of polarization with the calculated energy barriers [2]. Here, we attempt to explain the effectively favoring of the nonpolar-to-polar AFE transitions over the polar-to-polar FE domain switching. Through this work, we rationalize and provide an atomic-scale perspective of the AFE-FE phase transition in NNO-based ceramics to further engineer novel lead-free antiferroelectric oxides for energy storage applications.

Cu_2SiSe_3 as a Promising Solar Absorber: Harnessing Cation Dissimilarity to Avoid Killer Antisites AdairNicolson[1], SeánR. Kavanagh[1,2], ChristopherSavory[1], GraemeW. Watson[3] and DavidO. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]Trinity College Dublin, The University of Dublin, Ireland

Solar absorbers from the diamond-structure, adamantine family are the current market leaders in thin-film photovoltaics. However, current materials suffer from the use of rare and toxic elements, while emerging candidates such as CZTSSe suffer from killer defects originating from their complex quaternary composition and similarly sized cations.[1] To this end, we computationally investigated Cu_2SiSe_3 due to its favourable combination of a diamond-type crystal structure, yet cations with large size and charge differences.

Using hybrid DFT and Green's function methods, we calculated the electronic and optical properties, predicting a maximum efficiency of ~30% for a thin-film device of 1.5 μm. We then calculated the formation energies and electronic levels of all intrinsic defects at the hybrid DFT level to characterise the intrinsic defect thermodynamics. In doing so, we confirm the hypothesized high formation energies for antisite defects, in addition to a low concentration of potentially-harmful deep defects.[2] With its familiar structure and favourable band alignment, initial Cu_2SiSe_3 devices could leverage previously developed device architectures to rapidly test its performance experimentally.

Low-Refractive Index Silica Aerogel as Rear Reflector for Large-Area PERC Solar Cell Applications DamlaKoçak[1,2], KonstantinTsoi[2], HasanH. Canar[2], HasanAsav[2], AhmetE. Keçeci[2], BülentArikan[2] and SelçukYerci[1,2,1]; [1]Middle East Technical University, Turkey; [2]Odtu Gunam, Turkey

Increasing the path length of light in the absorber is one of the most effective optical solutions for dealing with light that is not fully absorbed in a single pass through solar cell devices [1]. The design to improve the path length should also have a high internal reflectance on the absorber surfaces to minimize the energy loss per light-surface interaction [2]. Recent studies show that SiN_x layers with low refractive index (~ 2) are also preferable to increase rear reflection [3] and passivation of the rear surfaces [4] for Si solar cells architectures such as PERC and PERL. To reduce light absorption in rear metal, inserting a thick non-absorbing reflector layer with a low refractive index n between the absorber and rear metal is very beneficial [5], since a lower n leads to a smaller critical angle at the rear surface and a lower probability that the light will be absorbed by the metal. Passivation is one of the most important parameters for solar cells. SiN_x layer is used for chemical surface and field-effect passivation of PERC solar cells. SiN_x layer on the rear surface is preferably thicker than SiN_x layer on the front surface as an anti-reflective layer to improve the rear reflection on the rear side of the cell by obtaining a film with a lower refractive index [4].
In this work, we studied the effects of a solution-based silica aerogel layer (by sol-gel method), which has a low refractive index and high porosity, inserted between the passivation layer and the rear metal to PERC solar cells. Large area (~156 mmX156 mm) PERC solar cells were fabricated using a thin-SiNx passivation layer (~20 nm), and it was investigated how the optical and thus the cell performance (i.e., J_{sc}, power conversion efficiency) improves when silicon aerogel is used between the passivation and rear metal. PERC solar cells with two different SiN_x passivation layer thicknesses (20 nm and 120 nm) were used for this study. Since silica aerogel is to be used as the rear reflector, the thickness of the thin SiN_x passivation layer (~20 nm) was chosen so that it would not negatively affect surface passivation [6].
Methyltrimethoxysilane (MTMS), methanol (MeOH), oxalic acid as acid catalyst, and ammonium hydroxide (NH_4OH) as base catalyst were used to synthesize aerogel solutions. The silica aerogel was sprayed on the rear side of the PERC with rear 20nm SiN_x and compared with the PERC without aerogel and the industrial PERC (there is ~120 nm SiN_x passivation layer on the rear side of the cell) with respect to the cell performance.
Transmission (T) and reflection (R) measurements show that the silica aerogel has an optical enhancement in the near-infrared (NIR at ~ 1200 nm wavelength) region. We have an increase of a ~ 25% in T+R spectra when aerogel is deposited on the top of thin-SiNx passivation layer on the rear side of the cell. Also, it was observed that PERC with thin-SiN_x spray-coated with aerogel on the rear side has the same optical performance as the industrial PERC with 120 nm rear SiN_x on the T+R spectra. The optical enhancement in this new PERC design also improves cell performance. We have demonstrated that the improvement in rear reflection increases the short-circuit current by ~1.6 mA/cm^2 compared between PERC with aerogel and without aerogel. In conclusion, we have shown that the proposed aerogel layers ultrasonically sprayed on the rear side of the PERC solar cells with a thin-SiN_x passivation layer achieved an efficiency of 19.9%, while the reference cell (PERC with thin-SiN_x and without aerogel) had an efficiency of 18.75%. Moreover, the PERC with aerogel performed as well as the industrial PERC solar cell with 120 nm rear SiN_x (20.1%) over a long period of time (~700 hours).

Inorganic Nanopillar Arrays Remarkedly Enhance Photovoltaic Performance of Flexible Perovskite Solar Cells ZhifengHuang; The Chinese University of Hong Kong, Hong Kong

Flexible perovskite solar cells (or PSCs) pave the way to conveniently powering a wide range of portable and wearable electronic devices, due to high power conversion efficiency (PCE), large-area fabrication, and potentially low cost. However, the commercialization of flexible PSCs is prohibited by environmental instability and low mechanical robustness. One-dimensional (1D) inorganic nanostructure arrays, functioning as charge transporting layers, have been proposed to solve these two problems. In-situ growth of 1D nano-arrays on polymer-based flexible electrodes is required but very challenging, mainly due to degradation of polymer-based electrodes at high temperature of in-situ growth.

We use glancing angle deposition (GLAD) at low substrate temperature to in-situ deposit nanopillar arrays (NaPAs) onto a flexible electrode for an assembly of flexible PSCs. The NaPAs are made of diverse inorganic materials, such as titanium, titanium oxides, tin oxides (functioning as electron transporting layers) and nickel oxides (serving as hole transporting layers). The as-grown NaPAs enhance light transmittance, facilitate light harvesting in perovskites, promote charge carrier transport and collection, facilitate the formation of large perovskite grains, prohibit perovskites from decomposition, and release mechanic stress. All these features cause large-area flexible PSCs to have PCE of >15%, small photovoltaic hysteresis, 10% degradation for approximately 800-hr storage, and 20% degradation by manual bending for around 400 times.

We devise an advanced technique of low-substrate-temperature GLAD generally adapted to in-situ deposition of charge transporting layers made of inorganic NaPAs on flexible electrodes, to significantly enhance optoelectronic performance, mechanic robustness, and environmental stability of flexible optoelectronic devices.

2:15 PM SF03.13.04
Zero-Dimensional Lead-Free Metal Halide Scintillator Suitable for Extreme Environments and X-Ray Imaging Joo HyeongHan and Won BinIm; Hanyang University, Korea (the Republic of)

Scintillators are widely used for radiation detection in various fields, such as medical imaging, nondestructive testing, and crystallography. X-ray-generating systems typically emit large amounts of heat and require a high thermal stability of scintillators, particularly for nondestructive testing or radiation detection performed under harsh conditions. Therefore, highly stable scintillators must be developed for application in extreme environments. Herein, we developed new zero-dimensional lead-free monoclinic phases of Cs_3TbCl_6 and Rb_3TbCl_6 metal halides. Surprisingly, Cs_3TbCl_6 and Rb_3TbCl_6 have retained over 90% of their original PL properties at 250°C. Cs_3TbCl_6 and Rb_3TbCl_6 polycrystals exhibit high light yields of 56,800 and 88,800 photons/MeV, respectively. Cs_3TbCl_6 and Rb_3TbCl_6 polycrystals also show low detection limits of 149.65 and 115.38 $nGyair s^{-1}$ due to their structural–optical properties, respectively. Furthermore, the fabricated thick films of Cs_3TbCl_6 and Rb_3TbCl_6 are applied to our homemade X-ray imaging system, and preferable spatial resolutions are obtained as compared with a commercial $Gd_2O_2S:Tb^{3+}$ film.

2:30 PM SF03.13.05
Efficient Photodegradation of Methyl Red Dye by Kaolin Clay Supported Zinc Oxide Nanoparticles with Their Antibacterial and Antioxidant Activities IdreesKhan and ZhangBaoliang; Northwestern Polytechnical University, China

Kaolin clay (KC) supported Zinc oxide (ZnO/KC) and ZnO nanoparticles (NPs) were prepared by a chemical reduction process and used for the photodegradation of methyl red (MR) as photocatalysts. Due to the interlayered porous structure of KC, we achieved a perfect association between ZnO NPs and KC. SEM image showed the irregular morphology of ZnO NPs, while ZnO/KC NCs were predominately round-shaped. Moreover, in both cases, NPs were present in dispersed and agglomerated forms with an average particle size way below 100 nm. The results acquired from photodegradation analyses showed that ZnO NPs and ZnO/KC NCs degraded about 82% and 99% of MR under UV light in a short irradiation time within 10 min. The recovered and re-recovered ZnO NPs and ZnO/KC NCs were also considerably photodegraded MR in an aqueous medium. The same NPs also exhibit promising bioactivities against two pathogenic bacteria, i.e., Citrobacter and Providencia. ZnO/KC NCs' antioxidant activity reached a reasonable 70% compared to the 88% activity of the standard ascorbic acid.

3:15 PM SF03.13.06
Moderate Temperature Chalcogenization of Highly Stable Metal Oxides—An Opportunity for Chalcogenide Perovskites ShubhanshuAgarwal, JonathanTurnley, ApurvaPradhan and RakeshAgrawal; Purdue University, United States

The importance of deploying solar panels for generating renewable energy has never been greater. The emergence of halide perovskites has brought hope for an efficient material with exceptional optoelectronic properties. This breakthrough has resulted in numerous efficiency and PLQY (photoluminescence quantum yield) records being surpassed. However, halide perovskites face inherent instability in the presence of moisture and air. Additionally, they rely on toxic lead in their crystal structure to achieve the ABX_3 structure, which gives rise to their exciting properties. These limitations must be addressed before halide perovskites can be widely used for energy generation.

On the other hand, chalcogenide perovskites possess a similar ABX_3 structure to halide perovskites, offering excellent electronic and optoelectronic properties. They are composed of abundant elements found in the Earth's crust and have shown a high light absorption coefficient. Chalcogenide perovskites are also defect-tolerant and exhibit high photoluminescence. However, the synthesis of chalcogenide perovskites involves high-temperature methods. Typically, they are synthesized by treating oxide perovskites with H_2S/CS_2 at temperatures exceeding 900°C. These high temperatures limit the substrates that can be used to create thin films of these materials for photovoltaic applications. Although some reports have demonstrated moderate-temperature synthesis, they rely on expensive organometallic precursors, hindering widespread adoption.

In this study, novel methods are presented for converting tailored precursor films to sulfides at temperatures below 600°C. One of the biggest challenges of synthesizing transition metal sulfide perovskites is their propensity to react with any residual oxygen in the system forming unwanted oxide phases. We have identified an innovative oxygen getter that removes any residual oxygen from the precursor film leading to phase pure sulfide perovskites. Furthermore, the method has been expanded to synthesize selenium-based transitional metal trichalcogenides from transition metal oxides. As a whole, these novel methods provide unique opportunities to utilize inexpensive metal salt precursors for forming precursor films and subsequently converting them to transition metal sulfides including perovskite films at low temperatures.

3:30 PM SF03.13.07
Evolution of Interfaces in Multi-Principal Element Alloy Nanoparticles VitaliyR. Yurkiv[1], AzadehAmiri[2], RezaShahbazian-Yassar[2] and FarzadMashayek[1]; [1]University of Arizona, United States; [2]University of Illinois at Chicago, United States

Multi-principal element alloy nanoparticles (NPs), composed of multiple elements arranged in an ordered intermetallic crystal structure, pose unique properties for a variety of applications. They can be used as catalysts, where their unique composition and structure can improve catalytic activity and selectivity. They also hold promise in energy storage and conversion, sensing technologies, and biomedical applications, among others. In this work, we seek to understand the structure and stability of grain boundaries (GBs) formed between various medium entropy alloy NPs, the mechanisms of metals diffusion through them, and its influence on NPs coalescence. The density functional theory (DFT) calculations supported by the high-resolution transmission electron microscopy (HRTEM) measurements are employed to understand the GB atomic structures, their evolution, and their chemo-mechanical properties. The DFT calculations are performed using the VASP (Vienna Ab initio Simulation Package) code with the plane wave basis sets and the projector augmented wave (PAW) pseudopotentials in the framework of the Perdew-Burke-Ernzerhof generalized-gradient approximation (GGA). For GBs structure creation, the Atomistic Tool Kit (ATK) software is used. The crystalline phase structure and GBs evolution of nanoparticles and their elemental composition and distribution are characterized by annular dark field scanning transmission electron microcopy (ADF-STEM) images with 512x512 pixels scanning resolution and energy-dispersive spectroscopy (EDS) analysis performed at 8c probe size on a JEOL ARM200CF scanning electron microscope operating at 200 kV.
Different size medium entropy alloy NPs containing various compositions of Pt, Cu, Ir and Ni elements, have been obtained through electron beam-induced co-reduction of mixed metal salts solution inside the liquid-cell TEM holder. The ADF-STEM images of the formed colloidal NPs were obtained at the end of the process on dry sample after liquid was removed. It was observed that there is an aggregate of multiple crystalline medium entropy alloy NPs of different sizes and orientations attached by amorphous grain boundaries and loosely bonded atoms at

the interface. The colloidal medium entropy alloy NPs have *fcc* structure with lattice constant of 3.89 Å. STEM-EDS analysis indicates a homogenous distribution of Pt, Cu, Ir, and Ni elements in NPs with atomic composition of ($Pt_{0.46}Cu_{0.3}Ir_{0.16}Ni_{0.06}$). The HRTEM measurements revealed the diverse GB structures consisting of (100), (110), (121), etc., surface orientations of the above-mentioned NPs composition. Based on the HRTEM results, the corresponding computational slabs have been built and optimized using ATK and VASP. Pt, Cu, Ir and Ni adatom diffusion inside grain and GB, after the optimization of all structures, were calculated. For each GB, several adatom positions with multi-atom bonding were identified. The activation energy of metal diffusion varies significantly depending on the slab's structure and the number of adatoms. A non-symmetric metal transition state for all considered structures and atoms, which indicates a complex multi-atom hopping mechanism, was identified. In addition, the DFT calculations are used to obtain electron density and the density of states for corresponding GB structures. Based upon the electron density profile the stability of analyzed interface with and without metallic adatoms is quantified.
Our combined experimental and modeling study provides valuable understandings into developing mitigation strategies towards a better understanding of medium and high entropy alloys for a variety of applications.

Engineering Macroporous Structure Towards Enhancing Mass Transfer and Catalytic Performance of Three-Way Catalyst Particles PhongH. Le and TakashiOgi; Hiroshima University, Japan

The increasing emission of pollutants from gasoline-power vehicles has prompted concerns regarding human health and the environment. To address this issue, researchers have focused on developing novel technologies to mitigate their adverse effects, and a three-way catalyst (TWC) has emerged as a crucial technique in this area since the 1970s. However, the TWC materials are composed of large amounts of costly and rare elements, including Rhodium (Rh), Palladium (Pd), and Platinum (Pt), which considerably increases their manufacturing expenses. Consequently, it is necessary to reduce the consumption of TWCs as their demand increases due to the global outbreak of transportation vehicles over the years. The promising method to overcome this challenge is to enhance their catalytic performance by appending the porous structure. Catalyst particles endowed with macroporous architectures have gained considerable attention due to their superior molecular diffusion capabilities and catalytic activities.
In this study, the macroporous TWC particles with interconnected macropore networks were synthesized via a template-assisted spray process. The synthesis of macroporous TWC particles requires precise control over various parameters. Furthermore, the mass transfer coefficients of the macroporous TWC particles were then investigated by measuring the CO_2 adsorption rate, allowing us to understand the influence of macroporous structure on internal mass transfer. The results demonstrate a significant enhancement in the mass transfer coefficient upon introducing macropores into the TWC particles compared to conventional aggregate TWC particles. However, a decline in the mass transfer coefficient was observed as the macropore size exceeded a certain threshold due to the presence of an extensive framework. To explore the practical implications of these macroporous TWC particles in the catalysis field, we conducted catalytic performance assessments using CO oxidation reaction as the model. Remarkably, the macroporous samples exhibited superior catalytic performance compared to their aggregate counterparts. These results demonstrate the critical role of macroporous structure in enhancing the catalytic performance of TWC particles.
In conclusion, our comprehensive study highlights the significance of macroporous structures in catalyst particles and their potential to revolutionize TWC efficiency. The profound improvements in mass transfer coefficients and catalytic performance provide valuable insights for designing advanced TWC materials that exhibit enhanced pollutant conversion capabilities.

4:00 PM SF03.13.09
Intrinsic Tensile Ductility in High Entropy Metallic Glass ZhiboZhang; City University of Hong Kong, China

Metallic glasses are an important material with a wide range of applications, such as in bio-medical engineering, aerospace engineering, automotive industries, micro-electro-mechanical systems and consumer products. Nevertheless, the Achille's heel of metallic glasses is short of tensile ductility at low temperature, which impedes their widespread applications as yet. To overcome this limitation, people have proposed different methods to toughen metallic glasses, including surface mechanical attrition treatment, architectured constructions, and deformation induced rejuvenation. Although these methods have shown potential for improving tensile ductility at room temperature, the reported results of intrinsic tensile ductility tend to be limited (< 1%) with a low strain hardening rate. In this work,Here we present a high-entropy metallic glass with unique multifunctional properties. This glass demonstrates exhibits a gigapascal yield strength of ~1.5 GPa, undergoes significant strain hardening that almost doubles its yield strength (~70% strength increase), and exhibits unprecedentedover two-fold increase in uniform tensile ductility compared to the previous records (~ 2%). These remarkable properties stem from the amorphous structure of our high-entropy metallic glass, which is composed of atoms with significant size mismatch. The shear banding in this HEMG is self-locked because of shear induced atomic diffusion. Our findings suggest a promising pathway to design stronger, more ductile glasses that can be applied in a wide range of technological fields.

Pantelides[4] and PatrickE. Hopkins[1]; [1]University of Virginia, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Southern California, United States; [4]Vanderbilt University, United States; [5]The University of Utah, United States; [6]University of Rhode Island, United States; [7]University at Buffalo, The State University of New York, United States; [8]Massachusetts Institute of Technology, United States; [9]Laser Thermal Analysis, United States; [10]Lehigh University, United States

Understanding and manipulating the microscopic mechanisms of ultralow thermal conductivities in crystalline materials has been the central goal of condensed matter and materials physics for the past decade, with many questions still unanswered. Given the broadband spectral nature in the transport of phonons and other vibrational modes in crystals, achieving a superior thermal insulator requires material classes that can restrict thermal transport of all modes in the thermally active vibrational spectrum; the strategy to do so requires different approaches based on the energy and dispersive nature of each individual mode. Here, we report on the ultralow thermal conductivities in the Ruddlesden-popper phase ($Ba_{n+1}Zr_nS_{3n+1}$, n = 3 and 4) crystals that are derivatives of inorganic perovskite chalcogenide Barium Zirconium Sulfide ($BaZrS_3$). The thermal conductivity of Ruddlesden-popper phases exhibits ultra-low amorphous-like values and trends due to the presence of intra-unit-cell rock-salt blocks inducing strong anharmonicity and a large fraction of localized and low velocity vibrational modes throughout the entire vibrational spectrum, thus achieving broadband restriction of thermal transport. Our study provides significant insight into the interaction between structural interfaces and vibrational modes that can cause ultra-low thermal conductivities in inorganic crystals in efforts to design ideal phonon or vibrational glasses for exceptional thermal insulation.

4:30 PM SF03.13.11
Understanding the Structure-Catalytic Property Relationship: From Nanoparticles to Single Atoms AgusR. Poerwoprajitno[1], RichardTilley[2] and DaleL. Huber[1]; [1]Sandia National Laboratories, United States; [2]The University of New South Wales, Australia

Understanding the surface structure-catalytic properties relationship is vital to design highly active and stable catalysts for energy-related applications.[1] This is because the catalytic reaction occurs only on the surface. Our research focuses on precisely controlling the surface structure of nanocrystals, surface facets and crystal structure that defines the active site.[2] This high level of control enables us to study the effect of different active site on catalytic reactions. The next step is to use this well-defined nanocrystal as substrate for second metal decoration as for complex reaction, such as methanol oxidation reaction (MOR), where the exposure of two metals on the surface is important to improve catalytic activity, stability and selectivity.[3] We showed a synthetic approach to control the decoration of Pt single atom on faceted Ru nanoparticles that have successfully avoid CO-poisoning in MOR. The Pt single atoms were formed by spreading Pt islands and was studied by in-situ environmental TEM (ETEM) at atomic-level. We also discuss our recent work on scaling up the nanoparticle synthesis using microfluidic incorporated with in-situ characterization and assisted by AI.

Understanding the Role of Entropy in Medium to High-Entropy Oxides and Alloys ChaochaoDun[1], ShuoLiu[2], JeffUrban[1] and MarkT. Swihart[2]; [1]Lawrence Berkeley National Laboratory,

United States; [2]University at Buffalo, The State University of New York, United States

The Hume-Rothery rules governing solid-state miscibility limit the compositional space for new inorganic material discovery. Here, we report a non-equilibrium, one-step, and scalable flame synthesis method to overcome thermodynamic limits and incorporate immiscible elements into single phase. Starting from prototype examples including (NiMg)O, (NiAl)Ox, and (NiZr)Ox, we then extend this method to a broad range of Ni-containing ceramic solid solutions, and finally to general binary combinations of elements. We report an “encapsulated exsolution” phenomenon observed upon reducing the metastable porous (Ni0.07Al0.93)Ox to create ultra-stable Ni nanoparticles embedded within the walls of porous Al2O3 nanoshells. This nanoconfined structure demonstrateshigh sintering resistance during 640 hours of catalysis of CO2reforming of methane, maintaining constant 96% CH4 and CO2 conversion at 800 oC and dramatically outperforming conventional catalysts. We have further fabricated high-entropy oxide nanoceramics with six typical crystal structures (Rock-salt, Spinel, tetragonal, Fluorite, and Rutile), with one of them with 22 elements for high-entropy fluorite. when using (MgCoNiCuZn)Ox as entropy dispersion of a "single-atom" like Pt, the loading amount can be as much as 10wt%, much higher than traditional 1wt% or 2wt%. The thermal stability and activity of these materials as a catalyst has the work-record performance for CO2 hydrogenation so far.

Fundamentals and Applications of Plasma Nonequilibrium at Interfaces JanBenedikt[1,1], ChristianSchulze[1], HeLi[1], MartinMüller[1], SadeghAskari[2] and ZoltanDonko[3]; [1]Kiel University, Germany; [2]KTH Royal Institute of Technology, Sweden; [3]Wigner Research Centre for Physics, Hungary

Plasma-generated high nonequilibrium fluxes of energetic ions, metastables, reactive radicals or electrons reaching the surfaces are widely used in the research and industry. Still, some of the microscopic interaction processes including ion induced secondary electron emission or electron reflection on realistic surfaces are not fully understood. Additionally, the *in situ* monitoring and control of for example ion energy-flux distribution function is needed to provide precise control of material processing needed for applications such as processing of 2D materials or manufacturing of components for quantum computing. This contribution will discuss the application of energy-resolved ion mass spectrometry (ERIMS) in two experiments used to analyze plasma-surface interaction and perform controlled material processing.

First, a technique that combines ERIMS measurements and 1d3v particle-in-cell /Monte Carlo collision simulations to determine effective ion induced secondary electron emission (SEE) yield and the effective elastic electron reflection probability parameters simultaneously and independently in a symmetric rf capacitively coupled plasma in argon [1]. It is possible, because SEE and electron reflection processes at the surface influence plasma and sheath properties and with it also the ion flux-energy distribution function (IEDF) measured at the electrode. In particular, the energy width and mean energy of the bimodal peak feature in the IEDF can provide the effective values of both parameters for any material on the electrode surface. The method was applied to stainless steel and aluminum oxide surfaces resulting in a good agreement with literature values.
Second, a new reactor with inverted electrode geometry was assembled which is combining ICP plasma with CCP bias applied to reactor wall to control the plasma density and ion energy separately at the small grounded electrode during the treatment [2]. The small size of the grounded electrode results in the largest voltage drop and largest ion energy there, which can be analyzed by ERIMS during the plasma treatment including the analysis of the sputtered or desorbed material on the ion composition. The CCP bias allow further control of the ion energy. We have observed previously that low-pressure plasma treatment improves electrochemical performance of transition metal oxides used at air electrode of zinc-air batteries [3]. We use this material here as a test substrate for the study of the effect of the ion energy on their performance in hydrogen and nitrogen discharges. Additionally, the nitrogen plasma has also been used to treat graphene and results relating ion IEDF and structural changes of graphene will be presented. The graphene has been chosen here as a model material for the 2D materials. Experiments with transition metal dichalcogenides and their monolayers will follow. All examples in this contribution are part of the larger research program at Kiel University focusing on the experimental and theoretical study of the plasma nonequilibrium at interfaces.

11:00 AM SF04.01.02
Optimization of High Dose Rate Plasma Immersion Ion Implantation for 8Cr4Mo4V Steel BinMiao[1,1], JunboNiu[1], JinmingZhang[2], XinghongZhang[3] and XinxinMa[1,1,3]; [1]Harbin Institute of Technology, China; [2]CETC Academy of Chips Technology, China; [3]AECC Harbin Bearing Co., Ltd., China

As the typical high-temperature bearing steel, 8Cr4Mo4V has excellent comprehensive performance, which is widely used as the bearing material and has made it increasingly popular in industrial and aerospace applications. Nowadays, the lack of service life of bearing has become its bottleneck which restricts the performance of aero-engine. How to solve or improve this problem is the focus for most surface engineering researchers at present. The traditional ion implantation technique generally takes dozens of hours or even longer duration in real applications, resulting in its obvious shortcoming of energy consuming and low efficiency. For the high-dose-rate plasma immersion ion implantation, very high ion current densities allow implementing ultrahigh dose implantation and the formation of nanoscale layer in shorter duration as compared to the conventional ion implantation. Therefore, high-dose-rate immersion ion implantation can be utilized to increase the efficiency and reduce energy consumption. In order to investigate the optimization of high-dose-rate ion implantation on mechanical properties, 8Cr4Mo4V

bearing steel was implanted with 10 to 12 keV nitrogen ions dose rates with fluences between 7.6×10^{17} ions/cm^2/h and 1.9×10^{18} ions/cm^2/h, and the implanted samples were analyzed by AvaSpec Multi-Channel Spectrometer, nanoindentation tester and residual compressive stress tester in this study. The obtained results reveal that the optimal implantation dose rate ranges from $(8\sim20)\times10^{17}$ ions/cm^2/h to meet the high implantation requirements. Given the furnace power supply constraints, the implantation voltage range of 10-12 keV and a minimum implantation frequency of 600 Hz are recommended. The implantation pulse width of 25 μs and working pressure of 0.5 Pa are also advised to attain greater implantation current density. The present work optimizes the parameters in the investigation of high-dose-rate ion implantation process, and the obtained results will be useful for structural scientists and engineers in real applications. Meanwhile, the results show that the temperature stabilizes around 350 °C at the implantation dose rate of approximately 1.5×10^{18} ions/cm^2/h. Meanwhile, the highest nanohardness value of 18.67 GPa is attained for the implanted samples at dose rate of 1.70×10^{18} ions/cm^2/h, which is 66.7% higher than that of the non-implanted sample. Compared to the as-received sample stress of 273.3 MPa, the maximum residual stress reached approximately 640 MPa at the dose rate of 1.38×10^{18} ions/cm^2/h, which was enhanced by 134.4%. This enhancement is advantageous for the practical applications of bearing steel.

11:15 AM SF04.01.03

Imaging-Constrained Fluid Simulation of Laser-Generated Plasmas Containing Multiple Chemical Species JacobPaiste[1], EricRemington[2], DorienCarpenter[1], NathanHumphrey[3], KamronStrickland[1], RobertArslanbekov[4], AlexeyVolkov[3], SumnerB. Harris[5], DavidB. Geohegan[5] and RenatoP. Camata[1]; [1]University of Alabama Birmingham, United States; [2]Samford University, United States; [3]The University of Alabama, United States; [4]CFD Research Corporation, United States; [5]Oak Ridge National Laboratory, United States

Laser-generated plasmas are complex electro-hydrodynamic systems with broad technical applications in materials science and engineering. They are widely used to etch, chemically modify, and fabricate materials both in bulk and thin film form. Although simulations of laser plasmas have been carried out for decades, only recently have developments in computational power and techniques allowed meaningful quantitative modeling of the long distance plasma expansions that are critical for understanding plasma processing and plasma interactions with materials surfaces.

In this work we describe a laser ablation/plasma fluid simulation model that can be constrained by gated-intensified CCD (ICCD) imaging data of the rapid expansion of the laser-generated plasma. The time-resolved image capture of the luminous portion of the plasma plume results in photon count data arrays that are processed for plume visualization, animation, and motion tracking. Our effective plasma fluid model incorporates well established features of laser ablation plasmas (thermal evaporation, bremsstrahlung emission from plasma electrons, photoionization, and free-free laser absorption by the plasma) and an additional effective plasma absorption coefficient that serves as a stand-in term for more sophisticated mechanisms that are impractical to account for directly due to computational cost or unavailability of physical parameters. The effective plasma absorption coefficient (a free parameter in the model) is determined by matching the simulated plasma evolution to the dynamics of the expansion as determined by the ICCD imaging data. Once the model has been constrained in this manner, full scale simulations of all plasma parameters and distribution are possible.

We apply this model to a plasma generated during ablation of a solid target of iron selenide (FeSe), which is used in plasma-mediated growth of superconducting FeSe thin films. The complex chemistry of this plasma requires the solution of Saha equilibrium equations for singly and doubly ionized Fe and Se species, while the fluid dynamic equations are solved using an average approach. ICCD imaging data reveals that plasmas produced with fluences of 0.9, 1.5, and 2.4 J/cm^2 of 25-ns, 248-nm excimer laser pulses in vacuum, have average plume speeds of 13.0, 17.0, and 21.7 km/s, respectively. When an argon (Ar) background pressure is introduced, the average plume speeds decrease into the 9-13 km/s range for 30-50 mTorr pressures. Our simulated expansion velocities span these ranges of plume speeds detected from ICCD measurements and are sensitive to the choice of the effective absorption parameter in the model. In this presentation, we describe how the ICCD imaging data allows determination of the best value of the effective parameter and full scale simulations of the expansion. Furthermore, we discuss how Direct Monte Carlo Simulation (DSMC) results can be used to validate our effective fluid model approach by comparisons of mass flux results, target surface temperatures, initial velocities, and energy conservation throughout the simulation.

11:30 AM *SF04.01.04

Methods for *In-Situ* Diagnostics of Plasma-Assisted Synthesis of NanomaterialsShurikYatom; Princeton University, United States

Plasmas are widely used for synthesis of various nanomaterials. Plasma-mediated methods offer industrial scale production of nanomaterials while being less expensive and environmentally friendly compared to chemical and mechanical methods of synthesis. They also hold a promise for well-controllable synthesis, due to the ability to control the plasma characteristics and plasma-induced chemistry. For many years, the understanding of the interplay between the plasma and the synthesized products was dependent on the ex-situ analysis and trial and error approach, where the synthesized material was collected from the reactor walls and analyzed by electron microscopes. Nowadays, it becomes more and more obvious that we need techniques that can detect and characterize nanoparticles and nanotubes in-situ, as they are being formed in the plasma. In this talk I will summarize the capabilities and the methods of *in situ* diagnostics of plasma, plasma induced gas-phase chemistry and synthesized nanomaterials. These diagnostics measure the plasma conditions, the precursor species to nanoparticle formation, presence and sizes of nanoparticles in the synthesis region, chemical composition of the nanomaterials. The following diagnostics are covered: optical emission spectroscopy, laser induced fluorescence, laser induced incandescence, fast frame imaging, coherent Rayleigh Brillouin scattering, nanomaterial extractor probe and others. Finally, I will discuss the future possibilities and directions for in-situ diagnostics of plasma-assisted nanosynthesis.

The Role of Plasmas in the Electrification and Decarbonization of Chemical Manufacturing ErayS. Aydil, AndreaAngulo, EnricoChinello and MiguelModestino; New York University, United States

Chemical manufacturing is the foundation of supply chains that provide society with more than 96% of all goods. It consumes 10% of global energy production, nearly all in thermochemical processes fueled by fossil fuel combustion, contributing 5.5% of the global CO_2 emissions and thus accelerating anthropogenic climate change. Chemical manufacturing plants comprise a network of reactors to synthesize mixtures of chemicals and separation units such as distillation to obtain purified products. Any energy needed but not produced by exothermic chemical reactors is supplied by fossil fuel combustion (86%) or brown electricity (14%). Recent decarbonization goals are driving the rethinking of this chemical manufacturing paradigm and its potential replacement with decarbonized production schemes powered directly by clean electricity. One of the options is to replace thermochemical reactors with electrically driven non-thermal plasma processes. We critically assessed technical, economic, and environmental factors to evaluate the prospects of this impending paradigm shift. Among bulk organic chemicals, we focused on ethylene, BTX (Benzene, Toluene, Xylene), and propylene as the highest volume chemicals by the energy consumed and CO_2 emitted: they account for >50% of the energy consumed (and thus CO_2 emitted) in the manufacture of basic organic chemical commodities. Specifically, we review the state-of-the-art production method, its economics and CO_2 emission, potential options for electrifying its manufacturing, including plasmas, the impacts of carbon pricing on their deployment, and the technological gaps holding back the deployment of these options. We aim at trying to answer the questions of (1) whether plasma reactors can replace thermochemical reactors in the economical manufacture of chemicals, (2) what chemicals should be targeted, and (3) what basic and applied plasma research is needed to make plasma production of bulk organic chemicals possible.

2:30 PM SF04.02.02

High-Efficiency Atmospheric Pressure Glowing Discharge using Stacked Wire Dielectric Barrier Discharge Reactor YueXiao, MruthunjayaUddi and Chien-HuaChen; Advanced Cooling Technologies, Inc., United States

Plasma-assisted processes enable an electrified and potentially sustainable chemical synthesis or surface modification technology. However, the design of current plasma processes is often a compromise between performance factors such as reliability, scalability, energy efficiency, and chemical conversion. For example, dielectric barrier discharge (DBD) reactors generate stable discharges with high conversion, but the energy efficiency is often limited by its filamentary discharge at atmospheric pressure which only allows limited contact between the reaction gas and the plasma filament. Other types of plasma reactors, such as microwaves, can achieve high energy efficiency with glowing discharge yet a reduced pressure is required. In this work, we report an innovative Stacked Wire Dielectric Barrier Discharge (SWDBD) reactor design that can generate glowing discharge at atmospheric pressure to significantly improve the energy efficiency of the DBD plasma reactor. The SWDBD reactor suppresses the formation of the filamentary discharge through a unique reactor structure and achieves a diffusive glowing discharge volumetrically. Compared with the conventional co-axle DBD reactor, the SWDBD reactor is demonstrated to increase the energy efficiency by ~100% for dry methane reforming with the same reactor volume and plasma power. Such SWDBD can also be easily scaled-up with adjustable discharge gap distances to facilitate applications such as large surface treatment, chemical reforming, air disinfection, etc.

Green Steel Production by Hydrogen-Based Plasma Reduction of Iron Oxides DierkR. Raabe, IsnaldiSouza Filho, HaukeSpringer and MaticJovicevic Klug; Max Planck Institute for Iron Research, Germany

Steel is the backbone material of our modern civilization. While it enables sustainability via its high recyclability rates or when used in wind turbines or magnets, its primary production has strong negative impacts on the environment. This is because iron is extracted from its oxides through redox chemical reactions that employ fossil C-carriers as reductants, producing about 2 tons of CO2 per ton of steel produced. This enormous number represents 7-8% of all CO2 emissions on the planet and qualifies ironmaking sector as the heaviest individual industrial CO2 emitter.
For solving this huge challenge we developed a transformative fully electrified technology route which is based on using hydrogen plasma for the reduction of iron oxides, with only water as by-product. The procedure consists of igniting a hydrogen plasma arc between an electrode of an electric arc furnace, slightly modified to support small partial pressures of H2 (e.g. 10%), and the ore to be processed. Inside the arc zone, the mutual collisions between electrons and hydrogen molecules (H2) allows for creating high densities of highly energetic hydrogen species, such as the proton (H+) [2]. These particles are more reactive than H2, thus they help to overcome the reaction's activation energy, enhancing the reduction kinetics. We study the reduction of the hematite ores by the hydrogen plasma including the transformation kinetics and chemical composition over several intermediate states. Micro- and nanoscale chemical and microstructure analysis show that the gangue elements partition to the slag oxides, revealed by energy dispersive spectroscopy and atom probe tomography. Si-enrichment was observed in the interdendritic fayalite domains, at the wüstite/iron hetero-interfaces and in the oxide particles inside iron. With proceeding reduction, however, such elements are gradually removed from the samples so that the final iron product is nearly free of gangue-related impurities.

3:30 PM *SF04.03.01
Microplasma Engineering of Nanomaterials Synthesis and Applications Wei-HungChiang[1], DarwinKurniawan[1], Yi-JuiYeh[1,2] and Yan-YiChen[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]National Taiwan University, Taiwan

Microplasmas are a special class of electrical discharges formed in geometries where at least one dimension is less than 1 mm. As a result of their unique scaling, microplasmas operate stably at atmospheric pressure and contain large concentrations of energetic electrons (1-10 eV). These properties are attractive for a range of nanomaterials synthesis and nanostructure engineering such as metal, semiconductor, and inorganic nanomaterials [1]. Recently, we found that the energetic species including radicals, ions and electrons generated in the microplasmas were capable of initiating electrochemical-assisted reactions for the nucleation and growth of graphene quantum dots (GQDs), silicon quantum dots (SiQDs), and metal nanoclusters (MNCs) [2-5]. Moreover, we discover a simple and controlled synthesis of metal/metal, metal/QD heterostructures using our unique microplasma engineering. In this presentation, I will discuss these topics in detail, highlighting the advantages of microplasma-based system for the synthesis of well-defined nanomaterials for detections of metal ions, SARS-CoV-2 proteins, cancer and neurotransmitter biomarkers. These experiments will aid in the rational design and fabrication of nanomaterials for nanotechnology-enhanced biosensors and may also have significant impact in emerging applications for next generation applications including optoelectronics, nanocatalysis for clean energy, biomedical applications.

4:00 PM SF04.03.02
Constriction of an Atmospheric Pressure RF Plasma for Si Nanocrystal Synthesis CameronPapson[1], SankhadeepBasu[1], AlexanderHo[1,2] and RebeccaJ. Anthony[1]; [1]Michigan State University, United States; [2]Fraunhofer USA, United States

Low-temperature plasma reactors have become popular for synthesizing semiconductor nanoparticles. In many cases, these nanoparticles exhibit exciting and novel optical and mechanical behavior, and plasmas offer unique tailoring of these properties. Low-temperature or non-thermal plasmas (LTPs) are considered to be room-temperature synthesis tools, due to the non-equilibrium between the highly energetic electrons and the low-temperature heavy species such as ions and neutrals. This means that LTPs can be used to synthesize materials that require high crystallization temperatures, such as silicon, while maintaining compatibility with a wide variety of substrates. For flow-through synthesis of nanoparticles at lower pressure (1-10 Torr) it's convenient to use radiofrequency (RF) power sources, and reactor sizes can be as large as 1-2" in diameter. However, this low-pressure regime also introduces difficulty in merging the synthesis process with other fabrication techniques. Thus, using mm-scale or μm-scale reactors at atmospheric pressure is an alternative strategy to generate nanoparticle-producing plasmas using RF power. Additionally, these small-scale standard-pressure reactors can be integrated with direct-write schemes to provide on-demand nanoparticle deposition in controlled patterns. Prior work by Kramer et al. (Phys. Rev. B, 2015) suggested that LTP synthesis of crystalline silicon nanoparticles at atmospheric pressure requires a much higher ion density and/or atomic hydrogen density as compared to the low-pressure operating regime. This has led to some speculation about how crystalline nanoparticles can be synthesized even in smaller-scale reactor volumes, when using RF power at atmospheric pressure. Here, we present our results on crystalline silicon nanoparticle synthesis using a mm-scale RF LTP at atmospheric pressure. Observation of the plasma indicates that it diffusely fills the reactor volume during nanoparticle synthesis, similar to low-pressure reactors. In that case, predicted ion densities are not high enough to result in crystalline nanoparticles for these weakly-ionized plasmas. However, high-speed imaging of the plasma during synthesis indicates that what is perceived at steady-state to be a diffuse plasma is in fact a fluctuating filamentary discharge, indicating that species densities in regions of the reaction zone may be much higher than predicted based on a diffuse full-volume discharge.

Here we present our results using a constricted RF plasma for generation of crystalline silicon nanoparticles with sizes ranging from 5 nm – 20 nm using an atmospheric pressure RF-driven millimeter discharge. The reactor was a quartz tube with a 1-mm inner diameter and external ring electrodes supplied RF power (13.56 MHz) ranging from 40 W – 115 W (nominal). Argon was flown at 100-300 sccm and a 1% SiH_4/99% Ar mixture was flown at 0.5-25 sccm during the reaction, and nanoparticles were collected at the exit of the tube onto glass substrates. We performed XRD and TEM to confirm the crystallinity and size of the Si nanoparticles. We imaged the plasma using a Photron high-speed camera at a frame rate of 3600 fps. Argon-only plasmas appeared diffuse even when imaged at this high speed. However, the addition of silane into the reactor led to a filamentary discharge under all synthesis conditions. We hypothesize that the larger sized crystalline particles arise via high rates of reactions in the constricted portion of the plasma, allowing these nanoparticles to reach the higher temperatures required for crystallization even if their diameters are too large for size-related melting temperature depression.

SESSION SF04.04: Plasmas at the Interface I

Leveraging Plasma Enhanced Atomic Layer Etching for Sustainable Catalytic Processing JaneP. Chang[1,2]; [1]University of California, Los Angeles, United States; [2]Harvard University, United States

ALE was developed in recent years to address critical needs in micro- and nano-electronics fabrication where precision in nano-scale patterning is required to integrate novel metal and metal alloys in nano-electronics, nano-photonics, spintronics, and sensors. Many of these materials are inert or less reactive, making it a challenge to turn a non-etchable material into an etchable one. Our previous work demonstrated that a viable ALE process utilizes chemically reactive and low energy directional oxygen ions to tailor the surface modification/conversion process and form a metal oxide layer while suppressing any deleterious sputtering. The surface reaction kinetics dictate the controlled and directional change in the materials' composition and properties, thereby enabling the chemical contrast needed to selectively remove the materials. Such an effective ALE process can potentially be used to de-poison catalysts, by removing just one atomic layer of material at a time (the poisoned layer). The site specificity in these ALE reactions can also help regenerate the preferred sites for catalytic reactions.

The feasibility of utilizing ALE to de-poison catalysts is based on strong and selective chemical reactions on the surfaces of metals. Interestingly, many of the materials requiring nano-scale patterning have been used as catalysts. While a chemical reaction leading to the formation of a strongly chemisorbed species is considered poisoning in catalysis, it is actually a necessary step in initiating atomic layer etching of metals. By identify a chemical reaction that can form strong chemical bonds, thereby modifying an atomically thin surface layer to form a new compound, a distinct chemical contrast can be created to allow one atomic layer of the modified surface to be selectively removed, leaving behind the unmodified material. This presentation will focus on the intersection of two interdisciplinary research areas for microelectronics and catalysis, leveraging what was achieved in ALE of metals to help de-poison/regenerate the catalysts. The specific examples include Ni and Cu (both are common and useful catalysts) because these two suffer sulfur and carbon poisoning (coking) as two major deactivation processes. The discuss will demonstrate the feasibility of utilizing ALE to remedy catalyst poisoning and make the catalytic processing more sustainable.

9:00 AM SF04.04.02
Facile Synthesis of Non-Precious Bimetallic ZIF-Based Hierarchical Nanocomposites as Efficient Electrocatalysts for Oxygen Reduction Reaction MahshidMokhtarnejad, ErickL. Ribeiro, DibyenduMukherjee and BaminKhomami; The University of Tennessee, Knoxville, United States

Zeolitic imidazolate frameworks (ZIFs) belong to a class of highly crystalline metal organic framework (MOF) materials that have increasingly found prominence in various materials technology applications due to their ultrahigh porosity and enormous internal surface areas. Such properties, together with the vast library of MOF structures that can be constructed from diverse combinations of both organic (ligands) and inorganic (metal nodes) counterparts, provide the incentives for the design and synthesis of uniquely tailored MOFs. Specifically, conversion of such designer MOFs into highly conductive and high-porosity hybrid nanocomposites (HNCs) consisting of transition metal/metal oxides interfaced with carbon (C) matrices can serve as a promising alternative for the synthesis of affordable oxygen reduction reaction (ORR) electrocatalysts. To that end, optimizing the performance of these classes of materials by tailoring their composition, structure, size, and morphology through an efficient synthesis route has emerged as an active area of research. This talk presents our recent efforts at using Laser Ablation Synthesis in Solution in tandem with Galvanic Replacement Reaction (LASiS-GRR) technique as an environmentally friendly, facile, and rapid route for the design and synthesis of unique core-shell bimetallic ZIF heterostructures as bi-MOFs. Pyrolytic post-processing of these bi-MOF structures yield hierarchical metal oxide/MOF-based functional HNCs as highly active ORR electrocatalysts. The LASiS-GRR technique employs high-energy laser plasma reactions as the rate-controlling step for initiating solution-phase galvanic reactions. The one-pot, two-step process introduced in this study enables tailoring the composition, structure, size, and morphology of composite bi-MOFs comprising Co-based MOFs encapsulated in Zn-based porous crystals (Co/ZIF-67@Zn/ZIF-8). Post-pyrolysis, these core-shell bi-MOF crystals are found to create hierarchical ZnO/ZIF@C HNCs that indicate superior ORR electrocatalytic performances under alkaline conditions. Overall, these findings not only elucidate the ability of well-designed LASiS-GRR protocols to tailor the morphology, structure and composition of complex MOF structures but also demonstrate the superior performance and stability of the ensuing post-pyrolyzed ZnO/ZIF@C HNCs as non-precious metal-based ORR electrocatalysts, when compared to commonly used Pt-/Pt-group metals (PGM)-based electrocatalysts.

9:15 AM SF04.04.03
Plasma Surface Modification of Graphitic Carbon Nitride for Improving Photocatalytic CO_2 Reduction Activity with a Ru(II)-Ru(II) Supramolecular Photocatalyst NoritakaSakakibara[1], TsuyohitoIto[2], KazuhikoMaeda[1], KazuoTerashima[2] and OsamuIshitani[1,3]; [1]Tokyo Institute of Technology, Japan; [2]The University of Tokyo, Japan; [3]Hiroshima University, Japan

For a sustainable energy management, effective conversion of CO_2 into energy-rich fuels is highly demanded as an alternative to fossil fuels and nuclear energy. Recently, hybrid photocatalyst combining a semiconductor and a supramolecular photocatalyst has been developed for realizing highly efficient CO_2 reduction using visible light [1, 2]. For example, the hybrid of graphitic carbon nitride (C_3N_4) and binuclear ruthenium(II) complex (**RuRu'**) demonstrated selective reduction of CO_2 to formic acid (HCOOH) under visible light irradiation and exhibited a very high durability with a turnover number over 33,000 with respect to the amount of **RuRu'** [2]. In this system, **RuRu'** is incorporated onto C_3N_4 via phosphonic acid anchoring groups of **RuRu'**, and electron donation from C_3N_4 to **RuRu'** drives photocatalytic CO_2 reduction. However, poor functional groups on C_3N_4 which can interact with the phosphonic acid anchoring group hinders interfacial affinity of **RuRu'** onto C_3N_4, which essentially prevents potential development for better photocatalytic system.
To gain better interfacial affinity, plasma surface modification should have a great potential. In this study, as a first example of this concept, C_3N_4 was treated with a non-equilibrium plasma in hydroquinone-containing aqueous solution [3]. The plasma treatment modified the surface of C_3N_4 selectively without influencing on the bulk properties of C_3N_4 such as crystal structure, bandgap energy, and chemical structure. By X-ray photoelectron spectroscopy and UV−vis diffuse reflectance absorption spectroscopy, deposition of oxygen-rich carbon layer based on sp^2 bonding structure was identified. Furthermore, the adsorption density of ruthenium complex with phosphonic acid anchoring groups onto C_3N_4 was improved by approximately three times, with the surface coverage of ~50%. Therefore, the interfacial affinity was improved by the surface modification of C_3N_4.
The influence of the plasma treatment of C_3N_4 on photocatalytic CO_2 reduction was investigated in the case of the aforementioned well-developed hybrid photocatalytic system with C_3N_4 and **RuRu'**. The hybrid photocatalyst of C_3N_4 and **RuRu'** was dispersed in CO_2-bubbled *N*,*N*-dimethylacetamide/triethanolamine mixed solution and irradiated under visible light. The surface modification improved the selectivity of HCOOH production and durability up to approximately 2 times with a turnover number of 50,000, which recorded the highest durability of hybrid photocatalysts so far. By the electron-spin resonance measurement and transient absorption spectroscopy measurement of plasma-treated C_3N_4, the enhanced activity was attributed to the accumulation of photoexcited electrons onto deep trapping sites of the oxygen-rich carbon layer, which promoted electron transfer from C_3N_4 and **RuRu'**. This result clearly demonstrates the advantages of plasma surface modification for the development of hybrid photocatalysts.

9:30 AM *SF04.04.04
Plasma-Assisted Atomic Layer Deposition of Oxygen Evolution Reaction Electrocatalysts MariadrianaCreatore; Eindhoven University of Technology, Netherlands

Anion exchange membrane water electrolysis is a potentially low-cost technology for renewable-energy driven hydrogen generation. Realisation of its full potential relies on the development of cost-effective, earth-abundant oxygen evolution reaction (OER) electrocatalysts, as alternative to the state-of-the art noble metal oxides. In this contribution I will address the synthesis of

two electrocatalysts, i.e., cobalt phosphate (CoPi) and cobalt nickel oxide by plasma-assisted atomic layer deposition and discuss the merit of digital control over film stoichiometry to generate insight on the activation mechanisms of these electrocatalysts.
CoPi is prepared by combining ALD cycles of CoO_x from cobaltocene ($CoCp_2$) and O_2 plasma, with cycles of trimethylphosphate ($(CH_3O)_3PO$) followed by O_2 plasma. We show that the Co-to-P ratio in the film can be tuned by combining the above-mentioned recipe with extra cycles of CoO_x. We demonstrate that ALD CoPi thin films undergo activation with increasing number of cyclic voltammetry (CV) cycles. During activation, the current density increases in parallel with a progressive leaching of phosphorous out of the electrocatalyst. These chemical changes proceed in parallel with structural changes in the electrocatalyst: measurements of the electrochemical surface area (ECSA) reveal that during activation, the ECSA of this film increases and that the electrochemical activity scales linearly with ECSA for all film compositions. Thus, the initial composition affects the activity of the catalyst indirectly by guiding the restructuring of the catalyst during cycling and the ECSA is a critical parameter in determining the activity of CoPi electrocatalysts. The present study discloses an opportunity for ALD in electrocatalysis: its digital control over chemical composition enables unravelling the ECSA-OER activity correlation.
The second study addresses an ALD supercycle process based on $CoCp_2$ and nickel methylcyclopentadienyl ($Ni(^{Me}Cp)_2$) and an oxygen plasma to investigate the influence of chemical composition and crystallographic properties of cobalt nickel oxide thin films on their electrocatalytic performance. Deposition of binary nickel oxide and cobalt oxide results in the growth of polycrystalline films of rock-salt and spinel phase, respectively. The mixed oxides display a transition from 2+ oxidation state-based pure rock-salt phase (<25 at.% Co) to the spinel phase consisting of mixed +2/+3 oxidation states (>75% at.% Co) upon increasing Co at.%, as verified by electron diffraction and XPS. XPS also reveals a linear increase in the Ni^{3+}-to-Ni^{2+} ratio with increasing Co at.%, which indicates that an inverse spinel structure is formed. The formation of a Ni^{3+}-rich inverse spinel cobalt nickel oxide between 55 and 75 at.% Co facilitates the formation of a semi-metallic state (10^2 S/cm) as opposed to the poorly conductive binary oxides. When CV measurements are carried out in 1M KOH, continuous activation behaviour is observed for rock-salt phase films, whilst increment of the Co at.% results in reduced film activation until virtually no activation of the spinel phase films is observed. The activation of the nickel-rich film is accompanied by irreversible redox changes from the +2 to +3 oxidation state as indicated by the integrated non-catalytic wave. The formation of an (oxy)hydroxide state is observed for the rock-salt dominated films, whilst oxidation states characteristic of a spinel- like oxide structure are observed for the cobalt-rich films. No changes in the transition metal ratios are observed after activation. Scanning electron microscopy images furthermore reveal that the transformation of the Ni-rich films is accompanied by surface restructuring. These results indicate that initial composition can significantly influence the electrocatalytic performance of ternary oxides and therefore highlight the importance of techniques such as atomic layer deposition to study their complex behaviour.

Improving the SiO_2 to SiN_x Etch Selectivity During Atomic layer Etching and Reactive Ion Etching SumitAgarwal; Colorado School of Mines, United States

In semiconductor device manufacturing, SiO_2 and SiN_x are two of the most commonly used dielectrics, which are patterned during various device processing steps using plasmas of fluorocarbon gases. During plasma etching, the etch selectivity of SiO_2 relative to SiN_x can be controlled by tuning process parameters such as the fluorocarbon or hydrofluorocarbon feed gas, dilution with other gases such as H_2 or O_2, and by tuning the ion flux and the ion energy distribution. Previously, we showed that selective functionalization of plasma-deposited SiO_2 or SiN_x with hydrocarbons can be used to enhance etch selectivity. Building on our previous work, using *in situ* optical surface diagnostics, we will show that this approach can be extended to atmosphere-exposed and partially-etched SiO_2 and SiN_x surface during atomic layer etching (ALE). In addition, we have also studied the mechanism for the enhancement in etch selectivity for SiO_2 over SiN_x by increasing the substrate temperature during reactive ion etching (RIE). Lastly, during RIE of SiO_2 and SiN_x, we will discuss the role of the C_4F_6/O_2 ratio in the feed gas in determining the etch selectivity.

11:00 AM SF04.05.02
Probing Plasma-Induced Surface Reactions via *In-Situ* FTIR and RamanLorenzoMangolini and MinseokKim; University of California, Riverside, United States

Non-thermal plasmas provide new ways of driving heterogeneous reactions at catalyst surfaces. These processes fall under the broad sub-field of plasma-catalysis, which has attracted great attention in recent years because of its promise of enabling the conversion of electrical into chemical energy. Such processes could help alleviate our societal dependence on hydrocarbons and heat-driven processes, paving the way for a long-term sustainable energy infrastructure. Several examples of these processes have been presented in recent years, including for ammonia synthesis, methane reforming, water-gas shift, and others. While promising, the community still lacks a microscopic-level understanding of how plasma-produced species interact with catalyst surfaces and adsorbates. Here we choose an organic monolayer as a molecular probe to investigate how a low-temperature plasma interacts and excites the adsorbates. We select phenyl phosphonic acid (PPA) as molecular tracer because of its strong response in both FTIR and Raman measurements. First, we prepare a nanostructured silver substrate to enhance the Raman response of the system. We protect the silver surface with a thin alumina layer grown by atomic layer deposition, since this is well-known to improve the thermal stability of the silver substrate. We then adsorb PPA onto the substrate and focus on the Raman signature from the aromatic benzene ring (1010 cm^{-1}) under plasma irradiation. We find that the molecule vibrational temperature, as determined by measuring the ratio between stoke and anti-stoke peaks, can exceed the substrate temperature by 80°C even at low plasma input power. In parallel with the Raman measurements, we perform temperature programmed desorption using FTIR to estimate the binding energy between PPA and alumina. In agreement with the Raman data, we measure a significant drop in binding energy under plasma exposure. Additional characterization of the plasma via a double probe will be presented, to correlate the plasma properties with the FTIR and Raman measurements. This work confirms that low-temperature plasmas can deposit energy in a very localized manner, increasing the effective temperature of adsorbates and in turn enhancing the rate of heterogeneous reactions.

11:15 AM SF04.05.03
Improvement in Performance of Hybrid Perovskite FAPI Solar Cell by Adlayer of Surface Engineered $FAPI_3$ Quantum Dots Layer BrunoAlessi[1], CalumMcDonald[1], DavideMariotti[2] and VladimirSvrcek[1]; [1]AIST: National Institute of Advanced Industrial Science and Technology, Japan; [2]Ulster University, United Kingdom

Formamidinium lead iodide (FAPI) thin films in the perovskite crystalline phase have recently attracted attention for single junction solar cells owing to their ideal bandgap, long photocarrier lifetime and intrinsic structural stability in respect to all-inorganic based perovskites of interest for solar cells. However, the performance and stability of cells based on FAPI bulk crystalline films is limited by the high density of trap states on the surface and within the lattice, which determine the appearance of deep levels acting as non-radiative recombination centers and result in the deterioration of device performance over time. Various strategies have been explored in to overcome these limitations such as film crystallization and deposition optimization, precursor engineering, tailoring the interface properties and energy gap. The formation of distinct bulk heterojunctions has also been proven to be experimentally non-trivial due to the inherent instability of these materials surface towards exposure to polar solvents. Nonetheless the integration of low dimensional perovskites[1] and the incorporation of nanocrystals with quantum confinement has proven to be a feasible way to ameliorate stability, boost carrier collection and tailor energy band gap at the same time.[2]

In this study we explore the potential of using adlayers (50 to 100 nm) of formamidinium lead iodide ($FAPbI_3$) quantum dot (QDs) on FAPI bulk films, to explore integration of QDs and fs laser induced surface engineered (SE) $FAPI_3$ QDs with FAPI bulk films, tailor energy gap, boost the carrier collection and increase the light absorption efficiency at shorter photon wavelengths. These $FAPbI_3$ QDs have been synthesized with a well-established hot injection method and surface-engineered QDs (SE-QDs) are obtained by processing the $FAPbI_3$ QDs with a fs-laser generated plasma treatment in liquid. We report that SE-QDs are affected both in particle size and surface state while retaining their structural and colloidal stability. We then proceed making solar cell devices based on SnO_2 and Spiro-OMeTAD as electron- and hole- transport layers and consider two different cases to distinguish the effect of QDs on the device performance. QD-only devices that are meant to understand the effects of surface engineering alone and devices with a thick microcrystalline $FAPI_3$ film (~600 nm) and thin adlayers of QDs (100 nm) both as synthesized and surface engineered and compare them against a control FAPI film solar cell.
In the former case (QD-only cells) we notice important relative improvements of average IV parameters of solar cells, above all bigger short circuit current and PCE (+20%) whilst only minor improvements in open circuit voltage and field factor, and overall figures in line with all-QDs based $FAPI_3$ cells. In the latter case (thin heterojunction cells) we observe a slight deterioration of IV characteristics with as-synthesized QDs adlayers, whereas marked improvements for most of the average IV parameters with SE-QDs adlayers. Notably a 7% increase in power conversion efficiency, with the record cell topping at 20.7% PCE, J_{sc}=25.6 mA/cm^2, V_{OC}=1.13 V and FF=70%. Additionally, when measuring again the IV characteristics after two months, a less severe decay in performance in respect to the control device is observed (e.g.: V_{OC} -4% for the control vs -2.5% for the SE-QDs device). We notice also that thin layers of QDs up to 100 nm have only minor influence on the optical absorption characteristics of the thicker FAPI film, hence we infer the improved performance as the result of more efficient photocarrier extraction. The thin adlayers of SE-QDs improve interface and determine a more favorable electron energy alignment between the FAPI film and the spiro-OMeTAD.

11:30 AM SF04.05.04
Novel Ampoule-Liked Microwave Plasma Process for the Sulfurization of Polycrystalline CVD Graphene CharlesModérie, MarianneLapierre, RichardMartel and LucStafford; Université de Montréal, Canada

Plasma processes have been proposed has an efficient and green path for graphene modification, in particular for n- and p-type doping. However, some modification can be limited by the plasmagen gas or by reactor contamination considerations as sulfurization. To generate sulfur-graphene, a new plasma-based process has been developed and characterized. Inspired by an ampoule reaction, solid sulfur S_8 and CVD graphene transferred on SiO2/Si substrates are place in a silica tube where a microwave (MW) surface-wave discharge is ignited in 10 Torr argon. In this pressure range, the plasma column is contracted[1] and the fundamental plasma properties strongly vary along the radial axis[2]. The proposed process relies on neutral gas heating by MW plasma generation and subsequent sulfur sublimation to create gaseous reactive sulfur for graphene functionalization. In this work, the argon plasma was first characterized by high and ultra-high-resolution emission spectroscopy, laser absorption spectroscopy and imaging. The neutral gas temperature was determined by the resonant and Van der Waal broadening of the Ar emission lines[3] (826 and 840 nm) over a wide range of experimental conditions. With such temperature, the sulfur concentration in the gas phase was estimated from the equilibrium vapor pressure. Then, the sulfur argon plasma was characterized with the same methods. In presence of sulfur, two distinct plasma phases were observed by emission spectroscopy: Argon-Sulfur contracted dual-phase in the center of the tube and diffusive mono-sulfur phase close the walls. This transition is consistent with previous findings in presence of gas admixtures for which the ionization potential of the trace gas is lower than the one of the main gas. Additionally, CVD graphene was exposed to the two-plasma phase system to functionalize the surface with sulfur atoms. Here, there is two main challenges to achieve functionalization: the creation of the C-S covalent chemical bonding and the defects generation induced by the plasma. To characterize the graphene-sulfur product, Raman spectroscopy and X-ray photoelectron spectroscopy (XPS) was done. In addition to the D, G and 2D Raman signals of graphene[4], a new band linked to sulfur functionalization is observed. XPS measurements were also made to confirm the C-S covalent bonding. This plasma-based process opens up new possibilities for 2D materials modification.

11:45 AM SF04.05.05
Plasma-Engineered Carboxylic Compound-Derived Graphene Quantum Dots as Multifunctional Nanosensors for Simultaneous Detection of Biomarkers and Metal Ions Yan-YiChen and Wei-HungChiang; Department of Chemical Engineering, National Taiwan University of Science and Technology, Taiwan

In the face of escalating environmental pollution and disease threats, the urgent need for efficient and sensitive environmental and biological sensors has become paramount for safeguarding human health and fostering sustainable development. Here, we leverage an atmospheric pressure microplasma system to synthesize graphene quantum dots (GQDs) using carboxylic compounds, specifically benzene polycarboxylic acids, including benzoic acid, phthalic acid, trimesic acid, and pyromellitic acid, as the carbon source. These GQDs are utilized in photoluminescence (PL)-based multifunctional sensors for diverse environmental and biological applications. Through accurate adjustment of the detection conditions, our sensor, based on a single material, demonstrates remarkable selectivity and sensitivity by simultaneously detecting biomarkers and metal ions such as folic acid (FA) and adenosine triphosphate (ATP) and aluminum and copper ions.
Our first innovation lies in the convenient, rapid, and environmentally friendly synthesis of GQDs with abundant carbon and oxygen functional groups from carboxylic compounds, achieved through the atmospheric pressure microplasma system. Microplasma eliminates the need for harsh chemicals, high temperatures, vacuum conditions, and toxic solvents. Additionally, we investigated the influence of carboxylic acid functional groups (COOH) by employing different benzene polycarboxylic acids in the synthesis process. TEM imaging supported our findings, revealing that the reduction of COOH functional groups in these benzene polycarboxylic acids increased the size of the synthesized GQDs, with a size distribution ranging from 2.4 nm to 5 nm, during the plasma treatment process.
The second innovation revolves around the plasma-synthesized GQDs, which can be tuned to serve as highly sensitive and stable nanosensors for biomarkers and metal ions. By adjusting the detection conditions, selective detection can be achieved. Moreover, we discovered several unique photoluminescence (PL) quenching mechanisms under different conditions, enhancing the sensing activity of GQDs towards target analytes. The successful development of this nanosensor enables simultaneous multifunctional sensing using a single material.
These findings hold great promise for advancing the frontiers of plasma technology in materials science and engineering while facilitating various applications in environmental monitoring, water quality analysis, food safety, clinical diagnostics, and pharmaceutical research.

SESSION SF04.06: Plasma Synthesis and Surface Engineering I
Session Chairs: Lorenzo Mangolini and Luc Stafford
Tuesday Afternoon, November28, 2023
Sheraton, Second Floor, Independence East

1:30 PM *SF04.06.01
Using Image Based Artificial Intelligence Growth Prediction to Improve SCD Wafer Dimensions and Growth Yield MatthiasMuehle[1,2], RohanReddy[1], ArjunSrinivasan[1], LukeSuter[1] and EliasGarratt[1,2]; [1]Fraunhofer USA, United States; [2]Michigan State University, United States

Single crystal diamond (SCD) is an attractive wide bandgap semiconductor material for a variety of applications ranging from advanced optics, solid state electronics to thermal management solutions. While lab-scale prototype demonstrations have demonstrated superior performance, utilizing diamond has been prohibitively expensive compared to more mature, commercialized semiconductor materials. This is attributed to the fact the SCD wafer size of suitable quality is smaller than 1 inch, and often as little as small as 3 mm x 3mm. For comparison, the commercially available wafer size for single crystalline Silicon Carbide is beyond 6 inches. A direct result is a lack of process scaling when processing individual diamond applications. The only way to overcome this is by controlling the size and quality of SCD wafers during chemical vapor deposition (CVD) growth to enable realization of wafers 2 inches in size and beyond either. This type of process control can be applied either for epitaxial layer outgrowth, or for tiled wafer growth. We are envisioning to address this challenge by developing an artificial intelligence (AI) based algorithm to predict SCD growth states (size and quality) through use of in-situ RGB images. Once established, this AI growth prediction can be incorporated as control system to increase SCD wafer size and quality, by adjusting process conditions before they achieve critical turnover points.

We are reporting on our efforts on AI algorithm development and validation. First, we installed a full-frame mirrorless interchangeable lens camera equipped with a macro lens to a CVD diamond reactor. Then a cumulative image-based AI pipeline consisting of three inter-connected thrusts was developed to model diamond growth. These are 1) Feature extraction pipeline, for extraction of geometrical features in the recorded imaged, 2) Defect detection pipeline, to extract macroscopic defect features in the recorded images, and 3) Frame prediction pipeline utilizing features, defects and reactor telemetry, to predict future image states 6, 8 and 12 hours into the future.

The objective for the feature extraction pipeline was to isolate and classify accurate pixel masks of geometric features like diamond, pocket holder and background, and their translation into geometrical shapes without the need of human-generated input. Our approach was enhanced to deliver results with high precision within the constraints of being limited to low-volume high-feature-complexity training dataset environments, given that data procurement, requiring physical SCD growth, is extremely time-consuming and expensive. Our best performing DL-based model achieved excellent accuracy metrics of >98% for the pocket holder, diamond top and diamond side features. Similarly, our DL-based defect detection pipeline achieved excellent accuracy metrics (>95%) for detecting center, polycrystalline and edge defects.

Prediction accuracies of ~99.9999% were obtained with minimal information loss between predicted and actual outputs. This constitutes a never-before obtained result of spatiotemporal (AI) prediction of diamond shape from in-situ obtained growth data obtained based on few inputs from data collected within an hour apart. This demonstrates the potential of these algorithms as a machine-intelligence-enabled solution for automated optimization and control of the diamond growth process.

2:00 PM SF04.06.02
Controlling Nitrogen Plasmas for Thin Film Synthesis of Complex Semiconductor, Superconductor and Magnetic Materials SageBauers; National Renewable Energy Laboratory, United States

Inorganic nitrides are recognized as highly functional materials for several applications, such as semiconducting GaN, superconducting NbN, and magnetic $Fe_{16}N_2$. Unfortunately, the stability of the N_2 molecule makes metal-nitride synthesis difficult, which precludes the functionalization of many predicted and promising nitride materials. One approach to the experimental realization and optimization of novel nitrides is to use nitrogen plasmas to either vibrationally excite N_2 or even rend the dinitrogen molecule into N* radicals, which are far more reactive. Over the last several years, our group has used this concept for the synthesis and optimization of several new nitride materials. This talk will introduce our work using nitrogen plasmas for the synthesis of new ternary metal-metal-nitride semiconductors and magnetic materials, as well as the optimization of nitride superconductors. Our work is based on reactive co-sputtering processes, where we use plasma parameters to control the nitrogen chemical potential both to realize novel phases as well as optimize known materials. We establish general rules where nitrogen activation enables the synthesis of nitrogen-rich nitrides (e.g., $ZnTiN_2$), which are required for semiconducting applications, but we also find that activation of dilute nitrogen concentrations enables the synthesis and optimization of metal-poor nitride materials needed for superconducting and magnetic applications (e.g., Mn_3GeN). We will also discuss our recent efforts to establish an autonomous synthesis assistant that is guided by in-situ monitoing of plasma emission spectra to optimize the composition of $ZnTiN_2$, an emerging ternary nitride material with promising properties as a CO_2 reduction photoanode.

2:15 PM SF04.06.03
Positive Ion Transport Study in High Power Impulse Magnetron Sputtering of Argon-Chromium using a Global Model Coupled to the Monte-Carlo Approach JoelleZgheib[1], Pierre YvesJouan[1] and AhmedRhallabi[1,2]; [1]Institut des Matériaux de Nantes Jean Rouxel, France; [2]Nantes University, France

PVD thin-film deposition is one of the most widely used processes in the semiconductor industry and other technological applications such as MEMS, gas and biological sensors. Thin film quality depends not only on the type of process used, but also on the process operating conditions. Beside conventional RF and DC processes, pulsed discharges such as HIPIMS (High Power Impulse Magnetron Sputtering) [1] have emerged in recent years. The advantage of HiPIMS is its possibility of working with a high metal ion flux over a pulse duration of the order of tens microseconds by injecting an instantaneous power of tens KWatts. This leads to achieve a higher conformity of the deposited film on 3D structures such as via and trench structures, while avoiding intense substrate heating thanks to heat dissipation during time "off".
In order to understand the electrical properties of HIPIMS plasma, we have developed a hybrid model based on a global 0D approach in the ionization zone, coupled to a Monte-Carlo model to study the transport of positive ions from the ionization region to the mass spectrometry entrance. The model is applied to argon plasma discharge and chromium target.
The global 0D model is based on the solving of the continuity equations associated with each species considered in the reaction scheme, i.e. Ar, Ar*, Ar^+, Cr, Cr^+, Cr^{++}, electrons [2]. These equations are coupled to the continuity equation associated to power. Solving the differential equation system in the HiPIMS discharge time domain, enables us to determine the average densities of the neutral and ion species, as well as the electron density and temperature in the ionization region as a function of time [2].
The Monte-Carlo model is based on a set of large number of ions from the ionization region, representing the fluxes of positive ions. Their trajectories are followed by solving Newton's equation until reaching the mass spectrometry entrance. The ion fluxes calculated by the global model in the ionization region are considered as input parameters for the Monte-Carlo model. Under the pressure and pulsed voltage conditions used, simulation results show the evolution of ion and neutral species densities, as well as electron temperature as a function of time. For voltages of hundreds of volts, with time "on" duration of 40 µs, the proportion of Cr^+ is much higher than Cr one revealing the ionization efficiency of the sputtered metal atoms. Monte-Carlo model results show a temporal spread of Ar^+, Cr^+ and Cr^+ peaks at the mass spectrometry entrance, compared with those obtained in the ionization region. This peak spread is due to ion diffusion through the plasma bulk and the geometrical asymmetry of the mass spectrometry entrance, with respect to the ionization region. The simulation results show the effect of the ion energy in the ionization region on the temporal peak behavior of ions in the mass spectrometry entrance. Time evolutions of normalized positive ion fluxes calculated from Monte-Carlo code reproduce well those obtained from mass spectrometry [3].

Current State of the Art of R&D for Fabrication of Single Crystalline Diamond Wafers YamadaHideaki; AIST, Japan

Variety of material constants of diamond are the bests amongst those of other competitive materials and attract researchers to realize several future applications. Many indexes of diamond to characterize performance as power devices are better than those of, for example, Si, SiC, and GaN, owing to its wide bandgap, large breakdown field strength and high thermal conductivity. This suggests potential to realize extreme improvements in efficiency of power control in, for example, Electric-Vehicles, power plants and its transmission principally. Especially, this extremely high thermal conductivity is expected to enlarge range of applications of other semiconductor devices with relatively low thermal conductivity, for example, GaN- and Ga_2O_3-based ones. On the other hand, quantum information, which can be controlled by electronic states in specific color centers of diamond, for example, Nitrogen-Vacancy (NV) centers, is known to be treated under steady state with coherence time which is longer than those of others. This may realize high performance quantum computers, information transmission equipment with high security, and variety of quantum sensors with high resolution and wide dynamic range.

To realize such fascinating industrial applications, it is indispensable to establish the way to produce single-crystalline diamond wafers with sufficient quality and size under acceptable cost. Artificial diamond was firstly reported by using high-pressure-high-temperature method, in which stable state of diamond is realized. This method is nowadays adopted to produce mechanical tools worldwide. On the other hand, it is considered practically difficult to realize inch size crystals for industrial applications by using this method. On the other hand, chemical vapor deposition (CVD) was also found to be the other way to obtain diamond crystals artificially. Several CVD methods with variety of radical sources have been proposed and proofed to be possible methods, for example, flames, hot-filaments, and plasmas. Among several plasma sources, microwave plasma (MWP) CVD has been widely adopted to grow diamond crystals especially for electronics and quantum applications because of its relatively high plasma and power-density without electrode near the top surface of the substrate. Especially, developments in techniques of crystal growth by using MWPCVD during recent 20 years realized remarkable market entry of artificial diamond as gemstones.

We have realized techniques to prepare free standing wafers with less loss, inch-sized wafers, and bulk diamond with thickness of several millimeters. To realize them, we tried to optimize the crystal growth technique by changing chamber shape, applying pulse mode discharge, superimposed microwave, accompanied with numerical simulation of the plasma to understand growth environment. In addition to the technique of the crystal growth, processing technique is one of the important issues to prepare diamond wafers, because diamond is hardest material with cleavage characteristics similar to Si. Recently, we confirmed that plasma-assisted polishing could realize very fine surface with less processing damages.

Now, we are going to apply such wafers for thermal management of electronic devices with high power density, and devices which can be applied to harsh environments. In the future, this material is expected to fulfill its true potential in the fields of 1) Power electronics, and 2) Quantum applications. These applications require reduction of dislocation density and control of impurity concentrations. We are now trying to solve these subjects by using plasma processing.

3:30 PM SF04.06.05
Photonic Properties of Thin Films Comprised of Plasma-Synthesized Gallium Nitride Quantum Dots DillonP. Moher[1], GuodongRen[2], RohanMishra[2,2] and ElijahThimsen[1,2]; [1]Washington University In St. Louis, United States; [2]Washington University in St. Louis, United States

Gallium nitride (GaN) is a promising material for power electronics and optoelectronics owing to its high electron mobility, high breakdown voltage, and wide, direct band gap. The synthesis of thin film and bulk crystal GaN has received much attention, which has resulted in the commercialization of GaN. However, few synthesis methods exist for freestanding GaN quantum dots (QDs), which can possess a tunable band gap above 3.4 eV. These ultra-wide-gap GaN QDs are promising for deep ultraviolet light sources and single photon emitters in quantum information technologies. In this work, Nonequilibrium Plasma Aerotaxy was utilized to synthesize GaN QDs and deposit them in flight as thin films on foreign substrates which are relevant for practical solid-state devices. The QD diameter was controlled between 3.6 and 7.4 nm. The particles were monocrystalline. The photoluminescence of the QD films increased steadily with time in air, after oxidation of the QD surfaces. There were two PL peaks: one in the ultraviolet, hypothesized to originate from band-to-band recombination, and another in the visible, hypothesized to originate from deep-trap-mediated recombination. Surprisingly, both PL peaks possessed a size dependence, in agreement with the Brus equation. Coating the GaN QDs with Al_2O_3 suppressed the PL peak in the visible, confirming that air exposure caused the defect-related PL.

Deoxidation of Metal Powders using Nonthermal Hydrogen Plasma for Optimized Reuse in Additive Manufacturing MichaelA. Denchy, JoshKintzer, PradeepKumar, TimSchmitt, MruthunjayaUddi, DevonJensen and Chien-HuaChen; Advanced Cooling Technologies, Inc., United States

Additive manufacturing (AM) processes face a significant challenge with an increasing oxygen concentration (predominantly as surface oxides) in metal powders during reuse cycles. This increased surface oxidation, occurring at the high temperatures encountered by powders during the printing process, ultimately surpasses the industry acceptable quality limits. Laser powder bed fusion (LPBF) AM processes, in particular, deposit metal powders layer by layer, resulting in waste of the feedstock, which can increase unit costs and have adverse environmental impacts. It is therefore essential to develop and optimize processes to enable the recycling and reuse of metal powders to establish a sustainable AM process industry-wide. To address this challenge, we report the application of a novel low-temperature non-equilibrium hydrogen plasma-based deoxidation process for efficient recycling and reuse of metal powder in AM processes. Our technique involves the highly reactive species generated in an H_2-fed low pressure plasma discharge dynamically interacting with used (oxidized) powder in a quartz tube reactor, reducing oxygen content without adversely affecting particle size or morphology. This process is also free of corrosive chemicals, with water vapor being the major by-product of the reaction. In a pilot study using CuSn10 (0-25 micron) powder, we achieved over a 60% reduction in oxygen content using hydrogen plasma compared to the oxygen content in oxidized CuSn10 powder samples, which is a significant improvement and well below the measured oxygen content of the virgin CuSn10 powder. An in-depth systematic characterization study (XRD, XPS, PSD, and IGF) demonstrating powder morphology, bulk particle structure, and chemical composition following hydrogen plasma treatment will be presented.

4:00 PM SF04.06.07
Tunability and Flammability of Plasma-Synthesized Silicon Quantum Dots KaterinaKusova, JakubKopenec, FilipMatejka, PavelGalar and TomasPopelar; Czech Academy of Sciences, Czechia

Silicon is the most sustainable, influential and critical material for our technological advancement. It is the material base for modern electronics, the second most abundant element in the Earth's crust and it has very low inherent toxicity. However, in its bulk form, it is practically unable to luminesce due to the indirect nature of its bandgap. This drawback is circumvented in silicon quantum dots (SiQDs). Countless other types of semiconductor quantum dots, such as CdSe, GaN or the modern CsPbI3 perovskites, are somewhat more efficient light emitters than SiQDs, however, they almost exclusively contain toxic or scarce elements. In addition to low toxicity, there is one aspect where SiQDs outperform their rival materials even when it comes to light emission. As opposed to other semiconductor QDs which are ionic crystals, the nature of the bonding inside the SiQDs' core is covalent. The higher degree of electron sharing associated with covalent bonding makes the electronic properties of SiQDs more sensitive to small changes in surface ligands or in the crystalline core. Thus, most likely as a result of covalent bonding, SiQDs exhibit much broader tunability of their light emission than QDs based on ionic crystals. This tunability makes SiQDs unique light emitters with interesting application prospects and, moreover, SiQDs can serve as a model material for other covalently bonded QDs.

With silicon being a high melting-point material, SiQDs can be advantageously synthesized in non-thermal plasma. However, synthesis in plasma is not the only fabrication route. One aspect in which the synthesis in non-thermal plasma is different from the other methods, be it annealing of Si-rich silicon oxides or electrochemical etching of crystalline silicon, is that it completely bypasses the step of annealing the material to its crystallization temperature. Thus, a question arises as to how the SiQDs synthetized in non-thermal plasma compare to those fabricated by other methods. Here, we will use the spectral tunability of photoluminsecence of SiQDs as a tool to monitor their electronic properties. We will focus mainly on the comparison of SiQDs synthesized in non-thermal plasma with those fabricated by electrochemical etching, because these two fabrication routes represent the completely opposite approaches with regards to the formation of the small crystals: whereas the low-temperature plasma bypasses the crystallization temperature, SiQDs fabricated by electrochemical etching are etched down from perfect bulk crystals. Moreover, we will discuss the possibility of tuning the faceting of the SiQDs produced in plasmatic synthesis and the mechanisms responsible for the thermal stability or instability of these QDs.

Chamber Aluminum Surface Characterization Study for Etching Process Stability Improvement ChengyaChu, Jia LingChen, TakujiSako, Chun ChaoChen and NoriyukiKobayashi; Tokyo Electron Limited, Taiwan

Plasma etching is a critical technique in semiconductor production. The mechanism is using RF power to induce plasma and giving a voltage to form ion bombardment to etch Si/SiO2/SiN material. Traditional plasma etching is anisotropic, only etch in one direction, so it faces a bottleneck for the 3D structure logic transistor/memory fabrication. As a result, TEL has developed an isotropic etching equipment, Certas, which doesn’t have plasma source, only gas-state chemicals. With gas diffusion, we can achieve isotropic etching and energy consuming.
For years study, we found the chemical etching stability differs while using different kinds of recipes. It can be divided into 2 kinds of recipe, depo less and depo rich recipe. The depo less recipe's etching rate (ER) will increase and gradually reach stable and saturated after sufficient seasoning. In contrast, the depo rich recipe's ER will keep decreasing and hard to reach stable even after large amount seasoning. With TEM/XPS/ellipsometer analysis, we try to figure out the possible mechanism. Based on the result, we assume the byproduct from etching process and chemical gas remain on chamber wall, Al surface, and those remained byproduct may outgas and make the chamber condition unstable during the mass production.
Stable production is the basic requirement in foundries. When new tools move into fab or tools keep idle for a while, engineers need to do seasoning to recover the chamber condition. However, it is difficult to define how many seasoning cycles does the tool need and how long the chamber will reach stable. Mostly, we just use off-line dummy wafer to monitor EA in long term and judge chamber stability. It is a very time and resource consuming method, so we are trying to find a better way.
For plasma etching process, optical emission spectroscopy (OES) is used as an end point detector (EPD) to precisely control etching amount to avoid over etching damage. For chemical etching process, we install a small chamber which has plasma source and by which we cna use OES to monitor the in-situ chamber condition. Through analysis the element composition from the chamber exhaust, we can know how many byproducts remain in chamber wall. By corelating the long-term off-line EA data, we think it is possible to monitor the chamber condition change by OES.
In this paper, we have studied the etching mechanism of depo less and depo rich recipe of chemical etching. Also, we have studied the Al surface status difference before and after the seasoning. At last, we collected OES data and found it is strongly corelated wit off-line EA. It seems to be a more efficient and scientific way to achieve stable chamber condition with minimum cost.

WITHDRAWN 11/13/2023 SF04.07 Plasma-Engineered Plasmonic Nanostructures for SERS-Based Detection of SARS-CoV-2 Nucleocapsid Protein and Spike Protein Variants Yi-JuiYeh[1,2], Kuo-LunTung[2] and Wei-HungChiang[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]National Taiwan University, Taiwan

Epidemiological control and public health monitoring during the outbreaks of infectious viral diseases rely on the ability to detect viral pathogens. Here we demonstrate a rapid, sensitive, and selective nanotechnology-enhanced severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) detection based on the surface-enhanced Raman scattering (SERS) responses from the plasma-engineered, variant-specific antibody-functionalized silver microplasma-engineered nanoassemblies (AgMEN) interacting with the SARS-CoV-2 spike (S) and nucleocapsid (N) proteins. The three-dimensional (3D) porous AgMEN with plasmonic-active nanostructures provide a high sensitivity to virus detection via the remarkable SERS signal collection. Moreover, the variant-specific antibody-functionalization on the SERS-active AgMEN enabled the high selectivity of the SARS-CoV-2 S variants, including wild-type, Alpha, Delta, and Omicron, under the simulated human saliva conditions. The exceptional ultrahigh sensitivity of our SERS biosensor was demonstrated via SARS-CoV-2 S and N proteins at the detection limit of 1 fg mL^{-1} and 0.1 pg mL^{-1}, respectively. Our work demonstrates a versatile SERS-based detection platform can be applied for the ultrasensitive detection of virus variants, infectious diseases, and cancer biomarkers.

8:00 PM SF04.07.03
Single-Step Aerosol-Assisted Atmospheric Pressure Plasma Deposition of Hybrid Nanocomposite Thin Films Containing Gold Nanoparticles ElèneBizeray[1], AntoineBelinger[1], SimonDap[1], FiorenzaFanelli[2] and NicolasNaudé[1]; [1]Laplace, Université de Toulouse, CNRS, INPT, UPS, France; [2]National Research Council (CNR), Institute of Nanotechnology (NANOTEC), Italy

Low-temperature atmospheric pressure plasma technologies offer exciting opportunities for the preparation of hybrid nanocomposite (NC) layers consisting of inorganic nanoparticles (NPs) embedded into an organic matrix [1]. To this end, recently, a growing number of studies have explored the combination of atmospheric pressure plasmas with preformed NPs dispersions in

aerosol form. However, this deposition strategy raises various problems, such as the risk associated with NPs handling as well as the severe NPs agglomeration in the NC thin films. Therefore, intense efforts are currently dedicated to optimizing safe-by-design deposition processes in which the nanocomposite constituents are synthesized in a single step in the atmospheric pressure plasma [3].
It is in this context that, as suggested by previous work [3], we propose to combine a parallel-plate dielectric barrier discharge plasma at atmospheric pressure with the aerosol of the solution of a gold salt (tetrachloroauric(III) acid trihydrate, $HAuCl_4 \bullet 3H_2O$) in a polymerizable liquid precursor (isopropanol), to be able to synthesize in a single step nanocomposite layers. This innovative process avoids the handling of nanoparticles since the gold salt reduction to form Au nanoparticles occurs in the plasma along with the growth of the organic matrix [3].
The chemical composition, morphology, and optical properties of the resulting NC thin films have been investigated using various techniques, such as Fourier-transform infrared spectroscopy, X-ray photoelectron spectroscopy, scanning electron microscopy, and UV-visible absorption spectroscopy.
Preliminary results have shown that we can synthesize in a single step a hybrid nanocomposite coating composed of gold nanoparticles embedded in an organic matrix deriving from the plasma polymerization of isopropanol. The influence of different experimental parameters, such as the solution composition and the electrical discharge conditions (applied voltage waveform, excitation frequency, etc.) have been studied. In particular, a dual frequency excitation is used to control the nanocomposite composition and morphology [4]. Indeed, the transport of the nanoparticles to the sample surface is mainly related to the electrostatic forces and therefore requires a low excitation frequency; in contrast, the matrix polymerization and the gold salt reduction need a higher plasma energy and thus a higher frequency.
Overall, these results provide new insights into the possibility of using a single-step aerosol-assisted plasma process to deposit hybrid nanocomposite thin films containing gold nanoparticles and into the ability to finely tune the properties of the layers by varying the process parameters.

A Soft Solution Route of Nano-Alumina Direct Patterning onto the Silicon Substrate in Ambient Condition SumantaSahoo[1], Yu-CyuanHou[2], Sheng-LinHuang[2], KripasindhuSardar[2], SatoruKaneko[3,4], Kao-ShuoChang[2], MamoruYoshimoto[4], MasahitoKurouchi[3] and MasahiroYoshimura[2]; [1]Radhakrishna Institute of Technology and Engineering, India; [2]National Cheng Kung University, Taiwan; [3]KISTEC, Japan; [4]Tokyo Institute of Technology, Japan

Functional oxides of nanostructure always require high-temperature reactions, as well as multi-step batch process technology for their fabrication. However, the proposed novel and unique, soft solution process has proven a state-of-art technology in one-step fabrication of various types, shapes, and sizes of oxides nanostructure[1]. Herewith, alumina nanostructures were micro-patterned directly onto the silicon substrate by this route in a very short period and at ambient conditions. In this process, electrochemically polished ultra-sharp tungsten (W) tips of various tip profiles have been used as a local activation by in-situ plasma emission. A very small amount of (~5 ml) polymerized aluminum-citrate matrix was taken as an electrolyte. The patterning of alumina onto the silicon substrate, hence fabricated by the submerged discharge plasma activation technology. The fabricated patterns were analyzed by scanning electron microscopy, Raman, and X-ray photoelectron spectroscopy.
From these analytical studies, we found that the above technique requires a low amount of process materials, single-step fabrication, operation at ambient conditions, and green process[2]. However, the great challenges are in controlling the submerged discharge plasma condition to achieve high-quality patterning in comparison to the highly sophisticated vacuum technology's fabrication systems.

This study was funded by the National Cheng Kung University 90 and Beyond (NCKU'90) project of grant no. D110-G2309, and in part by Amada Foundation under contract AF-2020227-B3, Tokyo Ohka Foundation for promotion of science and technology, with the collaborative research project of the Institute of Fluid Science, Tohoku University.

8:00 PM SF04.07.05
Effective Preparation of Graphene Nanoflakes via Microwave Plasma Enhanced Chemical Vapor Deposition for Applications in High-Voltage Electric Double Layer Capacitors Jui-YuTung[1], Kun-PingHuang[2] and Meng-JiyWang[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]Industrial Technology Research Institute, Taiwan

Graphene nanoflakes (GNFs), a form of vertical graphene named for its flaky morphology, have attracted attention due to their versatile 3D geometry and large surface area with open pores. It has been reported that GNFs retain the exceptional properties of graphene as an electrode material for energy storage. In addition, the porous framework promotes mechanical stability and flexibility, which is advantageous for the fabrication of lightweight and flexible devices.
Conventionally, the electrode preparation used for energy storage devices involves complicate composition of materials and multiple preparation procedures. The precursors used for electrode generally comprise of three components, namely the binder, dispersion solvent, and active materials. The procedures to prepare electrodes involve a series of steps which include dispersion, coating, and drying. The process of assembling a device is time-consuming.
For the preparation of GNFs, recent report has disclosed a method to directly synthesize GNFs on a substrate through plasma-enhanced chemical vapor deposition (PECVD), utilizing diverse power sources including microwave (MW), radio frequency, and direct current plasma. Typically, a blend of hydrocarbon compounds (CH_4 and C_2H_2) along with either H_2 or Ar gases are employed as the primary input materials for the purpose of synthesizing GNFs directly onto the substrate, without the utilization of any catalyst. High-density plasmas are useful to produce hydrocarbon radicals, such as CH_3 radicals that can facilitate deposition effectively for preparation of thin film with large surface area. With promising and stable PECVD process, the deposition of GNFs provides potential for scaling-up system. This research focuses on the preparation of GNFs utilizing microwave plasma enhanced-chemical vapor deposition (MPE-CVD) directly on Ti substrate to prepare binder-free electrode. For the preparation of electric double layer capacitors (EDLCs), the effects MPE-CVD parameters including gas composition, pressure, deposition duration, and applied power were studied and optimized.
In this study, MPE-CVD is composed of a microwave power supply with a frequency of 2.54 GHz, where the working gases Ar and CH_4 were excited in a quartz tube with a diameter of 2.5 cm and a length of 40 cm. Titanium with a thickness of 100 μm was used as the substrate for GNFs deposition due to its high thermal stability. Throughout the deposition procedure, the Ti current collector was positioned in the center of the plasma ignition section and perpendicular to the gas flow in order to obtain uniformly distributed GNFs. In the reaction chamber, the ratio of CH_4 to Ar varied from 40 to 80%, with a total gas flow rate of 40 sccm. The as-prepared GNFs/Ti electrodes can be used as the positive and negative electrodes that require no additional treatment. The performance of symmetric EDLCs assembled using the as-prepared GNFs/Ti electrodes was evaluated in a pouch cell by cyclic voltammetry and galvanostatic charge/discharge measurements where the cycling ability was conducted for 10,000 cycles.
In this study, microwave plasma drives the vertical development of GNFs effectively on Ti substrate. A growth rate of GNFs, 180 μm/h, is 15 times greater than the maximum value reported in the literature (11.40 $\mu m/h^1$). Furthermore, after 10,000 charge-discharge cycles, the Coulombic efficiency was 99.4% and the capacitance retention was 75%. In conclusion, the MPE-CVD system applied in this work facilitate the preparation of GNFs/Ti electrodes that is advantageous as an effective process compared to the conventional method with a significant rapid deposition rate.

Hydrogen-Assisted Sputtering Process for Enhanced Mechanical Stability of Oxide Thin Films in Flexible Electronics SeohanKim[1] and JoonhoBang[2,2]; [1]Uppsana University, Sweden; [2]Gyeongsang National University, Korea (the Republic of)

Transparent oxide semiconductors have gained widespread use in electronic devices such as flat panel displays and solar cells. The increasing demand for flexible devices necessitates ensuring the long-term stability of oxide semiconductor thin films under bending stress. Recent theoretical and experimental studies have identified hydrogen species as significant impurities in many oxide semiconductor thin films. In this study, we present a novel approach to fabricating the hydrogen-incorporated amorphous In-Zn-O and In-Sn-O thin films using a hydrogen-assisted magnetron sputtering process. Through careful optimization of the hydrogen concentration, we achieved remarkable improvements in the mechanical stability of the thin films while simultaneously preserving their electrical and optical properties. Notably, the introduction of hydrogen resulted in a gradual reduction in the compressive residual stress of the films,

highlighting its potential as a promising candidate for defect passivation in flexible electronics. These findings provide insights into enhancing the durability of oxide-based flexible electronic devices.

Selective Extraction of Hydrogen Molecules from Plasma using a Metal-Organic Framework Filter KyotaroTakagi, MoriyukiKanno, HitoshiMuneoka, KazuoTerashima and TsuyohitoIto; The University of Tokyo, Japan

Non-equilibrium plasma can promote various reactions through the contributions of energetic/reactive species, such as electrons, ions, radicals, and photons, while avoiding the environmental temperature elevation. Although synergetic effects of such species are making most of plasma applications attractive, in some cases, the existence of an excessively diverse species prevent us from achieving desired controllability. As for the charged particles, there are several techniques for selectively extracting certain reactive species, mostly using electromagnetic field. However, it is still difficult to selectively extract reactive neutral species.
One approach for separating neutral species from a gas mixture is by using sieves with microstructures [1] and metal-organic frameworks (MOFs) are attracting candidates for such sieves [2]. MOFs are porous materials composed of metal ions and organic ligands. By choosing the types of metal ions and ligands, it is possible to control pore structures, pore sizes, surface properties, morphology, and so on.
Here, we are demonstrating H_2 extraction from low-temperature Ar/C_3H_8 plasma by using zeolitic imidazolate framework-8 (ZIF-8) as a filter located in the plasma region. Quadrupole mass spectrometer was applied to analyze the atoms/molecules behind the ZIF-8 filter. By comparing with the no-filter case, it is indicated that ZIF-8 can selectively extract H_2 by impeding C_3H_8 transfer, although it is not yet perfect. We have also confirmed that the ZIF-8 filters were not significantly damaged in the tested conditions. Further details will be presented at the symposium.

8:00 PM SF04.07.08
Enhanced Electrocatalytic Activities of the Nitrogen-Doped Onion-Like Carbons Synthesized by Plasma Discharge Process in Solution SangYulLee[1] and Jung-WanKim[2]; [1]Korea Aerospace University, Korea (the Republic of); [2]InCheon National University, Korea (the Republic of)

A plasma discharge process, so called solution plasma process, was used to synthesize nitrogen-functionalized onion-like carbon (N-OLC) at various ammonia concentrations and the N-OLC was used as a catalyst support material for a catalytic oxygen reduction reaction (ORR) evaluation. With increasing ammonia concentrations up to 5 M, the amount of the nitrogen doping increased up to 1.7 at.%, which created a highly defective onion-like structure. The edge and defective sites induced from nitrogen atoms effectively provided with the nucleation sites for Pt clusters, which led to the stable dispersion and size-reduction of Pt nanoparticles (PtNPs), as revealed via XPS, XRD, Raman spectroscopy and electron microscopy. From the results of the electrochemical characterization, the PtNPs supported on the N-OLC with a nitrogen content of 1.7 at.% exhibited the highest electrochemically active surface area (ECSA), specific current density and half-wave potential. The enhanced (ORR) could be attributed to the defective outermost layers and the electronic modification. Moreover, even after an accelerated durability test (ADT) with 5,000 cycles, the N-OLC with a nitrogen of 1.7 at.% exhibited less degradation, indicating the excellent ORR durability. Experimental details will be presented.

8:00 PM SF04.07.09
Plasma Etched Vertically Aligned Carbon Nanotube Embedded Polyurethane Surface for Precision Semiconductor Wafer Polishing SukkyungKang[1], Ji-hunJeong[2], Hyun JunRyu[1], DongyeonWon[1] and SanhaKim[1]; [1]Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]Department of Mechanical Engineering, Massachusetts Institute of Technology (MIT), United States

Surface polishing and planarization process plays a significant role in achieving desired surface characteristics and ensuring product quality. The process is widely used in precision manufacturing industries including semiconductors, biosensors, displays, and battery packaging, and the requirements for precision polishing is ever increasing toward atomic scale. For productivity and quality, selection and optimization of the polishing pad and abrasive are essential, and realizing a precise surface topology for the polishing pads via advanced materials and plasma treatment can be an effective route for enhancing the efficiency and accuracy of the atomic scale polishing process.
In this study, we propose a novel composite abrasive pad comprising 1D nanoscale fibers embedded in a soft matrix material realized by plasma treatment during fabrication. Here, we synthesize vertically aligned carbon nanotubes (VACNTs) and utilize them as a mechanical abrasive for precision polishing. Different from other conventional precision polishing methods, where the nanoscale abrasives are dispersed in a solution and supplied separately to the polishing pad surfaces, we conceptualized a new composite pad using 1D nano abrasives embedded on the surface. Individual carbon nanotubes exhibit high hardness and have a diameter of less than 10 nanometers which is suitable for abrasion. And their high aspect ratio controlled to be up to 10,000 allows them to be firmly fixed onto the soft matrix material. For the realization of the VACNT-embedded polyurethane pad, the key fabrication step is the selective plasma etching of polyurethane using argon plasma to expose a portion of the VACNTs, thereby creating a fixed-abrasive pad structure. making it suitable for nano-scale composite surface processing. We investigate the selective etching behavior of VACNTs and polyurethane, by adjusting parameters such as power, gas flow rate, and etching time. We then further explore the optimum plasma condition which ensures the VACNTs maintain the vertical alignment without clumping. The plasma step also allows us to form nano-porous structures on the surface of the plasma-etched polyurethane polishing pads. These structures facilitate the circulation of the deionized water used in the polishing process and the storage and discharge of polishing residues, ensuring a defect-free process. By finely tuning the Ar plasma time, we control the size of the nano-porous surface structures and the RMS profile of the pad surface. Based on appropriate plasma treatment, the pad structure exhibits robust VACNT films impregnated with polyurethane, yielding a uniform distribution of the high-aspect-ratio VACNTs. Finally, polishing performance tests are conducted using a pin-on-disk setup on various wafers to correlate the relationship between the plasma-treated pad surface structure and its polishing performance. Our findings reveal that pads with a larger RMS profile removed material at a higher rate, but also decreased the polishing precision, resulting in a rougher surface on the copper wafers. However, by finely tuning the nano-structures on the pad surface via plasma treatment, we were able to strike a balance between the desired polishing precision and speed, and therefore achieve an overall enhancement.

8:00 PM SF04.07.10
What Impact Does Radio Frequency Power Have on the Growth Process and Optical Properties of Silicon Nitride Thin Films Made by RF Sputtering at Room Temperature?Edwin SebastianBarrera-Mendivelso and ArturoRodriguez-Gomez; Universidad Nacional Autonoma de Mexico, Mexico

Silicon nitride (SiN_X) is widely known for its exceptional hardness, making it a highly sought-after ceramic material. Its remarkable electrical and optical properties make it an excellent candidate for integration into microelectronics and photonics applications. Conventionally, SiN_X thin films are obtained through chemical vapor deposition (CVD) techniques, which necessitate high temperatures, thereby limiting the range of compatible substrates [1]. Despite ongoing efforts to optimize CVD processes and lower the required temperatures, their inherent high temperatures still pose challenges, particularly when working with temperature-sensitive materials [2].

In contrast, sputtering techniques offer a host of advantages over CVD techniques, including the ability to deposit SiN_X thin films at low temperatures without introducing hydrogen contamination [3]. However, achieving SiN_X thin films with desirable properties at room temperature remains a complicated task. Various parameters such as pressure, gas flow, bias voltage, and electrical power have been extensively investigated to comprehend their influence on the optical, electrical, and mechanical characteristics of SiN_X thin films [4]. Surprisingly, the impact of radiofrequency power (RF-P) on the structural and microstructural properties of these films, using a Si_3N_4 target at room temperature and in the absence of chemically active gases, has received limited attention.

This research delved into exploring the effects of RF-P on the growth of SiN_X thin films through non-reactive magnetron sputtering conducted at room temperature. Our findings revealed that when applying RF-P $\leq$ 50 W and limiting the deposition time to $\leq$ 120 minutes, the films exhibited polycrystalline silicon nitride particles in their α phase. By increasing either of these parameters, the formation of polycrystalline conglomerates of α-Si_3N_4 was facilitated, leading to improved film continuity and surface uniformity. Additionally, we observed a noteworthy increase in optical absorbance and a shift of the absorption edge toward the near-infrared (NIR) region when RF-P $\geq$ 50 W. Based on our results, we conclude that it is indeed feasible to grow thin SiN_X films at room temperature using our self-designed magnetron sputtering. These films demonstrate promising properties suitable for applications in electronic and optoelectronic devices.

Nonequilibrium Plasma Aerotaxy of $In_xGa_{1-x}N$ Nanocrystals DillonP. Moher and ElijahThimsen; Washington University in St. Louis, United States

Semiconductors that have high chemical resistance and photostability, tunable absorption/emission properties, and low toxicity are in high demand for solar energy conversion and solid-state light sources. The solid solution of indium nitride and gallium nitride ($In_xGa_{1-x}N$) is a promising material for such applications. The composition-dependent band gap of $In_xGa_{1-x}N$ may allow for tuning of the optical properties to efficiently harvest solar irradiance or achieve light emission across the visible/near infrared range. In reality, there are synthetic challenges associated with homogeneous thin film $In_xGa_{1-x}N$. The miscibility gap and strain-induced threading dislocations in $In_xGa_{1-x}N$ with intermediate *x* have largely prevented realization of full spectral tunability. Freestanding, spherical $In_xGa_{1-x}N$ nanocrystals stand to exhibit superior tunability by taking advantage effects at the nanoscale. Strain relaxation and size purification effects may aid in dislocation-free nanocrystal growth. Deviation from the bulk phase diagram at nanoscale particle size may stabilize nanoparticles with overall composition in the bulk miscibility gap, due to the cost of additional surface energy associated with phase segregation. Besides, freestanding nanocrystals are highly flexible for use in various applications. Yet, $In_xGa_{1-x}N$ nanocrystal synthesis is underexplored. In this presentation, the synthesis of $In_xGa_{1-x}N$ nanocrystals by Nonequilibrium Plasma Aerotaxy will be discussed. By feeding aerosols of indium and gallium metal, generated by thermal evaporation, into a nitrogen-argon low pressure, RF plasma, nanoparticles of pure gallium nitride, pure indium nitride, and their solid solution were produced. The composition of the solid solution was tuned by adjusting the molar feed rate of the metal aerosols. Progress towards achieving monodisperse, photoluminescent $In_xGa_{1-x}N$ nanocrystals with $x = 0.5$ will be presented.

Directional Thermal Conductivity Enhancement in Plasma-Surface-Modified hBN and Polyrotaxane Composites by Electric Field RuiHasegawa[1,2], KenichiInoue[1,2,3], HitoshiMuneoka[1], TsuyohitoIto[1], KazuhiroKirihara[2], TakashiAoyama[2], YoshikiShimizu[2], YukiyaHakuta[2], KohzoIto[1] and KazuoTerashima[1,2]; [1]The University of Tokyo, Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan; [3]Nagoya University, Japan

Recently, flexible materials with high thermal conductivity have been extensively studied, e.g. for applying to flexible devices. We have developed hexagonal boron nitride particles (hBN)/polyrotaxane[1] (PR) tough composite, which is a highly thermally conductive flexible insulator, by applying plasma-surface modification of hBN resulting in their higher dispersibility in the composite and enhancing toughness via using PR as a slide-ring material[2]. hBN is known to have anisotropic thermal conductivity, as in-plane direction shows about 20 times higher conductivity than out-of-plane direction. Therefore, thermal conductivity of such composites can be increased in one direction, if in-plane directions of hBN are oriented parallelly. Such demonstration has been achieved with hBN/polysiloxane composites, by applying electric field[3]. Electric field can not only orient hBN, but also form pillar-like structures of the oriented hBN, which could further increase the directional thermal conductivity. The purpose of this study is to synthesize tough composite sheets with high thermal conductivity in out-of-plane direction, by combining above-mentioned two approaches: (i) composites of plasma-surface-modified hBN and PR, and (ii) applying electric field for increasing thermal conductivity in the applied filed direction.
hBN with various sizes (0.2-23 µm) were pre-treated via plasma in liquid and the mixture, including hBN and PR, were exposed to an electric field during the polymerization. The results show that the thermal conductivity in the field direction is enhanced comparing with the case applying no electric field. It was also confirmed that blending different-sized hBN can improve the thermal conductivity by keeping same hBN content in the composites. For example, the higher thermal conductivity is achieved with 0.2-µm (10%) and 7-µm (90%) hBN, comparing with that with 100% 7-µm hBN. We attribute this improvement to stronger heat pass formation by smaller hBN bridging larger hBN in pillar-like structures.
The synthesized electric-field-applied composites show anisotropic properties in the thermal conductivity as well as their Young's modulus. Such composites show higher thermal conductivity in the electric field direction (out-of-plane direction of composite sheets) and lower Young's modulus in the direction perpendicular to the field (in-plane direction of composite sheets), comparing with those of composites without electric field application. These directional changes of properties are sometimes ideal for a thermal-conductive flexible materials. By optimizing the conditions, a flexible composite with elastomer-class flexibility (Young's modulus, perpendicular to the field direction: 58 MPa) and metal-class thermal conductivity (parallel to the field direction: 11 W/mK) has been achieved so far.
Further details, including hBN contents dependence and their blending-ratio dependence, will be presented at the symposium.

Sheraton, Second Floor, Independence East

8:30 AM *SF04.08.01
Nanocrystals by Atmospheric Pressure Microplasmas Oxide, Defects and Doping DavideMariotti; Ulster University, United Kingdom

Doping, defect engineering, quantum confinement and extending to clusters, ternary or high entropy oxides can create disruptive materials with new or improved properties. Atmospheric pressure microplasmas represent a viable synthesis platform to achieve exceptional tuning capability therefore achieving an exquisite control of the size, composition and defects of metal oxide nanoparticles. Microplasmas offer dial-up delivery of precursor radicals together with tunable temperature conditions for nanoparticle formation, followed by rapid quenching. These microplasma conditions can lead to unprecedented crystal structures that can be constructed in a bottom-up approach. In this contribution we will show how quantum confinement and extensive defects in metal oxide nanoparticles can produce very desirable opto-electronic properties. Therefore we will discuss the formation of metal oxides nanoparticles with gas-phase microplasmas as well as hybrid plasma-liquid systems. The pros and cons of these microplasma synthesis approaches will be revealed and opportunities explored also in terms of manufacturing scalability and process integration. We will further provide in-depth analysis of the metal oxide nanoparticles, including their application opportunities in energy conversion and storage. Examples will include oxides from Ni, Cu, Mn, Sn, Co, Mo and Zn. Finally we will provide future directions at the boundaries between ordered and disordered crystal structures.

9:00 AM SF04.08.02
Quantitative Analysis of Reactive Sites on Hexagonal Boron Nitride Treated by Plasma in Solution KenichiInoue[1,2,3], NaotoTakagi[1], TsuyohitoIto[1], YoshikiShimizu[3], KenjiIshikawa[2], MasaruHori[2] and KazuoTerashima[1,3]; [1]The University of Tokyo, Japan; [2]Nagoya University, Japan; [3]National Institute of Advanced Industrial Science and Technology, Japan

Hexagonal boron nitride (h-BN) is a superior material representing high thermal conductivity and electrical insulation, and h-BN/polymer composite materials have been developed for heat release sheets in electronic devices. In fabricating the composites, low reactivity of h-BN is a problem for surface functionalization and causes poor dispersibility in the polymer matrix [1]. Previously, we suggested the plasma processing is one of effective methods for surface modification of h-BN, because the excited species could break the stable B–N bonds and produce reactive sites on the surfaces [2]. The reactive sites, which are dangling bonds on h-BN, allow to functionalize with hydroxyl (OH) groups. Thus, the OH groups formed by plasma modification and subsequent oxidization leads to higher dispersion of h-BN in aqueous media and polymer matrix owing to increase of zeta potential [1,2]. The formed dangling bonds by plasma processing can be detected using electron spin resonance (ESR) measurements [2]. However, quantification of the dangling bonds and the functionalization kinetics have not been fully clarified. In this study, plasma processing in solution was performed on h-BN particles and gradual functionalization to the dangling bonds under an atmospheric environment was analyzed. We have quantified the dangling-bonds formation by plasma processing and revealed their time-variation due to the functionalization during exposure to air.
The plasma processing in solution was performed on h-BN particles (Maruka, AP-170S) as described in the previous paper [1]. The plasma was generated by a bipolar pulsed power supply

(Kurita Seisakujo, MPP-HV-04-300 kHz) in 1 L of distilled water containing 5 g of h-BN particles, using a stirring device (Nihon Spindle, Jetpaster). The applied pulsed voltage for plasma generation had a frequency of 300 kHz, a peak voltage of ±1 kV, and a pulse width of approximately 1 μs. The plasma-treated h-BN for 20 min was captured using a membrane filter and dried under vacuum. After the processing, the sample was exposed in an atmospheric environment at room temperature for up to 650 days. After the different exposure days, the samples were analyzed using an ESR spectrometer (Bruker, EMX-plus). Spin concentration in the h-BN were measured by calibration using aqueous solution containing 4-hydroxyl-2,2,6,6-tetramethylpiperidine (TEMPOL) as a stable radical standard. Surface number densities of dangling bonds were calculated with normalization of the spin concentration by the specific surface area, that was measured by using a surface area analyzer (Micrometrics, VacPrep061). A Fourier transform infrared (FT-IR) spectrometer (PerkinElmer, Spectrum100) was applied to analysis of OH groups on h-BN during air exposure days after plasma processing.
The surface number density of the dangling bonds on the plasma-treated h-BN was estimated to be 800 μm^{-2} at the 3-days exposure to air after the plasma processing, while that of the untreated h-BN was only 20 μm^{-2}. During exposure of the plasma-treated h-BN to air for up to 650 days, the surface number density decreased and reached to an equilibrium value of approximately 100 μm^{-2}. Besides FT-IR spectra showed increase of the B-OH peaks during exposure of the plasma-treated h-BN to air. Consequently, the dangling bonds on h-BN as reactive sites have an important role for OH functionalization on the h-BN surfaces and their quantitative analysis could enable the development of more effective surface modification by plasma processing to improve hydrophilicity and dispersibility of the materials.

9:15 AM SF04.08.03
Unlocking the Limits of the Plasma-Activated Liquids and Plasma Synthesis of Silicon Nanoparticles FilipMatejka[1,2], JakubKopenec[1,2], PavelGalar[1], TomasPopelar[1] and KaterinaKusova[1]; [1]Czech Academy of Sciences, Czechia; [2]University of Chemistry and Technology, Czechia

In the past years, the topic of nanoparticles of a broad variety of materials, mainly semiconductors, led to significant advances in science and technology. To make these materials more applicable, the search for variable methods of synthesis and surface modification is ongoing. Two groups of nanoparticles are of special interest. The first group are the sub-10-nm particles, which in case of several materials, e.g., silicon nanocrystals (SiNCs), exhibit efficient light generation (photoluminescence – PL). The properties of the generated light can be set up and modulated by the proper surface modification. The second group is represented by the particles with sizes around 100 nm, which can be employed in the production of batteries. Importantly, these larger particles with also benefit from surface modification, which will lead to better dispersibility in various liquids and thus simplify the fabrication of the battery anodes. In this study, we demonstrate that non-thermal plasma (NTP) is a powerful environment for both the synthesis of size-tunable SiNCs and the surface chemistry modification, considering its speed, simplicity and high reactivity. We overcome the limits of the NTP systems, showing the applicability of the NTP systems to synthesize the light emitting SiNCs, as well as the large ca. 80 nm SiNCs, and to provide a novel method of generating highly reactive liquid environment suitable for the SiNCs' surface chemistry modification.

The main complications with respect to the potential of synthetizing larger nanoparticles in the NTP low pressure synthesis of SiNCs are the charging of the surface and the depletion of the precursor. We solved this issue by employing a two-stage process. In the first stage, the crystalline sub-10-nm core is formed with the use of planar electrodes. In the second stage, the long plasma beam, generated by helix electrodes, with additional silane gas, are utilized to synthetize SiNCs ca. 80-nm in diameter. In combination with high yields and the speed of the NTP method, we achieve a broadly variable synthetic system. We can provide crystalline sub-10-nm cores, whose effective PL is tunable by the size from 700 nm to 950 nm, as well as the large particles.

Surface chemistry is another key factor for the properties of silicon nanoparticles. Recently, we have shown that with the proper settings of the NTP system using two needle electrodes (one submerged) and generating the transient spark discharge, the high in nitrogen species plasma-activated water (HiN:PAW) can be produced.[1] This HiN:PAW is suitable for the nitrogen enrichment of the SiNCs' surface, leading to enhancement and shifting of the PL, as well as improvement of dispersibility in water.[2] However, the generalization of this system to other liquids, i.e. the NTP activation of different organic liquids (PAOL) is not yet well-established, due to several drawbacks of these liquids, e.g., volatility or flammability. Here, we present a successful PAOL system, which solves the problematic behavior of organic liquid, mainly with the use of a novel designed reactor box. This system was applied on five different organic liquids with diverse structural (e.g., aromatic structure, aliphatic chains) and physical (e.g., polarity of molecule) properties, leading to a successful change of surface chemistry, accompanied by the tunability of the PL properties (position and intensity) and an improvement of dispersibility in different media. Therefore, with the use of the NTP activation of liquids, we achieved a novel adjustable system, which generates reactive environment suitable for tailoring of the SiNCs' surface chemistry, leading to broad applicability of light emitting SiNCs in a plethora of environments (e.g., water, polar, non-polar).

Plasma-Induced Modification of 2D Materials: The Case of Monolayer Graphene LucStafford; University of Montreal, Canada

Engineering of defects located in-grain or at grain boundary is central to the development of functional materials and nanomaterials. While there is a recent surge of interest in the formation, migration, and annihilation of defects during ion and plasma irradiation of bulk (3D) materials, the detailed behavior in low-dimensional materials remains most unexplored and especially difficult to assess experimentally. A new hyperspectral Raman imaging scheme providing high selectivity and diffraction-limited spatial resolution was recently adapted to examine plasma-induced damage in a polycrystalline graphene film grown by chemical vapor deposition on copper substrates and then transferred on silicon substrates. For experiments realized in nominally pure argon plasmas at low pressure, spatially resolved Raman conducted before and after each plasma treatment shows that the defect generation in graphene films exposed to very low-energy (11 eV) ion bombardment follows a 0D defect curve, while the domain boundaries tend to develop as 1D defects. Surprisingly, damage generation at grain boundaries is slower than within the grains; this behavior can be ascribed to a lattice reconstruction mechanism occurring preferentially at domain boundaries and induced by preferential carbon atom migration and carbon adatom-vacancy recombination. Based on exhaustive plasma characterization using Langmuir probes and optical emission and absorption spectroscopy, further studies were realized to compare the impact of different plasma environments promoting either positive argon ions, metastable argon species, or VUV-photons on the damage formation dynamics. While most of the defect formation is due to knock-on collisions by 11-eV argon ions through a mechanism that remains to be confirmed, the combination with VUV-photon or metastable atom irradiation is found to have a very different impact. In the former, the photons are mainly thought to clean the films from PMMA residues due to graphene transfer from copper to silicon substrates. On the other hand, the surface de-excitation of metastable species first impedes the defect generation and then promotes it for higher lattice disorder. While this impediment can be linked to an enhanced defect migration and self-healing at nanocrystallite boundaries in graphene, such effect vanishes in more heavily-damaged films.

This set of plasma-graphene experiments reveal that carbon adatom migration is essential for defect annihilation; however, the healing dynamics in such conditions remain unclear. Very recently, a new setup was specifically designed to examine plasma-surface interactions and to shed light on the defect recombination dynamics. Here, in-plasma Raman spectrometry is used to monitor the evolution of selected Raman peaks over nine points of the graphene surface. On one hand, for high-energy ions, defect generation progressively rises with the ion dose, with no significant variations after ion irradiation. On the other hand, for very-low-energy ions, defect generation increases at a lower rate and then decreases over a very long time scale after ion irradiation. Such self-healing dynamics cannot be explained by a simple carbon adatom-vacancy annihilation. Using a 0D model, it is demonstrated that that various mechanisms are in play, including carbon adatom trapping by Stone-Wales defects and dimerization. These mechanisms compete with the self-healing of graphene at room temperature, and they slow down the healing process. Such features are not observed at higher energies for which carbon atoms are sputtered from the graphene surface, with no significant populations of carbon adatoms. We believe that these experiments can be used as building blocks to examine the formation of chemically doped graphene film in reactive plasmas using, for example, argon mixed with either traces of N- or B-bearing gases.

Plasma-Based Oleic Acid Nanofilms on n-Al with Higher Energetic Performance than n-Al/Graphene Oxide Mechanical Mixtures PrawalP. Agarwal, RobertM. Rioux and ThemisMatsoukas; The Pennsylvania State University, United States

The energetic performance of nano-aluminum (n-Al) is inhibited by the presence of an oxide shell, which acts as a diffusion barrier and delays the contact of oxidizer and metal. In the last few years, graphene oxide (GO) has attracted attention as an additive to energetic material formulations. It has been reported in the literature (Zheng et al., ACS Nano, 2018, **12**, 11, 11366–11375) that GO added in a mechanical mixture (MM) with Al improves the ignition and combustion behavior of the solid fuel. In this work, we deposit thin films of organic-based materials onto n-Al and demonstrate superior energetic performance compared to Al/GO MM. We use oleic acid (OA) as a precursor for plasma-enhanced chemical vapor deposition (PECVD) of ultrathin films (2-10 nm) and study the oxidation behavior of the coated n-Al by thermal analysis (TGA/DSC). We find that the heat measured by DSC is a function of thickness and that the maximum amount of oxidative heat release corresponds to a 4 nm film. The nanofilms deposited by OA plasma are compared with n-Al/GO MM (different weight proportions) in terms of oxidation and heat release by thermal analysis (TGA/DSC). The energy enhancement in OA plasma-coated n-Al (39%) is higher than in n-Al/GO mixtures (25%) compared to n-Al (control). The chemistry and mechanism behind the enhancement in oxidative heat release are investigated by characterizing the materials. The presence of the coatings and their composition are characterized by high-resolution transmission electron microscopy (HRTEM), high-angle annular dark-field - scanning transmission electron microscopy - energy dispersive spectroscopy (HAADF-STEM-EDS), and X-ray photoelectron spectroscopy (XPS) of OA plasma films and GO demonstrated the presence of similar chemical functional groups in them. In addition to the higher heat release, the plasma films provide passivation against air and humidity, as demonstrated by accelerated aging tests at extreme temperature and humidity conditions. The nanofilms developed from PECVD can provide a cost-effective way to achieve functionality better than GO with longer storage stability and can be used in various nanoenergetic applications such as propulsion, energy storage, and space exploration.

Tailoring Magnesium Nanoparticles In-Flight via Non-Thermal Plasma for Enhanced Ignition BrandonA. Wagner, PankajGhildiyal, MahbubChowdhury, MinseokKim, MichaelR. Zachariah and LorenzoMangolini; University of California, Riverside, United States

Nano-sized energetic materials allow for better combustion performance compared to micron-sized materials. A significant drawback to using nano-scaled materials for combustion is their propensity for agglomeration and sintering upon ignition. [1] Magnesium (Mg) is a desirable fuel for energetics because of its high reactivity and high energy density. [2] However, the boiling point of its native oxide layer is greater than Mg, forcing ignition to proceed through a diffusion-limited process. [3] Directly coating Mg with an oxygen-containing silicon-based shell produces a nano-thermite system on the nanoparticle interface, accelerating reaction kinetics during ignition. [4] Hydrogenating Mg results in an ignition system that releases hydrogen (H_2) gas to alleviate sintering and agglomeration issues during combustion. Our work involves the in-flight modification of magnesium nanoparticles (NPs) by a low-temperature plasma process to circumvent oxide layer formation and boost ignition performance.

A two-step experimental setup was designed to nucleate Mg NPs by gas-condensation and to coat the surface via a silane plasma. Alternatively, hydrogen treatment was carried out by a hydrogen plasma. Ex-situ characterization of nanoparticle crystallinity, morphology, and chemical composition was accomplished by x-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), and energy-dispersive x-ray spectroscopy (EDS). For hydrogenated Mg (h-Mg) temperature-programmed desorption (TPD) and optical emission spectroscopy (OES) were also performed. Processing parameters were manipulated to incorporate more magnesium hydride (MgH_2) into the NPs.

For silicon-coated Mg (Mg/Si-SiO_x) NPs, combustion performance was tested against Mg NPs with bismuth oxide as a primary oxidizer for overall combustion. Ignition temperature, ignition time, and combustion products were characterized via temperature-jump time-of-flight mass spectrometry (Tjump-TOFMS), wherein a platinum wire was coated with sample and heated until ignition. Our findings suggest that the reaction onset of coated magnesium is faster due to the close proximity of the fuel and oxidizer during ignition. In addition, the ignition threshold and reaction timescale decreased in the coated samples compared to non-coated magnesium. For h-Mg NPs, combustion performance was analyzed by Tjump-TOFMS using different oxidizers to investigate the reaction mechanisms that affect ignition temperature and reaction kinetics during combustion. Our findings indicate that the hydrogen content can be tuned by adjusting the RF power of the plasma. Additionally, h-Mg combustion with a potassium perchlorate oxidizer lowers the ignition threshold.

Overall, these results confirm that non-thermal plasma processing is a powerful and versatile approach for the modification of nanoparticles, with particularly interesting application for the case of energetic nanomaterials.

High Entropy Materials Enabled by Microwave-Induced Plasma ShaneA. Catledge, BriaC. Storr, LukeMoore and Cheng-ChienChen; University of Alabama-Birmingham, United States

High Entropy Alloys (HEAs) and ceramics typically consist of five or more principal components that form a solid solution structure, instead of complex phases (e.g., intermetallics), and are stabilized by their high configurational entropy of mixing. We recently demonstrated a unique approach to synthesis of high entropy materials, including HEAs, enabled by microwave (MW)-induced plasma. This approach goes beyond conventional slow radiative heating by combining rapid MW energy absorption with enhanced chemical kinetics afforded by a plasma discharge. Conventional HEA formation relies on melting or long durations of intense mechanical agitation/alloying, often followed by subsequent heating/sintering steps to finally convert the mixture into a HEA solid solution. Our approach, facilitated by density functional theory calculations of entropy forming ability descriptors, involves thermal reduction of a five-component transition metal oxide powder mixture in a plasma reducing environment performed efficiently as a single step. Hardness and oxidation resistance measurements of the plasma-synthesized high entropy materials reveal substantial improvement over their non-HE counterparts. Current work is aimed at investigating reaction kinetics/pathways for HE materials made using this approach. Through the unique combination of plasma reduction of metal oxide precursors with the benefits of rapid MW heating/cooling, we anticipate highly efficient synthesis and fine microstructural control of HE alloy and ceramic systems.

11:15 AM SF04.09.04
Cluster Epitaxy of Iron Selenide Thin Films by Pulsed Laser Plasma Deposition NiteshR. Palagiri[1], DorienCarpenter[1], KamronStrickland[1], SumnerB. Harris[2], DavidB. Geohegan[2] and RenatoP. Camata[1]; [1]University of Alabama-Birmingham, United States; [2]Oak Ridge National Laboratory, United States

Pulsed laser deposition (PLD) is a well-established technique for epitaxial growth of a wide variety of thin film materials. In traditional epitaxy—typically carried out in high vacuum—the growth process involves the deposition of individual atoms or molecules onto a substrate, leading to the formation of a crystal lattice with a regular arrangement of atoms. For a given target material, tuning the laser irradiation conditions and the parameters of the PLD plasma, enables control of the kinetic energy and flux of depositing particles. This allows optimization of thin film characteristics, including reduction of the number density of point and extended defects. Further manipulation of the PLD plasma can be achieved using reactive or inert background gases. Collisions of the expanding plasma plume with background atoms, for example, slow and confine the expansion. This results in significantly altered gas dynamics and reduced kinetic energy of depositing species. The ensuing film micro- and nanostructure are often substantially different than achieved through vacuum deposition.

In this work we study the pulsed laser growth of thin films of the unconventional superconductor iron selenide (FeSe), using a plasma plume that is thermalized by an argon (Ar) background. The focused beam of a KrF excimer laser (248-nm wavelength, 25-ns pulse width) was used to ablate a rotating target synthesized from metal powder elemental precursors with nominal stoichiometry $Fe_{1.03}Se$. This chemical makeup is within the narrow stability range of the β-FeSe phase needed to achieve superconductivity in this system at low temperature. The laser spot size on the target was controlled using rectangular apertures placed in the beam path between the laser output window and the focusing lens. Films were grown on (100)-oriented MgO substrates in the 10-300 mTorr Ar background pressure range. A laser fluence of 1.0 J/cm^2 and a spot area of 6.4 mm^2 were used. The resulting films were analyzed using X-ray diffraction

(XRD), X-ray reflectivity (XRR), and atomic force microscopy (AFM). The luminous portion of the plasma plume was recorded with a time-resolved gated-intensified CCD (ICCD) camera. Symmetric θ-2θ XRD patterns indicate epitaxial growth of β-FeSe on MgO, with the c-axis of the tetragonal structure oriented normal to the substrate. Furthermore, XRD Φ-scans reveal four-fold symmetry of the (103) β-FeSe reflection, establishing that the c-axis oriented film also features in-plane epitaxy. AFM measurements show film surfaces with nanoporous structure exhibiting voids in the 10-25 nm range. This film nanostructure, allied to the in-plane and out-of-plane crystal alignment is consistent with growth by cluster epitaxy, in which the film building blocks are pre-formed clusters rather than individual atoms or molecules. These clusters may consist of hundreds to thousands of atoms bound together, likely as a result of plume thermalization, before arrival on the substrates. Films deposited in equivalent conditions, but under vacuum, show—via XRR measurements—significantly lower overall thickness due to the absence of voids. X-ray reflectivity data from nanoporous films exhibit additional fringes that can be ascribed to extra multiple internal reflections on the nanostructured layer. We discuss the effect of the inert background pressure on the film nanoporosity and correlate it to the plume dynamics expansion visualized in the ICCD data. We also show how the transport properties of porous films compare to non-porous β-FeSe grown in vacuum.

Kinetic Spray Deposition of Ceramics Enhanced by a Non-Equilibrium Mesoplasma Jet KentaroShinoda, MohammedShahien and MasatoSuzuki; National Institute of Advanced Industrial Science and Technology (AIST), Japan

Kinetic spraying of brittle materials such as ceramics is of interest as it can deposit ceramic materials at low temperature. Cold spraying of ceramics and aerosol deposition are known as this kind of processes. We consider the kinetic process can be used for a low-temperature repair technology as the element of remanufacturing in order to realize circular economy. However, compared to metals, which we can expect ductile plastic deformation, it is difficult to deposit brittle ceramics, limiting its capability and possibility. In order to deform and deposit such fragile materials, we need think additional energy source to activate the material adhesion and possible deformation. In this context, we utilize a non-equilibrium plasma jet called a mesoplasma, in which electron temperature is high to activate the particle surface, meanwhile a high-speed plasma jet can accelerate the particles to provide enough inertia to deform. The deposition rate can be increased by one-order of magnitude higher than that of a gas jet deposition. In this presentation, we would like to discuss the role of mesoplasma in kinetic spray of ceramic materials. The effect of surface enhancement and heating of particles is compared to that of increased particle velocity and internal energy. Properties and applications of some deposited structures with a controlled porosity will be introduced together with their microstructure development.

2:00 PM SF04.10.02
Reactive HiPIMS of Hydrogenated Amorphous Carbon using Toluene Precursor MonalisaGhosh[1], KerstinThorwarth[1], GötzThorwarth[2], OlesyaNakonechna[1], ArnoldMüller[3], ChristofVockenhuber[3] and SebastianSiol[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]IMT, Switzerland; [3]ETH Zürich, Switzerland

Hydrogenated amorphous carbon (commonly written as a-C:H), a class of amorphous carbon containing considerable amounts of atomic hydrogen (10 at%-60 at%) is used in many applications ranging from sensors to cutting tools, and biomedical applications [1-5]. The functional properties of amorphous carbon are largely governed by the H-content and sp^2/sp^3 ratio. However, precisely controlling these material properties during synthesis is challenging. HiPIMS (High Power Impulse Magnetron Sputtering) process has been successfully employed for the deposition of amorphous carbon especially diamond-like carbons [6-7]. The films deposited by HiPIMS typically exhibit smooth topography, better adhesion to the substrate, higher wear resistance, and higher sp^3 content.
In this work, we present a novel method to deposit hydrogenated amorphous carbon films using reactive HIPIMS in the presence of a hydrocarbon precursor (toluene). Toluene acts as the regulated source of hydrogen in the sputtered films. The hydrogen content is tuned by controlling different deposition parameters like the partial pressure of toluene, the reactivity of toluene via additional plasma activation by RF substrate bias, etc. The motivation for employing HiPIMS is to control the sp^2/sp^3 ratio and facilitate a more stable hydrogenation of the carbon network compared to conventional state-of-art methods like plasma enhanced chemical vapour deposition (PECVD).
The a-C:H films are sputtered from a rectangular graphite target using a HiPIMS power supply (power in the order of 0.5-3 W/cm^2) without any external substrate heating. The influence of composition (measured by ERDA/RBS) and structural properties (determined by Raman, SEM, and XPS) on the functional properties of the coatings are explored. We demonstrate that by changing the hydrogen content is controlled over a wide range (5 at%-36 at%) via which we can effectively control the properties of coatings like photoluminescence (about 100 folds increase in area under PL curve), hardness, and optical properties.
The study aims to provide new insight into a-C:H film deposition process via a HiPIMS process with additional control over the functional properties by independently controlling the sp^2/sp^3 ratio and hydrogen content.

Nonthermal Plasma Enabled Synthesis of Ultrafine Aluminum-Rich Corundum NanocrystalsAJCendejas, DariuszNiedzwiedzki and ElijahThimsen; Washington University in St. Louis, United States

Nanocrystalline $Cr_{2x}Al_{2(1-x)}O_3$ solid solutions offer a unique combination of chemical and thermal stability with optoelectronic and mechanical properties of interest for applications in catalysis, medicine, and structural materials. However, there exists an asymmetric miscibility gap in the range $0.02 < x < 0.7$ at temperatures below 1000 °C. Since sintering is extremely fast at high temperatures, synthesis of Al-rich corundum nanocrystals less than 50 nm in diameter has been elusive. In this work, we present a bottom-up synthesis of homogeneous α-$Cr_{2x}Al_{2(1-x)}O_3$ nanocrystals with ultimate grain sizes as low as 20 nm. The approach consists of the following: synthesis of size-controlled α-Cr_2O_3 nanocrystals via nonthermal plasma, subsequent atomic layer deposition of amorphous Al_2O_3 shells on the nanocrystals, and a final thermal annealing step to both crystallize the shell and homogenize the nanocrystals. X-ray diffraction, electron microscopy and energy dispersive X-ray spectroscopy were used to demonstrate complete mixing of Cr and Al in the particles. Temperatures as low as 850 °C resulted in complete homogenization of α-$Cr_{2x}Al_{2(1-x)}O_3$ nanocrystals. The ultrafine powders exhibited photoluminescence with a sharp emission line at 695 nm when excited by a 532 nm laser, characteristic of Cr^{3+} substitutions in the α-Al_2O_3 lattice. Additionally, the characteristic decay time of this emission was increased from 132.7 μs to 278.5 μs when the Cr concentration was diluted from $Cr_{0.4}Al_{1.6}O_3$ to $Cr_{0.02}Al_{1.98}O_3$.

Significance of Free Radicals and Unsaturated Bonds in Amine Plasma Polymers LenkaZajickova[1,2], LucieJanu[1], ViniciusSantana[1], MartinaBuchtelová[1], BeataBeliancinova[1], EvaDvorakova[1], DavidNecas[1], NadaSouawda[1], MatusSedivy[1] and PetrNeugebauer[1]; [1]Ceitec But, Czechia; [2]Masaryk University, Czechia

Amino-group-containing plasma polymers (PPs) have been of particular interest for various biomaterials applications because they allow amide covalent coupling and, under certain pH conditions, offer a positively-charged surface for electrostatic binding. Therefore, they were successfully applied to immobilize DNA and various proteins. However, assessing what plasma parameters and the film structural properties are essential for successful and stable immobilization is difficult. PPs do not have a well-defined structure of conventional polymers that can be described as a repetition of a particular unit and the molecular weight of the polymer chain. Since they are deposited from a complex environment of many gaseous reactants created by dissociating original gas feed, their chemical structure cannot be derived only from the starting reactants. We studied the plasma polymerization of cyclopropylamine (CPA) mixed with Ar in three CCP reactor setups and different plasma conditions. The response of immunosensors constructed with the plasma polymerized CPA (PP-CPA) films revealed the surprisingly long reactivity of the film surfaces. It opens the question of whether such phenomena could be explained by the free radicals (species with unpaired spins) trapped in the PP films. Therefore, we investigated the presence and dynamics of the free radicals in the PP-CPA films deposited under mild varied conditions using electron paramagnetic resonance (EPR). We detected a surprisingly high amount of unpaired spin density with the life time in months. Another open question in the performance of amine PPs is the role of primary amine groups (-NH2). In the example of two immunosensors having the same nitrogen and NH2 amount, we demonstrate that amount of NH2 groups detected by TFBA chemical derivatization cannot explain the efficientcy of the antibody covalent coupling and nitrile groups belong to other factors that should be taken into account for the surface reactivity in aqueous media.

4:00 PM SF04.11.02
Deposition of (Multi)functional Thin Films by Coupling a Dielectric Barrier Discharge with an Aerosol: Role of Pulsed Precursor Injection LauraCacot[1,2], LucStafford[1], NicolasNaudé[2] and RichardClergereaux[2]; [1]University of Montreal, Canada; [2]Laplace, France

Aerosol-assisted plasmas can be used to produce a wide variety of thin films, including homogeneous, nanotextured and/or nanocomposite coatings. For example, the nebulization of colloidal solutions, *i.e.* liquid solutions containing nanoparticles, in plane-to-plane dielectric barrier discharge (DBD) at atmospheric pressure has been used for nanocomposite thin film deposition. However, nanoparticles-loaded droplets in the aerosol lead to the deposition of aggregated nanoparticles embedded in the matrix.
Recently, a new process of nanoparticles injection in plasmas has been developed. This method consists in synthesizing the nanoparticles prior to their injection in the plasma in a low frequency pulsed injection regime. However, the impacts of the pulsed liquid injection on the DBD physics are still opening questions.

This work aims to study a pulsed-liquid-assisted DBD deposition process. In contrast with the continuous nebulization of solutions, pulsed injection causes a sudden increase of the quantity of precursor as droplets in the inter-dielectric space – the average velocity being in the 10 $m.s^{-1}$ range. We observed that depending on the process parameters (injection times, pulse frequency, continuous gas flow rate, etc.), the discharge stability is modified. These parameters are also critical for transport and evaporation of the droplets and so on the thin film deposition (here ppHMDSO). For example, by varying the different parameters of the pulsed-liquid-assisted DBD, we observe that the deposit can consist in different phases (liquid and solid) as a function of the time residency of the aerosol and the thickness of the deposited layer. Furthermore, the variation of the discharge frequency can also be a way to tailored the thin-film deposition. In that aim this parameter was change to obtain a operation diagram of the process and get a transition from misty to dusty plasma.

Oxygenate Production from Plasma-Activated Reaction of CO_2 and Ethane LeaWinter; Yale University, United States

Converting CO_2 to value-added chemicals using surplus light alkanes such as ethane is an attractive opportunity to move toward a circular carbon economy without requiring H_2 as a feedstock. Currently, the production of valuable oxygenated hydrocarbons such as alcohols, aldehydes, and acids from ethane involves either multistep, high-pressure heterogeneous catalysis processes or homogeneous catalytic reactions that entail significant product separation challenges. One-step conversion of ethane and CO_2 to oxygenates is not thermodynamically feasible under mild conditions and has not been previously achieved as a one-step process. To circumvent thermodynamic limitations, nonequilibrium plasma may be employed to overcome the activation barriers of the reaction under room temperature conditions. Furthermore, modular plasma-activated reactions are more easily adaptable to renewable electricity and small-scale CO_2 capture than large-scale thermally activated processes.

Nonthermal plasma was used to demonstrate one-step production of alcohols, aldehydes, and acids as well as C1–C5+ hydrocarbons under ambient pressure, with a maximum oxygenate selectivity of 12%. The effects of plasma power, feed gas ratio, and catalysts on activity and selectivity were investigated in an atmospheric pressure flow reactor using time-on-stream results. Isotope-labeling experiments were combined with plasma chemical kinetic modeling to reveal the reaction pathways. The reaction proceeded primarily via oxidation of activated ethane derivatives by CO_2-derived oxygen-containing species, demonstrating a mechanism that is fundamentally different from thermocatalytic alcohol synthesis. Results from this study illustrate the potential to use plasma for the direct synthesis of value-added alcohols, aldehydes, and acids from the greenhouse gas CO_2 and underutilized ethane under ambient pressure.

SESSION SF04.12: Plasma Processes for Biomaterials

Plasma Bio-Engineering: Next Generation Biointerfaces and Hydrogel-Based Hybrid Biomaterials BehnamAkhavan[1,2,3]; [1]The University of Newcastle, Australia; [2]The University of Sydney, Australia; [3]Hunter Medical Research Institute, Australia

Implantable medical devices are increasing globally, with hundreds of thousands of operations performed annually. However, many of these operations experience failure due to infection and/or poor integration with host tissues. Biomimetic functionalization of surfaces enables control over the biological response by signalling through immobilized proteins and other biomolecules. Here we present a novel approach for the fabrication of radical-rich organic coatings that are chemically and mechanically robust for the surface engineering of implantable medical devices. Our results demonstrate that multifunctional protein layers, peptide molecules, or even silver nanoparticles can be covalently immobilized on such radical-rich interfaces for improved cellular activity and enhanced antimicrobial properties. Our recent findings provide evidence of utilizing this technology for polymerization and covalent attachment of hydrogel layers, as well as tuning the orientation and density of immobilized molecules on surfaces by simply tuning pH or applying external electric fields during the biomolecule immobilization. The plasma bio-engineering approach presented here promises to create the next generation of bioactive materials and interfaces for biomedical implant applications and beyond.

9:15 AM SF04.12.02
Bioinstructive Microenvironments for Cell Culture, Tissue Integration and Nanomedicine enabled by Plasma Surface Activation MarcelaBilek, ClaraT. Tran, AaronGilmour, BehnamAkhavan, JameelSardharwalla, LauraHaidar, XuegeFeng, GiselleYeo and StuartFraser; University of Sydney, Australia

Materials used in biomedicine are selected according to bulk properties, such as mechanical, electrical and optical, required for particular in-vivo and in-vitro applications. However, their surfaces almost always provide suboptimal biological microenvironments and do not promote the desired biological responses.
This presentation will describe sustainable and readily scalable surface modification processes that use plasma to enable resilient and easily tailorable biofunctionalization of surfaces. We will examine how plasma activates a range of materials and structures for spontaneous, reagent-free, covalent functionalization with bioactive molecules and hydrogels. Typical time scales of cell culture and tissue integration necessitate covalent immobilization to prevent interface instability due to desorption and exchange with molecules in the surrounding aqueous environment. Functional molecules that can be immobilized to create tailored cell microenvironments include but are not limited to, oligonucleotides, enzymes, peptides, aptamers, cytokines, antibodies, cell-adhesion extra-cellular matrix molecules, and histological dyes. The covalent immobilization occurs on contact via radicals embedded in the surface by energetic plasma species.
After a review of the fundamental science, plasma processes to modify the internal surfaces of multi-well plates, porous scaffolds, and micro/nanostructures will be presented. Strategies to immobilize biological microenvironment patterns and hydrogels onto the plasma-activated surfaces and to prepare multi-functionalizable nanoparticles will be discussed, together with strategies to control the density and orientation of surface-immobilized biomolecules

9:30 AM SF04.12.03
Atmospheric Plasma Deposition of Methacrylate Bio-Based Composite Coatings for Enhanced Release Function and Antimicrobial Properties of Paper KamalBaba[1], MustaphaTabbaa[1], NicolasBoscher[1], PatrickChoquet[1], IndiraHusić[2], Arunjunai RajMahendran[2], JudithSinic[2], ChristophJocham[2] and HerfriedLammer[2]; [1]Luxembourg Institute of Science and

Technology, Luxembourg; [2]Wood K plus - Competence Center for Wood Composites and Wood Chemistry, Austria

Paper based functional coatings are traditionally made from low recyclable synthetic feedstock and wet chemistry approaches, potentially associated to longer processing times and higher material consumption. In this work, we address these aspects with the development of functional bio-based high-performance composite coatings reinforced with sustainable fillers using atmospheric pressure plasma as sustainable oriented coating technology.
Three different low viscosity acrylated Lignin based monomer, namely, Vanillyl Alcohol Methacrylate (VAM), Eugenyl Methacrylate (EM) and Isosorbide Methacrylate (IM), were used as resin, where seashell particles (SS), cellulose nanocrystals (CNC) as well as chitin from shrimp shell particles were used as sustainable additives. The methacrylation was obtained using methacrylic anhydride following an adopted procedure from *Stanzione et al*.
The polymerization of these different monomers was possible thanks to a liquid assisted dielectric barrier discharge approach and was evidenced by FTIR showing a successful conversion of double bonds during the plasma polymerization. Coatings of a thickness ranging from 0.5 to 2 µm was deposited on Si wafers and Glassine paper using Ar or N_2 as plasma gas and ultrasonic nebulization as monomer injection method. The degree of conversion was calculated from the FTIR spectra to assess the effect of the plasma parameters on the polymerization and coating properties. SEM pictures showed homogeneous coating and a uniform distribution of the particles. It was confirmed that the polymerization degree increases with the applied plasma power and decreases with the monomer delivery rate. The addition of SS and CNC particles to the VAM or EM coating influences the hydrophobicity and surface energy and it is believed that this affect also the release properties of the coated surface. The best release function of coated Glassine paper was obtained with the VAM composite coating (<250cN/25mm according to Finat 10/TESA 7475 test). The lower viscosity of VAM induces smaller droplets after ultrasonic nebulization and thus a better polymerization. The influence of particle addition on the physical properties of the composite coating was assessed by scratch test.
In another hand, Chitin particles were used as antimicrobial additive and were embedded in IM to deposit a composite coating. The effect of chitin loading on the antimicrobial properties of the plasma composite coatings will be discussed.

Synthesis of Piezoelectric ZnO via Plasma-ALD and its Application in Electronic Skins Anna MariaCoclite; Graz University of Technology, Austria

Plasma-enhanced ALD (PE-ALD) employs the high reactivity of plasmas as co-reactant in atomic layer deposition (ALD) processes with the advantage that lower substrate temperature can be used compared to the conventional thermal ALD. This opens the possibility of depositing inorganic films with very high specificity on polymer substrates, which is important for organic electronics and polymer-based nanodevices to name a few applications. This talk will provide insights into the deposition process of ZnO via PEALD and how the film properties can be controlled with the deposition parameters. In-situ spectroscopic ellipsometry was used to study the initial growth and interface formation during ZnO deposition on polymers and it showed that PE-ALD growth on the investigated polymers is a result of two competing processes: plasma etching of the polymer substrate and ZnO nucleation and growth. Despite the initial etching, resulting ZnO films are smooth and of comparable structural quality to those grown on silicon. In addition they are piezoelectric, with piezoelectric constant strongly dependent on the growth temperature.

Such piezoelectric ZnO was combined with stimuli-responsive hydrogels in core-shell geometries for an electronic skin concept. Such device geometry was obtained by templated PEALD of the ZnO followed by the initiated chemical vapor deposition (iCVD) of the stimuli-responsive film. The nanostructuration of the films lead to a location-specific signal detection. In addition, the combination of two different materials allowed the detection of three stimuli: force, humidity and temperature. The whole sensor device could be deposited on flexible substrates and used for on-skin sensor or as electronic skin. While the piezoelectricity of ZnO provides sensitivity to external force, the thermoresponsiveness of the hydrogel core provides sensitivity to surrounding temperature and humidity changes. The hydrogel core exerts mechanical stress onto the ZnO shell, which is translated to a measurable piezoelectric signal. A localized force sensitivity of 364 pC N^{-1} is achieved with very low cross talk between 0.25 mm^2 pixels. Additionally, the sensor's sensitivity to humidity is demonstrated at 20° and 40 °C, i.e., above and below the hydrogel's lower critical solution temperature (LCST) of 34 °C. The largest response to temperature is obtained at high humidity and below the hydrogel's LCST. The sensor response to force, humidity, and temperature is significantly faster than the system's intrinsic or excitation-induced time scale. Finally, the sensor response to touch and breath demonstrates its applicability as e-skin in real- life environment.

10:45 AM SF04.13.02
Direct Parylene Bonding for the Flexible Microfluidic Device Resistive Against the Absorption of Small Molecules MasahitoTakakuwa[1,2], DaishiInoue[2], KenjiroFukuda[2], TomoyukiYokota[1], YuyaMorimoto[3] and TakaoSomeya[1,2]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan; [3]Waseda University, Japan

Flexible microfluidic devices are expected to be realized as sweat and blood sensors integrated into next-generation wearable devices directly attached to the skin. Dimethylpolysiloxane (PDMS), a silicone material, is commonly used in flexible microfluidic channels due to its excellent transparency, flexibility, and biocompatibility. Micro-scale grooves are created on PDMS using techniques like soft lithography, and the flexible microfluidic channels are fabricated by bonding thin film polymers or PDMS using adhesives or plasma modification methods. While this method allows for convenient and low-cost fabrication, it also faces limitations regarding material-related issues, which restrict its usage. For instance, PDMS tends to adsorb low-molecular-weight materials and proteins, and it swells in the presence of organic solvents. Moreover, its gas permeability can lead to changes in the concentration of analytes. Modifying PDMS or covering it with other materials is a beneficial way to prevent these issues. In particular, a non-reactive and gas-barrier polymer called parylene, commonly used as an encapsulation film for organic photovoltaics, is a promising material to prevent these PDMS-related problems. However, directly bonding parylene-coated PDMS is challenging due to the high-temperature bonding process (above 160°C), which causes PDMS to deform easily. On the other hand, the method of first plasma-bonding PDMS and then depositing parylene inside the channels using chemical vapor deposition (CVD) proves difficult for complex channel shapes or narrow channels.
This study developed a low-temperature direct bonding method below the glass transition temperature of parylene using water vapor plasma treatment and steam heating. This method enabled the fabrication of microfluidic channels with parylene-coated PDMS by simply bonding them together, suppressing the adsorption of low-molecular-weight compounds. Straight microchannels with a width of 50 µm were created on PDMS, and a 1 µm-thick parylene film was deposited on the entire PDMS surface, including the lid PDMS. The bonding surfaces were hydrophilized using water vapor plasma treatment and aligned with clips to prevent misalignment. The flexible microfluidic channels were created by storing the assembled samples in a steam chamber for 24 hours. Then direct parylene bonding occurred. To evaluate the absorption of low molecular weight materials in microfluidic channels, Rhodamin was introduced into parylene-coated and PDMS-exposed microfluidic channels. After 15 hours of introducing Rhodamine, the width of Rhodamine was measured in each microfluidic device. As a result, the detection width of Rhodamine was 1.3 times wider in the PDMS channel without parylene coating. On the other hand, no diffusion was observed in the parylene-coated microfluidic channel developed in this study. Therefore, the absorption of Rhodamine was suppressed by the parylene-coated PDMS microfluidic channels. By fabricating and evaluating more complex channel patterns, it is possible to achieve a conveniently fabricated flexible microfluidic device that can be integrated as a sensor in next-generation wearable devices.

11:00 AM SF04.13.03
Synthesis of Tungsten-Doped Titania Nanopowders Prepared by Pulsed-Laser Decomposition in Liquid Precursor Bath MustafaMozael[1,2], StephenD. Tse[2] and BernardH. Kear[2]; [1]Loyola Marymount University, United States; [2]Rutgers, The State University of New Jersey, United States

Tungsten-doped TiO_2 (W-TiO_2) nanostructure is successfully synthesized by pulsed-laser ablation of a tungsten foil immersed in liquid titanium tetra-isopropoxide (TTIP). Interaction between the focused laser beam and the W substrate generates a submerged plasma, where vaporization of the W substrate and decomposition of the liquid precursor combine to produce W-doped TiO_2 nanoparticles upon quenching by the surrounding unreacted liquid precursor. The as-synthesized nanoparticles display various morphologies, including nano-spheres and nano-fibers, and occur in discrete, agglomerated and aggregated forms. Whatever their morphologies, all nanoparticles have non-crystalline or amorphous structures, primarily because of rapid condensation and quenching of vaporized species from the plasma-reaction zone. Interestingly, after heat treatment in air or oxygen, starting at ~400 C, transformation to the more stable anatase-TiO_2 phase occurs, but doped with tungsten. The phase transformation from anatase to rutile TiO_2 in the doped sample is shifted to higher temperatures 950 C compared to non-doped TiO_2 800 C. In

addition, the average crystallite size of TiO_2 (about 13 nm) is slightly reduced by doping with W (10 nm) as the ionic radius of W^{6+} (0.60 Å) is quite similar to Ti^{4+} (0.68 Å). Ultraviolet-visible spectroscopic characterization shows that W-doped anatase TiO_2 exhibits a higher UV and visible photochemical activity than un-doped anatase-TiO_2, where the band gap is reduced from 3.08 to 2.92 eV, compared to the un-doped TiO_2 nanostructures.

Directional Control of Infrared Emission in Tunable III-V Semiconductor Platforms MichellePovinelli, AlokGhanekar, BoShrewsbury, Tien HsingWang, RomilAudhkhasi, Hyun UkChae, RagibAhsan and RehanKapadia; University of Southern California, United States

We investigate the design of infrared metamaterials with directionally dependent emissivity and absorptivity. We envision an electrically tunable material for which the applied voltage perturbs the refractive index in the insulator layer of a metal-insulator-metal (MIM) metamaterial. We examine the options for tuning the angular dependence of emissivity for both confined MIM modes and extended Bloch modes. In the case of the MIM modes, we introduce a scheme for breaking the mirror symmetry of the unit cell via voltage perturbation. We show that the broken symmetry can be used to couple a previously hidden, or symmetry-forbidden “dark” mode to radiation. This creates a mechanism for switching on and off emissive spectral features in the infrared spectrum at normal incidence. In the case of extended Bloch modes, we consider the use of the index perturbation to double the period of the material. In an appropriately designed structure, we show that period doubling opens a band gap for off-angle radiation, splitting the emissivity features in the spectrum. We further consider possibilities for creating asymmetric emissivity as a function of angle. We show that when a Bloch mode metamaterial is designed to support diffraction orders, we can switch from a more isotropic emissivity to a more one-sided, directional emissivity. We present experimental results on the fabrication and characterization of the basic materials platform needed to achieve these theoretical effects. The platform includes a transferred GaAs layer containing a vertical p-i-n junction for tuning. We further characterize the measured spectral shift as a function of applied voltage. From the results, we can extract the typical index shifts that can be achieved in experiment. The results point to the potential for control over spectral and directional emissivity characteristics in electrically tunable semiconductor platforms.

11:00 AM SF05.01.02
Infrared Optics with Highly Anisotropic Materials HongyanMei[1], GuodongRen[2], BoyangZhao[3], JadSalman[1], Gwan-YeongJung[2], HuandongChen[3], ArashdeepS. Thind[2], ShantanuSingh[3], NickSettineri[4], SimonJ. Teat[4], BryanC. Chakoumakos[5], JayakanthRavichandran[3], RohanMishra[2] and MikhailKats[1]; [1]University of Wisconsin Madison, United States; [2]Washington University in St. Louis, United States; [3]University of Southern California, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]Oak Ridge National Laboratory, United States

The degree of birefringence (Δn) is a metric for optical anisotropy. Materials with large birefringence are sought after for polarization control (e.g., in wave plates, polarizing beam splitters, etc. [1–3]), nonlinear optics (e.g., for phase matching [4]), the realization of unconventional surface waves [5, 6], thermal radiation control [7], and the measurement of the Casimir torque [8]. Here, we demonstrate that a bulk uniaxial crystal with atomic-scale periodic modulations in its structure — $Sr_{9/8}TiS_3$ — has a record birefringence $\Delta n = n_e - n_o = 2.1$ ($n_e = 4.5$ and $n_o = 2.4$) within a broad transparent spectral window in the mid- to far-infrared.

We synthesized single crystals of $Sr_{9/8}TiS_3$ using the chemical vapor transport method and performed optical characterization to extract the complex refractive index (our preprint here: [9]). We combined polarization-dependent Fourier-transform infrared spectroscopy and spectroscopic ellipsometry to cover from 210 nm to 17 μm, we observed that in the low-loss region of $\lambda > 6$ μm, $Sr_{9/8}TiS_3$ has a birefringence Δn up to 2.1. This is by far the largest birefringence among reported anisotropic crystals, to the best of our knowledge, and in particular much higher than our past demonstration of birefringence in $BaTiS_3$, another quasi-one-dimensional crystal [10]. This extreme birefringence is a result of the enhancement of the extraordinary index due to structural modulations.

We resolved the atomic structure of $Sr_{9/8}TiS_3$ using single-crystal X-ray diffraction. To directly visualize the subtle structural modulations, scanning transmission electron microscopy was used. According to the first-principles density functional theory calculations, the enhancement of the permittivity parallel to the *c* axis is a consequence of the selective occupation of highly anisotropic states along the quasi-1D chain in modulated $Sr_{9/8}TiS_3$ while, in contrast, the electrons from the valence band states in hypothetical stoichiometric $SrTiS_3$ have an isotropic character and are localized on the S atoms.

At the conference, we will present several optical components and devices using this highly anisotropic material system, including ultra-thin wave plates for polarization control and planar polarized thermal emitters that have polarization anisotropy emitting in the normal direction and over a broad range of other angles. We will also discuss several special considerations for optical design when working with highly anisotropic materials, in particular the need for new types of anti-reflection coatings.

In conclusion, we demonstrated a new material platform with enhanced optical anisotropy, which is due to structural modulations in nonstoichiometric modulated crystal $Sr_{9/8}TiS_3$. Modulated $Sr_{9/8}TiS_3$ features the highest-ever degree of birefringence measured in the infrared spectral range. This group of materials can be great candidates for the realization of polarization control, thermal radiation control, unconventional light-matter coupling, and other applications in classical and quantum optics.

Anisotropic Thermal Magnetoresistance in Radiative Heat Transfer AntonioGarcia-Martin; Instituto de Micro y Nanotecnologia, CSIC, Spain

The possibility to create and manipulate nanostructured materials encouraged the exploration of new strategies to control the electromagnetic properties without the need to modify its physical structure, i.e. by means of an external agent. An approach is the combination of magneto-optically active and resonant materials (e.g. plasmonic modes), where it is feasible to control the optical properties with magnetic fields in connection to the excitation of resonances [1] (magnetoplasmonics). It has been shown that these nanostructures can be employed to modulate the propagation wavevector of SPPs [2], which allows the development of label free sensors with enhanced capabilities [3-5] or to enhance the magneto-optical response in isolated entities as well as films, in connection with a strong localization of the electromagnetic field [6-8].
Here we will show that they also play a crucial role in the active control of thermal emission and the radiative heat transfer (RHT) [9-11]. In particular Near Field RHT between two MO particles can be efficiently controlled by changing the direction of the magnetic field, in the spirit of the Anisotropic Magneto Resistance in spintronics [11]. This phenomenon, which we term anisotropic thermal magnetoresistance (ATMR), stems from the anisotropy of the photon tunneling induced by the magnetic field. We discuss this effect through the analysis of the radiative heat exchange between two InSb particles, and show that the ATMR can reach amplitudes of 100% for fields on the order of 1 T and up to 1000% for a magnetic field of 6 T. These values are several orders of magnitude larger than in standard spintronic devices. More importantly, this thermomagnetic effect paves the way for exploring heat transfer physics at pico- and even subpicosecond time scales, which are even shorter than the relaxation time of heat carriers. Moreover, we show that the heat flux is very sensitive to the magnetic field direction, which makes this effect very promising for the development of a new generation of thermal and magnetic sensors.

Optimal Control of Light at The Nanoscale AlejandroRodriguez; Princeton University, United States

Whether it be enhancing spontaneous emission from quantum defects or thermal radiation from hot objects, nanophotonic devices provide a means to control light all the way down to the nanometer scale. Here, we birefly review recent progress in our undesrstanding of fundamental limits to light manipulation through structural engineering. Focusing on several canonical photonic objectives---minimizing extinction from subwavelength emitters and enhancing heat exchange at the nanoscale, we show that recent convex optimization methods can be used to complement large-scale structural optimization techniques to provide a mechanism- and geometry-agnostic means of discovering nanophotonic laws.

Thermal Radiation from Single Sub-λ Resonators and Devices LoubnanAbou-Hamdan[1], AurelienSchmitt[2], SylvioRossetti[1], MarinTharrault[2], RemiBretel[2], ValentinaKrachmalnicoff[3], Jean-PaulHugonin[4], ChristopheVoisin[2], BernardPlaçais[2], RiadHaidar[5], Jean-JacquesGreffet[4], EmmanuelBaudin[2], PatrickBouchon[5] and YannickDe Wilde[3]; [1]Institut Langevin, ESPCI Paris, PSL , CNRS & ONERA, France; [2]LPENS, ENS, PSL, CNRS, France; [3]Institut Langevin, ESPCI Paris, PSL, CNRS, France; [4]Laboratoire Charles Fabry, IOGS, CNRS, France; [5]ONERA, France

The thermal radiation scanning tunneling microscope (TRSTM) uses a scattering-tip modulated in a direction normal to the surface of a heated sample to measure its near-field thermal radiation [1]. This is achieved by lock-in demodulation of the infrared detected signal, which filters out the far-field radiation. In past experiments, it was shown that the method allows one to measure images and spectra of the near-field thermal radiation [1,2]. The latter shows strong deviations from black-body radiation for polaritonic materials [2].

Inspired by the TRSTM, we have recently developed a new spectroscopy method called infrared spatial modulation spectroscopy (IRSMS) to measure the far-field thermal radiation spectrum of heated sub-wavelength sized objects. As it is a far-field spectroscopy method, it does not require any scattering probe at the sample surface, unlike TRSTM. The principle of the IRSMS is to use a lateral modulation of the sub-λ sized object on the heated substrate in the field of view of an infrared microscope combined with a Fourier Transform Infrared Spectrometer. Due to the light fall-off effect on the detector, lock-in demodulation allows one to filter out the overwhelming background thermal radiation from the heated substrate and thus to extract the spectrum of the sub-λ sized object.

We have used IRSMS first to investigate the thermal radiation from single sub-λ sized metallic or dielectric resonators. Metal-insulator-metal antennas exhibit a narrowband thermal emission associated to the confinement of gap plasmons [3], with the appearance of hybrid modes when antennas are in near-field interactions [4]. Dielectric microspheres are also attractive to tailor the thermal radiation spectrum. For single SiO_2 microspheres, we evidence the excitation of both surface phonon-polariton (SPhP) modes and geometrical electric and magnetic Mie modes. The transition from a phonon-mode-dominated to a Mie-mode-dominated emission spectrum is observed when considering different sphere diameters [5].

Next, we have used modulation spectroscopy to investigate the radiation produced by high mobility graphene-hBN field effect transistors. The infrared radiation from these heterostructures under bias exhibits features which are typical for electroluminescence [6]. It starts at the threshold bias of Zener-Klein tunneling, an effect initially demonstrated in graphene with hyperbolic substrate in noise thermometry measurements [7]. It involves a specific cooling mechanism of the electron gas with radiative emission, due to the electron-hole recombination, in electromagnetic near-field modes of the hBN-graphene heterostructure.

SESSION SF05.03: Phase-Change Materials
Session Chairs: Maxime Giteau and Michelle Povinelli
Monday Afternoon, November27, 2023
Sheraton, Third Floor, Hampton

2:15 PM SF05.03.01
Elaboration of Perovskite Thin Films with Metal-Insulator Transition for Infrared Optical Modulation ArthurTausch[1], FabienCapon[2], JérémieDrévillon[1] and KarlJoulain[1]; [1]Institut Pprime, France; [2]Institut Jean Lamour, France

Mixed valence manganites ($Re_{1-x}A_xMnO_3$, with Re a rare earth element and A an alkaline earth element) present a metal-insulator transition that is not only described by a strong variation in the material's resistivity but also by an optical contrast between the conductor and the insulator state from the near infrared to the mid infrared region of the electromagnetic spectra [1]. In the case of Samarium and Calcium mixed valence manganite, room temperature optical transitions were previously observed in Fourier Transform InfraRed spectrometry (FTIR) [2].

In this work, we demonstrate that ex-situ annealed $Sm_{0.5}Ca_{0.5}MnO_3$ thin films, deposited by magnetron co-sputtering under reactive O_2/Ar atmosphere, exhibit a thermochromic effect in the infrared region. As the temperature increases, charge carriers are freed and the material transits towards a metallic state. This transition was observed using Van Der Paaw measurement for temperature ranging from 80K to 873K. As the resistivity of the material decreases with temperature its infrared transmittivity decreases. The link between the electronic properties and the radiative properties of the material was explained using infrared variable angle spectroscopic ellipsometry as a function of temperature. The modelling of the ellipsometric datas using physical models such as Drude oscillators and Lorentz oscillators highlighted the transition from an insulating state at low temperature to a metallic state at high temperature. As the transition occurs around room temperature, the interest for passive infrared optical modulation applications was confirmed.

Using scattering matrix method for semi infinite thin films and an Improved Grey Wolf Optimization meta-heuristic algorithm [3], it is possible to optimize the emissivity decrease with temperature of a multi-layer material in the transparency bands of earth atmosphere knowing the variations in complex optical indexes with temperature [4]. Such tendency allows the control of the material's spectral radiance and therefore its detectability with thermography.

Tunable Narrowband Thermal Emitters using Phase-Change Materials: Design Rules for Simple Devices MaximeGiteau[1], MitradeepSarkar[1], LukasConrads[2], Maria PaulaAlaya[1], MichaelEnders[1], ThomasTaubner[2] and GeorgiaT. Papadakis[1]; [1]ICFO, Spain; [2]RWTH Aachen University, Germany

The ability to control the spectrum, the direction, and the polarization of thermal emission is critical for numerous applications, including infrared (IR) sources, thermal camouflage, radiative cooling, molecular sensing, and energy conversion. For many of these applications, narrowband IR emission is desirable. However, simple, lithography-free structures tend to have spectrally broadband emissivity. It is also valuable to achieve active control of thermal emission, enabling switching between *on* and *off* emission states or shifting the peak emission wavelength. In the mid-IR region, the spectral range of interest for thermal emission near room temperature, a common approach for active tuning has been phase-change materials (PCMs). Tunable narrowband sources have previously been achieved, albeit with relatively complex structures and a performance that is not ideal over the whole operation range. Furthermore, these devices have limited spectral tunability as they rely on the temperature dependence of the materials' resonances.
This work presents an analytical framework to design actively tunable narrowband thermal emitters at IR frequencies [1]. The proposed systems are lithography-free and consist of one or several thin emitter layers, a spacer layer that includes the PCM, and a back-side reflector. Numerically, we show near-unity *on-off* switching and arbitrarily large spectral shifting between two emission wavelengths using actual materials. Although our theoretical formalism assumes normal incidence, the performance remains near-ideal up to large angles. The presented framework is general and applies to *any* mechanism that modifies the optical properties of a material, such as electrical gating or optical modulation. Finally, we are currently working on an experimental demonstration using In3SbTe2, a non-volatile PCM that can be reversibly switched between a dielectric amorphous and a metallic crystalline phase in the entire infrared spectral range [2].

Variable Visible-to-Infrared Optical and Emissivity Properties of VO_2 and W-VO_2 Thin Films for Passive Smart Radiative Device Applications ArtitsupaBoontan, EricKumi Barimah, DavidP. Steenson and GinJose; University of Leeds, United Kingdom

Numerous technologies have been developed to regulate the temperatures of several space equipment within the allowable tolerance temperature range from -150 °C to 150°C to meet the operation requirements by rejecting or injecting Joule heating. A spacecraft is a typical example of such devices, which can be subjected to different thermal environments upon lunch, from the Earth's surface to outer space, for various missions. The thermal environment of these systems is controlled by dissipating heat through either passive or active processes. Many traditional spacecraft systems employ heat pipes, thermal switches and heaters to regulate the spacecraft temperature. Others use advanced thermal control devices such as the electric louvre based on microelectromechanical technologies comprised of a bimetallic and spring-actuated mechanism to manage the heat when it falls or rises above the allowable temperature range during operation. Even though there has been tremendous progress in smart radiative devices (SRD) over the years for thermal control designs via mass and size reduction with minimum or no electrical energy required using perovskites. The SRD consists of variable emissions to regulate the temperature by changing the environmental temperature concerning the phase transition property of the thermochromic materials. In addition, the SRD must have low emissivity at low temperatures to reduce heat loss and high emissivity at high temperatures allows it to dissipate heat through thermal radiation. A phase change material such as VO_2(M1) with a phase transition temperature of 68°C starts from a low-temperature semiconductor state to a high-temperature metallic state. This is accompanied by structural transformation from a low-temperature monoclinic (M) to a high-temperature rutile (R) phase. For instance, optical characteristics of spacecraft smart radiative devices have been demonstrated and reported, which consist of a multilayer thin film of VO_2 on silica or aluminium-silver substrate.
This presentation presents a direct method of fabricating SRD W-doped VO_2 thin films onto silica and silicon substrates from W-doped V_2O_5 precursor using a high repetition rate (75 kHz) femtosecond-PLD. Surface morphology and crystal structure characterisation of the SRD were investigated. In addition, visible to mid-infrared optical properties such as temperature-dependent solar absorptance, reflectance index, and variable emissivity of the phase change material VO_2 SRD device will be systematically investigated and discussed.

3:30 PM *SF05.03.04
Radiative Thermal Control with Thermochromic VO_2 Based Metafilms and Metamaterials LipingWang; Arizona State University, United States

In this talk, I will review recent progress from my research group on radiative thermal control with thermochromic VO_2 based metafilms and metamaterials. VO_2 thin films with excellent

phase transition behaviors were grown with unique furnace oxidation method from deposited vanadlium nanofilms. With co-sputtering technique or alloy targets, tungsten doped VO_2 thin films with reduced phase transition temperature ranges were also successfully obtained. Temperarture-dependent spectroscopic characterizations of undoped and tungsten doped VO_2 thin film from cryogenic to high temperatures were performed and the infrared properties at different phases were extracted from optical fitting. Nanophotonic metafilm and metamaterial structures incorporating VO_2 nanofilm or nanostructure were carefully designed and successfully fabricated. Variable infrared emissivity with large tunability were experimentally demonstrated upon VO_2 phase transition. Vacuum thermal and cryothermal test apparatus were developed and the variable radiative heat dissipiation were expeirmentally confirmed with these tunable metafilm and metamaterial emitters. In particular, their effects for space thermal control and radiative thermal rectification were experimentally studied along with thermal modeling.

SESSION SF05.04: Infrared Properties

Engineering Dynamically-Tunable Linear and Nonlinear Infrared Properties of Materials for Thermal Energy Harvesting and Photodetection SvetlanaV. Boriskina; Massachusetts Institute of Technology, United States

I will discuss several successful strategies to engineer dynamically-tunable optical response of semiconductor and polymer materials in the infrared spectral range. These include: (i) strain-induced mechanocaloric phase transitions in polymers, (ii) strain-gradient-induced inversion symmetry breaking in narrow-gap semiconductors and Weyl/Dirac semimetals, (iii) magnetic-field induced coupled magnetocaloric and magnetooptical effects in magnetic materials, and (iv) generation, evolution, and annihilation of optical vortices pinned to thin-film absorbers. The applications enabled by the above tunability mechanisms include persistent electric energy generation in flexoelectric photodetectors and thermoradiative cells [1], static and dynamic control of directional surface plasmon polariton modes propagation in Weyl semimetals or semiconductors [2,3], solid-state cooling, heating, and radiative transport control actuated by mechanocaloric and magnetocaloric effects [4,5], and spectrally-selective absorptance/reflectance switching via singular phase engineering in the interference optical near-fields [6,7].

This research has been supported in part by the MIT Lincoln Laboratory under award No.ACC-777 (for the flexoelectric energy harvesting), the Army Research Office under award No. W911NF-19-1-0279 (for the near-field radiative energy transfer), the DOE-BES program under award No. DE-FG02-02ER45977 (for the strain-engineering of polymers), the MIT-SUSTech Program (for the elastocaloric effects engineering), and the Korean Research and Development Program for ICT and Broadcasting (for optical vortex engineering).

4:30 PM SF05.04.02
Thermochromic Materials for Optimized Modulation of Solar Thermal Radiation in Windows and Their Combination with Mid-IR Thermal Insulation DanielMann and PascalBuskens; TNO, Netherlands

The built environment is responsible for more than 1/3 of the annual energy consumption worldwide. A major contributor to building energy demand are windows due to their transparency to thermal radiation. In general, the thermal radiation relevant for buildings can be divided into two wavelength regions of interest: i) near-infrared (IR) between 800 – 2500 nm, representing thermal radiation from sunlight; ii) mid-IR between 5 – 25 µm, representing thermal radiation from radiators. Furthermore, requirements for windows to transmit or block each of these regions depend on the climate and can change between seasons. In hot climates or summertime, windows should block solar thermal radiation to limit air conditioning demand. Whereas in cold climates and wintertime, windows should transmit solar thermal radiation to contribute to a building's heating demand, whilst preventing mid-IR thermal radiation from leaving the building. For moderate climates these changing requirements can only be met by smart adaptive glazing.
One of the most interesting materials for adaptive glazing are thermochromics (TC). These materials can change their optical properties upon a change in temperature. The most prominent representative is vanadium dioxide (VO_2). VO_2 can change its crystal structure from monoclinic to rutile at 68°C, inducing a change in electrical and optical properties. It is perfectly suited for solar heat regulating windows because of the following properties: i) switch between near-IR transparent and blocking; ii) potential for high visible transparency by limiting the switch mainly to the near-IR; iii) possibility to adjust the switching temperature in a wide range between 0 – 68°C; iv) cheap and abundant material; v) potential to use cheap and low energy intensive application methods; vi) autonomous switch and potential for application in regular glazing; vii) compatibility with existing energy efficient window coatings.
We have developed a high quality VO_2 nanoparticle that can be added via coatings or polymer films to various types of window products adding TC properties. The pigment is optimized to enable high visible transparency (T_{vis}) in combination with a substantial solar heat modulation (ΔT_{sol}), optimizing the energy performance of a window.
Here we present a detailed study on how the size and crystallinity of VO_2 nanoparticles influence the optical properties and functional performance of TC coated/laminated glass. We show that by increasing crystallinity ΔT_{sol} and T_{vis} can be increased simultaneously because of an increased fraction of functional material in the VO_2 pigment. Furthermore, we show that reducing the average particle size to <80 nm leads to appearance of plasmonic properties in the metallic (rutile) state of the VO_2 pigment. This results in increased absorption in the wavelength region between 780 – 1360 nm and in a corresponding increase in ΔT_{sol}. In addition, we show that integration of small VO_2 pigments in a transparent matrix can significantly increase T_{vis} whilst retaining a high ΔT_{sol}. Using all these optimizations in one coating we obtained a maximum ΔT_{sol} of 23% at a T_{vis} of 67%.
Since solar heat management is only one part of a window's interaction with thermal radiation, we also present a study on combining our TC solar heat regulating glasses with low-emissivity glass, blocking mid-IR thermal radiation. Here we show the importance of matching properties between both types of functional glasses to retain the solar heat regulating properties of the TC glass whilst adding thermal insulation in the mid-IR region. With this combination a perfect window with optimized energy efficiency, via shgc modulation of 13%, can be produced, which we validate via building energy simulations. We show that a building's energy efficiency in the Netherlands can be increased by up to 9% in comparison to state-of-the-art energy efficient windows, resulting in about 500€ energy cost savings per year for a single household.

4:45 PM SF05.04.03
Polarization-Induced Infrared Emissivity Control System for Precise Temperature Adjustment Do HyeonKim, Se-YeonHeo, YubinLee and Young MinSong; Gwangju Institute of Science and Technology, Korea (the Republic of)

The global energy and climate challenges require energy-saving solutions to achieve net-zero emissions worldwide. As a result, eco-friendly thermal management has become crucial in various sectors, including residential buildings and mobile devices. In this context, passive radiative cooling has emerged as a promising solution to address the global energy and climate crises by providing energy-efficient and zero-emission cooling. The high emissivity of objects in the mid-infrared (MIR) atmospheric window allows for radiative cooling, where heat is drawn from the objects and emitted to the cold outer space. This unique feature has sparked renewed interest in extensive research on passive radiative cooling, with successful experimental demonstrations in various applications such as wearable devices, solar cells, buildings, displays, clothing, roofs, and vehicles [1].
However, conventional radiative cooling technologies face limitations, such as undesired cooling in cold weather due to strong thermal emissions in a single state. Recent research has introduced dual-state emitters capable of switching emission spectra for cooling and heating purposes [2]. However, achieving precise thermal comfort temperatures, especially in moderate weather conditions like spring and autumn, requires continuous emissivity adjustment rather than simple on/off cooling switching. In this context, multi-state emitters with continuously adjustable emission spectra offer promising solutions for all weather conditions, although they have received limited attention in scientific investigations. Additionally, active emitters utilizing phase change materials provide thermoregulation functionality for all seasons but have constraints in customizing target temperatures due to fixed transition points.
Here, we propose a dynamic temperature-adjustable system with an infrared (IR) polarization valve as an energy-balancing channel. The system is composed of a one-dimensional grating emitter and an IR polarizer. A simple rotation of the polarizer allows continuous temperature modulation. Optical simulations are implemented to optimize the design of the thermal emitter, which comprises a one-dimensional silver grid on quartz. Our system achieves a wide range of emissivity, from 2 to 80%, by simple adjustment of the polarizer. This enables precise cooling/heating capabilities (-17 to 51 W/m^2). Theoretical calculations estimate the potential energy saving of over 20 GJ/year compared to conventional emitters across different climate zones when applied to roofs of buildings. Outdoor experiments validate the precise temperature regulation within a target range of 17-18 degrees (Celsius). The successful outdoor proof-of-

concept demonstration highlights the reliability and applicability of our approach in diverse situations such as residential buildings, farms, and wearable devices. Furthermore, we have confirmed the suitability of phase change materials, particularly GST, in our system using a glancing angle deposition technique. This result proves the versatility of our system and the potential for various applications, including thermal camouflage patches. Our findings contribute to advancing thermal management technologies for achieving net-zero emissions and sustainable energy savings in the face of global energy and climate challenges.

Tailoring Thermal Emission for Power Generation and Cooling JeremyN. Munday; University of California, Davis, United States

The thermal spectra of hot, warm, and cool bodies are all well-known and described by Planck's law for blackbody emission. However, for many modern technologies and applications, it is desirably to have significant deviations from this law to achieve directional or wavelength-controlled emission. In this talk, we will discuss the control of thermal emission for various applications. We introduce a novel approach that enables the creation of thermally stable structures at ultra-high temperatures (up to 2000 °C), allowing for tailored emission spectra. The specific application of thermophotovoltaics will be discussed. Additionally, we will describe an alternative geoengineering strategy to increase the Earth's radiative heat emission, potentially stabilizing or cooling the planet to help mitigate climate change by increasing the earth's thermal emission by 1 W/m^2. Finally, we will discuss our work on alternative power generation concepts to produce power after sunset by optically coupling to deep space and discuss the potential impact and limitations of such devices.

Breaking the Rules: Exploring Violation of the Kirchhoff Radiation Law in Experiments HarryA. Atwater; California Institute of Technology, United States

The understanding of emission of thermal radiation has been shaped by the Kirchhoff thermal radiation law, which asserts equality of the absorptivity and emissivity of a given object for each wavelength, direction, and polarization. This equality is built on reciprocity; and the use of reciprocal materials to demonstrate spatial and temporal coherence of thermal emission has proven a landmark in the nanophotonics community. We have experimentally measured inequality of the spectral emissivity and spectral absorptivity of a thermal emitter, and thus directly observe a violation of Kirchhoff's law. We achieve this by measuring the directional thermal emissivity and absorptivity from a nanophotonic structure in a magnetic field, which breaks the reciprocity conditions. We not only observe inequality in emissivity and absorptivity, but also demonstrate a new relationship between the two for the non-reciprocal photonic structure. Thermal emission phenomenon that can break free of Kirchhoff's law are of fundamental interest and may open a multitude of new applications; we will discuss further directions for experimental exploration of related phenomena.

9:00 AM SF05.05.02
Control Bandwidth and Contrast Between Emissivity and Absorptivity for Broadband Nonreciprocal Emitters BoZhao; University of Houston, United States

Broadband nonreciprocal emitters are indispensable in next-generation thermal and photonic applications, such as thermal camouflage and energy harvesting. Recently, multilayer structures consisting of magneto-optical materials with gradient doping levels have been explored for broadband nonreciprocity provided by a broadband ENZ effect. However, previous works all focus on achieving a monotonic contrast between emissivity and absorptivity, i.e., either the absorptivity or the emissivity is always larger than the other for a given direction over a broad frequency range. Here, we report that the contrast between emissivity and absorptivity of such multilayer nonreciprocal thermal emitters can be highly controllable by coupling a Fabry-Perot mode associated with an additional dielectric layer, making the contrast alternating positive and negative across the broad nonreciprocal bandwidth. Thus, the monotonic nonreciprocal bandwidth can be divided into multiple separated bands with alternating contrasts, and the number of the separated bands is proportional to the thickness of the dielectric layer. In addition, the introduction of the dielectric layer also can increase the absolute contrast between absorptivity and emissivity. Our approach of coupling a Fabry-Perot mode with ENZ effect represents a simple yet effective approach to obtaining multiband nonreciprocal thermal emitters, providing interesting new opportunities in thermal applications such as thermal circulators and isolators.

9:15 AM SF05.05.03
Bidirectional Thermo-Regulating Hydrogel Composite for Autonomic Thermal Homeostasis GyeongsukPark and StevePark; KAIST(Korea Advanced Institute of Science and Technology), Korea (the Republic of)

Thermal homeostasis is an essential physiological function for preserving the optimal state of complex organs within the human body. Inspired by this function, here, we introduce an autonomous thermal homeostatic hydrogel that includes infrared wave reflecting and absorbing materials for improved heat trapping at low temperatures, and a porous structure for enhanced evaporative cooling at high temperatures. Moreover, an optimized auxetic pattern was designed as a heat valve to further amplify heat release at high temperatures. This homeostatic hydrogel provides effective bidirectional thermoregulation with deviations of 5.04°C ± 0.55°C and 5.85°C ± 0.46°C from the normal body temperature of 36.5°C, when the external temperatures are 5°C and 50°C, respectively. The autonomous thermoregulatory characteristics of our hydrogel may provide a simple solution to people suffering from autonomic nervous system disorders and soft robotics that are susceptible to sudden temperature fluctuations.

9:30 AM SF05.05.04
A Novel Design of a Radiative Thermal Transistor Ju WonLim, AyanMajumder, RohithMittapally, Audrey-RoseGutierrez, YuxuanLuan, EdgarMeyhofer and PramodSangi Reddy; University of Michigan, United States

Thermal logic devices are of significant current interest for thermal management and have been extensively explored theoretically. However, there has been limited experimental progress on such devices. Here, we describe a novel radiative thermal transistor consisting of sub-micrometer thick membranes combined with a phase transition modulator whose dielectric properties can be controlled via temperature. Specifically, we show that when the modulator made of vanadium oxide (VO_X), which is analogous to the gate electrode of a transistor, undergoes a metal-insulator transition, it affects the radiative heat transfer between the emitter and receiver membranes. A thermal modulator, which is analogous to the source and drain electrodes of a transistor, enables control of radiative heat flow between a hot emitter and a cold receiver with a switching ratio of up to a factor of three. In contrast to past thermal transistors, the switching time of our nanomembrane-based thermal transistor is much more rapid (hundreds of milliseconds compared to minutes) due to the small thermal mass of our modulator. Our experiments are also complemented by detailed calculations that highlight the mechanism of thermal modulation. We anticipate that the advances reported here will open new opportunities to design thermal circuits or thermal logic devices for advanced heat flow control.

Electrochemical Dynamic Solar and Mid-Infrared Synergistic Tuning for All-Season Building Thermoregulation ChenxiSui; The University of Chicago, United States

The coldness of the deep universe and the hotness of the sun have been considered renewable thermodynamic resources for sustainable thermoregulation. How to utilize both resources showed drastic improvement in the past decade, enabled by the plasmonic and nanophotonic research. Remarkably, the rational photonic and thermal design has pushed forward the power and efficiency of daytime radiative cooling. In this presentation, we will introduce our recent research progress on electrochemical devices that can electrically switch between solar heating and radiative cooling states, by tuning their optical properties. Such a non-trivial and opposite spectral tuning requires the fabrication of the ultra-wideband transparent conductive electrode, which is transparent in both solar and mid-IR regimes, and the precise control of the plasmonic nanoparticles' morphology during the reversible metal electrodeposition. With the optimization of every device component, this device can maximize its solar reflectivity at the cooling state and minimize its thermal emissivity at the heating state, and thus can serve as the smart building envelope for year-round HVAC energy saving. Ideally, the device can help buildings save 19.2% of HVAC energy across the United States, based on the building energy simulation results. The durable electrodeposition and broad-band spectral tuning are confirmed by the DFT simulations and effective medium theory. In addition to the synergistic solar and mid-IR dual-band

tuning, our electrochromic device can tune the thermal emissivity with 0.85 contrast based on non-volatile and reversible metal electrodeposition, bringing vast opportunities for applications in space heat management, and thermal camouflage.

Controlling Infrared Emissivity: New Directional Capabilities and Radiative Cooling Applications AaswathP. Raman; University of California, Los Angeles, United States

Thermal emission over infrared wavelengths is ubiquitious making its control of great importance to a wide range of applications. In this talk, we will first introduce a new photonics-based framework to controlling both spectral and directional emissivity, gradient epsilon near zero (ENZ) materials. We will highlight demonstrations using both phonon-polariton-based materials as well as doped semiconductors, demonstrating both spectral and broadband directional tunability. We will next discuss radiative cooling applications enabled by such spectrally and directionally emissive materials. First we will introduce passive freezing desalination enabled by radiative cooling, as well as the radiative cooling of vertical facades in hot urban environments.

11:00 AM SF05.06.02
Passive Radiative Cooling using Randomly Micro-Structured Silicon Meta-Materials ArmandeHervé, NicolasLavielle, FrédéricMarty, GeorgesHamaoui, PhilippeBasset, TarikBourouina and ElyesNefzaoui; Université Gustave Eiffel, France

Decarbonized and low-energy technologies for heat management and conversion are critical milestones for climate change mitigation[1]. Cooling is one of the major fields where such technologies are required. Passive radiative cooling in its nighttime and daytime versions is therefore a promising technology to achieve those goals[2]. We consider in this work a silicon-based nanostructured meta-material with outstanding visible and infrared radiation absorption and emission capabilities, alternatively called Black Silicon due to its black color, as a candidate for nighttime passive radiative cooling. Indeed, we have recently shown that randomly micro-structured silicon surfaces can exhibit near-unit emissivity over a wide spectral range from the visible to the mid-infrared[3]. We have also shown that this range can be significantly extended and tuned by varying the silicon doping and the micro-structures aspect ratio[4–6] to reach the spectral range of the atmospheric transparency window (8 to 13 µm). These interesting radiative properties of Black Silicon combined with the different tuning possibilities open an avenue for using such materials for different thermal radiation control applications such as enhanced solar radiation absorption[7], infrared radiation sources[8], selective emitters, and passive radiative cooling[9]. In this contribution, we numerically compare Black Silicon with its flat silicon counterpart with respect to their radiative cooling power. We consider Black Silicon samples with different nano structuration aspect ratios and use their experimentally measured radiative properties. The radiative properties are measured using Fourier Transform Infrared Spectroscopy at room temperature. We show that the computed BSi cooling power is significantly larger than that of flat silicon by a factor up to 1.8 at 30°C with a cooling power of 75 W /m^2 and 140 W/m^2 for flat and Black Silicon, respectively. We also numerically investigate the influence of several parameters such as the conductive and convective heat transfer, the atmospheric transmittance spectra (idealized: rectangular function or realistic: with multiple absorption bands), and the operating temperature. We show that Black Silicon exhibits a larger radiative cooling power than a material with an ideal unit emissivity between 8 and 13 µm. Indeed, the considered atmospheric transmittance greatly influences the radiative cooling power. Finally, we perform nighttime radiative cooling experiments using black and flat silicon and compare experimental results with the numerical predictions.

11:15 AM SF05.06.03
Improving the Passive Radiative Cooling Properties of Anodic Aluminium Oxide Nanostructures on Aluminium Cristina V.Manzano[1], AngelMorales-Sabio[2], MarisolMartin-Gonzalez[1] and AlbaDiaz-Lobosp[1]; [1]Institute of Micro and Nanotechnology, Spain; [2]CIEMAT, Spain

Nowadays, a third of the total energy demand is destinated for cooling due to the consequence of the global warming, which results in higher temperatures and heatwaves. In this sense, a significant reduction in energy demand will be achieved
when passive radiative cooler technology is used. At the same time, it is important to develop low-cost, easy-scalable to industry materials.
In this study, we analyze how all the morphological properties and chemical structure of anodic aluminium oxide (AAO) nanostructures on Al influence on their optical properties and their radiative cooler properties. The thickness, interpore distance, porosity and counterions of the AAO affect significantly the cooling performance of these AAO-Al samples. A maximum cooling temperature of 8 celsius degrees was reached under direct sunlight in a summer day in Spain, which corresponds to a colling power of 175 W/m^2 when the nanostructures are anodized under certain conditions referent to thickness, porosity, and counterion. This cooling performance results of AAO nanostructures are higher than over previous studies, demonstrating the potential of AAO nanostructures to be used in thermal management applications.

11:30 AM SF05.06.04
Enhancing the Consistency of Porous Polymer Passive Daytime Radiative Cooling Paint in Outdoor Applications DongpyoHong[1], Ok SungJeon[1], Se HunLee[1], Yong JoonLee[1], In-SungLee[1], Ye RimKim[1], Yun JuLa[1], Young PyoJeon[1], Young JoonYoo[1] and Sang YoonPark[2]; [1]Advanced Institute of Convergence Technology, Seoul National University, Korea (the Republic of); [2]Kyonggi University, Korea (the Republic of)

Coating the building envelope with passive daytime radiative cooling (PDRC) paint has garnered enormous attention as an energy- and carbon-free alternative cooling technology. Achieving this goal requires the spontaneous formation of a suitable optical structure during the solvent drying process of the paint that effectively reflects sunlight and enables thermal emission through the atmospheric window (8-13 µm). In addition to their cooling abilities, PDRC coatings must also possess affordability, durability, and compatibility with diverse surfaces and climates for practical use.
Recently, porous polymer coating (PPC) has gained significant attention due to its numerous advantages, including cooling performance, cost-effectiveness, flexibility, and scalability. However, achieving consistent performance over a wide range of outdoor conditions is a challenge due to the morphology of PPC formed via the evaporation-induced phase separation method (EIPS), which is highly dependent on evaporation environment parameters such as temperature and humidity. Despite the advantages of PPC, there is a lack of systematic studies on the consistency of PDRC performance under varying environmental conditions of EIPS, and potential solutions to this issue have not been addressed.
In this study, we demonstrate the humidity vulnerability of PPC during the drying process and propose a simple strategy to mitigate this issue. Specifically, we found that the solar reflectance of PPC rapidly decreases with increasing humidity from 30% RH, causing the PPC to completely lose its PDRC ability at 45% RH and even become a solar-heating material at higher humidity levels. However, by adding a trace amount of reinforcements into PPC, we were able to maintain its PDRC performance up to 60% RH, resulting in a 1050% enhancement of areal coverage in the United States. This study highlights a crucial consistency issue for PPC-based PDRC paint that has been previously overlooked and offers engineering guidance to address this fundamental challenge for the development of reliable PDRC paint for industrial applications.

11:45 AM SF05.06.05
Oil-Paper-Umbrella-Inspired Passive Radiative Cooling using Recycled Packaging Foam YangLiu and YiZheng; Northeastern University, United States

Passive daytime radiative cooling (PDRC) is a promising energy-saving cooling method to cool objects without energy consumption. Although numerous PDRC materials and structures have been proposed to achieve sub-ambient temperatures, the technique faces unprecedented challenges brought on by complicated and expensive fabrication. Herein, inspired by traditional Chinese oil-paper umbrellas, we develop a self-cleaning and self-cooling oil-foam composite (OFC) made of recycled polystyrene foam and tung oil to simultaneously achieve efficient passive radiative cooling and enhanced thermal dissipation of objects. The OFCs show high solar reflectance (0.90) and high mid-infrared thermal emittance (0.89) during the atmospheric transparent window, contributing to a sub-ambient temperature drop of ~5.4 °C and cooling power of 86 W m−2 under direct solar irradiance. Additionally, the worldwide market of recycled packaging plastics can provide low-cost raw materials, further eliminating the release of plastics into the environment. The OFC offers an energy-efficient, costeffective and environmentally friendly candidate for building cooling applications and provides a valueadded path for plastic recycling.

SESSION SF05.07: Energy Conversion
Session Chairs: Pierre-Olivier Chapuis and Georgia Papadakis
Tuesday Afternoon, November28, 2023
Sheraton, Third Floor, Hampton

1:30 PM *SF05.07.01
Thermal Radiation as Electricity Generation's Nemesis AlirezaNojeh; University of British Columbia, Canada

Producing electricity from high-temperature heat is central to our energy system. Thermodynamic efficiency increases as the temperature difference across a heat engine increases, major traditional sources of energy inherently produce high temperatures, and waste heat recovery holds great promise. In the future, concentrated solar and thermal energy storage systems may also supply heat at high temperatures on a large scale.

The established technologies of converting high temperatures to electricity are based on turbines. These are large, complex, and expensive devices. To reach high conversion efficiencies at low cost and in flexible form factors, static heat engines are desirable. A prime example is a thermophotovoltaic cell, in which thermal radiation is harnessed by a photovoltaic device.

The most direct approach to generating electricity from heat is to use the hot electrons themselves as the working fluid. Indeed, thermionic energy conversion is a deceptively simple concept: heat an electrode to the point of evaporating electrons (historically known as thermionic emission), collect these electrons on a cold electrode, and circulate them back to the hot electrode through the electrical load. This elegant idea has been known since early 20^{th} century but, despite significant progress over the decades, its performance has remained limited and it has not become a practical technology. To understand why, one must look past the apparent simplicity of the thermionic converter.

As in other heat engines, the fundamental challenge in a thermionic converter is that of enabling the flow of electric charge while restricting the flow of heat. In this device, the Coulomb repulsion of the emitted electrons hinders further electron emission and transport. The simplest way to mitigate this space charge effect is to place the cold collector close to the hot emitter—at a distance of a few micrometers or less. At such small emitter-collector gaps, however, near-field radiative coupling causes major energy loss.

A thermionic converter is in fact a highly complex device. The emitter is strongly out of equilibrium—a hot soup boiling with many excitations and ripe with nonlinear effects. In addition to the thermal emission of electrons and far-field and near-field thermal radiation, thermal conduction and thermoelectric and other solid-state transport phenomena within the emitter, collector, and leads need to be accounted for. Add nanomaterials and nanostructures to the mix and you also have new physics. To analyze a thermionic converter realistically and accelerate technology development, all this must be treated simultaneously. Combing thermionics with complementary technologies such as thermoelectrics and photovoltaics will make the problem even richer. In the first part of this talk, we will discuss a multiphysics approach to modeling thermionic converters and some of the unexpected insights it provides in the context of example devices.

To engineer a thermionic converter to favor electron transfer over radiative coupling, we need to understand both phenomena to a greater degree than traditionally considered in these devices; fine-grained knowledge of the electron and photon energy exchange channels is required. In the second part of the talk, we will argue for the need for quantitatively meaningful spectroscopic approaches in this context, report on recent experimental developments on thermal electron and photon spectroscopy, and discuss directions to further advance this area.

2:00 PM SF05.07.02
Thermophotonic Energy Harvesting: Towards a Narrowband LED Emission JulienLegendre and Pierre-OlivierChapuis; CNRS - INSA Lyon, France

Converting low-grade heat into electrical power with thermophotovoltaic (TPV) cells has two main drawbacks. First, the emitter temperature is limited due to Planck's law thermal-radiation bound, which only allows for moderate power generation. Second, the thermal radiation emitted is located in the mid-infrared range and has usually a broad bandwidth, which makes it harder to convert it efficiently. To overcome these limitations, a thermophotonic (TPX) device has been proposed [1], in which a heated light-emitting diode (LED) is used as the active emitter instead of a passive emitter as in TPV. With such a device, the emission profile can be tuned by means of electroluminescence to a narrow peak in a spectral range matching better the bandgap of efficient TPV cells. With the development of LEDs and the increase of their achievable quantum efficiency, TPX has come out as an attractive concept for both energy harvesting and refrigeration [2]. One advantage is that the emitter temperature can stay moderate, close to few hundreds of degrees Celsius, in contrast to usual TPV emitters. The many studies on near-field (NF) thermal radiation and their application into efficient NF-TPV devices highlight the possibility to extend the concept to near-field thermophotonics (NF-TPX), where enhanced energy conversion is due to both electrical control and wave tunneling.
Using a radiative transfer solver based on fluctuational electrodynamics [3] – a framework allowing to deal with thermal and nonthermal (electroluminescent) near-field radiation – we demonstrate that using an LED as the active emitter allows to narrow the emission bandwidth to only few tenths of eV for both far-field and near-field devices. Even with such a narrowband emission, we show that the device works in fact far from the monochromatic limit (where the highest efficiency can be reached). Using a detailed-balance formulation [3] to obtain the electrical power generation/consumption of both LED and PV cell, we pinpoint that the efficiency at maximum power is almost divided by two compared to the monochromatic case for a 600 K LED. While these results are obtained numerically, it is actually possible to derive analytically the efficiency at maximum power for simple emission profiles. We therefore provide expressions for monochromatic and complete above-bandgap emission. Finally, we discuss the possibility to filter the emitter/absorber radiative exchange similarly to TPV if one aims at increasing the efficiency at the cost of output power.

2:15 PM SF05.07.03
Characterization of Composite Multilayer Films for High-Temperature Selective Radiation Emission Applications PeterBermel; Purdue University, United States

In thermophotovoltaics (TPV) applications, characterizing thin-film materials with high refractive index, high thermal stability and infrared transparency is important for designing appropriate structures. Here, we report spectroscopic ellipsometer measurements of several thin films in the wavelength range 210 nm to 2500 nm from room temperature to 1000 deg C. Our findings provide insights into the potential impacts of temperature change on the aforementioned applications, induced by the underlying changes in their electronic band structures. After characterizing magnesium oxide (MgO) and strontium titanate (STO) substrates, we characterize single composite layers of cerium oxide (CeO_2) and barium zirconate ($BaZrO_3$) deposited on top of these substrates. Finally, we apply these initial characterizations to understand data obtained from multilayer samples comprised of a combination of layers from all these materials, and project the potential performance for TPV applications.

2:30 PM *SF05.07.04
Radiative Heat Transfer in Nanoscale Gaps and its Application to Energy Conversion PramodSangi Reddy; University of Michigan, United States

Understanding radiative heat transfer in nanoscale gaps and devices is of considerable interest
for creating novel energy conversion devices. In this talk, I will first describe ongoing efforts

in our group to experimentally elucidate nanoscale radiative heat transfer. I will present our recent experimental work where we have explored how radiative heat transfer is modified in nanoscale gaps at room temperature and cryogenic temperatures. Specifically, I will describe a variety of instrumentation including novel nanopositioning platforms and microdevices, which we have developed to accomplish these measurements. Further, I will discuss possible applications of near-field thermal radiation for energy conversion and photonic cooling.

3:30 PM SF05.08.01
Broadband Thermal Management of Infrared Zero Contrast Grating KenAraki[1] and RichardZhang[2]; [1]Arizona State University, United States; [2]University of North Texas, United States

A Zero Contrast Grating (ZCG) is an at-wavelength grating that does not create a refractive index gradient at the interface of the slit array and the substrate. The physical mechanism behind its transparency is determined from the Fabry-Perot Round Trip (FP-RT) eigenequation. This is complementary to the High Contrast Grating (HCG). While ZCG has no index gradient at the output plane of the slit array, HCG has high index gradient which produces FP-RT of electromagnetic wave inside the rectangular periodic dips so that near-perfect reflectance is obtained. Once the index has no change at the output plane between the dips and the substrate, near-perfect transmittance of 99.9% is observed. Only the even-order waveguide mode of FP-RT is strongly responsible for deciding the transmittance band whereas HCG has both single and even-order waveguide modes that decide the cut-off wavelengths, creating a narrower reflectance band. Thus, ZCG is well-suited not only for broadband transmittance but also for broadband reflectance with an additional reflective layer. The study investigates the physical background of ZCG in IR and surveys the tunability using different materials such as high-index silicon, germanium, low-index fluorides, salts, and polymers, in comparison with HCG. In contrast to previous research done on optical filters and lasers using ZCG and HCG, the work proposes the use of 1D ZCG as a thermal imaging or IR transparency window where very low reflectance is required.

3:45 PM SF05.08.02
Improving Heat Transfer of Radiative Heat Sink-Integrated Electrocaloric Cooling Hyung RaeKim[1], Dong HyunSeo[1], Jae MinJeon[1], Gil JuLee[2] and Young MinSong[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

Although vapor-compression refrigeration (VCR) has achieved high efficiency, reliability, and relatively compact size, a global consensus demands the development of novel cooling technology beyond the VCR. The use of hydrofluorocarbons (HFCs) as refrigerants in VCR contributes significantly to global warming, thousands of times more than carbon dioxide (CO_2) [1]. In recent years, solid-state refrigeration methods utilizing the caloric effect, such as magnetocaloric and electrocaloric effects, as well as passive radiative cooling, have emerged as promising solutions. Among them, electrocaloric (EC) cooling shows a high coefficient of performance (COP), low power consumption, and direct usage of electricity [2]. EC cooling utilizes an adiabatic temperature change (ΔT) of the refrigerant induced by an external electric field. However, the maximum cooling performance of EC cooling is restricted by the temperature change of the refrigerant. Previous attempts to overcome this limitation and maintain the heat sink cool involve introducing multiple heat exchanges [3]. Nonetheless, the complex structure leads to thermal losses at device interfaces and significant costs. On the other hand, passive radiative cooling exploits the radiative heat exchange between Earth (~ 300 K) and cold outer space (~ 3 K) through the atmospheric window (8-13 μm), enabling an object to maintain a temperature below ambient temperature without external energy consumption. Conventional radiative coolers consist of a porous structure to achieve high radiative cooing performance by strongly scattering the solar spectrum (0.28-2.5 μm) [4]. However, the low thermal conductivity of the porous structure hinders the dissipation of large heat fluxes, making them unsuitable for heat sink applications.

In this study, we propose a radiative heat sink-integrated electrocaloric cooling (R-iEC) system to improve heat transfer and overcome the limitations within a unit heat exchange cycle. By incorporating the thermally conductive radiative cooler (TCRC) as a heat sink on the EC cooling device, the heat sink maintains its temperature below the ambient air temperature even under the large heat flux introduced by the EC effect. The TCRC, composed of boron nitride sheet (BNNS) and poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) matrix, exhibits high thermal conductivity of 1.41 W/mK in the through-plane direction. This thermal conductivity is 13 times higher than that of the pure PVDF-HFP matrix (0.12 W/mK). Additionally, the TCRC demonstrates high reflectance in the visible range (~ 99%) and high emittance in the atmospheric window (~ 95%). The EC refrigerant absorbs heat from heat sink and ejects heat through the heat sink by fluctuating from the heat source to the heat sink through electrostatic actuation. Consequently, the temperature span of the EC device is 1.6 K at the switching frequency of 0.2 Hz. To demonstrate the enhanced heat transfer and cooling performance of the R-iEC system, a comparison is conducted among the R-iEC system, (i) a metal heat sink, (ii) EC device, and (iii) radiative cooler. While the metal heat sink and EC device experience heating from direct sunlight, the R-iEC system demonstrates an outstanding cooling heat flux of ~ 87 W/m^2 and cooling temperature of 7.3 K, overwhelming other samples.

Multispectral Camouflage Surfaces Inspired by Cephalopods YinuanLiu, ZhijingFeng, ChengyiXu, AtrouliChatterjee and AlonGorodetsky; University of California, Irvine, United States

Wrinkled surfaces and materials are found throughout the natural world in various plants and animals and are known to improve the performance of emerging optical and electrical technologies. Despite much progress, the reversible post-fabrication tuning of wrinkle sizes and geometries across multiple length scales has remained relatively challenging for some materials, and the development of comprehensive structure−function relationships for optically active wrinkled surfaces has often proven difficult. Herein, by drawing inspiration from natural cephalopod skin and leveraging methodologies established for artificial adaptive infrared platforms, we engineer systems with hierarchically reconfigurable wrinkled surface morphologies and dynamically tunable visible-to-infrared spectroscopic properties. Specifically, we demonstrate architectures for which mechanical actuation changes the surface morphological characteristics; modulates the reflectance, transmittance, and absorptance across a broad spectral window; controls the specular-to-diffuse reflectance ratios; and alters the visible and thermal appearances. Moreover, we demonstrate the incorporation of these architectures into analogous electrically actuated appearance-changing devices that feature competitive figures of merit, such as reasonable maximum areal strains, rapid response times, and good stabilities upon repeated actuation. Overall, our findings constitute another step forward in the continued development of cephalopod-inspired light- and heat-manipulating systems and may facilitate advanced applications in the areas of sensing, electronics, optics, soft robotics, and thermal management.

Extended-Perimeter GaAs/InGaP Light-Emitting Diodes for Electroluminescent Cooling Lucvan der Krabben, NatashaGruginskie, Maartenvan Eerden, Jaspervan Gastel, PeterMulder, GerardJ. Bauhuis, EliasVlieg and JohnJ. Schermer; Radboud University, Netherlands

Electroluminescent cooling (ELC) occurs when the amount of optical energy produced by electroluminescence is greater than the injected electrical energy. To satisfy the first law of thermodynamics, this difference is supplied by the absorption of thermal energy from the crystal lattice, resulting in cooling. In contrast to conventional cooling technologies, such as mechanical compressor and thermoelectric cooling, ELC could open the pathway towards efficient, compact and pollution-free refrigerators with access to cryogenic temperatures. Light-emitting diodes (LEDs) based on the III-V semiconductor GaAs are a promising candidate for demonstrating ELC. However, exceptionally high internal quantum efficiency (IQE) designs are paramount to achieve this goal. A significant loss mechanism preventing unity IQE in GaAs-based devices is non-radiative surface recombination at the perimeter sidewall. To address this issue, an unconventional LED design will be presented in which the distance from the current injection point to the device's perimeter is extended while maintaining a constant front contact grid size. This effectively moves the perimeter beyond the lateral spread of current at the operating current density ($10^1 – 10^2$ A/cm^2). In addition, a theoretical model on current spreading in extended perimeter LEDs is developed to guide the device design and aid in the interpretation of current-voltage characteristics. Upon extending the perimeter, we have observed an order of magnitude decrease in the non-radiative recombination saturation current density, which is ascribed to a reduction in perimeter recombination due to the lower perimeter-to-surface area ratio. From devices fabricated with varying sizes and perimeter extensions, the optimal design is found to be a 450×450 μm^2 LED with 250 μm extension from contact to perimeter. This ultimately results in a 19% relative increase in external quantum efficiency, compared to a typical tight perimeter extension of 25 μm. Therefore, with extended perimeter LEDs, we can achieve a significant decrease in perimeter recombination. This is enabled by lowering the perimeter-to-surface area ratio, while minimizing the influence on the size of the active light-emitting diode area, thereby more easily allowing for high current densities. These findings aid in the advancement of electroluminescent cooling in LEDs and could prove useful in other dedicated semiconductor devices where perimeter recombination is limiting.

8:00 PM SF05.10.02
Tunable Thermal Emission with Oxides that Undergo Insulator-Metal Transition ShlokaShriram[1], ShriramRamanathan[2] and HusseinHijazi[2]; [1]Princeton High School, United States; [2]Rutgers University, United States

Correlated semiconductor materials such as VO_2 and $SmNiO_3$ display thermally tunable emissivity via insulator-metal transition (e.g. Kats et al, Physical Review X, 3, 041004, 2013). The carrier density can vary by several orders of magnitude across the phase transition boundary while the mobility is largely unaffected. Further, the transition can be triggered both thermally and through electrically driven Joule heating. By suitable choice of dopants on either the cation or anion site, it is possible to tune the insulator-metal transition (IMT) temperature by several tens of degrees as well as the hysteresis. The ability to tune the IMT temperature is of interest to diverse applications such as infrared thermal camouflage, thermochromic coatings for windows and radiative heat transfer in spacecraft. In this presentation, we will discuss our results on Rutherford backscattering spectroscopy of pristine VO_2 and aliovalent cation-doped systems such as (W, V)O_2 and (Nb, V)O_2 thin films on various substrates such as sapphire, SiN and GaAs. We will establish a relation between electron or hole doping density and transition temperature and hysteresis width for tunable thermal emission applications. We will then extend these analyses to the rare-earth nickelates to illustrate Nd-doping of $SmNiO_3$ to lower the transition temperature near ambient conditions. Finally, we will discuss the use of ion implantation technique to incorporate controlled density of dopants through the depth of a thin film and examine the resulting carrier concentration profile. We anticipate the results to be of broad interest to the community of researchers investigating novel materials for thermal radiation control.

8:00 PM SF05.10.03
Growth and Characterization of Sb-Based Dilute Nitride Semiconductors by Sputtering SachieFujikawa; Saitama University, Japan

III-V-N alloys have a property called giant band gap bowing, in which the band gap decreases with increasing nitrogen composition in the low nitrogen composition region. This is due to the fact that the electronegativity of N atoms is significantly different from that of group III and group V atoms. InSb1-xNx alloys can obtain an even smaller band gap by band gap bowing because InSb is a narrow-gap semiconductor. Far-infrared optical devices with wavelengths of 8~14 μm, which is the window of the atmosphere, are expected to have various applications. There have been reports on the growth of InSbN thin films by Molecular beam epitaxial (MBE) and metal-organic chemical vapor deposition (MOCVD) methods, but none by the sputtering method.
In this study, $InSb_{1-x}N_x$ was grown on GaAs (100) substrate by direct current (DC) magnetron sputtering method and characterized. $InSb_{1-x}N_x$ thin film was grown on semi-insulating GaAs (100) substrate by DC magnetron sputtering method using the InSb (atomic ratio of 1:1) target. All samples were grown at a growth pressure of 5.0×10^{-1} Pa, DC power of 0.10 kW, and growth time of 60 minutes. First, InSb thin films were grown by changing the growth temperatures to room temperature (RT), 150°C, and 300°C. As a result, we were confirmed that the peak intensities of (111), (220), and (311) planes increased as the growth temperature increased. Next, $InSb_{1-x}N_x$ was fixed at 300°C and the flow rates of Ar [sccm]and N_2 [sccm] were varied 50:0 (a), 49:1 (b), 45:5 (c), and 40:10 (d), respectively. As a result, we were confirmed that the peak intensity of $InSb_{1-x}N_x$ became weaker as the N2 flow rate increased. In sample (c), broad peaks were observed in the (111) and (220) planes of InSb, while no peaks were observed in sample (d). The N compositions of $InSb_{1-x}N_x$ revealed by Secondary Ion Mass Spectrometry (SIMS) analysis were x = 0 for sample (a), x = 0.014 for sample (b), x = 0.07 for sample (c), and x = 0.11 for sample (d). We also confirmed that $InSb_{1-x}N_x$ thin films with a maximum nitrogen composition of x = 0.20 can be grown by changing the flow rate ratio of Ar: N_2 to 0:10. From these results, we found that $InSb_{1-x}N_x$ can be fabricated by sputtering by controlling Ar and N_2 gases.

8:00 PM SF05.10.04
Scalable, High Thermal Conductive Electrospun/Sprayed Radiative Cooler for Efficient Thermal Management Dong HyunSeo, Joo HoYun, Abdullah AlMahmud and Young MinSong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Passive radiative cooling enables an object to maintain a temperature lower than the ambient air temperature without external energy consumption. To achieve efficient radiative cooling performance, the thermal emitter should exhibit solar spectrum reflection (0.28-2.5 μm) while emitting heat as radiation within the atmospheric window (8-13 μm) [1]. In practical applications with significant cooling requirements, such as data centers, vehicles, and communication base stations, the objects that need cooling often operate at temperatures higher than the surrounding ambient temperature due to substantial internal heat generation [2]. However, polymer-based photonic structures, commonly employed for their material properties and porosity to provide insulation, exhibit low thermal conductivity. Consequently, when these coolers are applied to high-temperature objects, they encounter heat resistance resulting from their low thermal conductivity, leading to the accumulation of cooling heat and a decline in cooling performance. To overcome these challenges, researchers have been investigating radiative coolers that possess enhanced thermal conductivity. One approach involves incorporating nanofillers, such as boron nitride, into the radiative cooler to improve both the overall thermal conductivity and solar reflectivity [3]. Nevertheless, achieving adequate thickness is crucial to ensure high reflectivity, which simultaneously increases thermal resistance. Consequently, a significant amount of high thermal conductivity filler material is required to offset this effect. On the other hand, reducing the thickness enhances thermal conductivity but diminishes the reflectivity characteristics. Therefore, optimizing the cooling device's properties, including its thickness, reflectivity, and thermal conductivity, is of utmost importance in achieving effective cooling performance.
In this study, we fabricated an electrospun/sprayed radiative cooler (ESRC) with high thermal conductivity as a thermal management method for high-temperature objects under outdoor conditions. The ESRC was fabricated using poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) and boron nitride nanosheets (BNNS) through electrospinning and electrospraying techniques. The nanofiber membranes were manufactured with a thickness of 700 nm, and the BNNS diameter was set at 500 nm to induce multiple scattering within the solar spectrum range. Electrospraying was utilized to minimize BNNS aggregation and ensure particle dispersion for effective light scattering and thermal diffusion. Furthermore, a hot press process was employed to stack the layers, creating a heat transfer path between BNNS layers, and reducing overall thickness. As a result, the reflectance of the entire solar spectrum was measured to be over 94%. Moreover, the ESRC demonstrated high thermal radiation within the atmospheric window, with measured emittance exceeding 95%. The total thickness of the fabricated ESRC was only 120 μm, resulting in exceptional flexibility. The thermal conductivity of the ESRC was determined using the hot disk method, revealing a through-plane thermal conductivity of 1.5 K/mK with 8.7 wt% loading of BNNSs. Compared to pure PVDF-HFP, the thermal conductivity was increased by a factor of 13.

Colored Radiative Cooling Structure Managing Full Solar Spectrum via Near-Infrared Reflection and Photoluminescence DongwooChae, HangyuLim, JisungHa, JaeinPark and HeonLee; Korea University, Korea (the Republic of)

Colored radiative cooling (CRC) offers an attractive alternative for surface and space cooling with preserving the aesthetics of the object. However, it is still deficient on CRC structure with vivid and ample color display, sophisticated performance investigation, retention of properties, functionality, and structural flexibility all at once. Thus, to manage the entire solar spectrum, a colored cooling structure comprising a NIR-reflective bottom layer and top colored layer with phosphor-embedded polymer matrix is proposed. The structure is paintable, vivid and ample colored, hydrophobic, and UV and water-resistant. In the daytime outdoor measurement, the structure exhibited lower temperature than their control group using commercial white paint by 4.7^{o}C, 7.2^{o}C, and 7.4^{o}C, for red, orange, and yellow color, respectively. After precise time-tracing temperature validation between the theory and the experiment, CRC performance enhancement from NIR reflection and PL effect was thoroughly analyzed and up to 16.1^{o}C of temperature reduction was achieved for orange color. Furthermore, experiments of hydrophobicity infusion and exposure to UV and DI water verified the durability of the colored cooling structure. Also, flexible film-type colored cooling structure was demonstrated using different bottom reflective layer such as silver thin film and porous aluminum oxide particle embedded poly(vinylidene fluoride-co-hexafluoropropylene), allowing a numerous materials sets of the colored cooling structure for vivid colored, functional, and durable CRC.

8:00 PM SF05.10.06
Adaptive Electrochromic Camouflage for Thermal and Visual Adaptation in Terrestrial Environments JunhyunPark, Su EonLee and BonghoonKim; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The demand for camouflage is increasing because of surveillance technologies such as UAVs and commercial satellites. Traditional camouflage methods fall short in the face of advanced detection technologies, including multispectral sensing, high-resolution imaging, and AI inspection. Designing multi-band camouflage capable of operating across different spectral bands, influenced by electromagnetic material properties, while achieving real-time adaptability to diverse environments presents a significant and even greater challenge.

Recent studies have extensively focused on enhancing camouflage performance across multiple spectral bands and adapting to diverse backgrounds. Techniques such as photonics crystals, metasurfaces, and nested structures mimic environmental radiative signatures, while electrochromism, phase-change materials, and physical transformation have explored switchable camouflage functions. This study presents an electrically controllable dual-band camouflage thin-film system for visual and thermal adaptation in various environments.

To effectively design camouflage for diverse environments, an investigation into the radiative properties of terrestrial surfaces was conducted. Despite the variation in surface colors, there exists a commonality in their infrared (IR) emissions. A dual-band camouflage strategy was formulated based on these shared IR emissivity characteristics. We studied unique camouflage requirements for well-illuminated and low-light environments. An essential tactic involves radiant cooling to modify color and solar range emissions.

The camouflage device design is composed of a thermally emissive layer and a color-changing layer for spectral-selective switching. The top layer enables solar transparency while the bottom adjusts colors. The device changes its color and solar absorption by layering electrochromic materials on emissive substrates and adjusting voltage (0 V = light colors / 2 V = near black). Tests in simulated environments demonstrate the device's adaptability to various backgrounds, depending on voltage and substrate type (rigid = 0 V / 2 V, flexible = 0 V / 2 V).

Outdoor experiments evaluated active double-band camouflage devices in a variety of virtual environments. Rigid samples were visually thermally camouflaged to environments of snow for 0 V and deep blue silt for 2 V. Flexible samples showed excellent visual camouflage performance to conditions of bright sand for 0 V and black soil for 2 V. Despite the windy conditions affecting the thermal vision test, the device matched the thermal signature in the target environment. The camouflage device, designed with high emissions, showed a cooling effect, and outperformed the non-cooling reference sample.

In conclusion, spectral designs for visual and thermal camouflage in two terrestrial environments were developed and assessed using electrochromic devices. The design enables seamless transitions between environments by adjusting visible spectral emittance. A practical camouflage solution was achieved without the need for laborious optimization and trial-and-error methods. Furthermore, the devices offer radiative cooling, flexibility, and compatibility with existing camouflage schemes, due to their large design degrees of freedom, thus benefiting security and defense applications.

SESSION SF05.11: Light/Heat Matter Applications

Modeling Photomolecular Absorption and Evaporation at Interfaces GangChen; Massachusetts Institute of Technology, United States

It has been observed that solar evaporation from micro/nanoporous structures floating on water surfaces can sometimes lead to evaporation rates surpass the thermal evaporation limit. We hypothesize that photons can directly knock off water molecular clusters without going through the thermal evaporation process and named this process the photomolecular effect. How could such a process happen despite that bulk water does not absorb in the visible spectrum? Here, we attempt to develop theoretical foundations for understanding and modeling this process. Boundary conditions for Maxwell equations dictate that the normal component of the displacement field is continuous across the two sides of an interface that is charge neutral. This condition means that a large electrical field discontinuity exists in the direction normal to the interface. Real interfaces, however, are never perfectly sharp and have finite thickness, implying that the electrical field changes over a similar distance. Starting from the Maxwell equations and including such a transition region, we develop a set of generalized boundary conditions, which are similar to what had been developed for studying plasmonic and photoelectric effects. For water, we hypothesize that the uneven field across polar water molecules at the interface due to the large electrical field gradient creates a driven force for photons to knock out hydrogen-bonded water molecular clusters. We develop a Fermi's golden rule-based argument to estimate the surface absorptance, which suggests that surface absorptance can indeed be appreciable.

8:30 AM SF05.11.02
Solar-Driven Thermocatalytic Ethylene Oligomerization AisuluAitbekova, MagelSu, MatthewSalazar, JonasPeters, TheodorAgapie and HarryA. Atwater; California Institute of Technology, United States

We have designed a solar-thermal flow-through reactor with a multi-layered selective solar absorber for thermocatalytic oligomerization of ethylene to generate multicarbon (C4-C6 hydrocarbons) products. The selective solar absorber has high absorptivity at visible solar wavelengths and high reflectivity at infrared thermal radiation wavelengths. When exposed to sunlight (3-sun intensity), the solar absorber reaches a temperature of 100 °C sufficient to drive an industrially relevant ethylene oligomerization reaction to convert ethylene into C4-C6 hydrocarbon solar fuels. Moreover, we demonstrate that this process works using a diluted ethylene stream gas directly produced by a CO_2 electrolysis cell that produces ethylene.

Thermocatalytic routes are widely used for the commercial production of fuel and chemicals due to high conversion rates, good selectivity, and scalability. However, today's thermocatalytic technologies are driven by the thermal heat from burning fossil fuels and thus generate greenhouse gas emissions that cause global climate change. To become low- and zero-carbon emission technologies, these processes need to operate on renewable energy. One way to accomplish this goal is to convert solar energy into heat required to run thermocatalytic reactions. Overall, our work presents a framework to convert CO_2, water, and sunlight into sustainable fuels.

8:45 AM SF05.11.03
Scalable Squid Skin-Inspired Materials with Tunable Heat-Managing Properties AleksandraA. Strzelecka, PanyimingLiu and AlonGorodetsky; University of California, Irvine, United States

In the global quest for greater sustainability, the implementation of innovative packaging solutions in the food and beverage industry plays an increasingly prominent role. Within this context, traditional metallized polymer films with static thermal infrared-reflecting functionalities remain among the most widely used materials in packaging applications throughout the world. However, the development of green and low-cost alternative technologies with the highly-desirable ability to dynamically manage the exchange of heat between the contents of packaging containers and surrounding variable-temperature environments still remains relatively challenging. Herein, we present scalable squid skin-inspired sustainable packaging materials with user-tunable dynamic heat-managing properties. The composites feature a low estimated starting material cost of ~ $ 0.1 USD per square meter, sizes of ~ 0.35 m^2 comparable to those of common metallized plastic films, the ability to modulate infrared transmittance by > 20-fold and heat fluxes by > 30 W/m^2 upon actuation with strain, and functional robustness upon significant mechanical deformation or after repeated mechanical cycling. The composites also feature adaptive infrared and dynamic thermoregulatory properties that can be computationally predicted via straightforward models. The described materials could represent a technological solution that addresses the combined cost, performance, and sustainability pressures facing the food and beverage packaging industry.

9:00 AM *SF05.11.04
Radiative Thermal Control of Spacecraft using Thermochromic Infrared Materials MichaelBarako; Northrop Grumman, United States

Thermochromic infrared surfaces have temperature-dependent emissivity spectra that enable radiators to respond to changes in the thermal environment. Spacecraft can leverage this unique behavior for autoregulating thermal control, where thermochromic surfaces are designed to passively transition between a high thermal emissivity (to radiate heat when hot) and a low thermal emissivity (to retain heat when cold). The “thermal emissivity” is defined as a total, hemispherical emissivity integrated across the entire hemisphere and a sufficiently wide infrared band to capture the majority of the emitted energy. This intrinsically broadband, omnidirectional characteristic presents a unique set of challenges for engineering variable emissivity materials (VEMs) for thermal control applications. In this talk, we introduce the materials, methods, and analyses of VEMs using thermal objectives, where spectral and directional infrared engineering is used to achieve passive control over temperature and heat flux. We show how the models and materials are validated calorimetrically and describe a novel set of thermo-optic characteristics used in both the design and system modeling of VEMs. Finally, we present a design space and optimization perspective for further development of VEMs for thermal control.

SESSION SF05.12: Thermal Radiation, Topology and 2D Materials
Session Chairs: Georgia Papadakis and Bo Zhao
Wednesday Morning, November29, 2023
Sheraton, Third Floor, Hampton

10:00 AM SF05.12.02
Versatile Infrared Properties of 2D Carbides and Carbonitrides (MXenes) DanzhenZhang[1], MeikangHan[1], AkashSingh[2], TetianaHryhorchuk[1], ChristopherE. Shuck[1], TengZhang[1], LingyiBi[1], BernardMcBride[1], VivekB. Shenoy[2] and YuryGogotsi[1]; [1]Drexel University, United States; [2]University of Pennsylvania, United States

Ultrathin films and coatings capable of controlling infrared (IR) emission are crucial for highly integrated thermal management systems, but are challenging to produce using conventional materials. Here, we report that the MXene family of two-dimensional carbides and carbonitrides offers a broad range of IR emissivity values (~0.06-0.59) with diverse colors, varying with MXene composition and structure. Specifically, 200 nm thick purple $Ti_3C_2T_x$ coating has an average IR emissivity of 0.06, while the emissivity of a gold Nb_2CT_x coating is 0.59 at wavelengths from 3 to 25 μm. We demonstrate that the IR emissivity can be finely tuned by combining different metals in solid-solution MXenes. Furthermore, the IR identification capability at varying temperatures was validated using different MXene coatings and patterned MXene fabrics. The versatility of MXenes at optical and infrared wavelengths provides a platform for developing MXene-based smart, flexible devices and wearables capable of selective and localized thermal management, aiming at radiative heating/cooling, IR identification, photothermal conversion, and thermal imaging.

10:15 AM *SF05.12.03
Functional Metasurfaces and Structures for Thermal Radiative Applications YiZheng; Northeastern University, United States

This invited talk will focus on passive radiative cooling and solar-driven water desalination technologies and the issues that have hindered their development for real-life applications. Our goals are to improve buildings’ energy efficiency by reducing the need for traditional vapor-compression cooling systems and to enhance freshwater production by taking advantage of renewable energy. Part 1: The compressor-based cooling systems, providing comfortable interior environments for infrastructures, account for about 20% of the total electricity consumption around the world. Moreover, the resultant heating effect and greenhouse gas emissions towards the environment accelerate global warming and climate change. An energy-efficient and eco-friendly cooling approach is highly demanded. The emerging passive daytime radiative cooling (PDRC) technique can achieve sub-ambient cooling effects under direct sunlight without any energy consumption by simultaneously reflecting sunlight and radiating excessive heat as infrared thermal radiation to the cold outer space through the Earth’s atmospheric window. Such an approach is becoming an attractive candidate for improving energy efficiencies for buildings, because it eliminates the need for coolant, electricity, and compressor required by traditional mechanical cooling systems. Part 2: Interfacial solar steam generation is emerging as a promising technique for efficient desalination. Although increasing efforts have been made, challenges exist for achieving a balance among a plethora of performance indicators—for example, rapid evaporation, durability, low-cost deployment, and salt rejection. We have demonstrated that carbonized agricultural waste can convert 98% of sunlight into heat, and the strong capillarity of porous carbon fibers networks pumps sufficient water to evaporation interfaces. Salt diffusion within microchannels enables quick salt drainage to the bulk seawater to prevent salt accumulation. These advantages, together with facial deployment, offer an approach for converting farm waste to energy with high efficiency and easy implementation, which is particularly well suited for developing regions.

10:45 AM SF05.12.04
Native Point Defects in HgCdTe Infrared Detector Material: Identifying Nonradiative Recombination Centers from First Principles WeiChen[1] and GeoffroyHautier[2]; [1]Université Catholique de Louvain, Belgium; [2]Dartmouth College, United States

We investigate the native point defects in the long-wavelength infrared (LWIR) detector material $Hg_{0.25}Cd_{0.25}Te$ using a dielectric-dependent hybrid density functional. The dielectric-dependent hybrid functional allows for an accurate description of the band gap (E_g) for $Hg_{1-x}Cd_xTe$ (MCT) over the entire compositional range, a level of accuracy challenging with standard hybrid functionals. Our comprehensive examination of the native point defects confirms that the two isoelectronic cation vacancies, namely V_{Hg} and V_{Cd}, are the primary sources of p-type conductivity in the LWIR material given their low defect formation energies and the presence of a shallow acceptor level near the valence-band maximum (VBM). Meanwhile, the cation vacancies exhibit a deep charge transition level (-/2-) that is situated at $E_g/2$ above the VBM, which is characteristic of nonradiative recombination centers that can be a major limiting factor affecting device performance. Our study does not support the assignment of other native point defects (such as mercury interstitial) as the origin of deep levels in p-type LWIR MCT.

11:00 AM *SF05.13.01
Controlling IR Thermal Emission with Metasurfaces Jean-JacquesGreffet[1,2], AnneNguyen[1,2] and BenjaminVest[1,2]; [1]Université Paris-Saclay, France; [2]Institut d'Optique, France

In order to shape an Infrared (IR) beam, a number of optical components have to be used. These include a IR source on the first place, a filter to control the spectrum, a polarizer and a retardation plate to control the polarization state and a lens to collimate the beam. Each component is bulky and has a transmission factor smaller than one. It is thus difficult to envision a lighting system within a micrometer thin device that could fit in any handheld device. Such an achievement can be done using light emitting metasurfaces.
In this talk, we will first explain what are metasurfaces and what can be achieved with them. We will describe some examples of metasurfaces operating in transmission by diffracting an incident beam. They can be used to steer an incident beam, modify its polarization or focus it.
Incandescent metasurfaces merge metasurfaces to control phase fronts and thermally excited random current densities emitting IR radiation. They are inherently different from metasurfaces as they are not illuminated by an incident coherent beam. We will discuss the operating principle of incandescent metasurfaces and their application to control the directivity, emission spectrum, polarization and intensity modulation beyond 10 MHz [1-2].

11:30 AM SF05.13.02
Preventing Overfitting in Infrared Ellipsometry using Temperature Dependence: Fused Silica as a Case Study ShenweiYin, DemengFeng, Jin-WooCho, TanujKumar, ChenghaoWan, HongyanMei and MikhailKats; University of Wisconsin-Madison, United States

Materials with vibrational resonances such as fused silica, quartz, and silicon carbide can be used for mid-infrared absorbers and thermal emitters [1], [2]. Here, we investigated fused-silica glass; while fused silica is perhaps the most-studied optical material in the visible and near-infrared, its mid-infrared properties are less known, with almost no data available above room temperature [3]. Apart from the use of this data in high-temperature applications of fused silica, temperature-dependent ellipsometry can provide a new source of information with which to evaluate oscillator models, in addition to the conventionally used goodness of fit.

We conducted temperature-dependent spectroscopic ellipsometry measurements on three different grades of silica from Corning: HPFS 7980 standard grade (-OH content 800–1000 ppm, metallic impurities <1000 ppb), 7979 IR grade (-OH content <1 ppm, metallic impurities <100 ppb), and 8655 ArF grade (-OH content <1 ppm, metallic impurities <10 ppb). For each sample, we performed temperature-dependent variable-angle ellipsometry measurements at wavelengths of 5–25 μm.

Subsequently, we performed fits on the experimental ellipsometric data, ψ and Δ. We observed 3 main features centered around the wavelengths of 9 mm, 12.5 mm, and 22 mm, known to be due to vibrational resonances [3]. A previous work that looked at reflectance data (rather than ellipsometry) at room temperature used 8 distinct Gaussian oscillators to fit the experimental data [3]. Similarly, we were able to achieve excellent fits at each temperature (7 temperatures total for each sample) using 7 Gaussian oscillators, observing that Gaussian oscillators fitted the data better than Lorentz oscillators, likely due to inhomogeneous broadening in the amorphous material. However, when we plotted the fitting parameters as a function of temperature, we observed nonphysical nonmonotonic temperature dependence of the oscillator positions, widths, and amplitudes, implying that our model could be improved.

After simplifying the model to 6 oscillators, we again fitted the experimental data independently at each temperature for each sample, observing a slight (but not very significant) reduction in the goodness of fit (the normalized mean-squared error (MSE) for Ψ and Δ as defined in ref. [4] was 1.3 with 7 oscillators and 1.6 with 6 oscillators, both indicating excellent fits). In our new fit with fewer oscillators, the oscillator parameters that contributed most to the optical properties changed monotonically with temperature, confirming the validity of our fits. By comparing the temperature-dependence trends among the oscillator parameters, we can effectively mitigate overfitting of the experimental ellipsometric data.
In addition to our demonstration of the use of temperature-dependent measurements to prevent overfitting of materials parameters, we generated highly precise and accurate datasets for the temperature-dependent mid-infrared optical properties of various grades of fused silica, which can be used for modeling infrared absorbers, thermal emitters, and other photonic structures. These datasets will be made publicly available.

Low-Symmetry Polaritonic Materials for Infrared Polarization Control KorayAydin; Northwestern University, United States

Two-dimensional layered materials have recently garnered burgeoning amount of interest due to their unique electronic, optical, thermal, mechanical properties emerging at the mono-to-few layer thicknesses. Most of research has focused on conventional 2D materials such as graphene and 2D TMDCs, having isotropic electronic and optical properties due to their crystal symmetry. Recently, layered materials such as black phosphorus and hexagonal boron nitride investigated for anisotropic crystal structure. In this talk, I will introduce α-MoO_3 as an anisotropic photonic and polaritonic material. α-MoO_3 is a layered material that exhibits both in and out-of-the-plane anisotropic polaritonic response at mid-IR wavelengths. We designed and experimentally demonstrated an anisotropic polaritonic absorber and showed that one can couple to all phonon modes and address them individually either using structural tunability or polarization control of incident infrared radiation. Moreover, I will introduce MOCVD grown β-Ga_2O3 as an emerging material for IR photonics applications due to its anisotropic crystal symmetry. Detailed numerical modelling and experimental characterizations highlighting unique IR properties for manipulating and controlling the polarization response will be discussed.

Hyperbolic Polariton Mode Conversion and Energy Redistribution in Engineered Van der Waals Structures Byung-IlNoh[1], SinaJ. Ghalekohneh[2], MingyuanChen[1], JialiangShen[1], JiahanLi[3], LixingKang[4], JamesH. Edgar[3], BoZhao[2] and SiyuanDai[1]; [1]Auburn University, United States; [2]University of Houston, United States; [3]Kansas State University, United States; [4]Chinese Academy of Sciences, China

Hyperbolic polaritons, which are highly confined light-matter waves, present a promising avenue for manipulating light and light-matter interactions at nanoscales. Recent advances in scanning probe optical techniques have enabled the imaging of hyperbolic polaritons in real space. However, current studies typically image only one branch of hyperbolic polaritons. In this work, we evidently imaged multiple branches of hyperbolic polaritons in engineered van der Waals (vdW) structures. Instead of conventional long-range fringes, our nano-infrared imaging demonstrates short-range beats by varying the edge symmetry through vdW stackings. Our combined experimental and theoretical results reveal the energy redistribution and mode conversion in hyperbolic polaritons. These advances hold great potential for polaritonic circuits, nano-optical sensing, nanoscale energy transfer, etc. (Oral)

Can Thermal Transport in Thin Films by Surface Phonon/Plasmon Polaritons be Experimentally Observed?AlexeiMaznev[1] and BaiSong[2]; [1]Massachusetts Institute of Technology, United States; [2]Peking University, China

Thermal transport in thin films mediated by surface polaritons (SPs) originally proposed by Chen et al. [1] is attracting intense attention of both theorists and experimentalists [2-5]. According to theoretical models [1,2], SPs become efficient in carrying heat when their mean free path (MFP) is long and they almost lose their polaritonic character and become similar to free-space electromagnetic waves. The long MFP of the heat-carrying SPs (~ 1 cm or longer) presents a formidable challenge for experimentalists: in order to observe the predicted SP contribution to thermal transport, the heat transfer length should be greater than their MFP [1]. This requirement is often not met in laser-based experiments where the characteristic length scale is determined by a microns-sized laser spot [4,5]. However, there is a more fundamental challenge: with a thin film sample size on the order of 1 cm, thermal radiation also becomes significant. We argue that from the experimental point of view, the energy exchange with the environment via thermal radiation is hardly distinguishable from thermal transport: since the hot side of the sample

radiates more than the cold side, to an observer it looks like an additional energy flux between the two sides. This becomes especially apparent when the temperature of the environment is set so as to minimize the total radiative loss of the sample, in which case the cold side of the sample effectively absorbs thermal radiation energy emitted by the hot side. We will present a theoretical model describing heat transport in a thin free-standing film in the presence of both conduction and radiative exchange with the environment and show that the relative contribution of the latter increases as the square of the sample size. In many cases, the radiative exchange will completely obscure the contribution of SPs. The presentation will be complemented by a discussion of experimentally relevant systems supporting phononic or plasmonic SPs such as silica glass and titanium thin films.

Exploiting and Controlling Lattice Symmetry for Infrared Nanophotonics and Thermal Transport JoshuaD. Caldwell; Vanderbilt University, United States

The field of nanophotonics is based on the ability to confine light to sub-diffractional dimensions. In the infrared, this requires compression of the wavelength to length scales well below that of the free-space values. While traditional dielectric materials do not exhibit indices of refraction high enough in non-dispersive media to realize such compression, the implementation of polaritons, quasi-particles comprised of oscillating charges and photons, enable such opportunities. Two predominant forms of polaritons, the plasmon and phonon polariton, which are derived from light coupled with free carriers or polar optic phonons, respectively, are broadly applied in the mid- to long-wave infrared. However, the short scattering lifetimes of free-carriers results in high losses and broad linewidths for the former, while the fast dispersion and narrow band of operation for the latter result in significant limitations for both forms. Within anisotropic materials, these optical modes can be induced to propagate with different wavevectors along different axes, or even be restricted to propagate only along a single direction. Here, we discuss the influence of crystalline anisotropy in dictating the polaritonic dispersion, including the recent observations from our group highlighting highly directional so-called hyperbolic shear polaritons in low-symmetry monoclinic and triclinic crystals, as well as the ability to control the wavelength and propagation direction of these modes using free-carrier injection and twist-optic concepts. Further, we highlight that such phonon polaritons can be employed as ultrafast and efficient carriers of thermal energy, providing alternative dissipation pathways for heat.

Thermomechanical Engineering of Mid-Infrared Phonon Polaritons in α-MoO_3NaveedHussain, MashnoonA. Sakib, ZhaoX. Li, H. KumarWickramasinghe and MaximR. Shcherbakov; University of California Irvine, United States

Polar van der Waals (vdW) materials, such as α-MoO_3, have enabled controlling light at the nanoscale over a wide range of wavelengths by leveraging the strong optical confinement of their hyperbolic polaritonic modes.[1,2] However, the extreme spatial confinement of phonon polaritons (PhPs) in these structures renders it hard to control their dispersion externally. [3-5] We show here that the hyperbolic PhPs in α-MoO_3 can be tuned by engineering phonon modes via introducing controlled oxygen vacancy defects by hot-pressing (h.p.) them to 350 °C with a period of 50 °C under a mild uniaxial pressure of around 0.1-0.2 GPa. The reduced oxygen supply during the thermal annealing results in loss of terminal oxygen through vdW gaps, leaving behind the oxygen vacancy defects. As measured by μ-Raman scattering investigations, the oxygen-to-molybdenum ratio (I_{B2g}/I_{B3g}) can be reduced to an order of magnitude (at h.p. of 350 °C), triggering a semiconductor-to-semimetal transition, probed by PL spectroscopy.[5] We also induced a controlled biaxial compressive strain up to -2.4%, demonstrated by a blue shifting of the phonon mode at 158.4 cm^{-1}. We used photo-induced force microscopy (PiFM) to investigate thermomechanically engineered PhPs, which matches well with the model we developed using FDTD simulations and PiFM data.[6] The data extracted from the dispersion curves demonstrate the successful tailoring of the PhP response of α-MoO_3 by introducing oxygen vacancy defects. The polariton lifetimes (τ) for pristine and h.p. flakes at 150 °C, were nearly identical, ranging from 3. 57±0.3 to 3.38±0.3 ps, respectively, exhibiting a negligible loss of only ~5.26%. When compared to pristine flakes of same thickness, oxygen-deficient α-MoO_3 provides an ultra-low-loss platform for PhPs, allowing for tuning of their polariton wavelength (λ_P) by ~11.84% and group velocity (v_g) by ~15.4%. We believe that engineering of phonon modes, which result in oxygen-deficient α-MoO_3, enable active tuning of mid-infrared PhPs, which has applications in super-resolution imaging, nanoscale thermal manipulation, boosted molecular sensing, and on-chip optical circuits.

Dynamic, Electrostatic Steering of Thermal Emission using Graphen/Metal Metasurfaces VictorBrar; University of Wisconsin--Madison, United States

This talk will describe the thermal emission from optical cavities that support long-range, delocalized Fabry-Perot modes, where one side of the cavity is bounded by a graphene-integrated metasurface. The graphene allows the reflection coefficients of the metasurface to be continuously tuned via electrostatic gating which, in turn, changes the properties of the confined Fabry-Perot modes. Those changes affect, for a fixed frequency, the directionality of the absorption and emission of the device and we show experimentally that this mechanism can allow the thermally emitted radiation at 6.6 um to be tuned by more than 16 degrees, with a peak emissivity maintained about 0.9. Theoretical calculations will also be presented that describe the maximum steerability of optimized devices that use real materials, and from those calculations it will be shown that this mechanism can allow thermal emission to be steered continuously by more than 60 degrees.

SESSION SF05.15: Radiative Cooling II
Session Chairs: Aaswath Raman and Yi Zheng
Thursday Morning, November30, 2023
Sheraton, Third Floor, Hampton

9:00 AM SF05.15.01
Highly Efficient and Versatile Daytime Radiative Cooler Based on Optimized Polymer-Ceramic Composite Fabricated via Facile Process JaeinPark, DongwooChae, HangyuLim, JisungHa and HeonLee; Korea University, Korea (the Republic of)

Radiative cooling is a carbon-free, zero energy technology that can substitute various energy-consuming cooling systems such as air conditioners and auto-chillers for cooling heat-generating machines. Previous reports on radiative cooling have focused mainly on the cooling performance, thereby overlooking the applicability, structural complexity, manufacturing complexity, and certain physical properties of the cooler. In this study, we present an efficient, applicable, and facile-fabricated radiative cooler composed of poly(vinylidene fluoride-co-hexafluoro propene) (P(VDF-HFP)) and alumina (Al_2O_3). Apart from being fabricated in the form of a freestanding sheet with 97.5% solar reflectance and 94.8% infrared (IR) emissivity, the P(VDF-HFP)/Al_2O_3-based radiative cooler (PARC) can be applied to solid substrates via simple coating techniques. This shows that the PARC can be introduced in architecture, clothing, and other fields that demand cooling. The PARC‘s cooling performance is experimentally proven by a sub-ambient temperature drop of 5.8 °C and the cooling power of the PARC is calculated to be 125.6 Wm^{-2} under the AM1.5 global spectrum, which is superior to that of previously reported radiative cooling emitters.

9:15 AM SF05.15.02
Biologically Inspired Nanostructured Porous Fiber for Passive Radiative Cooling MinjaeLee[1,2], ByunghongLee[2], Byung WookKim[3] and Seung HwanKo[1,1]; [1]Seoul National University, Korea (the Republic of); [2]Hyundai Motor Company, Korea (the Republic of); [3]Columbia University, United States

A great number of butterfly species in the warmer climate have evolved to exhibit fascinating optical properties on their wing scale which can both regulate the wing temperature and exhibit the structural coloring in order to increase their chances of survival. In particular, the *Archaeoprepona demophoon* dorsal wing demonstrates notable radiative cooling performance and iridescent colors based on its nanostructure of the wing scale that can be characterized by the nanoporous matrix with the periodic nanograting structure on the top matrix surface. Inspired by the natural species, we demonstrate a multifunctional biomimetic film that reconstructs the nanostructure of the *Archaeoprepona demophoon* wing scales to replicate the radiative cooling and structural coloring functionalities. We resorted to the SiO_2 sacrificial template-based solution process to mimic the random porous structure and laser-interference lithography to reproduce the nanograting architecture of the butterfly wing scale. As a result, the biomimetic structure of the nanograted surface on top of the porous film demonstrated desirable heat transfer and optical properties for outstanding radiative cooling performance and iridescent structural coloring. In this regard, the film is capable of inducing the maximum temperature drop of 8.45 deg, and the color gamut of the biomimetic film can cover 91.8% of the standardized color profile (sRGB).

9:30 AM SF05.15.03
Designing Radiative Cooling Walls with Passive and Active Controls YuanYang; Columbia University, United States

Passive daytime radiative cooling (PDRC) is an attractive electricity-free approach to reducing energy consumption of buildings. Current PDRC research focuses on roofs, but limited attention has been paid to the walls, which occupy a major portion of building envelopes. Unlike the roofs, the walls face both cold sky and hot ground, so either high emissivity or low emissivity is not the best solution. Here we develop a scalable cooling wall with asymmetric emissivity. The wall can simultaneously reflect the thermal radiation from the hot ground and remain emissive to the cold sky, to achieve further building cooling and even sub-ambient cooling, which are demonstrated by simulations and experiments. Such asymmetric emissivity shows temperature drops of 3.1 °C (peak) / 2.3 °C (daily average) compared to the control wall in the field tests. Taking the United States as an example, the proposed zigzag wall can work effectively over 29% area and benefit 45% population, providing up to 27 MJ m-2 year-round saving per wall area for a typical midrise apartment building. We further demonstrated mechanically dyanmic control of wall emissivity to further maximize energy saving.

Spectrally Engineered Textile for Radiative Cooling Against Urban Heat Islands RonghuiWu and Po-ChunHsu; The University of Chicago, United States

Radiative cooling textile has been considered as a promising method to achieve personal thermal comfort under the increasing global temperature. Since more than half of the world population resides in urban areas where the heat island effect exacerbates the local temperature rise, outdoor radiative cooling textiles should emphasize the heat exchange of the users under a metropolitan area scenario. While yielding high cooling performance when facing the sky, start-of-the-art radiative cooling textiles do not consider that the apparel is predominantly vertically oriented and underestimate the parasitic radiative heat gain from the hot ground and urban infrastructures. Here, we developed a mid-infrared (MIR) spectrally selective hierarchical fabric (SSHF) with emissivity greatly dominant in the atmospheric transmission window (ATW) through molecular design, minimizing the net heat gain from the surroundings. The SSHF also features a high solar spectrum reflectivity of 0.96 owing to the strong Mie scattering from the nano-micro hybrid fibrous structure. As a result, SSHF enables a considerable temperature drop of ~6.2°C under peak solar intensity of 1010 W/m^2 in outdoor thermal measurements. When vertically placed in a simulated urban scenario, it exhibits ~3.1°C cooler than commercial cotton fabrics. Moreover, SSHF has also demonstrated excellent breathability, washability, durability, robust mechanical property, and anti-UV aging property, representing remarkable long-term wearability. Supported by a comprehensive analysis of heat transfer between individuals and their environment, the selective spectrum design for vertical-facing textiles introduces an innovative and efficacious solution for passive personal cooling in urban areas, which not only holds the potential to curtail air-conditioning energy consumption but also serves as a preventive measure against heat-related health issues.

10:30 AM SF05.15.05
Enhanced Radiative/Evaporative Cooling from Air Eddies above Zebra Stripes: A Deductive Approach Se-YeonHeo and Young MinSong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Passive radiative cooling offers a sustainable way to effective temperature reduction, utilizing thermal imbalance of earth and universe and minimizing heat gain from surroundings. Numerous studies have demonstrated its environmentally friendly nature and high cooling efficiency, establishing it as a highly promising solution for sustainable cooling applications. In recent years, scientific research has unveiled that the cooling potential of evaporation (~320 Wm^{-2}) surpasses that of radiation (~150 Wm^{-2}), and implementation of evaporative and radiative cooling approaches has successfully achieved superior cooling performance compared to single reliance on radiative cooling methods. But evaporative cooling in nature exist in way for obtaining homeostasis; During the summer season, both plants exhibit active transpiration, and mammals experience increased sweat evaporation, as a means to regulate their body temperature and counteract the rise caused by the elevated ambient temperature. Conversely, in cold winter conditions, these phenomena occur less frequently as a mechanism to maintain a stable body temperature. Indeed, equation for evaporative rate(m') express that the rate of evaporation intensifies as temperature increases.

$m' = \theta(X_s(T_{body})-X(T_{amb}))$ (1)

where θ is evaporative coefficient, which equals to 25+19v where v is the velocity of air. X_s denotes the maximum humidity ratio of saturated air at the same temperature as the body. X is humidity ratio of ambient air at the temperature T_{amb}. Since the X_s increases dramatically with increased body temperature(T_{body}), smaller Tbody results in decreased m'. In other words, the cooler the body, the less evaporation occurs.

As for maximizing efficiency of evaporation, utilizing the heating power of nature, specifically the sun, has gained significant research interest, in modern society. This method, known as solar-driven interfacial evaporation, focuses on heating only the interface (i.e., the surface) rather than heating the entire medium (i.e., bulk heating). By reducing the thermal losses, an interfacial evaporation approach by selectively heating the air/liquid interface has demonstrated to have 45% higher evaporation efficiency than bulk heating based evaporation. Here we suppose that instead of merely heating the air-sample interface, generating convective heat flow of air around the sample could boost surface evaporation, inspired by the scientific discoveries presented by Cobb et al. (2022); The striking black and white striped pelage of zebras maintain a temperature difference, generating convective airflow as warm air rises from the black stripes and cool air descends onto the white stripes. This airflow, above and between the stripes, can induce chaotic or turbulent air patterns due to convection currents and facilitate the exchange of air and water vapor, thus aiding evaporative cooling.

In order to successfully demonstrate this, we employ zebra- patterned cellulose acetate(CA) fiberous network on the surface of the LiBr hydrogel sample. The hydrogel possesses the ability to absorb moisture from the atmosphere and retain the water within the structure, while the CA networks desired to wick the water for evaporation, facilitating continuous evaporative cooling. Given the numerical study presented by Austin et al. (2022) that zebra-striped roof buildings demonstrate lower internal temperatures in comparison to all-white roof buildings, the proposed statement appears to be plausible. The incorporation of a zebra-pattern atop a hydrogel, accompanied by localized heating of the sample surface corresponding to the regions occupied by the black stripes, paradoxically, has the potential to enhance the cooling performance beyond that achievable through sole radiative cooling or radiative/evaporative cooling methods.

SESSION SF05.16: Near-Field Thermal Radiation
Session Chairs: Mathieu Francoeur and Jean-Jacques Greffet
Thursday Morning, November30, 2023
Sheraton, Third Floor, Hampton

10:45 AM *SF05.16.01
Near-Field Thermal Radiation by Transdimensional Plasmonics and Subwavelength Structures ShengShen; Carnegie Mellon University, United States

Near-field radiative heat transfer has attracted enormous interest for energy conversion, solid-state cooling, and thermal management owing to the substantial radiation enhancement beyond Planck's law at nanoscale gaps. So far, effects of nonlocality to near-field thermal radiation have been examined only in the extreme near-field with gap sizes of a few nanometers. Also, our fundamental understanding of near-field heat transfer between subwavelength surfaces is still quite limited. In this talk, using transdimensional plasmonic materials, we experimentally demonstrate nonlocality in dielectric response alters near-field heat transfer at gap sizes on the order of hundreds of nanometers. We also report the first measurements of near field thermal radiation between coplanar subwavelength membranes over a broad range of temperature differences up to 190 K. Our measurement with membrane dimensions comparable to near-field separations shows maximum 20-times enhancement in heat transfer compared to blackbody radiation.

11:15 AM SF05.16.02
Identifying the Limits to Near-Field Radiative Heat Transfer Between Phonon Polaritonic Materials RohithMittapally[1], Ju WonLim[1], LangZhang[2], OwenMiller[2], PramodSangi Reddy[1] and EdgarMeyhofer[1]; [1]University of Michigan, United States; [2]Yale University, United States

Radiative heat transfer (RHT) between objects separated by nanoscale gaps, referred to as being in the near-field (NF) of each other, is known to impact applications ranging from energy conversion to thermal management of electronics. Recently, several experiments validated early predictions of orders of magnitude enhancement in NF-RHT, aided by surface phonon polaritons (SPhPs) supported in polar dielectric materials. While these experiments using SiO_2 validated the longstanding predictions of enhanced RHT, there remains a few unanswered questions: what is the fundamental limit to this NF-RHT and what material properties can enable this? Recent theoretical analysis [1] based on causal arguments suggests that the SPhPs in SiO_2 occur at a frequency far higher than the optimal. In fact, our optimization [2] for maximum NF-RHT suggests that materials supporting SPhPs close to an optimal frequency of 67 meV at room temperature can enhance this NF-RHT by 5-fold (a global bound) when compared to that of SiO_2. In this talk, I will first discuss our theoretical analysis and report on how we utilized a

custom-built nanopositioner to measure NF-RHT between Al_2O_3 - Al_2O_3 and MgF_2 - MgF_2 material systems. In these experiments, we observed a clear enhancement of NF-RHT beyond blackbody limit and even beyond that of SiO_2 at all gap sizes ranging from a few tens of nanometers to a few micrometers. Specifically, I will show that NF-RHT between MgF_2 at a gap size of 50 nm is 2.5-fold larger than that between SiO_2 and thus, approaches 50% of the global SPhP bound. The insights gained from these experiments and theoretical analysis will benefit exploration of materials further enhancing NF-RHT.

11:30 AM SF05.16.03
Intelligent Radiative Thermostat Induced by Near-Field Radiative Thermal Diode YangLiu and YiZheng; Northeastern University, United States

A radiative thermostat system senses its own temperature and automatically modulates heat transfer by turning on/off the cooling to maintain its temperature near a desired set point. Taking advantage of far- and near-field radiative thermal technologies, we propose an intelligent radiative thermostat induced by the combination of passive radiative cooling and near-field radiative thermal diode for thermal regulation at room temperature. The top passive radiative cooler in thermostat system with static thermal emissivity uses the cold outer space to passively cool itself all day, which can provide the bottom structure with the sub-ambient cold source. Meanwhile, using the phase-transition material vanadium dioxide, the bottom structure forms a near-field radiative thermal diode with the top cooler, which can significantly regulate the heat transfer between two terminals of the diode and then realize a stable temperature of the bottom structure. Besides, the backsided heat input of the thermostat has been taken into account according to real-world applications. Thermal performance of the proposed radiative thermostat design has been analyzed, showing that the coupling effect of static passive radiative cooling and dynamic internal heat transfer modulation can maintain an equilibrium temperature approximately locked within the phase transition region. Besides, after considering empirical indoor-to-outdoor heat flux, rendering its thermal performance closer to that of passive solar residential building walls, the calculation result proves that the radiative thermostat system can effectively modulate the temperature and stabilize it within a controllable range. Passive radiative thermostats driven by near-field radiative thermal diode can potentially enable intelligent temperature regulation technologies, for example, to moderate diurnal temperature in regions with extreme thermal swings.

11:45 AM SF05.16.04
Measurement of Photophoretic Forces of Rarefied Gases on Functionalized Surfaces GregAcosta[1], AmunJarzembski[2] and MohammadGhashami[1]; [1]University of Nebraska-Lincoln, United States; [2]Sandia National Laboratories, United States

In recent years, metamaterials and two-dimensional materials have revolutionized the fields of quantum mechanics and nanophotonics by introducing a new class of materials that can exhibit unique and exotic optical and thermal emission properties. This has been mainly driven by advances in nanofabrication and our ability to engineer surfaces with unique characteristics. Often, the surfaces of these materials are encountered by the presence of rarefied gases, where classical continuum description of the physical phenomena is no longer valid, and the non-continuum phenomena of gas-surface interactions (GSIs) dominate the energy transport from the surface to the gas particles. One example is the light-induced photophoretic levitation of nanostructured thin films and light-driven oscillators enabled by optical and photophoretic forces. Here, photophoretic or Knudsen forces (KFs) arise when a highly adsorbing material, immersed in a diluted gas, exchanges thermal energy via electromagnetic waves, thus inducing temperature inhomogeneities within the surface of the irradiated body. These temperature differences trigger non-equilibrium transport phenomena, where the gas particles and body collectively communicate with each other via GSIs. Here, the GSIs help transfer momentum from the thermally excited gas particles onto the surface, generating a temperature-driven force from the hot to the cold side of the body. On the other hand, if the temperature difference within the surface is negligible, Knudsen forces can still be induced by simply having different surface properties that modulate the efficacy of the GSIs. Although recent studies have demonstrated preliminary measurements of KFs for different gases and simple surfaces, there is little knowledge regarding how different surface characteristics affect the magnitude of the generated forces. Furthermore, there is no clear indication of to what extent the temperature gradient's magnitude along the surface affects the momentum exchange process between the impinging gas molecules. All these are important as KFs can play a major role in atomic force microscopy and photothermal-induced spectroscopy.

Hence, this work aims to perform an experimental investigation to unfold the nature of GSIs on the generation of Knudsen forces by measuring the force generated on smooth and functionalized surfaces for different temperature gradients, immersed in rarefied helium, nitrogen, and carbon dioxide gas. Here, surface functionalization will allow controlling the extent of GSIs by adjusting the net effect of specular/diffusive reflections in the form of the energy accommodation coefficients (EAC). As a preliminary step, we will follow the same procedure as our previous sub-continuum gas conduction investigations to characterize the GSIs by extracting the EACs for silicon and tungsten surfaces. Once the EACs are extracted, samples will be placed on a nanopositioning stage, equipped with a heating platform to heat samples to any desired temperature. Then samples will be brought into the proximity of a temperature-controlled suspended probe that helps detect the induced KFs via a laser interferometer. Then, adjusting the gap distance between the samples and the probe, in conjunction with the vacuum pressure, will allow us to measure the KFs forces for different transport regimes. The experimental results demonstrate a correlation between the measured forces and the value of the EAC extracted for all the samples. Furthermore, the magnitude of the force increases with the temperature gradient, as expected, due to an increase in kinetic energy. Lastly, it is shown that the forces generated by helium gas exceed those of nitrogen and carbon dioxide due to a high mismatch in the mean-free path. These results demonstrate that generated KFs can be altered depending on the type of gas-surface interaction occurring on the surface, paving the way to optimize this force by surface engineering.

SESSION SF05.17: Near-Field Thermal Radiation and Nanoparticles/Structures
Session Chairs: Rohith Mittapally and Bo Zhao
Thursday Afternoon, November30, 2023
Sheraton, Third Floor, Hampton

1:30 PM *SF05.17.01
Near-Field Radiative Heat Transfer Between Subwavelength Structures MathieuFrancoeur[1], LindsayP. Walter[2], LeiTang[3], LiviaM. Correa[2], ChrisDames[3] and JosephC. McKay[2]; [1]McGill University, Canada; [2]The University of Utah, United States; [3]University of California, Berkeley, United States

Near-field radiative heat transfer (NFRHT), a regime in which thermal sources are separated by subwavelength vacuum gaps, can exceed the blackbody limit owing to the tunneling of evanescent electromagnetic waves, which include frustrated modes and surface modes. The substantial enhancement of heat transfer in the near field could be exploited in various technologies, such as noncontact localized cooling and thermophotovoltaic power generation.

To date, NFRHT is still a laboratory-scale concept. The viability of potential NFRHT applications directly depends on the ability of enhancing and spectrally controlling the flux with designer materials, such as metamaterials and metasurfaces, made of subwavelength structures. However, the basic physics underlying the interactions between thermally generated evanescent waves and subwavelength structures is not well understood, partially due to the lack of numerically exact framework enabling predictions of NFRHT in complex geometries. The overall objective of this talk is to address this knowledge gap by first reviewing a novel method for solving NFRHT in complex geometries, and by then discussing recent results of NFRHT between two coplanar membranes of subwavelength thickness.

In the first part of the talk, we will introduce the discrete system Green's function (DSGF) method, which is a volume integral numerical approach based on fluctuational electrodynamics. In the DSGF method, thermal sources are discretized into cubic subvolumes, and all electromagnetic interactions are determined by numerically calculating the system Green's function between the subvolumes. NFRHT is then computed by simple mathematical operations to the system Green's functions. The DSGF method is numerically exact, and is applicable to an arbitrary number of finite, 3D thermal sources of any sizes and shapes separated by gaps smaller or larger than the thermal wavelength. We will review the verification of the DSGF method against exact results of NFRHT between two and three spheres, and briefly discuss its application to predict NFRHT between complex-shaped particles.

The second part of the talk will focus on DSGF predictions and experiments of NFRHT between two coplanar SiC membranes with thickness comparable to or smaller than their vacuum gap spacing of 100 nm. The results show that the radiative heat transfer coefficient increases substantially as the membrane thickness decreases. At room temperature, a maximum heat transfer coefficient h_{rad} of ~800 W/m^{2}K for a membrane thickness of 20 nm is measured and predicted. This h_{rad} value is ~5 times larger than that predicted between two infinite SiC surfaces (~150 W/m^{2}K) at the same vacuum gap, and is ~1200 times larger than the blackbody limit. A heat transfer coefficient of 800 W/m^{2}K would require a gap spacing of ~30 nm between two infinite SiC surfaces. In addition, the resonance of the heat transfer coefficient is broadened and redshifted as the membrane thickness decreases. We demonstrate via a modal analysis that the enhancement and spectral redshift of the heat transfer coefficient is due to the 2D confinement of the electromagnetic fields. Specifically, SPhP coupling between the membrane parallel edges

and between the perpendicular edges through corners generate resonant electromagnetic corner and edge modes dominating NFRHT.

The large enhancement of NFRHT mediated by resonant electromagnetic corner and edge modes could be exploited in a variety of applications, such as localized radiative cooling, thermal management technologies, and energy conversion devices. Multidimensional confinement of SPhPs in arrays of subwavelength structures could enable further modulation and enhancement of NFRHT.

2:00 PM SF05.17.02
Modulating Near-Field Radiative Heat Transfer in Multi-Body Systems SinaKhayam and MohammadGhashami; University of Nebraska-Lincoln, United States

Active control of near-field radiative heat transfer (NFRHT) between multi-body systems has attracted great attention. Investigation of innovative methods for controlling radiative heat flow, analogous to electric current manipulation, has attracted significant attention. This interest arises due to the growing importance of such techniques in nanodevices designed for thermal management and heat-to-electricity conversion. The ability to control the magnitude and direction of heat flow at the micro/nanoscale has enabled various devices such as thermal diodes, transistors, switches, logic gates/circuits, and memories. Several methods have been proposed and explored in the literature to optimize our leverage over thermal radiative transfer, including employing metal-insulator transition materials, applying a magnetic field to magneto-optical materials, and tuning the chemical potential of graphene. Despite the remarkable progress, the above methods are usually limited in their operating temperature or the achievable heat flow contrast. To overcome these constraints, researchers have started to pursue a temperature-independent and noncontact approach to modulate NFRHT with minimum structural change dynamically. In this regard, recent theoretical works on nanoscale radiative heat transfer involving multiple anisotropic bodies have suggested the potential of these materials to regulate radiative heat flows. Recent theoretical studies have demonstrated that anisotropic materials, whose properties depend on the orientation of their optical axis regarding thermal radiation, hold promise in regulating radiative heat flows. Adjusting their relative orientation makes it possible to easily enhance or suppress the overall heat flux. While controlling NFRHT between isotropic materials can be only achieved by fabricating nanostructured metamaterials like gratings or nanoholes, multi-body systems consisting of anisotropic materials will be a promising alternative for controlling NFRHT without changing the structural properties of the system.

This work presents a comprehensive theoretical study of near-field heat transfer in a three-body planar system with a uniaxial intermediate layer and examines the regulation effects of the relative orientation of the middle layer on the total radiative heat flux. In the proposed system, both source and the observer layers are made of polar material, which supports surface phonon polariton (SPhPs), while the middle layer is a uniaxial thin layer capable of supporting surface modes. By employing the launder formalism for NFRHT on a system consisting of three distinct planar plates, we show how the anisotropic properties of the intermediate layer can substantially mediate the overall radiative heat transfer within the system. This modulation approach is achieved by varying the orientation of the optical axis of the middle layer. Moreover, the effect of different materials, gap distances, and the thickness of the intermediate layer on the heat transfer regulation is investigated. Using this configuration, the equilibrium temperature of the intermediate layer can also be regulated by twisting and adjusting the relative angle of the intermediate layer. The proposed method enables the control of nanoscale radiative heat flux, offering great potential for thermal management applications via contactless heat flux control.

SESSION SF05.18: Radiative Heat Flow Control in Near and Far Field

Near-Field Radiative Heat Transfer in Vortex Matter: Role of Abrikosov Fluxons RaulEsquivel-Sirvent, ShunashiCastillo-Lopez, GiuseppePirruccio and CarlosVillarreal; Universidad Nacional Autonoma de Mexico, Mexico

One of the signatures of superconductivity is the formation of the Abrikosov vortex lattice in type-II superconductors in the presence of an external magnetic field. Here, we study the near-field radiative heat transfer between a spherical nanoparticle and a nearby planar substrate, both made of optimally doped ceramic superconductors. We show that the radiative heat flux displays a periodic spatial pattern congruent with the material optical response modulated by the Abrikosov lattice. The heat flux can be enhanced or tuned by varying the magnitude of the external magnetic field. This modulation is explained by analyzing the behavior of the Abrikosov vortices that behave as efficient heat transfer channels since, at their core, the material is not superconducting, although it is below the critical temperature.

2:30 PM SF05.18.02
Infrared Thermochromic Antenna Composite for Self-Adaptive Thermal Radiation Management IoannisPapakonstantinou[1], Francisco V.Ramirez-Cuevas[1,2], Kargal L.Gurunatha[1,3], LingxiLi[1], UsamaZulfiqar[1], SanjayanSathasivam[1], ManishTiwari[1] and IvanParkin[1]; [1]University College London, United Kingdom; [2]Universidad Adolfo Ibáñez, Chile; [3]JAIN University, India

Passive thermoregulation, the natural mechanism of living organisms to self-regulate their body temperature, holds excellent promise for decarbonizing cooling and heating systems. An effective route to artificially emulate this functionality is by engineering thermochromic materials that modulate radiative heat losses in response to the temperature of their surroundings. Yet, a technology that marries large thermal emissivity modulation with scalability, cost-effectiveness and design freedom is lacking in the field. Here, we fill this gap by introducing a new class of infrared thermochromic antennas exhibiting a dramatic enhancement (>180 times) in their absorption cross-section as their temperature rises. By embedding the antennas in a polymer matrix or by simply spraying them directly, free-form self-adaptive heat radiating composites are created with large emissivity switching (~0.6) that can be applied on virtually any surface. Overall, our research paves the way for thermoregulating coating, fiber, membrane, film, and other technologies that could find application in self-adaptive radiative cooling, heat sensing, thermal camouflage, and other.

2:45 PM SF05.18.03
Demonstration of Near-Field Radiative Heat Transfer via Hyperbolic Plasmon Polaritons in a Layered CdO Metamaterial WilliamD. Hutchins[1], SamanZare[1], AngelaCleri[2], MingzeHe[3], JoshuaD. Caldwell[3], Jon-PaulMaria[2] and PatrickE. Hopkins[1]; [1]University of Virginia, United States; [2]The Pennsylvania State University, United States; [3]Vanderbilt University, United States

As electronic devices continue to reduce towards nanoscale dimensions, understanding heat transport mechanisms at these scales becomes vital. In recent years, advances in nanotechnology and radiative engineering have introduced thermal radiation as a promising mechanism to tailor the magnitude and direction of heat transfer. Utilization of metamaterials extends our ability to manipulate radiative heat flow in nanoscale systems, especially with regard to near-field radiation which can exceed the blackbody limit by several orders of magnitude. The near-field heat transport in metamaterials is dictated by their geometry and optical properties of the constituents. One way to tune this flow is by the construction of a superlattice metamaterial by layering highly doped cadmium oxide (CdO) with varying carrier densities. Highly doped CdO allows for high electron mobilities while maintaining dielectric properties mechanically. Carefully constructed superlattice structures can support hyperbolic plasmon polaritons (HPPs) which may carry heat across interfaces at a significantly higher rate than conduction.

From an experimental perspective, previous investigations on the characteristics of HPPs were performed using measurements at equilibrium conditions, neglecting the information embedded in non-equilibrium. In this work, we use a unique ultrafast pump-probe technique that can detect specific heat-carrier modes with sub-picosecond time resolution. Our technique relies on a wavelength-tunable mid-infrared probe pulse, allowing us to directly resonate with plasmonic heat carriers, providing a direct measure of polariton dynamics (velocity, thermal lifetime, etc.) in nanoscale material systems. In particular, we investigate HPPs in a layered CdO metamaterial; the high-frequency plasmon modes in this material lend themselves to the potential for manipulation of thermal radiation in near room temperature conditions. Thus, we investigate the ultrafast thermal dynamics of HPP modes coupling to near-field thermal radiation via far-field sensing. We experimentally demonstrate, for the first time, the ability to thermally stimulate HPPs in a CdO metamaterial through remote heating of a metal contact. Our results open the door for future experiments to manipulate and guide heat carriers via heterostructures, which could increase thermal efficiency of microelectronics and photonics.

3:00 PM *SF05.18.04
Nanophotonic Control Over The Non-Equilibrium Temperature and Emitted Polarization State SanderMann; The City University of New York, United States

Thermal generation of light is a long-known technique capable even of producing designer quasi-monochromatic beams, but with a suitably chosen cascaded set of optical elements. For example, in order to produce a wave with spin angular momentum (SAM) or orbital angular momentum (OAM), a blackbody such as an incandescent light source emits uncollimated, broadband, incoherent and unpolarized light, which is then spatially filtered by a pinhole, collimated by a lens, spectrally narrowed by a filter, polarized by a polarizer, retarded by a waveplate, and then shaped spatially by a phase plate optic. Over the past two decades, leaps have been made in condensing these optical elements into single emitters: for example, it has been

demonstrated that linear or circularly polarized emission can be emitted directly from a suitably structured metasurface, but usually with significant emission of the conjugate emission state in the opposing direction, and with limited freedom over the polarization state. Here, I will present a new approach to generate arbitrary polarization states into any single direction of emission, based on nonlocal metasurfaces, completing a long standing search to condense the entire array of optical elements for manipulation of thermal emission into a single emitting metasurface. I will then discuss the generalization of Kirchhoff's law for arbitrary polarization states, demonstrating experimentally and theoretically how absorbed and emitted polarization states are related. Finally, I will discuss recent work on controlling the peak temperatures in nanophotonic structures in non-equilibrium situations (under either pulsed or strong incoherent illumination) through manipulation of the local density of optical states. Control over the temperature of e.g. catalytic sites in non-equilibrium environments can strongly benefit reaction rates, providing an additional nanophotonic lever to achieve more efficient operation of catalytic reactors and other thermal processes.

8:00 AM *SF05.19.01
Mid-Infrared Filterless Metasurface Photodetectors Cheng-WeiQiu; National University of Singapore, Singapore

Mid-infrared detectors are of critical importance for a variety of applications including thermal imaging, spectrometer, sensing and free space communication. High sensitivity, zero power consumption, fast response, simple CMOS-compatible fabrication processes, small footprint, wavelength and polarization selectivity are highly desired, while still being elusive so far especially at room temperature. In this talk, we will report a series of metasurface-mediated semimetal IR detectors based on hot carriers mechanism. Non-centrosymmetric metallic nanoantennas are deployed to break the symmetry of local electromagnetic field and induce directional flow of hot carriers in graphene, leading to large unbalanced mid-IR photoresponse at room temperature without external bias. We demonstrate zero-bias uncooled mid-infrared photodetectors with three orders higher responsivity than conventional bulk photovoltaic effect (BPVE) and a noise equivalent power of 0.12 nW $Hz^{-1/2}$. We further establish a scheme to realize configurable polarity transition by exploiting the vectorial and non-local photoresponse in hybrid metasurface of nanoantennas and graphene. By tuning the orientation of nanoantennas, polarization ratio (PR) values vary from positive (unipolar regime) to negative (bipolar regime), covering all possible numbers ($1 \rightarrow \infty/-\infty \rightarrow -1$). Polarization-angle perturbation down to 0.03° $Hz^{-1/2}$ in the mid-infrared range is demonstrated. We will also report on-chip filterless photodetectors in mid-infrared which solely responds to circular polarizations. Our works highlight the potential of hybridizing metasurface and semimetals for miniaturized polarimetry.

8:30 AM *SF05.19.02
Manipulating the Flow of Light & Heat at Nanoscale JiaZhu; Nanjing University, China

The first example is about passive cooling. Radiative cooling which sends heat to space through atmospheric transparency window without any energy consumption, is attracting significant attention. For radiative cooling to achieve high cooling performance, it is ideal to have a selective emitter, with an emissivity dominant in the atmospheric transparency window. However, so far scalable production of radiative cooling materials with selective emissivity has not been realized. Here I will present a hierarchical design for a selective thermal emitter to achieve high performing all-day radiative cooling. Moreover, it is revealed that this hierarchically designed selective thermal emitter shows significant advantage if being applied to alleviate Global Warming or to regulate temperature of the Earth-like planet.

The second example is about interfacial solar evaporation. We report that efficient and broad-band plasmonic absorber can be fabricated through a three dimensional self-assembly process. Because of its efficient light absorption and strong field enhancement, it can enable very efficient (>90%) solar vapor generations. Inspired by the transpiration process in plants, we report an artificial transpiration device with a unique design of two dimensional water path. The energy transfer efficiency of this artificial transpiration device is independent of water quantity and can be achieved without extra optical or thermal supporting systems, therefore significantly improve the scalability and feasibility of this technology. At the end, we would like to demonstrate that this type of interfacial solar vapor generations can have direct implications in various fields such as solar desalination, zero liquid discharge, sterilization and power generations.

9:00 AM *SF05.19.03
Radiative Heat Transfer and Thermalization in Ensembles of Nanostructures AlejandroManjavacas; Instituto de Optica - CSIC, Spain

Planck's law accurately describes the exchange of thermal radiation between macroscopic bodies separated by macroscopic distances. However, when the size of the objects or the distances between them become comparable to the thermal wavelength, this approach breaks down. In such subwavelength scenarios, radiative heat transfer between hot objects can exceed the limits set by far-field blackbody radiation due to the contribution of the near-field components of the electromagnetic field and the excitation of electromagnetic resonances of the material structures [1].

In this talk, we will review some recent advances in the theoretical description of radiative heat transfer between nanoscale objects. We will begin by introducing a theoretical framework to efficiently describe the thermalization dynamics of ensembles of nanostructures mediated by radiative heat transfer [2]. With the help of this formalism, which relies on an eigenmode expansion of the equations that govern the process, we will discuss the fundamental principles that determine the thermalization of collections of nanostructures with thousands of elements, revealing general but often unintuitive dynamics. We will also consider the radiative heat transfer between two nanostructures in rotation, which is influenced by the simultaneous transfer of angular momentum due to the Casimir torque. Specifically, we will show that, depending on the rotation of the nanostructures, the radiative heat transfer between them can be increased, decreased, or even reversed with respect to the transfer that occurs in absence of rotation, which is solely determined by the difference in the temperature of the nanostructures [3].

Physical AI for Soft Aerial Robotics MirkoKovac[1,2]; [1]Swiss Federal Laboratories for Materials Science and Technology (Empa), Switzerland; [2]Imperial College London, United Kingdom

Aerial robotics has become a key enabler of industrial automation and environmental interaction tasks with applications ranging from environmental sensing in forests, over water sampling in lakes to industrial manufacturing and repair. Most aerial robots however are rigid in structure and rely on accurate state estimation and controlled sensor-actuator loops to perform the tasks and navigate through the environment. Natural flyers on the other hand rely not just on flight control but also on smart and adaptive materials to expand their operational flight envelope and to increase the functionality of their wings allowing them to display an impressive range of skills. Recently, the robotics community has started to employ adaptive morphologies, smart materials and soft robotics methods in aerial robotics with the promise of achieving higher levels of system resilience and adaptation to complex or changing environments. In this talk I will present how animal-inspired soft robot design methods can greatly enhance aerial robotics capabilities and how adaptive morphologies and functional materials can be co-evolved in tandem with aerial robotic embodiments. The talk will also include application examples of such soft aerial robots placing sensors in forests, collecting water samples autonomously or landing on wind turbines to perform construction and repair tasks.

11:00 AM SF06.01.02
Room-Temperature Electrochemical Healing of Fractured Metals ZakariaHsain, MostafaAkbari, AdhokshidPrasanna, ZhiminJiang, MasoudAkbarzadeh and JamesH. Pikul; University of Pennsylvania, United States

Repairing fractured metals to extend their useful lifetimes advances sustainability and mitigates carbon emissions from metal mining and processing. While high-temperature techniques are being used to repair metals, the increasing ubiquity of digital manufacturing and “unweldable” alloys, as well as the integration of metals with polymers and electronics, call for radically different repair approaches.
This work presents a framework for effective room-temperature repair of fractured metals using an area-selective nickel electrodeposition process referred to as electrochemical healing. Based on a model that links geometric, mechanical, and electrochemical parameters to the recovery of tensile strength, this framework enables 100% recovery of tensile strength in nickel, low-carbon steel, two “unweldable” aluminum alloys, and a 3D-printed difficult-to-weld shellular structure using a single widely used nickel sulfamate electrolyte. Through a distinct energy-dissipation mechanism, this framework also enables up to 136% recovery of toughness in an aluminum alloy. Remarkably, this framework demonstrates that the restoration of tensile strength can be insensitive to nickel-metal adhesion, thus obviating the need for acid pre-treatments or multi-electrolyte processes.
To facilitate practical adoption, this work reveals scaling laws for the energetic, financial, and time costs of repairing fractured metal parts from the microscale to the meter scale. This framework could potentially enable a universal and scalable approach to repair fractured metals at various length scales and in diverse applications. Electrochemical healing could open exciting possibilities such as electrically controlled autonomous and preemptive repair, as well as enable 3D-printed metal structures optimized for repair through designed failure characteristics.

11:15 AM SF06.01.03
Dynamic, Remote-Controllable Electroactive Hydrogel Waveguide Architectures Oscar AlejandroHerrera Cortes; McMaster University, Canada

Remote-controllable waveguide architectures inspired by living organisms with unique flexible, camouflage and light-guiding properties, were printed using self-trapped beams of incoherent light. Made of electroactive hydrogels, light-guiding structures are generated within seconds through a nonlinear, self-inscription process that utilizes visible beams from light-emitting diodes (LEDs). Due to irreversible refractive index changes experienced by photoinduced chemical reactions, these self-trapped beams permanently inscribe cylindrical waveguides along their paths. Taking advantage of this phenomena, we can fabricate macro-scale remote controllable waveguide structures in the form of planar rectangular prisms and arrays of cylindric waveguides. We can also fabricate micro-scale structures, for remote actuation, in the form of rectangular prisms embedded with thousands waveguide units. By applying and varying external electric fields, we can then dynamically control the bending, angular orientation, and rotation (up to 360°) of these pliant light-guiding structures. This allows precise, remote control of the waveguided light output.

11:30 AM *SF06.01.04
Energy Storage and Harvesting in Multistable Metafluid OfekPeretz, EzraBen-Abu, AnnaZigelman, SefiGivli and AmirGat; Technion–Israel Institute of Technology, Israel

The thermodynamic properties of fluids play a crucial role in many engineering applications, particularly in the context of energy. Fluids with multistable thermodynamic properties may offer new paths for harvesting and storing energy via transitions between equilibria states. Such artificial multistable fluids can be created using the approach employed in metamaterials, which controls macro-properties through micro-structure composition. In this work, the dynamics of such `metafluids' is examined for a configuration of calorically-perfect compressible gas contained within multistable elastic capsules flowing in a fluid-filled tube. We study both analytically and experimentally the velocity-, pressure-, and temperature-fields of multistable

compressible metafluids, focusing on transitions between different equilibria. We first examine the dynamics of a single capsule, which may move or change equilibrium state, due to fluidic forces. We then study the interaction and motion of multiple capsules within a fluid-filled tube. We show that such a system can be used to harvest energy from external temperature variations in either time or space. Thus, fluidic multistability allows specific quanta of energy to be captured and stored indefinitely as well as transported as a fluid, via tubes, at standard atmospheric conditions without the need for thermal isolation.

SESSION SF06.02: Embodied Perception

1:30 PM SF06.02.01
Autonomous Alignment and Healing in Multilayer Soft Electronics using Immiscible Dynamic Polymers SamuelE. Root, ChristopherB. Cooper and ZhenanBao; Stanford University, United States

Self-healing soft electronic and robotic devices, like human skin, can recover autonomously from some forms of damage. Existing multi-layer devices generally employ a single type of dynamic polymer embedded with different functional nano–micro materials for each layer, to provide a cohesive interface between layers. In such devices, successful healing from damage requires precise manual alignment and re-contacting of the fractured interfaces, limiting functional recovery from diverse forms of damage, such as processes leading to imperfect registry of device layers. These limitations are especially prevalent for devices containing thin layers (< 100 μm). To overcome these limitations, we have designed a pair of dynamic polymers, which have immiscible polymer backbones, but identical dynamic bonding units (bisurea-based hydrogen bonding interactions), to maintain interlayer adhesion while providing selectively self-healing layers with similar rheology (and thus self-healing dynamics) over a convenient range of temperatures (25–100°C). Upon lamination, these dynamic polymers exhibit a weakly interpenetrating and adhesive interface, whose width and toughness are tunable with processing temperature. When multilayered polymer films are misaligned after damage, these structures autonomously realign during the healing process to minimize their interfacial free energy through a directional diffusion-mediated mechanism. Our experimental observations are captured by both coarse-grained molecular dynamics simulations and continuum phase field simulations, suggesting the generality of the proposed mechanism to other pairs of polymer backbones or dynamic bonding chemistries. As a demonstration of the utility of our approach, we fabricated several devices with conductive, dielectric, and magnetic particles that functionally heal after damage, enabling thin film pressure sensors, magnetically assembled soft robots, and underwater circuit assembly.

1:45 PMDISCUSSION TIME

2:00 PM *SF06.02.03
Soft Logic, Actuators and Stretchable Barriers using Liquid Metal MichaelDickey; North Carolina State University, United States

This talk will discuss ways to harness the unique properties of liquid metals for soft and stretchable components that are promising for soft robotics. Alloys of gallium are liquid below room temperature and are therefore extremely soft and flow in response to stress to retain electrical continuity under extreme deformation. While these properties have been used to create sensors and interconnects, there are other unique properties that can be utilized. For example, liquid metal is a fantastic barrier to gas and liquid transport. This property can be used to create hermetic seals that are near-perfect barriers, yet completely stretchable. This breaks a long-standing trade-off between stretchability and permeability of materials, thus enabling encasing materials for stretchable batteries. Liquid metals can also be used for energy harvesting by several modes. For example, by encasing liquid metal in hydrogel, it is possible to create electrical double layers (i.e. capacitor) at the interface between the metal and the gel. Deforming the gel increases the area of the capacitor, which can convert mechanical to electrical energy. Liquid metals can also be utilized for performing simple tactile logic, in which the response of an elastomeric material will change depending on the way it is touched. Finally, it is possible to use liquid metal to actuate soft robots using either surface tension to exert forces on surfaces or electrochemical formation of gas to expand pneumatic chambers. Combined, these advances have exciting implications for soft robotic materials.

2:30 PMBREAK

3:00 PM *SF06.02.04
Biomimetic Approaches with Stretchable Ionics Jeong-YunSun; Seoul National University, Korea (the Republic of)

As many devices for human utility target fast and convenient communications with users, superb electronic devices have been demonstrated as hardware for Human-Machine Interface (HMI) in wearable forms. Wearable devices for daily health-cares and self-diagnosis desire more human-like properties unconstrained to deformation. In this sense, stretchable ionics based on flexible and stretchable hydrogels is on the rise as another field to develop wearable devices for bio-applications due to two major reasons; i) ionic currents, choosing the same signal carriers with biological areas, and ii) the adoption of hydrogel ionic conductors which are intrinsically stretchable materials with bio-compatibility. Here, forte and current status of stretchable ionics as well as future applications whose positive effects can be magnified by stretchable ionics are going to be introduced.

3:30 PM SF06.02.05
Design and Fabrication of Electronic Skin with Sensing Capability of Tactile Stimuli for Robotics Jun ChangYang[1], SteveePark[2] and LuciaBeccai[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The need for new forms of electronics is emerging in various fields such as healthcare, robotics, and human-machine interfaces. Stretchable electronic Skin, compared to traditional rigid electronics, offers improved user convenience through various shapes and functions. Recently, electronic skin, inspired by human skin, has been developed to change shape easily and collect different physical sensations. However, there have been challenges in terms of durability and accurate tactile detection in polymer-based tactile sensors for robotics. This study aims to address these challenges by developing microstructured tactile sensors and robust soft-rigid interfaces with interlocking structures. Firstly, ultra-high sensitive capacitive pressure sensors based on a porous pyramid dielectric layer are presented, enabling accurate pressure detection unaffected by lateral strain and temperature. Secondly, bending sensors that utilize controlled microcracks in inverse pyramid structures, achieve a gauge factor of 74 with high linearity. Moreover, the sensors can be used in soft actuators capable of operating in liquid. Finally, Ferris Wheel-shaped islands architecture with interlocking structures are designed to suppress crack propagation at interfaces during mechanical deformation. Consequently, rigid components can be integrated into a soft polymer matrix, resulting in a highly durable electronic skin suitable for robotics applications.

3:45 PM SF06.02.06
Dynamic Haptic Exploration using Artificial Multi-Modal Mechanoreceptors for Active Robot Perception JiangtaoSu and XiaodongChen; Nanyang Technological University, Singapore

Benefitted from the various mechanoreceptors embedded in the skin and haptic exploration strategy of hands, human beings can recognize the hardness and texture of different objects with fine resolution. By contrast, existing tactile sensors for robotic application can only identify limited information when interacting with surroundings, lacking the multimodality like the various mechanoreceptors and proper sensing strategies to maximize desired tactile information. Here, we present a multimodal tactile sensor that can simultaneously detect normal and shear force with ultra high sensitivity and resolution. Moreover, the performance of the tactile sensor can be tuned by its geometrical parameters. Such tactile sensors can identify the hardness and texture of objects simultaneously, which is less reported for similar sensors. By integrating the tactile sensor on a robotic gripper, the robot can dynamically perform haptic exploration with different detecting modes. It turns out that the robot can achieve an object recognition accuracy of 93%. This research could provide a promising strategy for the sensing of robotic for a variety of applications, especially for object recognition and manipulation, human-machine interaction, and outer space exploration.

4:00 PM SF06.02.07
Multi-Detection Brush-Type E-Whisker HarukiNakamura[1,2], SatokoHonda[1], GurenMatsumura[1] and KuniharuTakei[2]; [1]Osaka Metropolitan University, Japan; [2]Hokkaido University, Japan

With the development of the Internet of Things (IoT) society, demand for a variety of sensors is increasing to collect many datasets for data analyses. Among them, whisker or brush-type sensors are interested in the application of industry and robotics. Brush-type sensors can be used to detect the surface morphology and target shape by contacting the object like rat whiskers, which should be useful for the robotic applications. However, the sensor that can measure such whisker/brush movement has yet to be fully developed. Although some electronic whisker (e-whisker) concepts have been reported previously, a lot of challenges to detect the movement of whiskers/brushes still remain such as multi-detections including movement amplitude, speed,

and directions etc and data analyses methods. To overcome these challenges, this study proposed out-of-plane e-whisker combined with 4 resistive tactile pressure sensors. Brush-type multiple whiskers were designed to collect multiple dataset precisely from the target. Due to movement of e-whisker, tactile pressure sensors show different outputs that can allow to distinguish bending amount, move direction, and move speed simultaneously. Furthermore, to feedback the robot quickly in real-time based on the sensing results, reservoir computing, which is one of the recurrent neural networks, is used to make real-time data analyses.
Fabrication process of brush sensor is briefly explained. First, laser-induced graphene (LIG) was formed by exposing CO_2-based laser over polyimide film. Due to thermal effect of polyimide caused by laser exposure, polyimide was reformed to be multi-layer graphene. The LIG was then transferred to polydimethylsiloxane (PDMS). Brush-like e-whisker structure, which is made of nylon, is attached on PDMS surface using a PDMS solution as a glue. Carbon black (CB) electrodes and silver ink as output electrodes were printed on polyethylene terephthalate (PET) film. The fabricated PDMS and PET films were then bonded using 3-aminopropyltriethoxysilane and oxygen plasma. The sensing mechanism of this e-whisker sensor is to measure contact resistance change between the LIG embedded in the PDMS and the CB electrodes on the PET films.
First, fundamental characteristics of the sensor were conducted. The whiskers on the tactile pressure sensor were moved from left to right with applied force from top, repeatedly. During the movement, resistance changes of 4 sensors were measured. The tactile pressure sensors can measure a relatively wide range of pressure from 20 Pa to 5.5 kPa. The sensitivity is ~0.33 %/Pa from 0 to 190 Pa and ~0.002 %/Pa from 190 Pa to 5.5 kPa. Due to wide dynamic range and high sensitivity especially at low pressure range, it was confirmed that e-whisker could detect the movement/bending of whisker structure. In addition to the movement detection, integrated 4 tactile pressure sensors clearly show the output difference by changing the movement velocity (0~100 mm/s), bending distance (1mm ~ 5 mm) and directions (8 directions), suggesting that this platform can measure detail bending information like animal whisker.
For the data analyses and output feedback system, real-time and quick data processing is required. As a detection system, we adapted reservoir computing, which enables highly accurate real-time detection in a small amount of computation time. By optimizing the algorithm of reservoir computing, bending distance (-5mm~5mm from the initial position) and movement velocity (0~100mm/s) were successfully predicted with the root mean square error <0.8 for bending distance and <10 for velocity.
In summary, this study demonstrated the brush-like e-whisker system using integrated tactile pressure sensor and reservoir computing. By optimizing the sensor design and data processing algorithm, the e-whisker can detect a variety of datasets, which can be potentially used for the robotic applications.

Mechanical Metamaterials' Journey to Cognitive Abilities AmirAlavi; University of Pittsburgh, United States

There is a relentless pursuit to explore novel forms of intelligent matter with advanced functionalities for various robotics applications. Here, I will introduce the scientific field of “mechanical metamaterial electronics (meta-mechanotronics)” as a platform for designing intelligent matter capable of achieving a level of cognition. Electronic mechanical metamaterials created under this paradigm enable a sense–decide–respond loop through sensing external stimuli, self-powering and processing the information. Relying merely on their constituent components for sensing and information processing, electronic mechanical metamaterials can establish a direct interaction mechanism between the external environment and electronics. Incorporating all of these capabilities into the fabric of materials could in theory lay the foundation for autonomous materials and structures with a level of artificial cognition. I will discuss mechanisms, fabrication processes and computational frameworks required to create electronic mechanical metamaterials. I will explain how insights into the mechanics, design, and implementation of the scale-independent meta-mechanotronic systems can be shared among disciplines ranging from micro/nano-electromechanical systems to large-scale civil structures.

4:45 PM *SF06.02.09
Embodied Fluidic Circuits for The Control of Soft Robots MichaelTolley; University of California, San Diego, United States

Robotics has the potential to address many of today’s pressing problems in fields ranging from healthcare to manufacturing to disaster relief. However, the traditional approaches used on the factory floor do not perform well in unstructured environments. The key to solving many of these challenges is to explore new, non-traditional designs. Fortunately, nature surrounds us with examples of novel ways to navigate and interact with the real world. Dr. Tolley’s Bioinspired Robotics and Design Lab seeks to borrow the key principles of operation from biological systems and apply them to robotic design. This talk will give an overview of recent projects in the lab that investigate the ways in which the use of non-rigid materials can help solve challenging problems in robotics. These projects seek to develop bioinspired systems capable of navigating the world by walking, digging, and swimming (inspired by animals like turtles, worms, and squid) and of interacting safely with humans and delicate objects.

Fluidic Shaping of Optical Components – From Eyeglasses to Space Telescopes MorElgarisi, OmerLuria, AmosHari, ValeriFrumkin and MoranBercovici; Technion - Israel Institute of Technology, Israel

The current method for fabricating eyewear lenses relies on the machining and polishing of semi-finished blanks. This fabrication process has not changed significantly in the past 300 years, relies on heavy mechanical infrastructure, and produces tremendous amounts of non-recyclable polymer waste.

We present a simple method, based on free-energy minimization of liquid volumes, which allows to quickly shape liquids into a wide range of ophthalmic lenses, without the need for any mechanical processing. At present, the method allows to produce any single vision prescription, including spherical and astigmatic corrections.

In the first part of the talk we will present the implementation of the method on earth - the fabrication is performed by injecting a liquid polymer into a bounding frame submerged within an immiscible immersion liquid with equal (or nearly equal) density. Under these conditions, surface tension dominates, and the curable liquid takes the shape of a symmetric lens (bi-convex or bi-concave). A meniscus lens shape can then be obtained simply by enclosing the bottom part of the lens in an impermeable chamber and adding immersion liquid to it in order to ‘inflate’ the polymer. After the desired shape is achieved, the liquid can be cured to produce a solid object. Due to the natural smoothness of the liquid, the lens has sub-nanometric surface roughness without the need for any polishing processes.

We developed a complete theoretical framework for the minimum energy state of the interface of the liquids, which describes the lens’ diopter and cylinder power as a function of the bounding frame shape, the injected volumes, and the density differences between the liquids. We will show the utilization of the theory toward the fabrication of the first eyeglasses based on fluidic shaping, and provide measurements of their shape and surface roughness. Lastly, we will show that our method is also suitable for the fabrication of complex optical components (i.e., freeform) simply by controlling the frame shape.

In the second part of the talk we will present our Fluidic Shaping experiments on board the international space station (ISS), in collaboration with NASA. In the first part of the experiment, conducted within the life sciences glovebox (LSG), the astronaut injected photocurable polymers into 30 mm (diameter) cylindrical frames contained with a custom polymerization box. Under weightlessness, surface tension dominates and drives the liquid into a minimum energy state in which the free surfaces assume a constant-mean-curvature shape. In the case of a cylindrical bounding frame, the result is a bi-convex lens with spherical surfaces. Once the liquid stabilized, the polymerization box’s lid was closed, and the lenses were solidified. In the second part, conducted outside of the glovebox, the astronaut injected water onto a 172 mm frame and created a plano-convex water lens. By injecting and aspirating water from the lens, we demonstrated the ability to dynamically control the lens’ power. We provide videos of the experiments, present the hardware we constructed, and discuss the design details, tradeoffs, and associated challenges in implementing this experiment in space.

We view this set of experiments as a first milestone in expanding in-space manufacturing capabilities to also include optical components. Due to its simplicity, low power consumption and essentially zero waste, Fluidic Shaping can serve as a fabrication infrastructure for future long-duration space missions that must be self-sufficient. In addition, due to its scale invariance, the method could potentially be used for the creation of large space telescopes, thus overcoming launch constraints.

3D Shape-Reconfigurable and Locomotive Electronics Based on Physical Intelligence Encoded Liquid Crystalline Polymer Composites WoongbiCho[1,1], JisooJeon[2], Min JeongHahm[1,1], Tae HeeHan[1,1] and Jeong JaeWie[1,1]; [1]Hanyang University, Korea (the Republic of); [2]Georgia Institute of Technology, United States

Beyond the passive deformation of flexible electronics by human hand or tethered mechanical strain, the autonomous shape-reconfigurable and locomotive electronics have a great potential for miniaturized electronics, which can transform their initial flat shape to a programmed 3D geometry, and/or transfer their body to desirable locations via asymmetric repetitive programmed actuation. The physical intelligence-encoded liquid crystalline polymers (LCPs) are great candidates for a main body of shape-reconfigurable electronics, due to their programmable molecular alignments resulting in macroscopic shape changes upon external stimuli. In this presentation, we introduce LCP composites to achieve shape-reconfigurable and locomotive electronics. To achieve electrical conductivity, we employed conducting fillers including reduced graphene oxide (RGO) and $Ti_3C_2T_x$ MXene as bilayered structures with LCPs. The bilayered structure enables the LCP composites to perform enhanced shape-reconfigurability and show the original electrical conductivity of the conducting fillers without deterioration. Furthermore, the RGO and MXene can provide high infrared light absorption to LCP composites, which can induce remotely controlled shape reconfiguration via the photothermal effect. We demonstrated in-plane bending and 3D torsional twisting of LCP composite bilayers under external stimuli including UV, NIR, and electrical power according to the chemical composition of LCP and types of conducting fillers. Finally, we introduced the Kirigami-engineered structure and collectively assembled structures to achieve diversified 3D morphed shapes and locomotion of shape-reconfigurable electronics.

9:15 AM SF06.03.03
Twisting Liquid Crystal Elastomer Fibers to Realize Fast and Slow-Twitch Thermomechanical Response MelvinA. Colorado Escobar and TimothyWhite; University of Colorado, Boulder, United States

Liquid crystal elastomers (LCEs) have been studied extensively and considered for functional use in applications such as soft robotics, smart textiles, and medical devices. LCEs undergo an ordered to disordered transition causing them to contract. The associated deformation in LCE fibers is analogous to muscles. This research is concerned with characterizing the orientation of LCE fibers in a twisted geometry and assessment of the thermomechanical response. We will show that the thermomechanical response of twisted LCE fibers spans a distinct geometric phase space. The fibers start in a rectilinear geometry and then spontaneously coil when heated. The inherent stimuli response of LCEs changes the twist density of the LCE fibers. The stimuli-response is dependent on the morphological constraints of the fibers (e.g., the twist density). A material with a fixed twist density can have different geometric actuation responses based on the load or force that is needed to be generated. Using the spontaneous coiling for actuation leads to fast actuation responses, increase in actuation stroke and ability to optimize work.

Autonomously Repeating High-Speed Motions in Soft Materials AlfredJ. Crosby; University of Massachusetts, United States

Soft materials, such as polymer gels, have long been realized as a potential platform for actuation in robotic systems; however, several challenges have limited their integration into translatable technologies. In particular, soft matter actuators are slow, unable to generate significant power, and typically require external intervention to initiate multiple, sequential actuation events. Recent results from our research group have demonstrated the ability to harness evaporation-induced stresses to initiate snap-through transitions, which can generate high velocity, high acceleration motions with swollen elastomers. Importantly, we discovered that certain combinations of materials properties and geometries allowed for the system to undergo multiple, consecutive snap-through transitions without external intervention. Here, we review these previous findings and introduce our latest research results focused on understanding the structure-property relationships that control the total energy flow of these self-repeating, high velocity events. The lessons learned are built upon the materials science principles that have been developed as part of a multi-university team, which takes inspiration from examples in nature including mantis shrimp and trap-jaw ants. These organisms use Latch-Mediated Spring Actuation (LaMSA) to achieve high power, impulsive movements by integrating actuators, elastic elements, and stability-mediating latches. The strategies and results discussed provide new insight into how polymer properties can combine with purposeful structural design to achieve complex, energy-efficient tasks, which can be used in the development of microscale robots.

10:45 AM SF06.04.02
Liquid-Crystal-Elastomer-Based Entangled Active Matter Systems AsafDana, MustafaK. Abdelrahman and TaylorH. Ware; Texas A&M University, United States

Soft materials in which individual components convert ambient free energy into mechanical work are commonly referred to as active matter. Physically entangled active matter is an emerging area of both living and man-made systems, where mechano-functionality of the collective emerges through physical interaction of individual elements. Liquid crystal elastomers (LCEs) are a class of stimuli responsive polymers that undergo large, reversible, anisotropic shape change in response to a variety of stimuli, including heat and light, making them ideal candidates for many applications, especially in the field of biomedical devices. LCE films that exhibit three dimensional folded and twisted conformations in response to variations in temperature were added magnetic particles to facilitate dynamic motion under a varying magnetic field. The combination of the induced dynamic motion from the magnetic field along with the temperature induced folding facilitates entanglement of the individual elements into a macroscopic multifunctional solid exhibiting emergent properties that are tunable with the variation of the temperature and the magnetic field. The outcomes of this project are expected to open the way for new active matter systems composed of dynamic entangling elements, where rich and non-intuitive material physics can be uncovered and applied towards the development of a variety of unique autonomous devices.

11:00 AM SF06.04.04
Polymer Dispersed Liquid Crystalline Elastomers (PDLCEs): Moldable Soft-Soft Materials for Different Actuation Geometries and Applications ValentinaDomenici[1], MatejBobnar[2], NikitaDerets[2], GeorgiosKordogiannis[2], BostjanZalar[2] and AndrazResetic[2]; [1]University of Pisa, Italy; [2]Jozef Stefan Institute, Slovenia

Soft-soft composites based on liquid crystalline elastomers (LCEs) were successfully prepared by optimizing a synthetic procedure were liquid crystalline elastomers in the form of microparticles are dispersed in an amorphous matrix, namely a silicone polymer one. These materials are called Polymer Dispersed Liquid Crystalline Elastomers (PDLCEs). The preparation procedure includes several steps in the presence of an external magnetic field with the aim to orient the LCE microparticles along a desired direction [1]. A detailed study based on 2H NMR spectroscopy on PDLCEs prepared under a different magnetic field strength [2] revealed a quite homogeneous distribution of orientation of the microparticles at a magnetic field higher than 4 Tesla. Under these conditions, thermomechanical response of these composites with different actuation geometries is highly correlated to the orientational order distribution of the LCE microparticles. Recently, we demonstrated the shape-programmability of these soft-soft composites prepared with main-chain liquid crystalline elastomers (MC-LCEs) [3]. In particular, PDLCEs based on MC-LCEs enable efficient morphing among the virgin shapes and the thermally-programmed and thermomechanically-controlled shapes. Several examples of shape-memory preparations and applications will be discussed.

Molecular Engineering of Liquid Crystalline Elastomers Containing Supramolecular Mesogens KristinL. Lewis, JonathanD. Hoang, DavidT. Kennedy, SarahS. Aye and TimothyWhite; University of Colorado Boulder, United States

Liquid crystalline elastomers (LCEs) are lightly crosslinked polymer networks that exhibit large deformations due to the disruption of liquid crystalline order when exposed to a stimulus. However, LCEs currently demonstrate a weak coupling of stimuli and response that limits the functional application of these materials. A recent effort by our group demonstrated that the inclusion of liquid crystalline mesogens formed with supramolecular bonds results in more rapid phase transitions due to the disruption of the hydrogen bonds. Here, we further analyze the effect of intra-mesogenic supramolecular bonds on the actuation of LCEs to better understand how these contribute to the overall order-disorder response. Benzoic acids are shown to form

dimers within the crosslinks that can be disrupted with temperature as well as with the nematic to isotropic phase transition of the overall network. By including these dimers with conventional three ringed liquid crystals as well as nonconventional two ringed mesogens with reduced intermolecular interactions, we probe how the disruption of H-bonds is affected by the surrounding network and heat. We also examine the structure-property effect by varying the supramolecular mesogen itself to analyze the connection between H-bond strength and actuation dynamics. This is demonstrated by including benzoic acid derivatives along with molecules containing functional groups such as pyridines to result in single H-bonds. Varying the strength of hydrogen bonds and mesogenic intermolecular interactions results in improved performance of the LCEs. Overall, this effort's purpose is to both understand the influence of H-bond interactions on LCEs and then tailor the response of these soft actuators through molecular engineering to improve LCEs as functional materials.

11:30 AM *SF06.04.06
Low Density Actuators for Soft Robotics by Programming the Responsivity of Liquid Crystalline Polymer Networks and Elastomers TimothyWhite; University of Colorado, United States

Liquid crystalline materials are pervasive in our homes, purses, and pockets. It has been long-known that liquid crystallinity in polymers enables exceptional characteristics in high performance applications such as transparent armor or bulletproof vests. This talk will generally focus on a class of liquid crystalline materials referred to as liquid crystalline elastomers. These materials were predicted by de Gennes to have exceptional promise as artificial muscles, owing to the unique assimilation of anisotropy and elasticity. Subsequent experimental studies have confirmed the salient features of these materials, with respect to other forms of stimuli-responsive soft matter, are large stroke actuation up to 75% as well "soft elasticity" (stretch at minimal stress). This presentation will survey our efforts in directing the self-assembly of these materials to realize distinctive functional behavior with implications to soft robotics. Most notably, enabled by new chemistries amenable to facile processing methods we have prepared liquid crystal elastomers with distinctive actuation and mechanical properties realizing more than 100 J/kg work capacities in homogenous material compositions. Fibers and yarns are promising geometries to further enhance the exceptional stimuli-response of these materials.

SESSION SF06.05: Actuation II

1:30 PM SF06.05.01
Heterogeneous Polymer Composites for High Stiffness 4D Printed Electrically Controllable Multifunctional Structures JavierM. Morales Ferrer[1], RamonE. Sanchez[1], SophieCaplan[1], Wimv. Rees[2] and JohnW. Boley[1]; [1]Boston University, United States; [2]Massachusetts Institute of Technology, United States

4D printing is a rapidly emerging field in which 3D printed stimuli responsive materials are used to produce morphing and multifunctional structures, with time being the fourth dimension. The materials used for 4D printing are generally soft (elastic modulus range 10^{-4} – 10 MPa) when undergoing shape change, which limits the scalability, actuation stress, and load bearing capabilities of current applications. Here, to address these limitations, we introduce heterogeneous polymer composites as a new class of stiff 4D printed materials. These composites are comprised of an epoxy matrix with a tunable cross-link density and a plurality of isotropic and anisotropic nano and micro fillers. Using this as a platform, we generate a palette of inks that span a large range of negative and positive linear coefficient of thermal expansion ($-19.1 \pm 0.3 – 128.8 \pm 1.2$ ppm $^oC^{-1}$) with an elastic modulus range that is four orders of magnitude larger than existing 4D printed materials ($0.34 \pm 0.1 – 38.6 \pm 1.4$ GPa), and tunable electrical conductivities ($0.7 \pm 0.1 – 2.0 \times 10^3 \pm 0.2 \times 10^3$ S m^{-1}) for integrated Joule heating actuation and sensing. Using electrically controllable bilayers as building blocks, we design and print a 3D self-standing lifting robot, with record lifting capabilities (~888 times its own weight) and actuation stress (~6 MPa) for 3D printed actuators and comparable performance for commercially available actuators. Moreover, we were able to implement a closed loop control to our lifting robot to achieve autoregulated actuation with response that lie within 4.8% and 0.8% overshoot and undershoot, respectively. Furthermore, we design and print flat surfaces that morph into different self-supporting complex 3D surfaces. Finally, we combined our inks to 4D print an electrically controlled crawling lattice robot that can carry up to 144 times its own weight.

1:45 PM SF06.05.02
Synthesis and Characterization of Sequence Defined Monodisperse Liquid Crystalline Oligomers Chun Lam ClementChan, ShawnM. Maguire, EmilyC. Ostermann, CallieC. Zheng, JakeH. Cedar and EmilyC. Davidson; Princeton University, United States

The actuation and soft elastic behavior of liquid crystal (LC) polymers have led to their use in applications ranging from soft robotics to elastocaloric devices. However, the behavior of a main-chain LC polymer differs markedly from that of its constituent monomer and is influenced by factors including molecular weight, sequence, and molecular weight dispersity. LC oligomers and polymers of controlled length and sequence are challenging to achieve through typical step-growth LC synthetic strategies. As such, we demonstrate a new LC synthetic approach based on iterative exponential growth (IEG) to prepare a series of monodisperse triazole-linked LC oligomers of precise lengths. We map the effects of increasing molecular weight on the thermal transitions of these discrete LC materials. These results are contrasted with the behavior of comparable species prepared via conventional step-growth polymerization. Furthermore, by preparing LC monomers decorated with different functional groups, sequence-defined co-oligomers and co-polymers can be prepared, illustrating the effects of sequence and functionality on LC phase behavior. These studies highlight important factors affecting LC phase transitions, establishing design rules for tailored and precise LC behavior.

2:00 PM SF06.05.03
Activated Metals for Thermal Actuation in the Context of Biomedical Applications EvaRemlova[1,2], VivianR. Feig[1,3] and GiovanniTraverso[3,1]; [1]Brigham and Women's Hospital, Harvard Medical School, United States; [2]ETH Zürich, Switzerland; [3]Massachusetts Institute of Technology, United States

The advancement of biomedical robotics relies on innovative actuation schemes and the utilization of advanced materials. To date, the practical applications of heat-actuated systems still appear limited, and further research is needed to explore new heat generation methods for actuating robotic structures. However, heat-based actuation faces constraints due to its high power requirements, restricting its use outside clinical settings. To address this, we have developed an in vivo heating method using liquid metal-activated aluminum and water. We established a consistent activation method and characterized heat generation through thermal imaging and heat flux measurements. Demonstrating its potential, we used this method to thermally actuate a gastric resident device made from Nitinol, a shape-memory alloy. This novel *in situ* heat generation technique offers advantages and promising future directions for broader applications in biomedical technology.

2:15 PM SF06.05.04
Soft Robotic Myriapods via LCEs JamesT. Waters and AnnaC. Balazs; University of Pittsburgh, United States

Myriapods, such as centipedes and millipedes, represent a promising avenue for bioinspired robotics, with many legs allowing the device to retain functionality even after one leg has been damaged. However, the need for a complicated set of separate parts to control each of these many limbs makes construction difficult. Liquid crystalline elastomers (LCE's) represent an ideal material to overcome these challenges. Non-linear coupling and feedback between shape changes and light and temperature stimuli allow LCE devices to exhibit a diverse array of actuation and programmed responses without the need for internal mechanisms. This greatly simplifies the fabrication of many-legged soft robots. Using a finite element simulation model, we demonstrate how such an LCE device can be shaped and magnetically programmed so as to induce walking behavior in response to light stimuli.

2:30 PM SF06.05.05
Improved Performance of Soft Robotic Artificial Muscles Through Compositing High Dielectric Polymeric Materials ErinRutledge, ChuckRutledge and MichaelRowe; Toyota Research Institute of North America, United States

Electrically driven artificial muscle soft actuators assist in propelling automotive companies closer to the lightweighting of equipment while moving the environment closer to carbon neutrality. The innovativeness of this technology stems from muscles found in the natural world. Electrostatically based artificial muscles have not previously performed at an advantageous level that could adequately challenge electric motors. Artificial muscles are electrically driven flexible capacitors. A hydraulic response (muscle flexing) is yielded after a voltage is applied to the electrodes causing the attractive forces between them to move the internal dielectric fluid. The dielectric constant between the two-electrodes of this parallel plate capacitor dictates the capacitance of the artificial muscle, and therefore, the attractive force between the electrodes. In our soft robotics actuator, this translates directly as output force. Numerous polymeric insulating materials have been investigated as coatings for these electrodes. High dielectric constant PVDF-TrFE-CFE has always been an attractive candidate material because of the correlation of dielectric constant to higher output forces. Prior to this phase in our research, integration of this material into an artificial muscle has proven daunting. However, through compositing with PVDF-HFP, the integration of this material into the fabrication of artificial muscles was successful. A performance improvement of 4.5x was demonstrated using a

composite insulating layer of PVDF-TrFE-CFE and PVDF-HFP versus a control muscle that used only 12 μm PVDF-HFP electrical insulation. An 800 g load was lifted with ~150% stroke using only an applied application voltage of 2,250 V, by an artificial muscle made with 10 μm PVDF-TrFE-CFE and 4 μm P-VDFHFP electrical insulation. This substantial improvement is ascribed to the influence of the high dielectric constant of PVDF-TrFE-CFE (50) compared to that of PVDF-HFP (10). Additionally, it was found that adding a ~10 N force to the edge of the artificial muscles' electrodes acted as a closing assistance, increasing the weight the muscle could lift while maintaining ~150% stroke. This led to the optimization of the electrode design with the aforementioned composite insulation. A series of artificial muscle electrode designs were fabricated using various thicknesses of PVDF-TrFE-CFE composited with 4 μm PVDF-HFP to optimize the ratio of relative polymer thicknesses necessary to maximize performance. Our results demonstrated that a 3:1 ratio (13 μm PVDF-TrFE-CFE: 4 μm PVDF-HFP) performed consistently with ~150% stroke lifting up to 700 g. Such results show how manipulation of capacitive effects can be achieved in layering of different polymeric materials and achieve manipulation of soft robotic artificial muscle output force. These artificial muscles are currently being tested for use in a device that will act as a suction cup that will be applied in existing robotic equipment.

3:15 PM *SF06.06.01
Self-Pumping Tubing: Fiber-Format Electrohydrodynamics MichaelSmith and HerbertR. Shea; Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland

Fiber-based devices are at the heart of wearables. We report here a fluidic pump in the form of a stretchable and flexible fiber, enabling the benefits of fluidic systems and associated soft actuators to be deployed in a wearable context. Our pumps consist of two continuous helical copper electrodes embedded within the walls of a 2 mm diameter polyurethane tube. The pumps generate pressure silently and without any moving parts using the principle of charge-injection electrohydrodynamics. The tubing itself becomes the pump, affording vast design freedom in the implementation of wearable fluidic circuits, which we illustrate with demonstrations of wearable haptics (glove), mechanically active fabric sheets and thermoregulatory textiles (shirt). The maximum pressure generated by each pump is proportional to its length, with each meter of fiber generating 100 kPa of pressure, or flowrates of 50 ml/min, at an applied electric field of 8 kV/mm. To function, the liquid being pumped must be a dielectric fluid with a high breakdown strength. Here, we use the dielectric fluid Novec 7100, a non-toxic, non-flammable methoxy-fluorocarbon. Judging by specific pressure and specific flowrate, the fiber-shaped pumps outperform by more than an order of magnitude the conventional miniature pumps that they replace. The scalability, simplicity and bi-directional pumping capabilities of these fiber pumps enables a wide range of wearable applications that are not possible with conventional pumping technologies.

3:45 PM SF06.06.02
Untethered Soft Robotic Systems with an Embodied Redox Flow Battery Achieved through Robust Adhesion for Assembly ChongchanKim and RobertShepherd; Cornell University, United States

Redox flow batteries are demonstrating their potential in the field of soft robotics by offering possibilities to enhance embodied energy efficiency through their multifunctionality. Integrating these batteries into the system can boost efficiency due to their versatile capabilities. The electrolytes within the embedded battery serve both as storage for electrochemical energy and as essential components for structural integrity and force transmission. However, the water-tight sealing required on the ion exchange membrane makes it challenging to fully leverage the advantages of the Redox flow battery.
Here, we present the untethered worm-like crawling robot powered by pod batteries integrated into the worm body. The pod cell is a pre-sealed pouch made with ion exchange membranes, reducing wasted space for sealing and increasing the effective area of electrodes so that it can reach the power requirements for the actuation. We fabricated the pod battery with a robust bond (~500 N/m) between ion exchange membranes and soft materials which allows a flexible and reliable power system even in the complex body shape of the worm during its actuation. The reliable bonding ensured battery functionality and simplified the fabrication process. Moreover, it enabled an exploration beyond conventional battery designs, allowing for diverse form factors for embodied energy systems.

4:00 PM SF06.06.03
A Bioresorbable and Miniaturized Ultrasound-Mediated Nanogenerator for *In Vivo* Electrical StimulationXiaoXiao, XiangchunMeng and Sang-WooKim; Yonsei University, Korea (the Republic of)

Implantable medical electronics (IMEs) provide practical approaches for diagnosis, treatment, and rehabilitation. However, conventional IMEs often rely on non-biodegradable batteries and require invasive surgical implantation. Long-term battery insertion can lead to performance degradation and corrosion, necessitating multiple surgeries for device maintenance and replacement[1]. Moreover, major surgeries and bulky implants also pose additional challenges due to the risk of postoperative complications and the potential for acute and chronic injuries[2]. Therefore, there is a significant demand for developing IMEs with biocompatibility, biodegradability, high reliability, and miniaturization.

As an emerging technology, triboelectric nanogenerators (TENGs) offer an innovative solution to address these limitations. Here, we present a bioresorbable, injectable, and ultrasound-mediated triboelectric nanogenerator (UB-TENG) for in vivo electrical stimulation. The UB-TENG comprises a molybdenum electrode and a biodegradable polyurethane friction layer synthesized from poly(3-hydroxybutyrate-co-3-hydroxyvalerate) and polycaprolactone. The miniature size of the UB-TENG enables direct injection into the desired site using a piercing needle, minimizing the risks associated with long-term implantation and reducing trauma. By utilizing capacitive triboelectric technology, the UB-TENG can be noninvasively powered by ultrasound[3], and we have successfully demonstrated the modulation of UB-TENG efficiency by varying the ultrasound intensity. UB-TENG provides a safe and sustainable electrical output in various conditions, delivering a continuous alternating electric field of up to 0.92 V mm^{-1}. Cell experiments have confirmed the effectiveness of the delivered electric field in promoting cell migration and proliferation, indicating the significant potential of UB-TENG in accelerating wound healing. Our findings support the potential of UB-TENG as a novel energy solution for IMEs, offering the possibility of mitigating infection and chronic inflammation.

Self-Powered Triboelectric Charges-Generated Microbial Blocking Textile by Harnessing Kinetic Energy In-YongSuh[1] and Sang-WooKim[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

Air-transmitted pathogens induce up to 650,000 respiratory disease-related deaths annually from seasonal influenza by inhalation, ingestion, and/or skin contact. Micron-sized aerosols containing these hazardous bacteria/viruses are inevitably released into the air, resulting from the daily motions of the infected people. Considering the long floating distances (~kilometers) of the small-sized aerosols, air-transmitted pathogens exist ubiquitously in the surrounding environment, making widespread pandemics exponentially and rapidly spread all over the world. In addition to the urgent challenges to preventing pathogen infection, the most used personal protection device, face masks, can lead to obvious pressure drops and uncomfortable long-term wearing while only protecting the facial area instead of the full skin. Alternative methods, such as antimicrobial textiles can utilize the nanomaterial-modified functional fabrics for effective microbial prevention, whereas suffering from limited treatment throughput, high cost, and potential toxicity from nanomaterial release.
In this study, we propose a novel microbial blocking textile for efficient bacterial and viral blocking in the air. We applied an optimized triboelectrification fabric (PTFE and nylon) and structure (rib-knitted) to build a two-layer textile that harvests human motion to generate triboelectric charges for effective microbial blocking based on electrostatic repulsion. The self-powered triboelectric charges-generated microbial blocking textile (TC-MBT) was developed to overcome the insufficient treatment throughput and obvious pressure drops of conventional air-transmitted pathogen protection methods such as face masks and filters. Our work provides a proof-of-concept for highly efficient and self-powered microbial blocking with low pressure drop, which could be applied for personal protection applications to fill the urgent need for air-transmitted pathogen protection.

4:30 PM *SF06.06.05

Bioinspired Liquid Battery Solutions that Store Oxygen and Enable 850 Wh kg^{-1} Catholytes for Instantly Recharging Robots and Electric Aircraft JamesH. Pikul; University of Wisconsin–Madison, United States

Autonomy in robotic systems is limited by the lack of flexible, high energy density storage technologies. Typically, the energy storage system is optimized independently from the rest of a robot's actuation, sensing, and control systems so that most technologies focus on making battery packs as small and as light as possible. This approach leads to low system-level efficiencies and energy densities. For example, current battery architectures based on solid intercalation materials store 250 Wh kg^{-1} and require > 1 h to recharge, but animals can store ~2,000 Wh kg^{-1} and operate continuously. The clear gaps in energy density and operational capability between machines and animals motivate new ways to store electrochemical energy via bioinspired designs.

Designing robots with multifunctional energy storage systems allows size, weight, and power trade-offs to be reevaluated. Animal circulatory systems use blood to transport oxygen and nutrients while simultaneously regulating temperature, removing waste, and helping to fight infection. Biology takes advantage of the inherently high theoretical specific energy of oxygen reduction processes without the need for each cell to access the surrounding environment.

Inspired by this functionality and the large number of high specific energy reactions that use gases, we developed a catholyte capable of storing 15 mg/L of dissolved oxygen and used it to discharge zinc-air flow batteries in a multifunctional actuator flow cell (MAFC) that also provided linear actuation. The catholyte was an emulsion with silicone oil droplets suspended in 0.5M potassium hydroxide, stabilized by a surfactant (Span-60). We extracted energy directly from the oxygen in this fluid with a fully submerged electrode that was not exposed to surrounding air. This enabled oxygen reduction to occur in a fully closed system with no need for a gas diffusion electrode or triple-phase boundary. Our electrolyte can remain stable for months, shows high oxygen reduction reaction (ORR) kinetics, and can be re-oxygenated with atmospheric air. We achieve 4.6 mW/cm^2 peak instantaneous power density at 5.6 mA/cm^2 discharge current density in a stationary tubular flow cell (STFC) configuration.

The last part of this talk will report an electrochemical stomach that near-continuously powers electric aircraft and robots by ingesting small molecules as beverages and converting that chemical energy to electricity by pairing them with metals. We demonstrated a 10.4 Ah stomach that delivers an energy density of up to 850 Wh $kg_{stomach}^{-1}$ at 192 A $kg_{stomach}^{-1}$ and restored the chemical energy of a robot dog in 1 minute. The stomach powered a commercial quadcopter and doubled the flight time of the manufacturer's state-of-the-art batteries. Owing to the diversity of small molecules, we tailor beverages to enable 1,447 Wh kg^{-1} discharge energy density or fire-safe energy storage.

8:00 PM SF06.07.01
Development of a Low-Cost, Flexible and Ultra-Thin Capacitive Tactile Sensor For Monitoring Tool-Tissue Interactions and Grasping Performances of a Surgical Robotic Magnetic Microgripper AnastasiaAubeeluck, HaniNaguib and EricDiller; University of Toronto, Canada

With advancements in miniaturization and wireless actuation for robot-assisted minimally invasive endoscopic intraventricular surgery, surgeons are unable to acquire tactile sensory feedback necessary for safe tool-tissue manipulations. To enhance surgical performance and reduce the risks of tissue trauma, haptic technologies need to be integrated onto micro-scale surgical tools to provide tactile information. However, current sensors cannot be integrated for robot-assisted minimally invasive surgery (RMIS) for pediatric neurosurgery due to low force range and small scale criteria. This study proposes a novel 24 mm^2, ultra-thin and flexible capacitive tactile sensor for the interior jaws of a disposable surgical magnetically-controlled microgripper (4 mm in diameter). The sensor seeks to enable real-time monitoring and regulation of tool-tissue manipulation forces, thereby improving grasping performance and the overall quality of surgical procedures. To lower fabrication cost, the multiple layers of the capacitive sensor were screen-printed and assembled to produce a thin flexible sensor with an overall thickness of 100 µm. Furthermore, to improve sensor performance in terms of range and sensitivity, four different morphologies were developed for the dielectric layer, integrated into the sensor design, and characterized in terms of performance. The dielectric layer optimization consisted of tuning and processing Thermoplastic Polyurethane (TPU) into a suitable ink for screen printing large surfaces and microstructures. The final optimized sensor had a grid-like micro-structured dielectric design and demonstrated a sensing range of 0.01-1.3 N. Its electromechanical performance was modeled as a bi-linear response with two sensitivity modes and had a hysteresis of 8.8%. The sensor also showed a repeatable response to applied cycling loadings with a maximum response signal decay of 1.85%. This study highlights that screen printing method can be used as a low-cost alternative to fabricate high performance tactile sensors to be integrated to the interior jaw of the disposable microgripper designed for endoscopic intraventricular surgeries.

Graphene Origami with Bendability and Foldability JiwooKim, Dong HoonMoon and Gwan-HyoungLee; Seoul National University, Korea (the Republic of)

Origami has been used a straightforward and controllable method to fabricate 3D patterns in nano/micro-scale for soft robotics and complicated architectures. Here, we report graphene origami technique for 3D patterning by using poly(methyl methacrylate) (PMMA)-coated graphene. The graphene was grown on a silicon substrate. High etching resistivity of graphene to XeF_2 gas and its flexibility enable fabrication of the complicated 3D nano/microstructures with reduced fabrication steps, compared to conventional lithographic methods. By exposing the PMMA/graphene film to e-beam and selective patterning of graphene, we can bend the suspended the PMMA/graphene film upward or downward. With this bidirectional folding function, we can create the 3D graphene origami structures with multiple folds. Our work shows a novel way to fabricate 3D graphene structure with controllable folding and reversible bending and high potential of graphene Origami in fabrication of nano/micron-scale machines.

8:00 PM SF06.07.03
Unravelling the Dual-Responsive Behavior of Anthracene and PNIPAM Bilayer Soft Actuators: Reversible Actuation via Visible Light and Temperature AnasSaifi[1,2], CharuNegi[1] and KamleshKumar[3]; [1]CSIR-Central Scientific Instruments Organisation, India; [2]Academy of Scientific & Innovative Research, India; [3]Central University of Jammu, India

Soft robotics, inspired by natural organisms, have gained popularity due to their ability to exhibit physical changes in response to environmental stimuli. Among the various stimuli, light has attracted the most attention due to its remote-control capabilities, high spatial and temporal resolution, and ease of fine-tuning. The pursuit of integrating multiple stimuli into a soft actuator stands as a pivotal role in the quest for the advancement of smart materials. In the present study, a multi-responsive soft actuator with bilayered architecture was designed and fabricated. Here, the bilayer is composed of a visible light-responsive PVA-Anthracene layer and a thermoresponsive PNIPAM layer. Interestingly, each layer is designed to respond to a specific stimulus enabling them to perform efficiently in both dry and aqueous environments. The bilayer soft actuator was characterized through a comprehensive set of techniques encompassing UV and FTIR spectroscopy for molecular analysis, optical microscopy to confirm the fabrication of the bilayer structure, and tensile testing to assess its mechanical properties. The multiresponsive soft actuator exhibited rapid and reversible actuation with a bending angle of 153° under blue light, and complete rolling was observed when the temperature of the solution was raised above the critical solution temperature of PNIPAM. The visible light responsiveness is attributed to the photodimerization of anthracene moiety whereas the temperature responsiveness is a consequence of the phase transition of PNIPAM above LCST. The tunable actuation of the film was demonstrated with different blue light intensities and anthracene dye concentrations, as well as varying the concentration of the PNIPAM for thermomechanical behaviour. This works holds promising implications in the fields of robotics, biomedical engineering, and adaptive structures, requiring controlled actuation in both dry and aqueous environments.

8:00 PM SF06.07.04
Imbibition-Induced Autonomous Wetting of Liquid Metal Ji HyeKim[1], sooyoungkim[2], SanghyukWooh[3], JiungCho[4], MichaelDickey[2], Ju-HeeSo[5] and Hyung-JunKoo[1]; [1]Seoul National University of Science & Technology, Korea (the Republic of); [2]North Carolina State University, United States; [3]Chung-Ang University, Korea (the Republic of); [4]Korea Basic Science Institute, Korea (the Republic of); [5]Korea Institue of Industrial Technology, Korea (the Republic of)

Gallium-based liquid metal alloys (GaLMs) are in liquid phase at room temperature and have the attractive properties, including high electrical/thermal conductivity, low toxicity, and high deformability, making them ideal for use in stretchable and deformable electronic pathways. Controlling the interfacial characteristics of GaLMs with underlying substrates is essential for depositing, printing, and patterning GaLMs. However, the high surface tension of GaLMs makes it difficult to create thin films with uniform height. We present an effective method for producing flat thin films and patterns of GaLMs, by introducing microstructured metallic features on which GaLMs rapidly and spontaneously spread in the absence of a native oxide. The enhanced wetting characteristics of GaLMs on the microstructured metallic surface are induced by imbibition, which enables large-area uniform coating and patterning of the liquid metal. The

GaLM-coated polymer substrates prepared by the method maintain electrical connectivity even in a stretched state and after repetitive stretching cycles. The imbibition-induced wetting principle of the liquid metal provides several advantages: 1) coating and patterning GaLMs occurs spontaneously without external force, 2) the thermodynamically-favorable wetting of GaLMs forms stable metallic thin film, and 3) the thickness of the GaLM thin film can be well-controlled by varying heights of the metal-coated microstructures. This approach also reduces the amount of GaLM required for thin film formation, making it a cost-effective and efficient method for electronic applications.

8:00 PM SF06.07.05

Droplet Micro-Robotic System with Generality of Liquid Types and Biocompatibility RuotongZhang[1], HaisongLin[1,2] and AndersonShum[1,2]; [1]The University of Hong Kong, China; [2]Advanced Biomedical Instrumentation Centre, Hong Kong Science Park, China

The flexible and deformable nature of micro soft robots offers an alternative for transporting soft, fragile or microscale materials. Among them, droplet robots, based on their fluidity, are capable of adaptively navigating through tortuous environments with physical obstacles, as well as carrying and transporting biological/chemical samples of interest for medical diagnostics, drug development, and chemical/material synthesis. However, different target samples will require different droplets environments that serve as their carrier. For example, living cells require specific buffers as carriers to maintain biological activity, while some water-soluble nanoparticles need to be transported in organic fluids. Therefore, a robotic system that is compatible with a variety of organic/inorganic liquids and the carried bio/chemical samples needs to be developed. Here, we propose a multi-physics droplet robotic system that can actuate various liquids through a movable electrostatic field. In particular, the droplet-driven unit is composed of a hybrid of electret and magnetic materials. The electret section which carries electrostatic charge can generate a non-uniform electrostatic field that polarizes and attracts the droplet, while the magnetic section can be controlled under a programmed localized electromagnetic field. In our work, the droplet robotic system demonstrates a high compatibility with droplet volume (nL-mL), liquid types (inorganic/organic), and samples carried by the droplet (living cells/proteins/nanoparticles), thus providing a general hardware platform for delivering a wider range of different biological/chemical samples in an automated manner.

8:00 PM SF06.07.06

Charge-Accumulating Flutter-Type Triboelectric Nanogenerator as High Performance Self-Powered Portable Device DeokjaeHeo[1], SunghanKim[1], JinkeeHong[2] and SangminLee[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

For a triboelectric nanogenerator (TENG), achieving both a high RMS (root-mean-square) output current and a portability remains a challenge. Herein, a charge accumulation fluttering based triboelectric nanogenerator (CAF-TENG) with an ultrahigh RMS output current, an average power density and an outstanding portability is proposed. Because of the electron accumulation and electrostatic discharge mechanism and electrical-mechanical fluttering device design, the CAF-TENG can generate an RMS output voltage, RMS output current, and average power output density of 44 V, 36 mA, and 26 mW cm−3, respectively. The maximum peak output voltage and current are 508 V and 1.6 A, respectively. The CAF-TENG is optimized via quantitative RMS voltage-current database and mechanical behavior analysis. The wind-driven CAF-TENG can power 2000 commercial LEDs matrix and charge high-capacitance capacitors or commercial lithium batteries. Furthermore, a respiration-driven mask-valve-integrated CAF-TENG is fabricated, which can power 40-W commercial lamps and operate a commercial Bluetooth tracker sensor by charging a capacitor. These results suggest that the CAF-TENG can function as a self-powered portable device in everyday life. Moreover, these findings will provide a new guideline for improving the electrical output level of existing TENGs.

8:00 PM SF06.07.07

Soft Actuators Based on Liquid Crystal Elastomers and Laser-Induced Graphene AlexanderDallinger[1], StellaDrewes[1] and FrancescoGreco[2,2,2]; [1]TU Graz, Austria; [2]Scuola Superiore Sant'Anna, Italy

Laser induced graphene (LIG) is a porous conductive carbon material produced by laser-induced pyrolysis of polymer precursors with applications in soft electronics/robotics and wearable electronics, among others. LIG conductors are conveniently created in a single synthesis/patterning step by laser scribing with a CO_2 or UV laser onto a polymer precursor such as polyimide. A subsequent transfer of the LIG onto a stretchable support such as polyurethane (PU) is used to create soft, flexible and stretchable LIG conductors. These soft conductors are then used in a composite with a liquid crystal elastomer (LCE), where the LIG acts as a joule heating element. The LCE is synthesized via click chemistry and poured into a mold where a partially cross-linked elastomer is created. The partially cured elastomer is pre-stretched and fully cured by UV irradiation. The LIG/PU and LCE are bonded together to form a multi-composite soft actuator. By applying a current to the LIG heating elements, a nematic-isotropic transition is induced in the LCE, resulting in contraction of the actuator. The contraction can be reversed by turning off the current and cooling the actuator. An linear actuation strain of about 60% is achieved. The combination of LIG as a heating element and LCE as an active actuation material is a promising approach to bio-inspired actuators with comparable performance to muscles.

8:00 PM SF06.07.08

Effects of Crosslink Density on Photomechanical Jumping of Glassy Liquid Crystalline Polymer Networks Min JeongHahm[1,1], JisooJeon[2], WoongbiCho[1,1] and Jeong JaeWie[1,1,1]; [1]Hanyang University, Korea (the Republic of); [2]Inha University, Korea (the Republic of)

In nature, jumping is a key survival strategy for living animals as it allows them to rapidly navigate through rough terrains and overcome obstacles that are often several times their body size. In our previous report, we newly demonstrated a continuous and directional UV-induced photo-mechanical jumping of polymer monolith by introducing snap-through buckling of super twisted nematic (STN) structured azobenzene functionalized liquid crystal polymer networks (azo-LCNs). However, the intense light conditions of 0.3 W cm^{-2} intensity and the long-term UV irradiation required for high jumping have raised concerns over the possible bond breakage and the subsequent decrease in the jumping capacity. Herein, we control the duration of UV irradiation for photopolymerization to vary the crosslink density and investigate the effect of the structure-property relationship on mild-condition jumping. Crosslink density-controlled azo-LCNs are heated to various substrate temperatures and irradiated upon different light intensities to achieve a systematic investigation of jumping heights. When the curing time is reduced from 60 min to 5 min, the storage modulus (E') of the azo-LCN monolith is successfully lowered from 74.8 MPa to 33.1 MPa in the plateau regime, and the bending curvature is increased from 2.1 mm^{-1} to 4.4 mm^{-1}, respectively. The reduced stiffness of the azo-LCN body increases the photomechanical strain response under actinic UV light, thereby allowing the body to store greater photo-induced potential energy. Remarkably, a maximum jumping height of 15.9 mm is reached at a milder light intensity of 0.1 W cm^{-2}, which is a 214% increase in height compared to the previous result obtained at identical UV light conditions.

8:00 PM SF06.07.09

Autonomous Magnetic Swarms of Microrobot Assemblies KijunYang, SukyoungWon, Jeong EunPark and Jeong JaeWie; Hanyang University, Korea (the Republic of)

Collective actuation of microrobot swarms has emerged as a versatile tool to succeed challenging tasks for a single microrobot. However, the unpredictable interactions among the microrobots and segregated movements of the microrobots present inherent constraints for the multi-functionality system. Herein, we report an autonomous magnetic swarm of magnetic microrobots through programming magnetic anisotropy in the microrobots. Due to the magnetic anisotropy, multiple microrobots assemble in a deterministic manner. Hundreds of magnetic microrobots can agilely rotate in their frontal plane while preserving their assembled configuration. Through the pivoting, the magnetic swarm of microrobot assemblies with high chain length facilitates the capability to climb obstacle. Meanwhile, the magnetic swarm with high packing density can transport cargo via rotational force of the microrobot assemblies. We will discuss multi-functionality of the autonomous magnetic swarm capable to lift heavy obstacle, tumble high barrier, and cleave high surface tension materials.

8:00 PM SF06.07.10

Towards Intelligent Soft Robots: A Data-Driven Approach to Unlock the Potential of Magnetically Responsive Materials AlpC. Karacakol, YunusAlapan and MetinSitti; Max Planck Institute for Intelligent Systems, Germany

Soft robots have emerged as a new branch of robotics with deformable bodies to achieve adaptability to dynamically changing unstructured environments and safe interaction with life forms ranging from cells to humans. Miniaturization efforts in soft robotics for operation in confined, small, and remote spaces are challenging because conventional batteries, actuators, and on-board processors are not available at smaller scales. The challenges of power, intelligence, and actuation at smaller scales have led to the incorporation of stimuli-responsive materials in soft robotics, where the actuation mechanism is based on the encoded response of the robot body to the external stimuli at the material level. Among the wide range of proposed external stimuli such as temperature, light, chemical, electric and magnetic fields, magnetic fields are particularly promising due to their safe and transparent interaction around biological tissues. Magnetically responsive soft materials with fast response and untethered control capabilities at small scales in confined environments make them ideal candidates for minimally invasive clinical operations within the human body. Advances in the spatial programming of magnetic soft materials have enabled micron-scale high resolution, 3D directionality, and multi-material compositions, resulting in a vast design space with intricate coupled magnetic and mechanical responses of soft robots. While the design space is immensely enriched, existing designs rely on an intuitive trial-and-error approach with fixed morphologies and simplified magnetic programming, drastically limiting the achievable capabilities. Here, we present a generic and experience-free method for programming both the 3D structural design and the 3D magnetic profile of magnetic soft robots for desired 3D shape morphing and behavior. The design algorithm is based on a continuous exploration of the design space through design candidates generated by MAP elites and the exploitation of promising designs guided by a predictive neural network (NN) model. The selected promising designs are tested in a computationally inexpensive simulation engine capable of evaluating the dynamic behavior of magnetic soft robots. The resulting best-performing designs for desired 2D and 3D shape-morphing of beams inspired by mathematical functions and complicated sharp-cornered objects are experimentally demonstrated,

demonstrating the Sim2Real transfer. The developed design strategy is also used to achieve desired dynamic behaviors without a defined target shape-morphing, including maximizing the number of turns, maximizing the height, and minimizing the bounding sphere volume for soft magnetic beams and plates. The superiority of the data-driven design strategy is highlighted in the high-performance jumping behavior of magnetic soft robots, where the intuitive design adapted from the literature failed to lift off the surface. Furthermore, the data-driven designed robots are shown to be capable of complex locomotion behaviors with simple control signals compared to the fine-tuned complex ones. The data-driven design strategy presented here provides a systematic and versatile platform to bridge the gap between advances in material functionalities and fabrication and programming methods, thus unlocking the potential of stimulus-responsive soft robots for real-world applications.

8:00 PM SF06.07.11
Bio-Inspired Magnetic Soft Kirigami Robot for Biomedical Application YizongLi and ShanshanYao; Stony Brook University, United States

Soft robots that are untethered have the potential to revolutionize medical monitoring due to their minimally invasive nature. Although progress has been made in the design and activation of these robots, given the intricate and ever-changing environment of the human body, there is still a need for a comprehensive untethered soft robot that can adapt to different environments. Taking inspiration from the locomotion of snakes, we introduce a soft kirigami robot that overcomes these challenges. This robot can deploy sensors, perform real-time wireless sensing, and adapt to a wide range of environments within the human body. Its capabilities include deployability, steerability, obstacle crossing, locomotion in both wet and dry conditions, climbing, inverted crawling, exceptional load capacity (up to 150 times its own weight), and high-speed locomotion (0.25 body lengths per second at 1 Hz actuation). By demonstrating these comprehensive locomotion abilities, the soft kirigami robot showcases its potential for various biomedical applications.

8:00 PM SF06.07.12
Artificial Intelligence Enabled Wearable Device for Sensing and Classifying Data Integrated with High-Performance Piezoelectric Yarns DabinKim[1], ZiyueYang[1], JaewonCho[1], DonggeunPark[2], Dong HwiKim[1], JinkeeLee[1], SeunghwaRyu[2], Sang-WooKim[3] and MisoKim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Yonsei University, Korea (the Republic of)

Piezoelectric polymer fibers are essential components in creating intelligent fabrics with adaptable shapes and energy-converting capabilities for wearable health and activity monitoring. However, producing high-performance smart polymer fibers has been challenging due to their low piezoelectric performance. In this work, high-performance piezoelectric yarns are presented that are both structurally robust and mechanically flexible. We achieved this by adding barium titanate nanoparticles (BTO, $BaTiO_3$) to poly(vinylidene fluoride-trifluoroethlene) (P(VDF-TrFE)) during electrospinning to increase the electroactive β-phase formation. The optimally selected BTO-15 fiber mat-based device exhibited a substantially enhanced voltage of 167.31 V under mechanical bending, which was higher than that of its pristine counterpart. The resulting BTO-doped P(VDF-TrFE) mats were transformed into yarns, where the degree of β-phase crystallinity is found to be significantly higher in the yarns than in the mats, showing that the yarns could be a more favorable structural platform for piezoelectric performance. Furthermore, a BTO-15 piezo-yarn device was fabricated and tested, which exhibited an output of 16.17 V. Also, tensile tests were performed on the BTO-doped mat and BTO-doped yarns which results in the yarns being mechanically strengthened and having significantly improved elastic modulus and ductility compared to the mat. Finally, the BTO-doped piezo-yarn devices were woven into cotton socks as we denoted “piezo-socks”. This can monitor and identify body signals during seven human motion activities, such as jumping, running, and stair-climbing, by using convolution neural network algorithms designed for classification achieving a high accuracy of 99.6 %.

8:00 PM SF06.07.13
Direct Current-Generating Triboelectric Nanogenerators Based on Tribovoltaic p-n Junction with ChCl-Passivated CsFAMA Perovskite SeraJeon[1], DabinKim[2] and Sang-WooKim[1]; [1]Yonsei University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Herein, we develop direct current-generating triboelectric nanogenerators (DC-TENGs) based on the tribovoltaic p-n junction using n-type perovskite (CsFAMA) and p-type conductive polymer (PEDOT:PSS); CsFAMA based DCTENG is shown to generate a high DC power output of about 2.1 $\mu A\ cm^{-2}$ (current) and 0.33 V (voltage). We also introduce choline chloride (ChCl) to passivate the defects inside CsFAMA to improve the power-generating performance of DC-TENG by increasing triboelectric charge density, carrier mobility, and built-in potential, which are the key factors that determine device performance. Due to the synergetic effect of reduced defect sites ($5.0\times10^{15}\ cm^{-3}$ to $1.0\times10^{15}\ cm^{-3}$), enhanced electron mobilities ($1.0\times10^{-2}\ cm^2\ V^{-1}\ s^{-1}$ to $2.3\times10^{-2}\ cm^2\ V^{-1}\ S^{-1}$), and modulated work function, the passivated CsFAMA-based DC-TENG generates an output current density of 11 $\mu A\ cm^{-2}$ and an output voltage of 0.80 V. Our results are expected to contribute to the development of high-performance DC-TENGs by presenting a promising strategy that involves controlling the triboelectric semiconducting interface.

8:00 PM SF06.07.14
Autonomous Synchronization of Lobed Loops Made from Liquid Crystal Elastomer Fibers: Untethered Gait-Like Motion Through Spontaneous Snap-Through Dae SeokKim[1] and ShuYang[2]; [1]Pukyong National Univeristy, Korea (the Republic of); [2]University of Pennsylvania, United States

The rapid transition between equilibrium states, known as snap-through, allows for the storage and release of elastic energy, enabling quick movements observed in organisms such as the Venus flytrap and hummingbird, which seize insects in mid-flight. Soft robotics have been investigating these mechanisms to achieve repeated and independent motions. In this study, we present a novel approach involving the synthesis of curved liquid crystal elastomer (LCE) fibers as fundamental units capable of undergoing buckling instability when exposed to heat on a hot surface. This leads to autonomous behaviors, including snap-through and rolling. By interconnecting these fibers into lobed loops, where each fiber is geometrically constrained by its neighbors, we achieve autonomous, self-regulated synchronization, occurring at a frequency of approximately 1.8 Hz. Additionally, the attachment of rigid beads to the fibers allows for precise control over actuation direction and speed, reaching velocities of up to 2.4 mm/s. Finally, we demonstrate the utilization of these loop structures as robotic legs, enabling various locomotion patterns reminiscent of natural gaits.

8:00 PM SF06.07.15
Dispersions of Carbon Nanotubes in Liquid Crystals Show Accumulating Responses to Electric Fields KaylaHellikson[1], HarrisonRoot[2], NarcrossHannah[2], GeorgiaKaufman[2], EmilyHuntley[2] and BryanKaehr[2]; [1]Texas A&M University, United States; [2]Sandia National Laboratories, United States

Mixtures of liquid crystals (LCs) and carbon nanotubes (CNTs) have been shown to act as switches in response to an electric field. These composite systems can display resistive memory, mimicking neuronal behavior such as synaptic plasticity and providing opportunities to develop new classes of neuromorphic materials. Typically, minute concentrations of nanotubes (< 0.001 wt%) are mixed into an alcohol solvent, diluted, tediously dispersed into liquid crystal solutions, and evaluated using small gap (< 5 um) electrodes. However, our efforts to reproduce results with these mixtures has been challenging. In this work, we investigate LC mixtures that are saturated with CNTs. These “two-phase” systems display hallmarks of neuromorphic materials such as memory, reset and accumulation in response to pulsed electric fields. We show electric-field induced CNT solubilization in LC “solvents” and parallel field alignment are the dominant mechanisms governing response. These effects are not restricted to micron gapped electrodes but are apparent across mm distances and translated into polymer dispersed liquid crystals, useful for device level applications. Overall, this work provides a foundation to develop tunable, neuromorphic materials that can remember and respond to electrical environments.

8:00 PM SF06.07.16
Reversible Chemotaxis of Janus Emulsion Droplets BradleyD. Frank and LukasZeininger; Max Planck Institute of Colloids and Interfaces, Germany

Organisms move in response to chemical stimulation as chemotaxis, recognizing environmental changes and transducing that information into directed motion. Emulating nature, many reported motile soft colloids utilize chemical stimuli to interact with their environment, including liquid which move using their fluid interface to generate Marangoni flows by physical or chemical stimulation. Current reports which utilize Marangoni-flow directed motion have been limited to a single programmable interface, yielding uncontrolled or unidirectional motion. We present a system where chemotactic speed and direction are reversible and responsive to the environment, using dynamically reconfigurable biphasic droplets whose shape is also responsive to the environment. A bi-phasic droplet in a binary surfactant mixture moves dependent on the magnitude of gradients and the droplet morphology, mutually determined by interfacial tension balance and competition. For droplets with two exposed interfaces to the environment, each interface is programmable to a separate gradient acting on the droplet, where droplet behavior is dependent on both the magnitude of the external gradients and the surface area that gradient acts upon. The reconfigurable nature of the presented system enables interactive and adaptive behaviors in response to a changing local environment. With this internal degree of freedom and response to the environment, we present theoretical and experimental insight into the generation of multi-responsive adaptive soft-matter. Utilizing droplet interactions with the environment in kind, the behavior of the droplets can be utilized to understand novel gradients. Soft-matter with internal feedback mechanisms are adaptive agents in response to bio(chemical) stimulation, such as the decision to move toward or away from a stimuli.

8:00 PM SF06.07.17
A Bimodal PVDF Sensor for Integration Into a Signal-Dense Multimodal Tactile Finger PeterBallentine, EricT. Chang, MateiCiocarlie and IoannisKymissis; Columbia University, United States

The types of tasks robots are capable of are in part limited by the lack of an adequate robot “sense of touch.” The human “sense of touch” takes in pressure, vibration, texture, curvature, and temperature via the skin’s biological transduction modes and synthesizes detailed information about the contact. Meanwhile, combining these modalities on a signal-dense tactile robot finger to detect the stimuli that make up the human “sense of touch” remains an open problem. Currently, many state-of-the-art robotic tactile sensors are unimodal, solely relying on a single transduction mode (e.g., optical, capacitive, resistive, etc.) to take in stimuli. We hypothesize that utilizing multimodal sensing capabilities will allow us to achieve richer and more meaningful tactile feedback for robotic applications.

In this work, we will present a bimodal polyvinylidene fluoride (PVDF)-based sensor and its subsequent integration into a larger multimodal sensing system for a tactile robot finger. The PVDF-based sensor consists of a thin sheet of PVDF with metal photolithographically patterned on both sides, and is capable of both piezoelectric and projected capacitance sensing modes for measuring relative movement (i.e., vibration) and proximity, respectively. We will integrate the PVDF into a sensing system including 10 MEMS microphones, an accelerometer, and 8 temperature sensors on a PCB under PDMS; 9 capacitive force sensors suspended within the PDMS; and the bimodal PVDF sensor suspended in the PDMS above the other sensors. Within this setup we plan to optimize the thickness and stiffness of the PDMS between each layer as they relate to signal transmission and sensor durability, as well as the chemical functionalization of the PDMS surface to improve durability and surface texture. We will then collect the overlapping signals from each sensor type and utilize machine learning techniques to determine how to best utilize sensor data for force regressions, touch localization, texture classification, and radius of curvature detection. The eventual aim of the project is to incorporate the complete sensing system into a robotic finger and utilize its multimodality to enable more dexterous robotic manipulation.

8:00 PM SF06.07.18
Electroluminescent Display Based on Field-Interactive Microparticles for Camouflage and Environmental Monitoring Jong WoongPark, DonyoungKang, HyungsukLee and CheolminPark; Yonsei University, Korea (the Republic of)

The development of displays that mimic the color-changing ability and external stimulus-sensing ability of biological skins is of significant interest for emerging robotics and biomedical applications. Here, we present an alternating-current (AC) electroluminescent display that can change the area, color, and luminance by using microparticles which interact with electric and acoustic fields. Dielectrophoretic force produced by AC electric field controls the amount and area of percolated carbon particles that form a conductive gate, enabling light emission from the ZnS phosphor-doped polymer layer. Different stacking combinations of emissive layers enable a wide-range color tuning in a single device by varying the electric field, which may be suitable for camouflage when integrated into the skin of soft robots. The display is also capable of sensing acoustic waves and visualizing the information by luminance change as the conductive gate collapses. Arrays of acousto-interactive displays were successfully used for environmental monitoring and non-destructive testing, where defects, air bubbles, and obstacles inside structures and fluid channels were visualized due to acoustic impedance mismatch. Our platform provides a path forward to engineer active camouflage and displays for soft machines.

8:00 PM SF06.07.19
Chemically-Generated Mechanical Patterns in an Array of Elastic Posts MoslemMoradi, OlegShklyaev and AnnaC. Balazs; Department of Chemical Engineering, United States

Artificial cilia platforms have been used to create pumping, mixing and sensing in microfluidic devices by a number of stimuli such as electrostatic or magnetic fields, light, thermal, pH and pneumatical actuations. To further improve these platforms, fundamental investigations on the actuating strategies for cilia and fluid manipulation are necessary. Using 3D simulation, we study the potential for enzymatic chemical reactions to generate convective flow that controls dynamic patterns formed in an array of elastic posts (modeling the cilia) tethered to the bottom surface of a millimeter-size fluid-filled chamber. We assume that some of the posts are coated with reactant-specific catalysts that promote localized chemical reactions and thereby drive buoyancy-driven flows. These buoyancy-driven flows arise due to density differences between reactants and products, which in turn generate the inward or outward flow depending on the density of the products. The flows produced around the enzyme-coated posts impose a fluid drag on the chemically-passive flexible neighboring posts, which can bend and assume flow-induced configurations. This chemo-hydro-mechanical coupling generates different patterns, which can be controlled by different arrangements of the coated posts and different chemical reactions.
The results of our simulations show that the stability of the patterns depends on the elastic properties of the posts. Steady state patterns are formed when the bending modulus of the posts is larger than a certain threshold. Patterns formed by less rigid posts do not reach steady configurations and the flow becomes chaotic at relatively low Reynolds number, which is useful for mixing. We focus on posts beyond this threshold, and consider two final steady configurations. In the first case, we simulate an infinite array of posts located in a periodic domain; in the second, we consider a finite array of elastic posts located in the simulation box with no-slip boundary conditions. In both cases, the flexible posts are arranged into a square lattice and attached to the bottom wall of the domain.
To generate patterns, we use three different enzymatic reactions localized at the specific posts. We assume that one catalase-coated post is pinned in the middle of the array, two AP-coated posts (AP is acid phosphatase) at the middle and two urease-coated posts located at the corners of a unit square array of posts. Addition of the appropriate chemicals (hydrogen peroxide, PNPP or urea) generates fluid motion around different posts and induces distinct patterns in the entire array that contains both active and passive posts. The resulting patterns possesses different symmetries depending on the position of coated-post, and the boundary conditions of the domain. Our computational simulations can provide guidelines for fabricating surface-anchored elastic posts that generate microscopic flows with the desired dynamic properties for a range of fluidic applications.

8:00 PM SF06.07.20
Engineering Confined Fluids to Autonomously Assemble Hierarchical 3D Structures OlegShklyaev, AbhrajitLaskar and AnnaC. Balazs; University of Pittsburgh, United States

The inherent coupling of chemical and mechanical behavior in fluid-filled micro-chambers enables the fluid to autonomously perform work, which in turn can direct the self-organization of objects immersed in the solution. Using theory and simulations, we show that the combination of diffusioosmotic and buoyancy mechanisms produce independently controlled, respective fluid flows: one generated by confining surfaces and the other in the bulk of the solution. With both flows present, the fluid can autonomously join two-dimensional, disconnected pieces to a chemically active, “sticky” base and then fold the resulting layer into regular three-dimensional shapes (e.g., pyramids, tetrahedrons, and cubes). Here, the fluid itself performs the work of construction and thus, this process does not require extensive external machinery. If several sticky bases are localized on the bottom surface, the process can be parallelized, with the fluid simultaneously forming multiple structures of the same or different geometries. Hence, this approach can facilitate the relatively low-cost, mass production of 3D micron to millimeter sized structures. Formed in an aqueous solution, the assembled structures could be compatible with biological environments, and thus, potentially useful in medical and biochemical applications.

8:00 PM SF06.07.21
Mechanoreceptor-Inspired Gelatin Hydrogel Sensor Based on Switchable Ionic Polarization So-HeeKim[1], Hong-JoonYoon[2], Dong-MinLee[3] and Sang-WooKim[1]; [1]Department of Materials Science and Engineering, Yonsei University, Korea (the Republic of); [2]Department of Electronic Engineering, Gachon University, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Triboelectricity-based touch sensors are great advantages in terms of cost, simplicity of design, and use of a wide range of materials. However, it is hard to measure the extent of deformation of materials since the performance solely relies on the level of contact electrification between materials. To overcome this limitation, we introduce an ion-doped gelatin hydrogel (IGH)-based touch sensor that can measure not only contact with objects but also deformation by a certain level of force. Switchable ionic polarization of the gelatin hydrogel is found to be instrumental in allowing for different sensing mechanisms when it is contacted and deformed. The results show that ionic polarization relies on conductivity of the hydrogels. Quantitative studies using voltage sweeps demonstrate that higher ion mobility and shorter Debye length serve to improve the performance of the mechanical stimuli-perceptible sensor. It is successfully demonstrated that this sensor offers dynamic deformation-responsive signals that can be used to control the motion of a miniature car. This study broadens the potential applications for ionic hydrogel-based sensors in a human–machine communication system.
To take advantage of these properties of IGH, we developed dynamic mechanical stimuli-perceptible sensor capable of accommodating continuous tactile information about contact and deformation events. Dynamic tactile sensing-based communication was successfully demonstrated. This study broadens the potential applications for ionic hydrogel-based sensors in a human–machine communication system.

8:00 PM SF06.07.22
3D-Printed Micrometer-Scale Wireless Magnetic Cilia with Metachronal Programmability ShuaizhongZhang[1,2], XinghaoHu[1,3], MengLi[4,1], UgurBozuyuk[1], PatrickOnck[5] and MetinSitti[1]; [1]MPI for Intelligent Systems, Stuttgart, Germany; [2]Yanshan University, China; [3]Northwestern Polytechnical University, China; [4]Massachusetts Institute of Technology, United States; [5]University of Groningen, Netherlands

Biological cilia play essential roles in self-propulsion, food capture, and cell transportation by performing coordinated metachronal motions. Experimental studies to emulate the biological cilia metachronal coordination are challenging at the micrometer length scale because of current limitations in fabrication methods and materials. We report on the creation of wirelessly actuated magnetic artificial cilia (MAC) with biocompatibility and metachronal programmability at the micrometer length scale. Each cilium is fabricated by 3D nano-printing a proteinous hydrogel beam affixed to a hard magnetic microparticle. Specifically, we used hard magnetic FePt Janus microparticles (FePt JMPs) and silk fibroin to 3D print biocompatible and programmable MAC arrays at a length scale close to biological cilia using two-photon polymerization in combination with magnetic actuation controls.
Magnetic, mechanical, and biological properties of the fabricated cilia were systematically investigated, showing that our cilia were mechanically tunable and robust, biocompatible, and

biodegradable. Programmable metachronal coordination can be achieved by programming the orientation of the identically magnetized FePt Janus microparticles, which enables the generation of versatile microfluidic patterns. Upon applying a uniform rotating magnetic field of as small as 3 mT, each cilium performed a whip-like reciprocal motion consisting of a slow forward stroke and a fast backward stroke. The difference in the orientation between neighboring FePt JMPs endowed the MAC array with heterogeneous magnetization directions, initiating a metachronal wave within the MAC array when subjected to a uniform rotating magnetic field.
We showcased the design and fabrication of MAC arrays to generate translational flows and locally circulating flows. This work could provide an experimental platform for biocompatible and programmable microcilia arrays with a large design space for future potential applications in microfluidic devices and cilia-inspired biomedical soft microrobots.

8:00 PM SF06.07.23
A Wet-Bioadhesive Triboelectric Nanogenerator for Emergent Wound Closure and Electricity-Accelerated Healing XiangchunMeng, XiaoXiao and Sang-WooKim; Yonsei University, Korea (the Republic of)

Emergency medical situations such as surgical incisions and vascular rupture necessitate prompt intervention, or they can result in a range of life-threatening complications, including significant blood loss, infection, and even death. While conventional surgical sutures, staples, and adhesives can achieve hemostasis, they rely heavily on surgical expertise or the use of specialized equipment, and the presence of bodily fluids can significantly impede the quality of wound sealing. Additionally, the rate of wound healing is another crucial factor. Drug-loaded smart adhesives have received considerable attention, but meantime they raise concerns regarding drug toxicity and resistance. Therefore, it is a daunting but essential task to develop innovative strategies for managing emergent wounds and promoting accelerated wound healing.
In this study, we proposed a novel ultrasound-driven wet-adhesive triboelectric nanogenerator (WA-TENG) to treat acute wounds for instant wound sealing and electricity-accelerated healing. WA-TENG comprises two components: a bottom wet-adhesive layer and an upper TENG component. When attached to the wet tissues, the wet-adhesive layer can form covalent bonds with tissues to achieve faster (~5 s) and stronger adhesion with high interfacial toughness (~150 J m^{-2}). When stimulated by ultrasound, the dielectric and conductive layers of TENG can generate continuous contact-separation movements to produce an electric field (E-field) of up to 0.86 kV m^{-1}. Experiments conducted both *in vitro* and *in vivo* demonstrate that it substantially accelerated wound healing due to the E-field-enhanced cell migration and proliferation. Notably, WA-TENG is composed of biocompatible and biodegradable materials, which will not harm tissues and can self-degrade without the need for surgical removal. It is anticipated that this multifunctional electrical device will not only facilitate surgical procedures in hospitals but will also be a portable and self-help medical device for emergency wound care.

8:00 PM SF06.07.24
Effect of Temperature, Moisture and Mechanical Strain on PIB Thin Film Barriers for Implantable Soft Robots UmarRaza and KyungjinKim; University of Connecticut (UConn), United States

Advances in electro-ionic soft actuators hold significant protentional as next generation bioelectronic interfaces due to mechanical compliance and operation in agreement with soft biological tissues and low voltages. However, current devices call encapsulation strategies to accommodate high mechanical demands and long-term stability in physiological environment changes, such as maintaining biocompatibility and withstanding temperature and moisture variations. In this study, we investigate a durability of poly vinylidene fluoride-co-hexafluoropropylene (PVDF-co-HFP) honeycomb architecture electrolyte by encapsulating it with a biocompatible polyisobutylene (PIB) thin film. PIB is known for its excellent moisture barrier properties among existing elastomers; therefore, we expect durable performance under its hermetic encapsulation. The encapsulation is prepared of a 60% (w/w) solution of PIB in hexane to possess an elastic modulus on the order of 10 KPa, same as the modulus of PVDF-co-HFP electrolyte and in the range of most body tissues. Both PIB and PVDF-co-HFP demonstrate temperature endurance withstanding up to 332 and 250 degree celsius, respectively. A low water vapor transmission rate (0.61 g/m^2/day) is measured, ten folds lower than that of bare PVDF-co-HFP with an addition of 7.5 micro-meter PIB encapsulation layer. The PIB encapsulated soft actuator maintains 68% of its mechanical durability after 40,000 cycles of zero to tension fatigue loading at room temperature. A cantilever actuation test of the PIB encapsulated actuator shows a large tip displacement (15.90 mm) at a low voltage (±1.5V) under 0.1 Hz, 37 degree celsius, 50% relative humidity (RH). Most importantly, while the unencapsulated actuator immediately degrades in a few cycles at 37 degree celsius , 50% RH, 0.1% applied strain, PIB encapsulated soft actuator performs up to 6500 dynamic actuation cycles without any functionality degradation. PIB encapsulated soft actuator system demonstrates exceptional durability against mechanical fatigue and stability at the elevated temperature and humidity, making it one step closer to meeting the prerequisite for future soft biomedical robots that enable long-lasting safe operations.

8:00 PM SF06.07.25
Transition of Plastic Deformation to Elastic for Crumple-Recoverable Electronics YeonwookRoh, Je-SungKoh, DaeshikKang and SeungyongHan; Ajou University, Korea (the Republic of)

Crumpling is one of the easiest, quickest, and most efficient ways to pack sheet-like electronic devices at a high compression ratio. Today, rolling or folding of many electronic devices has been attempted for portability, whereas due to the disordered and irreversible plastic deformation that may affect the electronic functions, crumpling is not applicable to conventional electronic devices. Inspired by butterfly wings during the emergence process with variable stiffness, the heterogeneous integration of three materials (i.e., an elastomer, silver nanowires, and a shape memory polymer) in this study enables thermal modulation of the mechanical properties between soft (2 MPa) and stiff (1315 MPa) or between conditions suitable for crumpling and free-standing operation, respectively. The crease that is common for the crumpled sheet due to the inordinate folding and stretching becomes invisible after smoothing the surface via thermal treatment. The demonstration of this platform includes crumpling and packing of touch panels into capsules, while a flat and smooth surface for reliable touch sensing is obtained after unpacking. The results in this article suggest the ability to use a simplistic design to secure the function of crumpled electronics without having to compromise the electrical and mechanical characteristics.

8:00 PM SF06.07.26
Chemo-Responsive Soft Colloids: Autonomous Soft Robots with Decentralized Intelligence LukasZeininger; Max Planck Institute of Colloids and Interfaces, Germany

Autonomous regulation of molecular recognition and binding-induced chemical events are essential processes through which natural systems exert control over complex biological functions. Chemical information can be processed with high fidelity and highest substrate specificities are achieved as multiple individual or combinations of independent chemical equilibrium-driven interactions are translated into a specific response. Key to the realization of artificial materials that present similarly sophisticated active and adaptive properties requires combining the concept of molecular recognition-induced responsivity with a thermodynamically metastable, active, and dissipative material platform.
In nature, microorganisms harness energy gradients to prompt mechanical responses. Examples for chemo-mechanical signal transductions include the molecular transport mediated by motor proteins, as well as diffusiophoretic and electrophoretic reactions of whole cellular ensembles. The conversion of chemical concentration gradients into mechanical energy enables active colloidal systems to move, and hence also forms a basis to control complex emergent behaviors observed in multibody systems, including a self-regulated ability to communicate, evolve, and self-organize into patterns or networks. Synthetic efforts to emulate these behaviors target the design of active dissipative material systems that autonomously regulate their motile behaviors in response to their immediate chemical environment.
In our contribution, we will highlight the concept of droplet force gradient sensors. We will share our recent discoveries that responsive complex emulsion droplets present a comprehensive set of tools for understanding and reporting complex chemical environments. Droplet force gradient sensors are surfactant-stabilized complex emulsion droplets that can morphologically reconfigure triggered by changes in surfactant concentration, tilt out of gravitational alignment caused by droplet-internal thermo-capillary fluid convections, and move chemotactically in response to interfacial tension differentials. Thus, within one platform, responsive droplets provide as both, a tool to monitor and visualize transient gradients in temperature and chemistry *in-situ* as well as an active colloid that exhibits programmable actuation in response to changes in its immediate chemical environment.
We will demonstrate how the speed and directionality of the droplet chemotaxis can be reversibly and controllably altered depending on the internal morphology of the droplets. This entails systems that solely based on their internal geometry can be designed to display programmable motion towards or away various chemoattractants or -repellents, with the latter including bacteria. We will also show how targeting two or more separate and independent responsive modalities of complex droplet force gradient sensors can yield adaptive droplet ensembles. Droplets with logic gate decision making skills can adapt and autonomously modulate their response to the environment and thus provide a basis toward the design of artificial life-like soft colloids that exhibit an intrinsic decentralized chemo-intelligence and perform collective functions with strong implications for future soft robot and sensor technologies.

8:00 PM SF06.07.27
Autonomously Motile “Moonwalking” Microbeads with Internalized Hierarchical Magnetic Architectures AbhirupBasu, EricBuchsbaum, JosephB. Tracy and OrlinD. Velev; North Carolina State University, United States

Self-propelling or “active” particles directed by external fields continuously consume and dissipate energy, thereby creating localized field and flow gradients, and enabling autonomous movement. The development of colloidal rollers responsive to magnetic fields offers the potential for external control of their macroscopic motion using magnets. In the current study, we report a new pattern of dynamic active motion with our micro-scale architectures in non-Newtonian fluids where colloidal micro-rollers on a solid substrate rotate and translate in directions some of which are intuitively not expected. These micro-scale rotators are synthesized by internally embedding iron oxide nanoparticles (MNPs) inside microdroplets of a polydimethylsiloxane (PDMS) precursor and assembling the MNPs into organized structures using a static magnetic field. Rotating magnetic fields, even with a low field strength and low rotation frequencies, can induce a strong torque on these microbeads due to the presence of the organized structures. The microbeads can therefore exhibit clockwise or counter-clockwise

rolling with forward or backward displacement. Surprisingly, when we placed these rollers in shear-thinning fluids, we established a fascinating new backward movement pattern, which we refer to as “moonwalking.” In this new dynamic pattern, the translation is opposite to the one expected by the rotational direction of the particles. We hypothesize that this reversive motion results from differing shear forces acting on the top and bottom of the particle. The “moonwalking” motion was found to increase with increasing viscosities until a critical rotational velocity where the microbeads lose alignment with the magnetic field and oscillate in place. This propulsion behaviour can help us to guide the forward or backward propulsion of the rollers without changing the field type and just by tuning the properties of the medium or the rotational frequency. The novel phenomenon in the single particle translation dynamics observed introduces a new physical principle of active propulsion. This new phenomenon has the potential to deepen our understanding of fundamental principles of autonomous materials and may open the door to future applications of active rollers in advanced biomedical applications.

8:00 PM SF06.07.28
A Dynamically Responsive Surface with Switchable Wettability for Efficient Evaporation and Self-Cleaning Abilities GregoryParisi and ShankarNarayan; Rensselaer Polytechnic Institute, United States

Evaporation is crucial in applications such as nanoscale fabrication, inkjet printing, heat transfer, and self-cleaning electronics. This study demonstrates a switchable surface that dynamically transitions between superhydrophobic and superhydrophilic states. Superhydrophobic surfaces are renowned for their intrinsic self-cleaning properties and notably sluggish evaporation kinetics. On the other hand, superhydrophilic surfaces exhibit rapid evaporation kinetics and induce evaporative cooling effects, making them advantageous for heat dissipation and cooling applications. This study proposes a switchable surface that seamlessly shifts between these two states based on external stimuli.
To facilitate the understanding of this switchable surface, the study employs a self-cleaning superhydrophobic aluminum substrate coated with an amino-silane (N-(2-aminoethyl)-11-aminoundecyl-trimethoxysilane). Typical nonwetting coatings, such as lauric acid and FDTS (perfluorodecyltrichlorosilane) are also compared in terms of wettability and evaporation kinetics. During periods of low heat loads, the surface capitalizes on the self-cleaning nature of superhydrophobicity, reducing energy waste and minimizing maintenance needs. Conversely, when subjected to high heat loads, the dynamic transition to a superhydrophilic state facilitates rapid evaporation, thus unlocking effective evaporative cooling effects. By combining these dual characteristics, the proposed surface transcends conventional boundaries, offering multifaceted benefits. The experimental concept is underscored by an in-depth analysis of evaporation rates using both calorimetry and contact angle goniometry. Addressing the complexities arising from superwetting surfaces, which challenge the precise determination of droplet boundaries, this research predicts evaporation rate of both wetting and nonwetting surfaces.

Development of a Soft Gripper Capable of Controlling Buoyancy in Water MinchaeKang, SuyeonSeo, EunsolPark, YejiHan and Min-WooHan; Dongguk University, Korea (the Republic of)

Underwater soft robots have the potential for a wide range of uses, including exploration, search, and rescue. In particular, the recently studied underwater soft robot is safer and more effective to employ than the current rigid robot since it can adapt easily to the environment. It also has a flexible and deformable body that allows it to adapt to challenging underwater environments and interact with various underwater creatures and structures. This soft gripper can manage buoyancy and shift its location in water up and down by changing the volume of the internal air without relying on an external device or mechanism. It is possible to function as a gripper while changing buoyancy in this situation. The gripper can grasp objects when the buoyancy is low and the amount of air content is little; conversely, when the amount of air is high and the buoyancy is low, the object can be carefully placed. The soft buoyancy gripper actuates using the stress differential between two soft polymers. When the soft polymer with relatively low elasticity is put on top of a thin, soft polymer that has been stretched and glued on both sides, the polymer can be rolled inward. In addition, when an air layer is formed between the two polymer layers, gripping and buoyancy can be controlled according to the amount of air injected into the device. At this point, several objects were held in place while the device's location in relation to the volume of air injected was examined. This will allow the soft robot to move in a small space and swim, crawl, and be utilized for a variety of tasks like environmental monitoring, search and rescue operations, and underwater exploration. Hence, this soft robot can carry out challenging duties by ascending and descending to different sea depths. The buoyancy control system of this underwater soft robot is an essential component that enables diversity and adaptability in water, and it has the potential to revolutionize underwater exploration and study. It has the benefit of being able to approach and operate intimately without hurting the marine environment and living organisms, which makes it particularly useful for ecological research and preservation. As a result, the described underwater soft robot may represent an innovative technology with numerous possible uses.

This work was supported by the National Research Foundation of Korea(NRF) grant funded by the Korea government(MSIT) (No.2018R1A5A7023490), by the Korea Institute of Machinery and Materials (KIMM) funding (NK242C), and by the Ministry of Trade, Industry, and Energy (MOTIE) and the Korea Institute for Advancement of Technology (KIAT) through the International Cooperative R&D program (Project No. P0016173).

8:00 PM SF06.07.30
Photoactive Smart Polyethylene/MoS_2 Bilayer Actuators for Locomotive Soft-Robots LaritzaMedi[1,2], FelipeOlate-Moya[1,3], NestorPerea-López[4], MauricioTerrones[4] and HumbertoPalza[1,3]; [1]Universidad de Chile, Chile; [2]Universidad del Bío Bío, Chile; [3]Impact, Center of Interventional Medicine for Precision and Advanced Cellular Therapy, Chile; [4]The Pennsylvania State University, United States

The development of smart materials is becoming increasingly important due to their potential applications in various fields such as medicine, aeronautics, biomedicine, and electronics, among others. In particular, soft actuators which can be fabricated using an active bilayer, consisting of a photoactive material and a passive layer that provides structural integrity. As these two layers have different thermal expansion coefficients, an external stimulus that changes their temperature generates an out-of-plane deformation. This provides a large mechanical mismatch to external stimuli, thus endowing them with unprecedented features such as: ultra-sensitivity, programmability, superior compatibility, robustness and ease of fabrication [1]. This type of actuators can be activated by a wide range of stimuli such as light, heat, humidity, electric field, magnetic field, among others. The light stimulus is one of the most promising for applications that require remote actuation, such as soft robotics, where MoS_2 is highlighted as a 2D nanostructure with outstanding NIR absorption [2].
In this work, we designed and fabricated photoactive bilayer actuators consisting of a MoS_2 active layer and a polymeric passive layer. We analyzed the effects processing on the response of the bilayer for directionality and velocity control. The active layer is obtained using a Langmuir-Blodgett based method. MoS_2 nanosheets were characterized by UV-vis, Raman, XRD, SEM, TEM and AFM techniques, exhibiting an average lateral size of 512 nm and 20 nm thickness. While for the passive layer a commercial polyethylene (PE) is used, characterized with UV-vis, Raman and DSC, with 26% crystallinity and a Young's modulus of 180-250 MPa. These bilayers were characterized by a passive layer thickness of 13 µm, and an active layer consisting of MoS_2 nanosheets stacked in the basal plane (002). Noteworthy, the bilayers presented photo actuated response that depend on the number of MoS_2 coatings. For 8 MoS2 coatings, having a thickness of 725 nm, the bilayer had a response time of 1.9 s, recovery time 3.5 s and inverse of the actuation radius of 0.5 mm^{-1}. Furthermore, the strain can be modulated by patterning both the bilayer and the PE to control the direction of displacement, as an example we created structures having locomotion or mimicking the opening movement of a flower or the flutter of a butterfly. These actuators are promising structures to be applied in soft robotics with remote activation.

8:00 PM SF06.07.31
Untethered, Battery-Free Multifunctional Soft Robot System SungkeunHan, Jeong-WoongShin and Suk-WonHwang; Korea University, Korea (the Republic of)

Development of untethered small-scale soft robots has become increasingly important in various industrial and biomedical fields due to their extensive applications, such as manipulation and drug delivery. There are different ways to actuate freely movable robots, such as using light, thermal, pH, and magnetic sources. However, the robot can only perform simple tasks like moving and gripping with these methods. Here, we present a new platform has been developed that integrates a soft robot and a multifunctional electronic system, which can magnetically control varying locomotion (including morphing, crawling, rolling, and rotating) and electrically operate multi-modal functions (temperature/strain sensing, optical/thermal stimulation). The integrated system has undergone extensive studies of magnetic materials and evaluations of the stability of electrical components to ensure it is available for use in various fields. With gradual improvements in size, modulation, and various monitoring and active functions, this device will provide emerging systems for diverse fields such as bio-medical applications, diagnosis and on-demand treatments, and environmental monitoring.

8:00 PM SF06.02.02
Highly Compressible 3D-Printed Soft Magnetoelastic Sensor for Human-Machine Interfaces HyeonseoSong[1], YeonwooJang[1], SuwooLee[1], Youn-KyoungBaek[2] and JiyunKim[1]; [1]UNIST, Korea (the Republic of); [2]Korea Institute of Materials Science, Korea (the Republic of)

Tactile sensors for human-machine interface (HMI), that convert mechanical stimuli into electrical signals, have gained great attention in various applications. In particular, self-powered soft

sensors such as piezoelectric, triboelectric, and magnetoelastic soft sensors have shown great potential due to their safety, adaptability, and low production and maintenance costs. However, piezoelectric and triboelectric sensors have high internal impedance, which lowers the current flow, reducing the current density and the output power density. Furthermore, their output sensing performance is susceptible to humidity conditions of the surrounding environment, including even sweat on the skin. On the other hand, soft self-powered tactile sensor based on magnetoelastic mechanism has the potential to provide high output power density due to their high current density and more reliable output performance regardless of humidity.
Here, we present highly compressible 3D-printed soft magnetoelastic sensors (H-MELS) by using 3D printing methods with sacrificial mold, which allow us to program the material, and mechanical properties of H-MELSs, influencing the mechanoelectrical converting performances of H-MELS. In addition, we developed elastomeric magnetic composite materials for a magnetic part and elastomeric electrical parts using a coiled-copper coil to fabricate H-MELSs. This strategy allows us to achieve highly scalable and compliant 3D architectures made of very compliant materials for 3D soft magnetoelastic sensors, and even integrate them into robotic systems as a robot operation units and robot's perception units for practical Human-Machine Interface applications. We believe H-MELS with high compressibility in various form factors leads to significant advancements in design and manufacturing of self-powered soft sensors for human-machine interfaces.

8:00 PM SF06.11.08
A Soft, Self-Sensing Tensile Valve for Analog and Programmable Control of Soft Pneumatic Actuators Jun KyuChoe, JunsooKim, HyeonseoSong, JoonbumBae and JiyunKim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Soft robots offer great promise for applications that require safety and adaptability, particularly in the face of unpredictable variations. To unlock their full potential for autonomy and intelligent interaction with the environment, perception capabilities with continuous sensing and control of soft actuators are essential. However, soft robots still mostly rely on complex connections of rigid electronics both in hardware and software for perception. These include, for example, bulky and expensive sensors, controllers, and valves in pneumatically actuated soft robots. While there have been recent attempts to develop soft equivalents of individual rigid components, the integration of sensing and control systems without increasing the structural complexity or form factor is challenging to achieve without compromising the complete softness or capabilities.

Here, we introduce a soft self-sensing tensile valve (STV) that combines the functionalities of strain sensors and control valves to directly convert applied tensile strain into distinctive, pre-programmed output pressure states using a single constant pressure source. By utilizing a mechanism we refer to as "helical pinching," the STV achieves physical sharing of both sensing and control structures, resulting in all-in-one integration in a compact, linear form factor.

8:00 PM SF06.04.03
Scalable, Addressable, Artificial Muscle Bundles AlexanderL. Evenchik, EunBiOh, AlexanderQ. Kane and RyanL. Truby; Northwestern University, United States

Skeletal muscle continues to serve as an inspiration for the design of scalable, energy efficient, soft robotic actuators with distributed sensorimotor capabilities. However, our ability to produce soft actuators that mimic skeletal muscle remains limited. Liquid crystal elastomers (LCEs) are one promising class of materials whose high power density and large, contractile actuation strain approach the performance of biological muscle. Despite these advantages, the common actuation stimuli needed to drive LCEs are hindered by severe limitations. In addition to low actuation bandwidth, thermally-driven or thermotropic LCEs are energy inefficient, while photo-driven or phototropic varieties are limited to thin form factors that typically bend rather than contract. Here, we present LCE composite fibers that linearly contract while enabling in-line delivery of target stimuli. We demonstrate that bundling individual artificial muscle fibers introduces new capabilities such as scalability, amplified force output, and addressable actuation. Moreover, we show that our overall design strategy for artificial muscles alleviates stimuli transport-related challenges of existing LCE soft actuators by coupling the actuation stimuli with the active material. Our artificial muscle fiber bundles, which integrate scalability and addressability in a manner not yet seen in LCEs and other soft robotic actuators, provide a step towards designing material systems that truly mimic the performance and controllability of skeletal muscle. They serve as a platform for future multifunctional, artificial muscle designs that tightly integrate distributed actuation, sensing, control, and energy capabilities.

Woven Active Textiles and E-Skin Enable Controllable Tunable-Stiffness Flapping Foils FrancescoGiorgio-Serchi; University of Edinburgh, United Kingdom

Flapping foils represents the natural mode of propulsion for the vast majority of aerial and aquatic organisms. Despite its supposed simplicity, this type of propulsion manifests a subtle complexity which has fascinated academics for decades. In recent times, the role of structural flexibility of fins and tails in determining the overall propulsive efficiency of self-propelled organisms and robotics artefacts has attracted attention because of its implications for the optimal design of bioinspired vehicles as well as energy harvesting devices. In particular, the opportunity to actively adjust the stiffness of an otherwise passive-elastic, man-made flapping foil offers unprecedented potential in attempting to match the propulsive efficiency of the biological counterpart. On one hand, tuning the structural flexibility of a flapping foil permits to align the natural frequency of the structure with that of the flapping motion, enabling to exploit the benefits of resonance in magnifying power output; on the other hand, control over the temporal pattern of stiffness variation enables enhanced capability for manoeuvrability and disturbance mitigation. To achieve this, flapping foil systems will require actuators which enable active stiffness tuning along with dedicated sensors for online estimation of the foil spatial configuration.
Here we present the design of new variable-stiffness flexible foils by means of active textiles. These consist of bundles of thin fluidic artificial muscles which can be woven into planar arrangements with a periodic pattern, thus giving rise to a fabric with adjustable, anisotropic stiffness. The foil is studied under dynamic actuation resemblant of the cyclic mode employed during flapping routines, ultimately identifying the range of flapping frequencies where resonant modes can be triggered. In parallel, we develop a stretchable, capacitive electric skin embedded with a capacitance-to-deformation transformer which provides realtime, millimeter-accuracy estimation of the foil camber during actuation.
The combination of active textiles and e-skin offers the chance to develop advanced flapping-based propulsors with fine, closed-loop control over the stiffness and spatial configuration of the foil, enabling unprecedented performances and further narrowing the gap between biological and man-made systems.

9:00 AM SF06.08.02
Soft Multi-Material Magnetic Fibers and Textiles HritwickBanerjee and FabienSorin; École Polytechnique Fédérale de Lausanne (EPFL), Switzerland

Magnetically responsive soft materials are envisioned as the next building block in a myriad of applications including in minimally invasive surgical procedures, due to their untethered, safe, and versatile properties. However, constructing highly integrated magnetic fibers with extreme aspect ratios, that can be used as steerable catheters, endoscopes, or in medical textiles still remain a significant materials and processing challenge. Here, we present multi-material thermal drawing as a materials and processing platform to manufacture 10s of meters long, soft, ultra-stretchable, yet highly resilient magnetic fibers with a diameter as low as 300 μm[1]. We identified magnetorheological elastomers with varied elastomeric matrices and hard magnetic micro-particles (neodymium–iron–cobalt–boron) as fillers. The composite exhibits rheological traits compatible with thermal drawing with tunable mechanical and magnetic properties, resulting in controllable actuation performance. By carefully controlling the viscosity during drawing, we show that we can slow down thermal reflow driven by surface tension and conserve micro-scale geometrical features and textures. To characterize the fibers post-drawing, we first used computed tomography that revealed a very good distribution of the fillers that was enhanced compared to the preform level. We then characterized the mechanical properties of the fibers that can withstand strains greater than 1000%. Subsequent magnetic hysteresis measurement revealed a strong magnetization on par with state-of-the-art magnetic composites, resulting in the ability to lift up to 370 times its own weight under an applied magnetic field. The fibers are also amenable to being magnetized with different orientations along their length, and to be weaved into functional textiles. The magnetic textile can be programmed to selectively shape morph and can sustain extreme mechanical deformation or several machine-wash cycles. They can apply force or pressure and could constitute a promising next generation of magnetic-based surgical tools and medical textiles for rehabilitation and soft prosthesis.

9:15 AM SF06.08.03
Magnetically Induced Stiffening for Soft Robotics LeahT. Gaeta and TommasoRanzani; Boston University, United States

Inherent compliance of soft robots renders them safe for many applications such as object manipulation, surgery, haptics, and wearable devices. Stiffness modulation is essential to soft robot

design so that these robots can reverse compliance and institute more rigidity when needed. Relevant examples include robot reconfigurability, weight-bearing tasks, and force transmission. This has led to significant research on variable stiffness structures whose designs allow a soft robot to be flexible and compliant until interaction with its environment, when it switches from an inherently low-stiffness state to one of more rigidity. Variable stiffening mechanisms include pneumatically-controlled jamming and thermally-induced phase change materials. In jamming-based stiffening, granules, stacked layers, or fibers are packed into an encasing that as a whole is compliant and of low-density. Upon application of vacuum pressure, the overall structure increases density and solidifies within milliseconds. Despite fast response time, jamming methods lack portability due to reliance on pneumatic pressure lines, which are bulky and cumbersome in wearable or autonomous applications. Thermally-controlled phase change materials, such as shape memory polymers, induce a stiffness change when subject to electronically-controlled heat. They have the advantage of portability via electronic control, but often require high temperatures and have slower response time on the order of tens of seconds.
Combining the advantages of these two stiffening methods, quick response time from pneumatic-based jamming with portability of thermal-controlled phase change materials, we present a magnetically-induced stiffening mechanism that requires scaffolding structures immersed in magnetorheological fluid. Magnetorheological fluids consist of micron-scale iron particles suspended in carrier fluid such as water, and solidify with a characteristic yield stress and viscosity when subjected to an external magnetic field. We exploit the response of magnetorheological fluid to applied magnetic fields to induce rapid stiffness changes, while investigating how the addition of scaffolding structures enhances and increases achievable stiffening ranges. These scaffolding structures are borrowed from pneumatic-based jamming and include stacked 51µm thick polyester layers, 7 µm thick fiber filaments, and 2.4 mm diameter granules. Suspending these materials in 80% iron (by mass) magnetorheological fluid and encasing them in a textile pouch, we create magnetorheological jamming beams (MRJ beams) which are flexible, compliant, and have tunable stiffness with applied magnetic fields.
We investigated the stiffening response of MRJ beams subjected to various magnetic field strengths using two methods: by exploiting the yield stress increase of magnetorheological fluid using a single row of permanent magnets, and by inducing a clutch on the MRJ beam using dual rows of permanent magnets with aligned poles that exploit yield stress effects and compress the beam via magnetic attraction. Scaffolding materials in MRJ beams amplify the stiffening response in the presence of applied magnetic fields in both methods, with stiffness percent changes ranging from ≈10% - 75% and ≈50% - 345% for single and dual row magnet architectures, respectively. We also present an analytical model to provide initial estimates of achievable stiffening ranges as a function of magnetic field to inform soft robot design. We introduce portability by employing electropermanent magnets (EPMs) which require minimal energy to operate, can be electronically-controlled, and can change magnetic field strength in ≈500 µs. Embedding EPMs within an MRJ beam demonstrated electronically-controlled real-time stiffness change in a weight-bearing task. This work paves the way towards customizing soft robotic designs that require portability and fast response time stiffness tuning, such as in many human-robot interactions.

Developing Ionoelastomer Heterojunctions for Low-Voltage Electroadhesion RyanC. Hayward; University of Colorado Boulder, United States

Our group has recently reported the use of heterojunctions between oppositely-charged ‘ionoelastomers’, i.e., low glass-transition polyelectrolyte networks, for a number of electromechanically responsive devices. In particular, they offer promise as low-voltage reversibly switchable electroadhesives, with potential applications including in soft robotics. Because voltages applied in reverse bias are dropped largely across the nanometer-scale ionic double layer formed at the interface between the two layers, large Maxwell stresses and corresponding enhancements in adhesion can be generated using applied potentials of < 10 V, in contrast to the kV levels generally required for established electroadhesives based on dielectric layers. We have focused tuning the composition of the ionoelastomer layers to lower their surface energy and improve the contrast between ‘on’ and ‘off’ state adhesion, in addition to improving their ionic conductivity. By considering the design of the ionoelastomer/electrode interface, the effects of surface topography, and the geometry of the adhesive pads, we have achieved electroadhesive clutches that support higher forces per unit area than previous dielectric-based systems, while operating at two orders of magnitude lower potential.

10:30 AM SF06.08.05
Multimaterial 3D Printing of Poly(ionic liquid) Diodes for Soft Ionotronic Robots AlexanderQ. Kane and RyanL. Truby; Northwestern University, United States

Overcoming long-standing challenges in soft robotic control requires new strategies for coupling perception and computation in soft, multifunctional materials. Ionotronic approaches have largely remained unexplored despite recent progress in soft ionotronic actuation and power methods. Poly(ionic liquids) are a promising class of materials that can combine elastomeric behavior with high ionic conductivity. However, current methods of patterning soft poly(ionic liquid) elastomers are limited, requiring low-throughput procedures to produce even simple forms and devices. To address this challenge, we present an integrated, multimaterial 3D printing and material design framework for fabricating poly(ionic liquid) composites as stable, ionotronic sensing and control elements for soft robots. We harness the chemical modularity of poly(ionic liquids) to formulate four inks that enable ionotronic devices to be printed in one complete process. In addition to printing and characterizing ionic diodes fabricated with our technique, we demonstrate other architectures and devices enabled by our method. We anticipate that our work can be adapted to equip next-generation soft robots with soft controllers, on-board power generators, and distributed sensing mechanisms.

10:45 AM SF06.08.06
Effect of Heat-Induced Adjustable Stiffness at the Contact Interface on the Gripping Force of a Bipolar Electrostatic Chuck ShigekiSaito, JeremyGavriel, JuntianZhou and YukiTaoka; Tokyo Institute of Technology, Japan

This research endeavor aims to investigate the effect of heat-induced adjustable stiffness at the contact interface on the gripping force of a bipolar electrostatic chuck (ESC).

The bipolar ESC serves as a gripping mechanism specifically designed for delicate objects such as thin films and plates, functioning through the utilization of two electrodes that generate an electric field upon the application of a potential difference. This electric field induces charges or dipoles on the surface of the object, facilitating its attraction to the chuck via Coulomb forces. Given the device's dependence on this distinctive gripping mechanism, the condition and material properties of the contact surface play a pivotal role in determining the gripping force. Previous investigations have predominantly focused on enhancing the structural aspects of the device, encompassing surface smoothening techniques and the incorporation of rotational freedom for the end-effector. Nonetheless, owing to its inherently rigid structure, the ESC encounters difficulty in establishing a substantial real contact area, consequently constraining the gripping force within the boundaries defined by the applied voltage and the ESC's dimensions.

To address this inherent limitation, the present study proposes a novel concept revolving around the manipulation of the contact surface's stiffness. Specifically, two variations of bipolar ESCs were fabricated, differing in the materials employed for the contact surface (ABS, Nylon). By supplying current to the electrodes, the generation of heat was facilitated, thereby enabling to exert control over the stiffness of the covering material through temperature adjustments. To determine the gripping force exerted by the two ESC variants, a glass slide was employed as the target object, and the magnitudes of forces acting the object and the proposed ESC were meticulously recorded under the multiple conditions. The influence of the adjustable stiffness was subsequently observed by analyzing the variations in the device's gripping force. Additionally, experiments were conducted wherein voltage was not applied, serving to quantitatively evaluate the adhesive forces at play, particularly those arising from van der Waals interactions. The results unveiled a noteworthy increase in the gripping force upon the reduction of the contact surface's stiffness, with the ABS-type exhibiting a gripping force enhancement of 1.682 times, while the Nylon-type witnessed a 1.833-fold increase. Furthermore, it was discerned that the gripping force surpassed the combined magnitudes of the electrostatic and adhesive forces, thereby underscoring the existence of a complex interplay between these two dominant forces. In an attempt to gain further insights into the underlying mechanisms, the ESC/glass system was modeled as a two-body problem, subsequently subjecting the influence of low stiffness to comprehensive analysis from the vantage points of contact and fracture mechanics.

The findings of this study represent a significant stride towards the development of bipolar electrostatic chucks endowed with tunable stiffness, thereby facilitating the reliable and repeatable manipulation of delicate objects. By surmounting the constraints imposed by conventional ESCs, this research endeavor holds the potential to engender a more effective gripping capability, spanning across a broader spectrum of objects. This acquired knowledge would contribute to the future progress of robotics in the field of film or plate handling.

11:00 AM SF06.08.07
Light-Powered Soft Steam Engines for Self-Adaptive Oscillators and Biomimetic Swimming Robotics ZhiweiLi; Northwestern University, United States

Oscillation plays a vital role in the survival of living organisms in changing environments, and its relevant research has inspired many biomimetic approaches to soft autonomous robotics. However, it remains challenging to create soft oscillators that can work under constant energy input and actively adjust the oscillation mode in response to environmental changes. Here, we present a steam-driven photothermal oscillator operating under constant light irradiation for continuous or pulsed, damped harmonic mechanical oscillations. The key component of the oscillator is a hydrogel containing Fe_3O_4/Cu hybrid nanorods, which can convert light into heat and generate steam bubbles. Controllable perturbation to the thermo-mechanical equilibrium of the oscillator can thus be achieved, leading to either continuous or pulsed oscillation depending on the light intensity. Resembling the conventional heat steam engine, this environment-dictated multimodal oscillator uses steam as the working fluid, enabling the design of self-adaptive soft robots that can actively adjust their body functions and working modes in response to environmental changes. We then developed an untethered biomimetic neuston-like robot (neusbot) based on this soft steam engine, which can adapt its locomotion mechanics between uniform and recurrent swimming to light intensity changes and perform on-demand turning under continuous light irradiation. Fueled by water and remotely powered by light, this unique hydrogel oscillator enables easy control over the oscillation dynamics and modes, offering a promising approach to self-adaptive soft robots and solar steam engines.

11:15 AM SF06.08.08
Laser Induced Graphene for Soft Robotics: Actuators and Sensors AlexanderDallinger[1], StellaDrewes[1], Anna ChiaraBressi[2] and FrancescoGreco[2,1,2]; [1]Graz University of Technology, Austria; [2]Sant'Anna School of Advanced Studies, Italy

Laser Induced Graphene (LIG) is a porous conductive carbon material produced by laser-induced pyrolysis of polymer precursors, with applications in soft electronics/robotics and wearable electronics, among others.[1–3] Here, we present some examples of our studies on LIG-based soft actuators and sensors.
LIG conductive tracks are conveniently created through a single synthesis/patterning step by laser scribing with a CO_2 or UV laser onto a polymer precursor like polyimide.
By embedding the LIG into a stretchable and soft elastomeric matrix (i.e. polydymethylsiloxane-PDMS or polyurethane-PU), conductive and stretchable composites are created.
We realized various kinds of soft actuators based on LIG composites. In one case, by coupling the LIG/PDMS composite with a thin film of a smart humidity-responsive hydrogel (poly-(N-vinycaprolactam), pNVCL) deposited by means of initiated chemical vapor deposition (iCVD), we realized a multi-responsive soft bending actuator, capable of self-sensing.[4] In a second case, soft heating elements made of a LIG/PU composite were coupled with a Liquid Crystal Elastomer (LCE), a thermoresponsive material featuring excellent actuation properties like large actuation strains and reversible linear actuation process. In both cases the LIG served as a Joule heating element to resistively heat the active materials and trigger an actuation.
Also, embedding thin, flexible, lightweight LIG piezoresistive sensors into the body of soft pneumatic actuators is investigated as a mean for the integration of pressure (touch) and bending sensing capabilities.
Finally, LIG from bioderived polymer precursors is investigated to enable novel sustainable approaches to soft robotics.

11:30 AM *SF06.08.09
Control of Soft Robots MonicaOlvera de la Cruz; Northwestern University, United States

The design of materials with biological functions is a challenge that involves a delicate balance between structural form and function. We have explored external stimuli such as light and magnetic field to actuate and induce locomotion of soft materials functionalized for example with superparamagnetic and/or ferromagnetic components. I will describe the shape changes and materials parameters required to drive and direct these soft materials.

SESSION SF06.09: Soft Robotic Materials II

Sheraton, Second Floor, Back Bay D

1:30 PM SF06.09.01
Protein-Based Robotic Materials for Healing and Propulsion AbdonPena-Francesch; University of Michigan, United States

Recent progress in soft robotics has motivated the search for new robotic materials and actuators that can replicate biological functions and behaviors (such as sensing, healing, powering, etc.) with various degrees of autonomy and complexity. Proteins are uniquely well-positioned to bring new solutions to these challenges, as they offer high versatility, specificity, and control in their self-assembly to regulate their emergent structures and properties. In this talk, we will introduce cephalopod-inspired proteins with a segmented block design that self-assemble into β-sheet nanocrystalline structures. These β-sheet nanocrystals act as physical and reversible crosslinking structures in supramolecular protein networks that regulate the physical properties. We demonstrate the dynamic properties of squid-inspired polypeptides in self-healing protein networks with healing strength and kinetics surpassing those typically found in other natural and synthetic soft polymers, and in self-regulated porous structures for chemically-powered microrobot propulsion. This family of cephalopod proteins and their biosynthetic derivatives have opened new opportunities in bioinspired design for adaptive functional materials and soft devices with enhanced autonomy and durability, and we will demonstrate their implementation in self-healing and reconfigurable soft actuators and in self-powered microrobots for aquatic locomotion.

1:45 PM SF06.09.02
Smart Materials with Tunable Properties Based on Low Melting Point Alloys WanliangShan; Syracuse University, United States

Smart materials with tunable properties such as mechanical stiffness and electrical conductivity have ample applications in soft robotics as actuating and sensing units. These smart materials typically are achieved through polymer-matrixed composite structures containing conductive reinforcement components. The stiffness change typically is realized through phase change of the reinforcement or glass transition of the matrix. Low melting point alloys (LMPA) in the form of layers and long fibers have been recently used in composite structures with tunable stiffness due to its low energy barrier for activation and high electrical conductivity. In this talk, we explore the possibility of dispersing LMPA into a polymer matrix to achieve robust smart materials with highly tunable properties. In the first approach we start with an LMPA foam with randomly distributed interconnected pores, and then infiltrate the LMPA foam with uncured elastomer such as polydimethylsiloxane (PDMS) to form a robust bicontinuous foam composite with stiffness change of three orders of magnitude. In the second approach we mix both LMPA particles and conductive fibers into an elastomer matrix to form a percolative network of particles and fibers within the matrix, such that the resultant smart materials have tunable electrical conductivity and mechanical stiffness. Recognizing the lack of appropriate analytical models for the mechanical and electrical properties of these smart materials, we have used effective medium theory informed by microstructure information to estimate their stiffness and electrical conductivity. Our experimental and modeling results are in good quantitative agreement. We also demonstrate the superior performance of these novel smart materials based on LMPA foam and LMPA particles in soft robotics applications.

2:00 PM SF06.09.03
Opposite Deformability of Shape-Changing Polymers in Response to a Single Stimulus YuxingYao[1], XiaoguangWang[2], MilanWilborn[3] and JoannaAizenberg[3]; [1]California Institute of Technology, United States; [2]The Ohio State University, United States; [3]Harvard University, United States

Efforts to enhance the capabilities of dynamic systems have been dedicated to the development of “intelligent” soft matter actuators that can undergo logic-based mechanical deformations, enabling adaptive structural morphing and modulation of interactions with local environments. The prevailing soft material building blocks rely primarily on a single transition between bistable states to achieve such functionality. To expand deformation behaviors, one current trend involves superimposing either geometric design or kinetically controlled transient behaviors onto bistable actuators. Complementary to this trend, another promising avenue is to develop a material building block that exhibits two (or more) transitions within itself. This would enable more complex logic-based mechanical deformations, such as subsequent deformations in opposite directions, which could significantly expand the repertoire of encoded mechanical deformations and related functions in a more efficient way, requiring fewer building blocks. However, there are no general chemical design strategies to realize arbitrary, opposite motions in soft material building blocks.
In this work, we report an end-on liquid crystalline elastomer (LCE) that exhibits two-step, opposite mechanical deformations, characterized as a contraction followed by an expansion relative to the starting point along the alignment axis in LCE microstructures under a continuously changing stimulus. By arbitrary manipulation of LCE alignment axis with a magnetic field, we can further extend such opposite deformability to different deformation modes, including tilting and twisting. Moreover, we demonstrate such phase-driven opposite deformability can be readily translated to macroscopic objects and enable the reversible manipulation of the sign of Gaussian curvature in radially aligned films, which was previously challenging to attain.

2:15 PM SF06.09.04
Magnetic Putty as a Reconfigurable, Recyclable and Accessible Soft Robotic Material MengLi[1,2], JunghwanByun[2], AniketPal[2], GauravGardi[2] and MetinSitti[2]; [1]Massachusetts Institute of Technology, United States; [2]MPI for Intelligent Systems, Stuttgart, Germany

Magnetically hard materials are widely used to build soft magnetic robots, providing large magnetic force/torque and macrodomain programmability. However, their high magnetic coercivity often presents practical challenges when attempting to reconfigure magnetization patterns, requiring a large magnetic field or heating. This work presents magnetic putty as a robotic material

that is easy to shape in 3D and can autonomously self-heal, allowing recovery from mechanical damage and assembly of parts without adhesives. The magnetic putty is a soft composite made of hard-magnetic particles embedded in a viscoelastic silicone putty matrix. The interplay of its mechanical and magnetic properties is explored experimentally. The viscoelastic behavior is influenced by particle magnetization and the application of external magnetic fields. At the same time, its mechanical properties affect its magnetic properties, such as coercivity, remanence, and retention. The magnetic putty combines the benefits of hard- and soft-magnetic materials—high remanence and low coercivity—having large magnetic force under small fields and an easily reconfigurable magnetization profile. We show that the magnetization of magnetic putty can be easily reoriented with maximum magnitude using an external field that is only one tenth of its coercivity. We also describe how its magnetic field-induced stress changes under alternating magnetic fields. We show that, at a low magnetic field frequency and large field magnitude, it becomes an analog frequency doubler. We also demonstrate using magnetic putty as a robotic material to build reconfigurable magnetic setups, shapable magnets with adaptive polarities, recyclable magnetic robots, and growing bioinspired rotating vines. We envision that this easy-to-access material can provide the soft robotics community with a research and educational tool to explore fundamental questions and fast prototype magnetic soft robots.

3:30 PM *SF06.10.01
Heterogenous, Reconfigurable Robot Swarms as Multifunctional Materials ZeynepTemel, ShaYi and KatiaSycara; Carnegie Mellon University, United States

Recent breakthroughs in materials science, electronics, distributed computing, and manufacturing have led to an innovative category of multi-purpose substances known as robotic materials. Composite materials have developed capabilities such as detecting damage or auto-repair. However, none of the current state-of-the-art composite materials successfully combines the aspects of sensing, actuation, computing, and communication all into one [1]. One approach to creating autonomous robotic materials is to use robot swarms that can create functional configurations. Examples of creating functional structures using individual agents are observed widely in nature. For instance, ants have shown the ability to create functional structures like bridges by joining together and collaboratively performing tasks in a complex environment [2, 3]. Inspired by these organisms, reconfigurable robot swarms are capable of connecting with each other to form complex structures in rigid and flexible ways, resembling active, autonomous materials.

Robot swarms have shown the ability to display group behaviors that are unachievable by a solitary robot [4-6]. Additionally, robots that can physically link and engage with one another, known as self-reconfigurable robots, exhibit enhanced behaviors. Their use cases span from reshaping to adapting to various terrains [7], creating dynamic infrastructures [8], aiding in cooperative transportation [9, 10], to participating in search and rescue operations [11]. Existing connection methods between robots, whether mechanical or magnetic, may be complex to produce, require a significant amount of power, bear a constrained load capacity, or are only capable of forming inflexible structures. In addition, in most of these examples, agents have exactly the same characteristics, which limits the overall performance due to the lack of diversity of functionalities and operations.

Our recent work focuses on creating a system of robot swarms, PuzzleBots, where the robots can dynamically join to create useful structures such as bridges and ropes and disengage to independently explore their surroundings. This robot system is based on a mobile platform that measures 5cm in all dimensions and weighs around 70g. So far, we have demonstrated the creation of one-dimensional “line” and two-dimensional “mesh” configurations [12, 13] for overcoming negative obstacles in environments, explored the benefits of physical heterogeneity for enhanced mobility and control [13], and introduced the coupling flexibility between robots to adapt uneven terrain [14]. Our current efforts focus on building three-dimensional functional structures and sensing strategies for autonomy and distributed data collection during the desired motion. These robots have the potential to be used as building blocks to design active, multifunctional materials and to simulate the resulting behavior of any multifunctional material at different size scales.

4:00 PM SF06.10.02
Reconfigurable Tensegrity Robot with Relocatable Extensible Strut and Variable Stiffness Tendon SuwooLee, HyeonseoSong, Jun KyuChoe and JiyunKim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

For robots to be effectively employed in diverse scenarios, they need to facilitate seamless collaboration with both other robots and humans while being capable of adapting to unfamiliar environments and diverse terrains. In pursuit of this objective, extensive research has been conducted on soft smart materials that exhibit responsive behavior to a wide range of stimuli, leading to significant advancements in the field of soft robotics. Furthermore, to facilitate the integration of diverse functionalities alongside the progress in smart materials, efforts have been dedicated to the development of synergistic combinations with a variety of structures.
The tensegrity structure, inspired by biological systems, consists of prestressed tendons and rigid compressed struts. Tensegrity structures have garnered interest from researchers in the field of robotics due to their lightweight nature, inherent structural integrity, and remarkable ability to undergo substantial volume changes. Nonetheless, a drawback of the tensegrity structure lies in its inherent limitation of being capable of assuming only a predetermined shape set during its initial fabrication. Consequently, this restriction hinders its ability to effectively adapt to diverse environments, as it lacks the capacity for versatile shape transformations.
In this study, we present the fabrication of a reconfigurable tensegrity robot that encompasses intelligent functionalities into the smart tendon and strut devices. By doing so, we aim to addresses the limitations inherent in conventional tensegrity structures push the boundaries of tensegrity robotics and enable greater adaptability and versatility. The robot is endowed with three control parameters necessary for shape transformation, namely, variable-stiffness tendon, extensible strut, and relocatable strut, each of which plays a pivotal role in the overall mechanism.
The inclusion of particles within the tendon enables the realization of substantial alterations in stiffness with notable speed, owing to the jamming. Through the manipulation of stiffness, the robot is capable of both facile deformation in response to external forces and maintenance of structural integrity against collapse. It also facilitates the locking of the structure in a desired shape. A pneumatic-driven roller positioned external to the tendon can traverse along its length, offering the means to reposition the connected strut. The relocatable strut provides the robot with the ability to transform into a diverse range of shapes beyond the initially programmed structure by achieving considerable adaptability. The strut functions as an electrically operated linear actuator. A variation in the length of a single strut provides the ability to tilt the structure, whereas adjusting the length of all struts allows for alteration of the overall scale of the structure. To ensure smooth movement of strut location, the length of the linear actuator can be tuned to match the distance between the tendons when repositioning the strut.
As a result, we developed two distinct types of tensegrity robots: a triangular prismatic structure and an icosahedron structure. These robots exhibit shape- changing capabilities, which were previously unattainable in conventional tensegrity designs. Notably, the icosahedron structure introduces a novel control parameter for gait generation. Furthermore, the modularity of the tendons facilitates the construction of diverse tensegrity structures beyond the triangular prism and icosahedron exemplified in this study. In the future, we expect that these advancements can lead to the development of the next generation of adaptive and shape-changing robots, potentially reaching a level of sophistication that rivals biological systems, which possess localized

encoding of shape information.

4:15 PM SF06.10.03
Physical Artificial Intelligence in Untethered Soft Aerial Robots for Safe Environmental Interaction and Perching PhamH. Nguyen[1,2] and MirkoKovac[1,2]; [1]Empa, Switzerland; [2]Imperial College London, United Kingdom

As the next generation of aerial robots looks to widen its functionality and adaptability to multiple environments, the conditions required for its successful deployment has also increased. Previously, classical challenges aerial robots have had to face ranged from propeller noise, payload capacity, operational longevity, and robustness to collision and disturbances (physical obstacles and natural disturbances), just to name a few. But in order for the aerial system to effectively study natural habitats, aerial robots need to be capable of safely adapting and interacting with the unconstrained environment. One example of this is highlighted in the struggle aerial robotic systems have to tolerate collisions in order to safely land from a fall or successfully dynamically perch on objects with unknown shapes, sizes and textures.

To approach this problem, we made efforts to introduce compliance through the utilization of soft structures, in order to enhance mechanical impact protection, share functionality between flight and perching through shape reconfiguration, without any additional cost of reduced agility and flight time due to any extra payload.
In order to accomplish this, we looked at two approaches: (1) Shared functionality between flying and perching through metamorphic bistable origami-design soft arms. (2) Utilize a lightweight, fabric, inflatable, soft-bodied structure that can pneumatically vary its body stiffness to achieve intrinsic collision resilience. This is utilized in tandem with a lightweight bistable grasper that reacts upon contact with the perching object.

In the first approach, we noted how gliding aerial mammals morph their arms when transitioning between gliding flight and perching. Here, the developed quadrotor arms transition between two morphing stiffness states of flying and whole-body perching, utilizing a single-direction tendon drive. The quadrotor arms are bistable and are capable of collapsing around the perch within 0.97s. The arms are developed utilizing a layered technique between carbon-fiber, polyamide, and pre-stretched latex layers. With this setup, we were able to achieve approximately 30% overall mass reduction by this shared functionality. This setup was tested both indoors and outdoors in a forest environment.

In the second approach, we focused on the adaptable body of soft aerial robots. We developed an inflatable woven fabric soft body and arms for the quadrotor that can intrinsically vary its body stiffness on the fly for collision resilience. With this system, we highlighted its capabilities to repeatedly endure and recover from collisions in three-dimensions, supporting even harsh falls towards the ground without breaking its structure. In tandem with an equipped hybrid fabric-based bistable grasper that curls upon impact to conform around the perching object, we demonstrated the importance of having a soft body for improving the perching success rate on different objects significantly compared to the same system with a conventional rigid quadcopter frame.

Overall, in order to push the boundaries of current aerial robot designs to operate in cluttered environments and extend their range of functionalities, it is important to synthesize life-like soft aerial robots with shared physical artificial intelligent features and functionality, exploiting compliance as a key to do so. This will then push the next generation of aerial robots to not only improve their aerodynamic adaptability, efficiency, or maneuverability, but also lead to novel adaptations in adaptive manipulation and perching, aerial-aquatic-terrestrial transitions, withstanding dynamic collisions, reconfiguration for traversing through tight spaces, self-healing from damages, and adhesion in multi-modal environments.

Towards Autonomous Kirigami Materials for Insect Scale Robotics KaushikJayaram, HeikoKabutz, WilliamP. McDonnell, HariK. Hari Prasad and AlexHedrick; University of Colorado Boulder, United States

A major differentiating factor between engineered systems (e.g., an F-16), and their animal counterparts (e.g., a fruit fly) is robustness, or the ability to consistently perform in adverse conditions. While animals thrive in dynamic environments by continually adapting to current circumstances, engineered systems are rigid, relying on predesigned mechanisms and routines, which reduces their overall reliability. It is hypothesized that animals achieve robustness by tightly integrating sensing, actuation and feedback control in redundant, hierarchical structures throughout their bodies. This approach starkly contrasts with the incremental incorporations of analogous systems in modern engineered platforms and it is this lack of effective integration which is limiting their use in mission critical applications like recon, search and rescue and enemy engagements. These effects are severely felt in the performance of autonomous robots especially at the small scale where offloading processing to powerful computers is not an option.
A promising framework upon which inherently robust engineered systems can be built, is with so-called “robotic materials” (RM), i.e. a medium that tightly integrates local and redundant sensing, actuation, processing and communication. Readily available RMs would add unprecedented capabilities to our engineered systems but unfortunately, it is challenging to fabricate these materials. Popular additive manufacturing techniques like 3D printing, CMOS/MEMS fabrication are not ideal for integrating vastly different materials technologies or creating intricate features (at the micron scale) in a scalable, low-cost approach. One promising manufacturing method is the kirigami based stack laminate approach (Smart Composite Microstructures (SCM), Printed Circuit Microelectromechanical Systems Fabrication (PC-MEMS), etc.), which combines additive and subtractive processes selectively to successfully build individual RM components: (structure) insect scale robots, (sensing) stretchable sensor networks, (actuation) shape changing structures and (processing/communication) flexible electronics, but it has yet to be used to integrate these features into a single medium consistently. We will present our group's latest research on extending the PC-MEMS fabrication approach to begin to approach the promise of robotic materials and realize autonomous functionality. Specifically, we take advantage of femtosecond laser micromachining to pattern diverse materials including variety of smart materials which could not be previously fabrication using traditional laser processing. My research will focus on the development of a microrobotic smart leg with robust closed loop sensing and actuation, based on a laminate robotic material (LRM), helping to solve the manufacturing and system integration challenges of building LRMs. This platform will be used to study novel RM control algorithms, and the associated improvements to flight robustness after sustaining damage.

5:00 PM *SF06.10.05
Deployable Soft Origami Modular Robotic Arm with Variable Stiffness using Facet Buckling KyuJinCho; Seoul National University, Korea (the Republic of)

Robots that share activity spaces or physically interact with humans typically benefit from appropriate payload capacity, extensible workspace, low weight, safety, and space efficiency. The soft origami design and mechanism can meet many of these beneficial factors; however, achieving a high payload capacity remains challenging. In this talk, we present a soft origami arm module with high variable stiffness (x300) and spatial efficiency (compressed x3.1). The buckling of facets into a cylindrical tube followed by its pressurization, enables the arm to be highly stiffened. High-pressure capacity was obtained via the sewing-heat press fabrication process. We used a pneumatic pressure–tendon pair and utilized the frictional force between origami and tendon to prevent unintentional gravity-induced deformation while deploying. An analytical model was developed and compared to the experimental results. With our modular design, we could easily build functional robotic structures. Two robotic demonstrations were performed to examine the expandability of the modules. A variable-length robotic arm that mimics a human arm was built to manipulate typical objects. Additionally, a soft rover, which could carry 14 kg of weight and change its volume 29 times for improved spatial efficiency, was developed. This research suggests a new design methodology for practical soft robotic systems.

Design of Low Energy Actuation Pathways in Origami-Based Morphing Structures PhilBuskohl; Air Force Research Laboratory, United States

A hallmark of living systems is the capacity to sense, assess and respond to environmental stimuli. Physical reconfiguration is a pervasive response to the environment for many living systems, such as leg actuation to achieve locomotion or shape change for camouflage or energy harvesting purposes. The soft robotics community has long taken inspiration from this feedback loop and the clear need for tractable morphing strategies to access multiple physical conformations to achieve diverse and energetically efficient tasks. Origami concepts are one strategy to address this morphing structure design problem, by segmenting global shape change into a series of folding operations. The interplay between stretching, folding, and facet bending modes in origami structures generates a complex energy landscape of morphing pathways and multistable states to utilize. However, identifying rigid and deformable folding paths in this high-dimensional and non-convex energy landscape is challenging. To help address this, we leverage the nudged elastic band algorithm to identify low energy folding paths between stable configurations in this landscape. The nudge elastic band technique is a global method that optimizes each point along the path to follow the gradient of the energy function, while also

maintaining separation between the points to provide adequate resolution along the path. We demonstrate the utility of this approach for discovering sequenced folding motions, distinguishing between rigid and deformable folding paths, and finding low energy folding paths between stable states in multistabilty origami structures. The presentation will conclude with a discussion how physical reconfiguration can also contribute to the assess domain of the sense, assess, respond feedback loop and the need for strategies to consolidate this feedback loop by maximizing their intrinsic compatibility.

Reprogrammable 2D Metamaterials: A Dynamic Approach to Spanning the Eigenvalue Space DanielRevier[1] and JeffreyLipton[2]; [1]University of Washington, United States; [2]Northeastern University, United States

Metamaterials, which exhibit unusual macro-behavior determined by their microstructure rather than their chemistry, are an evolving field with potential applications spanning from photonic and phononic bandgaps to auxetics and cloaking. However, designing these materials is a complex process, often requiring specialized expertise, advanced machine learning, or intensive computational algorithms. To address this, we propose an intuitive and streamlined approach to designing 2D mechanical metamaterials by specifically programming degrees of freedom (DOFs) in their construction.
Our method harnesses Straight Line Mechanisms (SLMs) as a single DOF, unimodal material, which can be arranged into specific symmetry patterns (three-way, four-way, and six-way), to sample the entire 2D metamaterial space. The metamaterial's properties can be programmed and reprogrammed by pivoting the mechanism, enabling a dynamic transition through the design space. This approach not only simplifies the design process but also offers adaptability similar to an electronic Field-Programmable Gate Array (FPGA), which can be reprogrammed after manufacturing to perform different tasks, thereby permitting the properties of the metamaterial to be altered and optimized as needed.
We delve into the design space by exploring the available eigenvalues in Cauchy elasticity, which defines the eigenvalue gamut. We further analyze the constraints and unique aspects of the gamut boundaries by probing the space through different symmetry patterns, with and without mirror symmetry, which influences the material's chirality. Moreover, we show the reconfiguration of a single lattice can transition smoothly between extremal properties, showcasing the potency and versatility of our design principle.
Our work provides a novel framework for the creation of reprogrammable, planar mechanical metamaterials. Our strategy facilitates the creation of unique structures like handed shearing auxetics and isotropic materials with Poisson’s ratio approaching +/- 1 and 0. This approach demystifies the complex design process, offering flexibility to span the entire planar elastic tensor space and adapt to varying mechanical needs over time, making it a promising tool for the future of materials science.

9:15 AM SF06.11.03
Digital Composite with Independently Programmable Mechanical Properties XiaoyueNi; Duke University, United States

Non-living materials typically exhibit fixed properties. The pre-set mechanical characteristics often compromise stability, performance, and efficiency, limiting the maximum potential of materials in varying conditions. Artificial materials that can actively change and adapt properties are highly desired. Here, we introduce a digital composite that comprises a grid of "voxels," each capable of individually transitioning between a soft, fluid state and a rigid, solid state. Each voxel is a chamber of liquid metal embedded within a silicone matrix, digitally controlled via local joule heating. This allows for real-time programming of the material's emergent mechanical properties based on collective voxel behavior. This system serves as a tangible simulation platform for experimentally investigating the mechanics of multi-material composite systems. Using this platform, we demonstrate the capability to program a variety of mechanical properties independently through statistical topological parameters. The resulting composites, which can be extended into 3D, can emulate a range of natural soft materials. The real-time programmability enables the material to produce desired stress-strain responses, exhibiting unconventional mechanical behaviors. The ability to digitally fine-tune the complex mechanics of materials introduces unprecedented flexibility in the microstructural design of materials for specific applications.

Embodied Control in Soft Robots via Stimuli-Responsive Modules QiguangHe, RuiYin, YucongHua, WeijianJiao, HangShu, ChengyangMo and JordanR. Raney; University of Pennsylvania, United States

Robots typically interact with their external environment via feedback loops involving multiple sensors, microcontrollers, and actuators constructed from rigid electronic components that can be bulky, complex, and mechanically incompatible with soft materials. In this work, we explore strategies for embodying autonomous control of the trajectory and function of pneumatic soft robots. We specifically aim to embody the control system and its feedback loop via stimuli-responsive modules that can be moved, added, or removed from the robot to produce different behaviors in response to the surrounding environment. As one example, we build a kirigami-inspired robot that autonomously steers itself in response to variations in light or heat in the local environment by using liquid crystal elastomers (LCEs) in the control modules. The LCEs activate or deactivate modules to produce variable mechanical constraints in the kirigami, resulting in bending and steering of the robot. Additionally, we use analogous stimuli-responsive control modules to regulate the pneumatic logic of the soft robot, further expanding the range of autonomous functional changes that the robot can undergo. We show how decisions based on multiple stimuli can be achieved via logical combinations of these inputs.

10:30 AM SF06.11.05
Digitally Programmable Architected Materials with Static and Dynamic Reconfiguration for Soft Robots HangXu; Concordia University, Canada

Some bio-materials can morph and adapt to environmental changes. For example, pinecone scales disperse seeds due to their bi-layer structures bending in dry autumn. Inspired by nature, scientists are developing architected materials with programmable static and dynamic reconfigurations. They change their shapes in response to environmental changes and thus are in high demand for various applications that need to move or deform, such as actuators of soft robots.
Traditional reconfigurable architected materials program exotic physical properties into their layout in an analog manner. Analogous to analog computers, analogue programming has a continuous range of inputs and outputs, which are susceptible to manufacturing inaccuracy and environmental disturbances. In contrast, digital programming operates on symbols and numbers with discrete values, usually zeros and ones. Since it would take a significant error to mistake a one for a zero or vice versa, digitally programmable devices are robust to the inaccuracy of components and more resilient in the face of noise. Furthermore, devices with digital programmability are versatile in diverse problems, contrary to analog units. Although recent efforts have produced programmable architected materials with digital logic operations [1] and stable memory [2], they have not demonstrated digitally programmable graphics and configurations analogous to that of digital devices, such as Character Encoding, in which graphical configurations can be stored, transmitted, and transformed via assigned numbers.
Here we overcome this challenge by using a design framework for a multistable architected material with static and dynamic reconfiguration. Our design comprises a tessellation of physical binary tetrahedral building blocks (Bi-TB), analogous to digital bits, with clearly delineated transformation phases. Each Bi-TB can be reversibly switched between two mechanically stable states (acting as phase transformation) using mechanical, thermal or electrical stimuli. We construct the cube-shaped Octet-truss unit cell via eight Bi-TBs, analogous to one digital byte containing eight bits. These units can independently and reversibly snap each of the eight corners between two mechanically stable positions. That way, all unit cells can deform and, when connected, provide multi-directional shape changes, including scale, linear, rotate, shear deformation, or their combinations. Under reversible deformation associated with a set of binary numbers, the architected materials yield markedly different mechanical properties; specifically, the stiffness and strength can be programmed to range over an order of magnitude. The digitally programmed reconfiguration can achieve either static functionalities, such as load-carrying construction versatile to different loading conditions, or dynamic functionalities, such as actuators. The precision-controlled reversible reconfiguration with multi-degree of freedom (MDOF) in this design paradigm will facilitate the development of advanced forms of soft robots. The soft robots integrated with developed architected materials will support a wide range of applications, including precision surgery and contour recognition via artificial intelligence (AI).

Kirigami-Based Compliant Mechanisms and Metamaterials for Multiaxis Optical Tracking for Machine Vision and Energy-Harvesting Applications ChaoHuang, MaxShtein, ErinEvke, Yu-WeiWu, MichaelArwashan, ByungjunLee and StephenR. Forrest; University of Michigan–Ann Arbor, United States

Novel actuation strategies have emerged in recent years to create unprecedented capabilities in soft robotics. One such strategy uses compliant mechanisms inspired by the Japanese arts of *origami* (folding) and *kirigami* (cutting). In this work, we use *kirigami* to create a polymer-based one-piece compliant mechanism that allows for optical tracking over a solid angle sweep of over 110^{o} in two axes and using compact dimensions, realize 80-fold or greater optical concentration. We also show how this structure scales to an arbitrarily large array, yet the displacement required to achieve the angular sweep remain compact and independent of the number of elements and areal extent of the array, and examine multi-parameter array optimization to reduce semiconductor usage to reduce the cost solar electricity below that of stationary silicon panels. We further discuss use of novel materials and other robotics and autonomous material applications of such single-piece, compliant mechanisms.

11:00 AM SF06.11.07

Formation of Buckled Equilibrium Shapes in Growing Polymer Gels SantidanBiswas, VictorYashin and AnnaC. Balazs; University of Pittsburgh, United States

We study the effects of boundary constraints and structural patterning on the morphology of growing polymer gels using computer simulations. The 3D simulation model is based on the gel lattice-spring approach, and accounts for the neo-Hookean gel elasticity, polymer-solvent inter-diffusion, and structural changes in the polymer network in the course of growth. These gels exhibit growth by incorporating monomeric units from the surrounding solution into their network. At Stage 0 of growth, a flat parent gel swells in a solution of monomers and cross-linkers until reaching equilibrium. The presence of boundary constraints (hard walls) during swelling of the parent gel causes a spatially non-uniform distribution of monomer solution in the gel sample with the degree of swelling close to the constrained surfaces being less than that far from them. The gel loses its initial flat shape and buckles. With the walls remaining in place, we then model Stage 1 of growth which consists of polymerization and cross-linking of the species, which diffused into the parent gel during swelling, followed by the chain-exchange with the primary network to form a random copolymer network (RCN). After the removal of the sol fraction, the resulting RCN gel is put back into the initial solution and swells until equilibrium under the same boundary constraints. The resulting Stage 1 RCN gel almost replicates the shape of Stage 0 parent network buckled due to the confinement. In effect, the shape of the Stage 0 parent gel templates the morphology of the subsequently grown gel. Moreover, when the grown RCN gel is detached from the walls, it does not relax back to a flat configuration but remains in a buckled state. The growth fixes an energetically unfavorable, deformed shape into a stable configuration. We consider several scenarios of growth of the RCN gels with a stable buckled shape by introducing various combinations of the boundary constraints and structural patterning of the growing gel through varying the crosslink density in a sample. In all cases considered, upon releasing the boundary constraints, the grown RCN gels take an equilibrium buckled shape with a shape pattern governed by the compositional heterogeneity during the growth process. These gels can be used as building blocks for polymeric materials design, and have potential applications as actuators, shape morphing materials, and controlled gradient materials.

11:15 AM SF06.11.09
Harnessing Non-Uniform Pressure Distributions: The Next Generation of Soft Robotic Actuators YoavMatia[1], GregoryH. Kaiser[2], RobertShepherd[2], AmirGat[3], NathanLazarus[4] and KirstinH. Petersen[2]; [1]Ben-Gurion University of the Negev, Israel; [2]Cornell University, United States; [3]Technion–Israel Institute of Technology, Israel; [4]University of Delaware, United States

The primary goal of this work is to demonstrate how to teach a set of bladders a specific behavior - embodying code into matter. Specifically, we discuss complex motion in soft, fluid-driven actuators composed of elastomer bladders arranged around a neutral plane and connected by slender tubes is demonstrated. Rather than relying on complex feedback control or multiple inputs, the motion is generated with a single pressure input, leveraging viscous flows within the actuator to produce nonuniform pressure between bladders. Using an accurate predictive model coupling with a large deformation Cosserat rod model and low-Reynolds-number flow, all dominating dynamic interactions, including extension and curvature, are captured with two governing equations. Given insights from this model, five design elements are described and demonstrated in practice. By choosing the relative timescales between the solid, fluid, and input pressure cycles, the tip of the actuator can obtain almost any desired trajectory and can be placed anywhere temporarily within its 2D workspace. Finally, a six-legged untethered walking robot showcases the benefits of viscous-driven soft actuators. This work lays the foundation for a new class of morphologically intelligent, soft robotic appendages capable of complex deformations and multifunctionality without explicit drivers; whereby generating nonuniform pressure distributions, their infinite degrees of freedom can be exploited.

The Design and Fabrication of an Entirely Soft Multi-Stable Magnetic Microarchitecture TaylorGreenwood, NahidHasan, PaiWang and Yong LinKong; University of Utah, United States

The ability to achieve geometric reconfiguration of soft architecture is highly desirable for implantable and ingestible biomedical devices. However, triggering and sustaining multiple stable configurations in a dynamic environment without a continuous energy input remains challenging. Previous demonstrations require the persistent application of a magnetic field; or rely on the modulation of environmental factors (e.g., temperature, light) susceptible to dynamic perturbation. Here we demonstrate the design and fabrication of a soft multi-stable magnetic microarchitecture capable of rapid, on-demand, and reversible reconfiguration that is preserved even after adverse mechanical, chemical, and thermal experiences. The robust volumetric reconfiguration is enabled by an entirely soft, magnetically programmed, rationally designed inclined-beam bi-stable microarchitecture. We envision that such capability can enable new classes of soft biomedical devices with exceptional versatility and durability in dynamic environments.

1:45 PM SF06.12.02
Programming Control of a Versatile Ferrofluid: The Exploration of Multifunctional Liquid Robotics JinggeChen[1,2], LiangyuXia[2], YuxuanSun[2], QuanliangCao[2] and VickiL. Colvin[1]; [1]Brown University, United States; [2]Huazhong University of Science & Technology, China

The macroscopic and microscopic responsiveness of ferrofluid to external magnetic fields endow it considerable intelligence and rich functionality, which inspires liquid robotics that can realize arbitrary deformation and perform various functions. Here a versatile ferrofluid is developed, its intelligent manipulation, extensive applications and motion sensing are explored. The ferrofluid is made up of sterically stabilized ultra-small magnetic nanoparticles prepared by a facile one-pot method and purified under a temporary induced aggregation state, showing strong stability, flexible mobility, substantial magnetization, and adjustable concentration. Furthermore, the locomotion and morphology of ferrofluid can be manipulated by a programing control platform that integrates display, drive, control, and cooling modules. This device generates sequential predesigned magnetic fields through the programmable activation of specific electromagnets. Moreover, the intelligent multi-dimensional actuation of substances with a wide range of densities could be accomplished by this ferrofluid in cooperation with permanent magnets manipulated by a robotic arm. This ferrofluid is also developed into a vibration sensor through aligning the magnetic moments in ferrofluids and detecting the flux change in vibration. In addition, the flow, concentration, and speed of ferrofluids can be detected by coupled coils. Such fabrication, control, operation and sensing explorations are central for the development of liquid robotics.

2:00 PM SF06.12.03
Backswimmer Inspired Buoyancy Mechanism for Underwater Robotic Swimmers and Potential Applications for Cooperative Motion DrorKobo and Bat-ElPinchasik; Tel Aviv University, Israel

The backswimmer is an aquatic insect, capable of regulating its buoyancy underwater. Its abdomen is covered with hemoglobin cells, used to bind and release oxygen reversibly. Upon entering the water, the insect entraps an air bubble in a superhydrophobic hairy structure on its abdomen for respiration. This bubble, however, can change its volume through regulated oxygen flow from the abdominal hemoglobin cells. In this way, it can reach neutral buoyancy without further energy consumption. In this study, we develop a small, centimeter scale, backswimmer-inspired robotic swimmer (BackBot) with auto-buoyancy regulation through controlled nucleation and release of microbubbles. The bubbles nucleate and grow directly on onboard electrodes through electrolysis, regulated by low voltage. We use 3D printing to introduce a three-dimensional bubble-entrapping cellular structure, in order to create a stable external gas reservoir. To reduce buoyancy forces, the bubbles are released through linear mechanical vibrations, decoupled from the robot's body. Through pressure sensing and a Proportional Integral Derivative control loop mechanism, the robot auto-regulates its buoyancy to reach neutral floatation underwater within seconds. This mechanism comprises the basis for creating a group of robotic swimmers with auto-motion control, and for studying cooperative effects, reciprocal and non-reciprocal virtual interactions between group members.

Silicone Printing With AMULIT: Additive Manufacturing at Ultra-Low Interfacial Tension ThomasAngelini and SenthilkumarDuraivel; University of Florida, United States

In several of his works, P.G. de Gennes told a story about tribespeople of South America who made boots by coating their feet with natural liquid latex that solidified into rubber. The story was intended to illustrate how small changes in the composition of phases of soft matter can lead to large changes in their rheological and material properties. This story also represents an elegant example of manufacturing with soft materials. Unfortunately, it is generally challenging to create complex structures with precision and accuracy when working with phases of soft matter, including silicone. The tendency of soft materials to slump, spread, flow, stretch, bend, and fail limits how we fabricate soft structures; for the most part, soft matter must be molded. One way to side-step the mold is to leverage embedded 3D printing, in which a liquid phase is extruded into a second support material that holds the liquid in its deposited shape, to be solidified or processed at a later time. In this talk I will describe the embedded 3D printing methods and materials our lab has developed that enables the shaping of soft matter while in its

liquid precursor state, focusing on 3D printing silicone-based inks. We have found that fabricated structures can be deformed or broken apart by very small forces because all the materials involved are either liquids or extremely soft solids. I will show how these disruptive forces arise from interfacial tension between printed inks and the support materials. To mitigate interfacial forces, we recently developed a method called “Additive Manufacturing at Ultra-Low Interfacial Tension,” in which we attempt to minimize the chemical differences between the ink and support material, eliminiating the disruptive role of interfacial tension in embedded 3D printing. With this new approach we have fabricated complex and finely detailed silicone structures that accurately model human anatomy. Stable features as narrow as 8 micrometers can be fabricated with the AMULIT technique, and functional 3D printed silicone structures are as robust and durable as their molded counterparts. Moving forward, we believe the AMULIT technique will be a useful tool in developing new compoents for soft robotics and autonomous materials.

3:15 PM *SF06.12.05
Rapid Manufacturing of Elastomers, Thermosets and Composites with Tunable Multifunctional Properties NancyR. Sottos, JustinePaul, LuisRodriguez Koett, PranavKrishnan, JavierBalta, SamehTawfick and JeffreyMoore; University of Illinois-Urbana-Champaign, United States

Complex patterns and gradients integral to the structure and function of biological materials emerge spontaneously through reaction-diffusion controlled processes during morphogenesis. In contrast, functional patterns in synthetic materials are created through multistep manufacturing processes requiring masks, molds, or printers. Current additive manufacturing techniques for fabricating complex, architected materials often face limitations in achieving the desired level of complexity and control without extensive human intervention and additional tools. Inspired by reaction-diffusion systems in nature, our work seeks to harnesses rapid reaction-thermal transport during frontal polymerization to drive the emergence of spatially varying patterns and tailor properties of polymers and composites during the manufacturing. Tuning of the reaction kinetics and thermal transport enables internal feedback control over thermal gradients to spontaneously pattern morphological, chemical, optical, and mechanical properties of structural materials. A range of experimental tools are exploited to characterize the evolution of the microstructure and properties, including IR imaging of the temperature history and front evolution, differential scanning calorimetry to determine degree of cure, wide angle x-ray scattering, nanoindentation and mechanical testing to assess changes in thermomechanical properties. Functionally graded and patterned regions with two orders of magnitude change in modulus and over 200°C change in glass transition temperature are achieved in thermoset polymers. Small perturbations in the fabrication conditions lead to remarkable changes in the strength, elastic modulus, and toughness of the resulting materials. This ability to control mechanical properties and performance solely through the initial conditions represents a significant advancement in the design and manufacturing of advanced multiscale. Moreover, we envision that more sophisticated control of reaction-transport driven fronts may enable spontaneous growth of structures and patterns in synthetic materials, inaccessible by traditional manufacturing approaches.

3:45 PM SF06.12.06
Fully Printed Micro-Patterned Electrochemical Actuators JiZhang, QingshenJing, TomWade, ZhenchengXu, LiamIves, DiandianZhang, JeremyJ. Baumberg and SohiniKar-Narayan; University of Cambridge, United Kingdom

Submillimetre or micrometre scale electrically controlled soft actuators have immense potential in microrobotics, haptics, and biomedical applications. However, the fabrication of miniaturised and micro-patterned open-air soft actuators has remained challenging. In this study, we demonstrate the microfabrication of trilayer electrochemical actuators through aerosol jet printing, a rapid prototyping method with 10 μm lateral resolution. A fully printed 1 mm × 5 mm × 12.2 μm ultrathin PEDOT:PSS/Nafion/PEDOT:PSS actuator is successfully actuated in air under voltages from ±0.1 V to ±0.8 V, giving deflection angles proportional to the applied voltage, and reaching a peak-to-peak deflection of 0.25 rad (14 degrees) under a ±0.8 V 0.1 Hz square wave. The thinness of this AJP actuator reduces the proton transport length and flexural rigidity, hence causing relatively fast response and large deflection under low voltages. Next, we fully printed an actuator with two individually controlled submillimetre segments and demonstrated its multimodal actuation. The convenience, versatility, rapidity, and low cost of our microfabrication strategy promises future developments in integrating arrays of intricately-patterned individually-controlled soft microactuators on compact stretchable electronic circuits.

4:00 PM SF06.12.07
Hybrid 3D Printing of Wireless Stretchable Tactile Displays with Robust Sensing and Actuation RamonE. Sanchez; Boston University, United States

Current manufacturing methods for prototyping soft tactile displays rely on complex techniques with limited scalability that are incompatible with stretchable electronics. This work presents a stretchable wearable tactile display with sensing and feedback capabilities manufactured by hybrid multi-material 3D printing in a single fabrication process. The electrical wiring and sensing elements of the display are 3D printed using a strain-induced electrically conductive liquid metal emulsion, which exhibits the shear yielding and shear thinning behavior necessary for direct ink writing (DIW). The actuators and off-the-shelf electronics are combined with the LM emulsion through automated pick-and-place. Once the LM emulsion and the electronics are integrated on a 3D printed polymer base with walls, they are packaged with liquid elastomer and cured. Upon mechanical activation of the LM emulsion composite through axial and lateral strains of 200% each, they reached a conductivity that is within an order of magnitude of the bulk LM. The sensing elements are force sensing resistors (FSR) composed of printed filaments on a spiral architecture. Electro-mechanical characterization of the sensors indicated that their sensitivity and response time were directly related to their conductivity. Upon further activation of the FSR at compressive strains of 60%, their conductivity increased to the same order of magnitude as the bulk LM, and a sensitivity of 0.05 kPa^{-1}, which is an order of magnitude higher than that of the electrical wiring. To show the capabilities of the tactile display, we fabricated two self-contained devices, one with an embedded array of FSR, and one with an embedded array of actuators. The device with the array of FSR collects data in the form of tactile patterns, collecting both the location and magnitude of the signal, and transmitting this data wirelessly in real time. The device with the array of actuators receives this signal and reproduces the tactile pattern for an immersive and synchronized tactile experience between two individuals.

4:15 PM *SF06.12.08
New Materials for All-Printed Soft Robotics ShlomoMagdassi; Hebrew University of Jerusalem, Israel

Additive manufacturing, which is the process of fabrication through printing, brings new opportunities in the general field of material science and in particular, in soft robotics. Here we describe new materials and processes for making soft grippers with embedded sensors, starting from a solution of monomers and oligomers, and dispersion systems. The utilized printing materials result in highly stretchable objects that are the base for fabricating actuators which are the main component of soft grippers. Furthermore, several responsive materials will be presented, which bring sensing abilities, thus enabling the fabrication of autonomous soft grippers. The sensing is obtained by unique designs of the grippers and embedded electrically conductive particles. These grippers can adapt to different shapes, apply holding forces tailored to the object's mechanical properties, and provide information to the control system for optimal operation.

SESSION SF06.13: Biohybrid Autonomous Materials

Active Gels Driven by the Belousov–Zhabotinsky Reaction ShingoMaeda; Tokyo Institute of Technology, Japan

We explore research on autonomous gel actuators and gel machines driven by chemical reaction networks. We focused on the BZ reaction. The BZ reaction consists of a typical chemical reaction network. The Belousov–Zhabotinsky (BZ) reaction, known as a chemical oscillation, is a chemical reaction that induces self-oscillation in concentration. The catalyst of the BZ reaction is covalently bonded to the polymer chain so that the BZ reaction occurs only inside the gel, and the change of the osmotic pressure associated with the oscillation of concentration causes periodic swelling and shrinkage of the gel. The essence of the coupling between the BZ reaction and the gel is that the swelling and contraction motion of the gel can sufficiently follow the chemical reaction, and we have designed peristaltic motion of polymer gels and self-walking gels.
Recently, we have proposed a new hypothesis regarding the temperature–compensated biological clock using temperature–responsive BZ gels. The temperature compensation of the biological clock is the property of maintaining a constant cycle regardless of changes in temperature, and the mechanism of the temperature compensation is not clearly understood. By constructing a mathematical model of the temperature–responsive BZ gel and analyzing it theoretically, we found that the temperature compensation can be realized by offsetting the effect of temperature change by volume change of the BZ gel. Our experiments also showed that the temperature–responsive BZ gel exhibits temperature compensation, and we succeeded in designing an artificial biological clock.

8:30 AM *SF06.13.02

Self-Regulated Hydrogel Actuators - Tuning Actuation with a Pinch of Salt BilgeBaytekin; Bilkent University, Turkey

Self-regulation is an essential property for maintaining the vitality of living organisms. Helping the organisms respond to internal and external changes, self-regulation is also the basis of the autonomy of all living systems. The complex biochemical feedback for self-regulation is hard to replicate directly in artificial systems. However, it was previously shown that artificial self-regulation can also be achieved in material systems by designing proper combinations of the systems chemical and physical features. Previously, we constructed electronics-free artificial systems mimicking heliotropism (sun tracking) and nyctinasty (leaf opening) in plants. In these systems, dehydration/rehydration cycles were employed to cause the actuation and feedback. In this work, we use some common salts doped in the hydrogels to tune the bending behavior of hydrogel actuators. The bending rate of the 'salty' actuators parallels the physical-chemical differences of the ions in the salt. With the actuator parts made up of essentially the same hydrogel, including different salts, responding to the same input at different rates, the programmability of an overall hydrogel material for more complex motion can be achieved. The straightforwardly achievable, programmable, and tunable 'embodied intelligence' in autonomous hydrogel materials can be used in soft robotics, soft sensors, and environmental monitoring.

9:00 AM SF06.13.03
Autonomous Microtools Built from Soft-Stiff Micro-Fabricated Actuators SandraEdward[1], HollyM. Golecki[1] and BryanKaehr[2]; [1]University of Illinois at Urbana Champaign, United States; [2]Sandia National Laboratories, United States

Photothermally actuated microbots with the ability to capture and release objects on the microscale have widespread applications in the medical field for microsurgery or selective cell extraction. Light driven micro-actuators can be fabricated with environmentally responsive materials compatible with 3D printing and have the advantage of being programmable, wireless, and of high resolution. Compliant microbots can deliver site-specific therapeutics with autonomous control in dynamic environmental conditions. In this presentation, we describe the design, fabrication, and testing of a hybrid stiff-soft microgripper system on the tip of a 200-micron diameter core fiber. The stiff, yet compliant exoskeletal gripper head is autonomously actuated by soft active hydrogels that can react to forces generated due to external light power from the fiber optic or from environmental factors like pH or temperature. Compliant skeletal structures are fabricated using 2-photon polymerization additive manufacturing directly on the end of optical fibers. In this work, we explore the design and functionality of tools to facilitate gripping, cutting, and clamping actuation mechanisms. To control actuation, we demonstrate current regulated growth of hydrogels within the printed gripper structure. We test different methods to functionalize the gel component of the actuator to reduce heat losses, increase the efficiency of the gel and the system, and increase the total actuation displacement. In one adaptation, pNIPAM gels are functionalized with metallic nanoparticles to improve photothermal absorption. Additionally, liquid crystal elastomers can also be aligned using electric fields to form soft actuators within printed tools. To evaluate the hybrid microgrippers, we test for optimal print parameters, elastic recoil, response time, accuracy, and cyclic durability. This work provides a foundation to study stimuli-responsive photothermal micro-scale optical tools to expand the scope of tools available for minimally invasive surgical procedures.

9:15 AM SF06.13.04
Towards Sustainable and Robust Soft Robots using Dynamic Covalent Polymer Networks AleixCosta Cornellà, FrancescaFuria, SeppeTerryn, BramVanderborght, GuyVan Assche and JoostBrancart; Vrije Universiteit Brussel, Belgium

Despite all the efforts that are being put into it, materials used for soft robots currently do not offer a complete sustainable solution as i) they are easily damaged, ii) the materials used are fossil-based and iii) the materials used are normally permanently crosslinked, which hinders its processability, recyclability and biodegradability. A material that is increasingly used in soft robotics because it offers a solution to these problems is gelatin. However, it is highly susceptible to changes in environmental conditions such as temperature or humidity, which highly limits its use in real-world applications.
Introducing dynamic bonds into polymer networks can produce materials that can be more easily processed, applied, and recycled than their permanent counterparts. Moreover, they show improved toughness, stretchability, and the ability of healing physical damage. This dynamic bonding can be introduced into the polymer by means of supramolecular interactions, dissociative dynamic covalent bonding, or associative dynamic covalent bonding (vitrimers). All three systems have their strengths and weaknesses, but they all suffer from the same compromise, which is having to choose whether to be able to self-heal/reprocess at mild conditions and having long-term mechanical stability. To be able to self-heal at mild conditions you need materials with fast relaxation dynamics, however, fast relaxation dynamics are undesirable in most applications like in soft-robotics as the material behavior becomes heavily time and temperature dependent. Here, we developed a method to tailor the relaxation time regime in dynamic polymer materials to address this inherent issue. We've combined two dynamic covalent bond chemistries with completely different relaxation dynamics, both in time scale and in its mechanism. More specifically, we've combined Diel-Alder bonds based on furan and maleimide and β-hydroxy ester bonds. By tuning the ratio between Diels-Alder bonds and β-hydroxy ester bonds it is possible to access the complete range of relaxation times between the two mechanisms. And more importantly, the two mechanisms can be observed in the same material but at different times scales. This allows to develop materials that can partially relax at mild conditions, which are enough for self-healing, but not show creep as the network doesn't fully relax, as well as showing shape memory capabilities.
The materials are also designed guided by the 12 principles of green chemistry. They are synthesized using 100% bio-based raw materials, based on fatty acids, without using any solvent, and are potentially (bio)degradable. As all the components have a similar backbone, the mechanical properties of the materials don't vary much between materials with different ratios of associative and dissociative bonds. The Young's modulus of the whole range of materials sits around 1.5 ± 0.5 MPa at room temperature.
With this strategy the design of the mechanical properties is decoupled from the relaxation dynamics. Combining two types of dynamic bonds with very dissimilar relaxation dynamics empowers a range of applications where the materials can be tailored according to its application, its processing, as well as the timescale of its use. These applications include 3D printing, which is one of the biggest challenges for dynamic covalent bonds, and soft-robotics.

Wearable Devices and Structural Designs for Neural Interfaces Jang-ungPark; Yonsei University, Korea (the Republic of)

Recent progress in optoelectronic devices for wearable electronics demands their outstanding mechanical deformability for versatile systems in daily life. Especially, rapid advances in neurotechnology enable bidirectional communication between the nervous system and engineered devices. The precise recording and stimulation of typical target neurons by neural interfaces with adequate materials and structures can provide revolutionized medical applications, including the diagnosis and treatment of neurological disorders. Thereby, a proper understanding of the electronic device and its interfacing biological surroundings is necessary. Here, this talk presents the fundamental concepts of neural signaling, neural recording, and stimulation to introduce neural interfaces with wearable electronic devices. Then, we summarize the considerations of the materials and introduce a variety of materials that satisfy the requirements. Furthermore, the key challenges for next-generation neural interfaces are considered, and future directions are explored based on recent studies.

10:30 AM SF06.13.06
Soft Sensory Robots Based on Stimuli-Responsive Hydrogels for Electronic Implants WubinBai; University of North Carolina at Chapel Hill, United States

Living organisms with motor and sensor units integrated seamlessly exhibit effective adaptation to dynamically changing environments. Taking inspiration from coherent integration between skeletal muscles and sensory skins in human, we present a design strategy of soft robots, primarily consisting of an electronic skin (e-skin) and an artificial muscle, that naturally couples multifunctional sensing and on-demand actuation in a soft, biocompatible platform. here, we will describe an *in situ* solution-based method to create the e-skin layer with a series of sensing materials (e.g., silver nanowires, reduced graphene oxide, and poly(3,4-ethylenedioxythiophene) polystyrene sulfonate) incorporated within a polymer matrix (e.g., polyimide and polydimethylsiloxane), imitating human skin with complex receptors to perceive various stimuli. Biomimicry designs (e.g., starfish and chiral seedpods) of the soft robots enable various active motions (e.g., bending, expanding, and twisting) on demand and realize good fixation and stress-free contact with tissues. Furthermore, integration of a battery-free wireless module into these soft robots enables robotic operation and communication without tethering, thus enhancing safety and biocompatibility of the soft robots as minimally invasive implants. Demonstrated examples range from a robotic cuff enclosing around a blood vessel for precise detection of blood pressure, a robotic gripper holding onto a bladder for accurately tracking bladder volume, an ingestible robot residing inside stomach for pH sensing and on-site drug delivery, to a robotic patch wrapping onto a beating heart for quantifying cardiac contractility, temperature and applying cardiac pacing, highlighting the application versatilities and potentials of the bioinspired soft robots. Our designs of soft robots could establish a promising strategy to integrate a broad range of sensing and responsive materials, for forming highly integrated systems for medical technology and beyond.

Magnetic Surface Microrollers for Endovascular Navigation UgurBozuyuk[1,2] and MetinSitti[1,2]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]ETH Zürich, Switzerland

Mobile microrobots offer great promise for minimally invasive targeted medical applications to overcome the current limitations in cargo delivery thanks to their precise controllability. The circulatory system represents the ideal route for the navigation and delivery of microrobots; however, blood flow impairs the propulsion of microrobots. Magnetic surface rolling microrobots, or "surface microrollers" emerged as an attractive microrobotic platform for navigation in blood vessels utilizing decreased flow velocities on the blood vessel walls. In this work, we assess the navigation potential of the surface microrollers in blood vessels for future drug delivery applications. First, we started developing the microrobotic platform from scratch. Then, we characterized their locomotion characteristics, which yielded the fastest magnetic microrobot in its size scale in the literature, corresponding to 80 body lengths per second. Then, its upstream

locomotion performance in physiological blood flows was characterized in microfluidic chips; the results have shown significant potential for navigation in blood flows. Furthermore, the antibody-modified surface microrollers could also recognize the cancer cells during active locomotion and deliver chemotherapeutics to cancer cells, showing the platform's multi-functionality. Having confirmed the system's potential, we explored the hydrodynamic barriers for locomotion in physiological blood flows in detail. The hydrodynamic barriers can be classified under three main topics: 1) Surface microtopography effect, 2) Confinement effects, and 3) Flow rate/velocity effects. The surface microtopography of the vessel walls, in the same size scale of surface microrollers (3-8 μm), unexpectedly creates a significant barrier for locomotion. Even though the locomotion is high-speed and unimpeded on flat surfaces, the surface microtopography effect can entirely stop the locomotion of spherical microrollers due to unfavorable hydrodynamic interactions between microroller and surface microtopography, revealed in computational fluid dynamics (CFD) simulations. We have demonstrated that rod-shaped microrollers render minimal interaction with the neighboring boundaries, thus smoothly locomoted on such textured surfaces. The problem can also be solved by using bigger-sized spherical microrollers, and then the surface microtopography effect disappears. Next, we investigated the physical confinement effect on the surface microrollers, which would be encountered in small blood vessels such as capillaries and venules. Our experiments demonstrated that the locomotion efficiency of spherical microrollers drastically decreases in confined spaces, even causing reverse locomotion in circular confinements. The CFD analysis revealed that the impeded locomotion is due to out-of-plane rotational flows rather than translational flows generated during locomotion. Hence, a slender microroller design, generating smaller rotational flows, outperforms spherical microrollers in confined spaces. Last, we characterized different flow rate/velocity effects on surface microrollers. In a CFD model, we investigated the upstream locomotion performance of surface microrollers in main blood vessel types in the systemic circulation. The results have demonstrated that the microroller locomotion halted in the small vessels due to increased flow and confinement effects. In contrast, the locomotion seemed fully and partially possible in the venous and arterial flow. Having explored the limitations and possibilities, we have demonstrated the upstream locomotion of biocompatible and high-performance microrollers in venous flow under real-time imaging, confirming the previous findings. Overall, we comprehensively investigated the potential of magnetic surface microrollers in blood vessels for their future drug delivery applications.

DNA-Based Nanomaterials with Robotic Functions MarcelloDeLuca[1], SebastianSensale[1], WolfgangPfeifer[2], Chao-MinHuang[1], MichaelPoirier[2], CarlosCastro[2] and GauravArya[1]; [1]Duke University, United States; [2]The Ohio State University, United States

DNA nanotechnology is a promising approach for creating soft robotic nanomaterials due to its ability to create nanostructures of unprecedented geometric complexity and high programmability. While recent advances have led to dynamic DNA devices capable of undergoing complex motions, the size and functionality of these structures remains limited [1]. In this talk, I will describe our recent efforts in designing and modeling complex multicomponent DNA nanomaterials with tailored or emergent dynamic behaviors characteristic of smart robotic systems. I will begin by discussing a software we developed that uses feedback from coarse-grained molecular dynamics simulations to automate the design of freeform 3D DNA nanostructures and their assemblies [2]. I will then show how we used this framework along with mesoscopic models, simulations, and statistical mechanics to create 1D arrays of sterically interacting DNA origami structures that can communicate mechanical signals along the array [3,4] and 2D arrays of interacting DNA rotors that can undergo intriguing order-disorder transitions akin to, and beyond, the Ising lattice [5]. Such systems capable of exhibiting complex dynamic, organizational behavior could be harnessed for applications in sensing, soft robotics, optics, and energy harvesting.

Soft Robotic Capacitive Sensing for Force Measurement in Neurosurgical Procedures DanielVan Lewen, CatherineWang, Hun ChanLee and SheilaRusso; Boston University, United States

Neurosurgical procedures require a high level of accuracy to complete tasks within the delicate region of the brain. Current tools for moving brain tissue (i.e., tissue retraction to expose cancerous lesions) during these procedures are mostly made out of stainless steel and create localized regions of pressure. These tool-tissue interactions can be harmful and lead to postoperative complications (i.e., hampered neuromotor and neurocognitive functions) , especially when the forces are applied over longer periods of time. Research on soft robots is rapidly expanding within the field of surgical robotics due to their ability to safely interact within human tissue, a trait which can reshape tissue interactions in neurosurgery. However, they have generally been difficult to control due to nonlinear behaviors. Using principles of morphological computation, various design techniques have been developed to control the behavior of soft robots, such as the application of origami-inspired folding patterns. For soft robots to be deployed in neurosurgery, greater control through the integration of soft sensing is required by surgeons during these procedures.
This work presents an origami-inspired soft robot with integrated capacitive sensing for measuring force during tissue retraction in neurosurgical procedures. The robot employs an origami-inspired actuation technique in which a circular Miura origami pattern creates well-defined contraction and expansion ratios. A thermoplastic wrapping allows for expansion to be controlled via vacuum pressure. To embed a sensing modality in the robot, an individual origami unit cell is modified to become a capacitor that changes in capacitance when force is applied. The force results in displacement between the capacitive plates. The retraction process can therefore be monitored by the surgeon to ensure that dangerous levels of forces are not exceeded. The sensing origami units are fabricated using a layering technique which embeds a fluidic stiffening actuator within an elastomer dielectric. Thin copper films, laser cut in the shape of the origami unit cell, sandwich this dielectric layer to create the plates for the capacitive sensor. Three sensing unit cells are integrated into the circular Miura pattern at evenly spaced locations and connected electrically in series. The hyperelastic properties and shape of the dielectric are chosen to sufficiently displace the plates so that a full range of forces of 0-3 N (typically found in neurosurgery) can be measured.
Calibration of the sensing unit demonstrates the relationship between force and capacitance giving a model which can output force measurements. The force range and sensitivity are analyzed through characterization experiments of the sensors on the robot giving an indication of the sensing behavior during force application and folding of the robot. Response of the system over time shows the correlation between actual applied force and capacitance over time. Finally, an in-vitro setup was developed to model the retraction process in the brain and demonstrate the robot’s ability to retract brain tissue and sense the distributed forces. Development of this sensing mechanism gives a method for both monitoring and controlling the pressure on the brain during robotic tissue retraction, demonstrating the potential of soft robots in neurosurgery.

11:30 AM *SF06.13.10
Strain-Programmable Bioadhesive Hydrogels and Their Biomedical Applications HyunwooYuk; SanaHeal, Inc., United States

Stimuli-responsive hydrogels such as hydrogel actuators that change size and/or shape upon diverse stimuli (temperature, light, chemical gradient, swelling, electrical/magnetic field) have been widely studied in academic research. Despite their interesting nature and properties as a class of smart materials, their translational applications have been relatively unexplored due to various practical limitations. Recently, stimuli-responsive hydrogels combined with other functionalities have emerged to expand their potential utility in diverse applications. As one of the recent examples, in this talk, we will discuss strain-programmable bioadhesive hydrogels as a new class of fully programmable and bio-integrative smart material for biomedical applications. We will introduce the unique hydration-based shape memory mechanism of the strain-programmable bioadhesives from both experimental and theoretical perspectives. We will further introduce several translational biomedical applications of the strain-programmable bioadhesives for the control of swelling in implantable hydrogels, programmed mechanical modulation of biological tissues for accelerated wound healing, and bioadhesive integration of implantable devices. We will close this talk with future perspectives on the potential use of strain-programmed bioadhesive hydrogels as soft robotic materials for diverse biomedical applications where integration and programmed mechanical modulation of biological tissues can synergistically merge.

Computational Combustion Study of Reactive Metal Nanoparticles as Solid Additives PriyanshuLuhar[1], SujinKim[2], Hyung SubSim[2] and SungwookHong[1]; [1]California State University,

Bakersfield, United States; [2]Sejong University, Korea (the Republic of)

Energetic nanoparticles, those particularly including Ti-Al-Mg components, have attracted significant interest due to their potential applications in combustible fields. Ti-Al-Mg reactive materials typically consist of a mixture of titanium (Ti), aluminum (Al), and magnesium (Mg) in varying proportions. The combination of these elements offers a favorable balance between energy density and safety, making them suitable for a range of applications. Previous studies have explored the synthesis, characterization, and applications of Ti-Al-Mg reactive materials. For instance, Belal *et al.*[1] investigated the burning rate of mechanically activated Al-Mg composites. Their research highlighted mechanical activation of Al–Mg nanoparticles decreases the ignition temperature of the particles and enhances their reactivity. Furthermore, Kochetov and Sytschev[2] explored the influence of Mg content on the thermal properties and reactivity of Ti-Al-Mg composites. Their findings demonstrated that the interaction between Mg, Al and Ti can result in a lightweight composite suitable for applications at high temperatures, which is crucial for tailoring their performance in specific applications. While previous experimental studies have successfully investigated combustion performance of those reactive materials, molecular-level understanding of thermal behaviors of Ti-Al-Mg nanoparticles has yet to be achieved. Here we perform reactive molecular dynamics simulations based on ReaxFF[3,4] to investigate initial oxidation processes of three nanoparticles (Ti, Al, and Mg). Our RMD simulations reveal molecular-level reaction steps for the combustion process of the reactive nanoparticle with and without an aggregation effect. Our RMD simulations will help guide an experimental design of a novel metamaterial using Ti-Al-Mg composites, providing a valuable input for the community of solid-fuel propellants.

Reactive materials comprise particulate systems or multilayer materials consisting of two or more materials reacting with each other after they are ignited. The reaction initiation is possible using different sources of energy transfer, for example, an electric spark, laser pulse, mechanical forces or heating the whole system to a certain temperature. The reaction propagation velocity and the maximum reaction temperature in multilayer systems depend on the constituents in the bilayer stack and their thickness, as well as the heat transfer and loss conditions. In powder systems grain size and the thermal contact area are further parameters that allow tuning the reaction propagation velocity and the maximum reaction temperature. Typically, these two characteristic values are largely reduced in powder systems compared to compact bilayer systems. For the different application fields of the reactive materials, a well-designed reaction propagation velocity and maximum reaction temperature are of great importance. In this study, the tuning of the properties of the self-sustained reaction is studied theoretically by introducing a non-reactive material between two reactive material elements. For the study, the Ni/Al bilayer system was chosen. The Ni/Al elements were placed on a silicon wafer covered with 1 µm thick silicon dioxide. The spaces between the multilayer reactive material elements were filled with different non-reactive materials covering a wide range of thermal properties (SiO_2, Si_3N_4, AlN, Si, diamond). On top of this heterogeneous layer, a 1 µm thick sealing layer was placed consisting of the identical material or another material. The carried out two-dimensional simulations demonstrated that embedding material allows scaling the ignition transfer time and the heat propagation velocity to values in a wide range. For example, for a transfer length of 1 µm the ignition time can be designed from nanoseconds to several microseconds. Consequently, in contrast to previous results embedding materials allow scaling the properties of the self-sustained reaction in heterogeneous reactive material systems. A detailed analysis and comparison of the obtained results to experiments will be given.

Keywords: reactive multilayers; heterogeneous material, self-sustained reaction; nickel; aluminum; reaction propagation control; simulation

Al/Ni reactive multilayer system with a high exothermic reaction enthalpy as a heat source which is useful in low-temperature bonding and soldering in the packaging of microsystems applications. The phenomenon of a self-propagating reaction can be suspected that the released heat through the local mixing of multilayers is enough to heat the end-to-end material and induced a self-sustaining reaction front that transfers through the sample with a characteristic velocity and a specific temperature. The current study presents a unique opportunity to investigate the processes that control the reaction front velocity and emitted temperature by structuring the Al/Ni multilayers. The structuring of the Al/Ni multilayers by lithography is quite a challenging process. In the current study, we prepared structured 5 µm Al/Ni multilayers on the etched Si/SiO_2 substrates and intentionally created spaces between Al/Ni structures with different thermal properties. These structured Al/Ni multilayers have different spaces between different Al/Ni elements to observe the reaction front and emitted temperature from one element to another. A two-dimensional numerical model was also developed to study the effect of heat loss and thermal properties from the spaces on the Al/Ni self-propagating reaction path. The self-propagating reaction was initiated by an electrical spark on the surface of the Al/Ni multilayers. The reaction front was recorded with a high-speed camera. Activation energy is fitted with these velocity data from the high-speed camera to adjust the numerical model. The calculated reaction front temperature of the self-propagating reaction was compared with the temperature obtained by time-resolved pyrometer measurements. X-ray diffraction results confirmed that all reactants reacted and formed the AlNi phase. SEM analysis showed the morphological changes that occurred after the reaction on Al/Ni multilayers. Finally, it is predicted that: (I) The maximum spaces between the elements can stop the reaction front; (II) By reducing the heat loss through the substrate can propagate the reaction front through spaces; (III) Designing the thermal properties of the spaces between the reactive elements enables the modification of the properties of the self-propagating reaction.

Thermally Triggered Lubricating Ligands in Dynamic Nanocrystal Superstructures YifanNing[1], ShengsongYang[1], Yi-YuCai[1], JunXu[1], RuipengLi[2], YugangZhang[2], CherieR. Kagan[1] and Christopher B.Murray[1]; [1]University of Pennsylvania, United States; [2]Brookhaven National Laboratory, United States

The unique physics and applications of superlattices (SLs) have motivated the investigation of nanocrystal (NC) self-assembly as a promising synthetic method for mesoscale materials. However, assembled superstructures often lack dynamics due to the limited mobility of building units, restricting the potential for manufacture and post-treatment of high-quality NCSLs and narrowing the application in smart materials. Here we introduce a novel approach using a customized dendritic ligand that exhibits liquid crystal-like behavior to realize dynamic SLs. The ligands act as a thermally triggered lubricant between NCs and allow the substrate-bounded (dried) thin films to transform from poorly ordered aggregates to SLs with high crystallinity and

preferred orientation simultaneously when subjected to thermal activation. The dendritic structure of the ligand ensures excellent thermal stability of individual NCs at 90 °C over three days. A connection between the dynamics of SLs and the molecular properties of the ligands is established through a systematic analysis comparing ligands with varying components, softness, and functionalities. The design, kinetics, and application of lubricating promesogenic-ligands can be generalized to pave the way for unlocking more stimuli-responsive mesoscale metamaterials from NCSLs.

8:40 AM SF02/SF03/SF04/SF06/SF07.05
Real-Time *In-Situ* Characterization and Monitoring of Liquid-Phase Nanoparticle Exfoliation using Ultrasonic Spectral AnalysisKigoziMusazi[1], ZheChen[2], SarojPramanik[1], HertantoAdidharma[2], MaohongFan[2] and YuchengLan[1]; [1]Morgan State University, United States; [2]University of Wyoming, United States

Nanomaterials are playing crucial roles in various fields such as renewable energy, energy storage, and sensors. Liquid-phase exfoliation is an effective and cost-efficient method for producing large quantities of nanoparticles in laboratory settings. However, it is challenging for controlling and determining the exfoliation procedures. In this study, we present an innovative platform for the digitization and frequency spectral analysis of ultrasonication data, focusing on the ultrasonic waveforms emitted during the exfoliation process. The platform integrates an ultrasonic receiver, computer-based signal analysis and filtering components, besides ultrasonication sources, to capture and analyze the unique characteristics of the ultrasonic spectrum. We demonstrate the real-time in-situ detection of nanoparticle information, including size and morphology, through frequency spectral differences and bandwidth analysis. By leveraging machine learning techniques, we aim to monitor and optimize the liquid-phase exfoliation procedure based on the characterization of nanoparticles using ultrasonic characteristics, enabling significant time savings and improving exfoliation efficiency through the implementation of artificial intelligence in the control and optimization of nanoparticle production.

Deposition of Double-Layered TiO_2 Thin Films with Porosity-Dependent Photoelectrochemical Activity TimurAtabaev, KuralayRustembekkyzy and AmirZholdasbekov; Nazarbayev University, Kazakhstan

Porous TiO_2 thin films with a double-layered structure were successfully prepared using a conventional spin-coating deposition method. A range of characterization techniques, such as scanning electron microscopy, X-ray diffraction, X-ray photoelectron spectroscopy, and photoluminescence were employed to assess the morphology, structural and optical properties of prepared TiO_2 films. Photoelectrochemical (PEC) measurement tests revealed that prepared double-layered TiO_2 thin films exhibit porosity-dependent photocatalytic activity. For example, TiO_2 films with optimized porous structure demonstrated an increase in photocurrent density by a factor of ~ 2.23 (to 141.7 μA cm^{-2}) and photoconversion efficiency improvement by a factor of ~ 2.14 as compared to non-porous double-layered TiO_2 reference films. Possible mechanisms responsible for these experimental observations are proposed, discussed, and validated experimentally.

8:50 AM SF02/SF03/SF04/SF06/SF07.07
Remarkably Durable Silver Finish with Exceptional Wear and Fretting Corrosion Resistance for Electronic Interconnections BenjaminSteimle, JamieChen, MiguelRodriguez, MargitClauss, PatriciaTaintor and KristenGriffin; DuPont, United States

To maintain signal and power reliability, next-generation automotive, telecommunications, aerospace, and other high-performance applications require electronic connectors with metal contact finishes that provide higher conductivity, higher durability & lower coefficient of friction (CoF). These interconnections must survive the routine mechanical wear, environmental corrosion, and high temperatures they are subjected to through assembly and operation. As a result, metal contact finishes must withstand rigorous performance evaluation and qualification prior to their widespread adoption in next-generation electronics. One critical performance test evaluates the wear and fretting corrosion of two surfaces in direct contact. This test simulates a high vibration environment using low-amplitude linear reciprocating motion at high frequency for tens of thousands of cycles to induce slip between metal contacts. Any resulting damage of surface finishes through physical wear or oxidation may cause failures that impact connector performance, including reusability and electrical conductivity.
Here, we present a unique electrodeposited high durability silver finish that maintains exceptional wear performance and electrical conductivity during fretting corrosion tests. Our novel silver finish outperforms current industry-standard connector finishes across a range of operating conditions relevant to automotive, telecommunication, and industrial applications. Unlike traditional silver finishes that require external lubrication to mitigate their propensity to cold-weld, our unique deposit does not require external lubrication. We show that our high durability silver is resistant to cold-welding and wear at increasingly harsh fretting test parameters, thereby preventing a common failure mode of existing connectors where nickel or copper underlayers are exposed and corrode to form insulating oxides. Resistance to fretting corrosion is necessary as electronic connector application requirements shift towards increased voltage, service lifetime, and interconnection reliability. Further, improved durability in electrically conductive finishes enables innovation in connector design and electronic system architecture.

9:05 AM SF02/SF03/SF04/SF06/SF07.08
Synthesis and Photovoltaic Characterization of Layered Hydroxide Nanomaterials via Atmospheric DC Micro-Plasma Techniques GraceFarrell[1], SarojPramanik[1], WillieRockward[1], GregorySevern[2] and YuchengLan[1]; [1]Morgan State University, United States; [2]University of San Diego, United States

Layered hydroxide nanomaterials have gained significant attention as promising renewable energy materials. In this study, we systematically synthesized period 4 transition metal hydroxide nanomaterials, including cobalt (Co), nickel (Ni), copper (Cu), and zinc (Zn) hydroxides, in aqueous solutions using DC micro-plasma techniques. The synthesis was conducted at room temperature under atmospheric pressures. The crystallinity of the synthesized nanomaterials was evaluated using X-ray diffraction and electron diffraction, while Raman scattering was employed to analyze their chemical bonding. Optical properties were characterized using UV-vis spectroscopy, and morphology was examined through electron microscopy analyses. To assess their applicability in solar energy conversion, the nanomaterials were fabricated into dye-sensitized solar cells (DSSCs), and their photovoltaic behaviors were measured. We also investigated the influence of atomic radius and electron negativity on the morphology, microstructure, optical properties, and photovoltaic performance of the nanomaterials. Furthermore, we studied the plasma reaction occurring at the gas-liquid interfaces during synthesis. The results demonstrate that these plasma-produced hydroxide materials can generate carbon-free renewable energy from solar sources.

9:10 AM SF02/SF03/SF04/SF06/SF07.09
From Transparent to Black Amorphous Zinc Oxide Thin Films through Oxygen Deficiency Control MagdalenaNistor[1], FlorinGherendi[1], DanielaDobrin[1] and JacquesPerrière[2,3]; [1]NILPRP - National Institute for Laser, Plasma and Radiation Physics, Romania; [2]Sorbonne Universités, France; [3]CNRS, France

Zinc oxide (ZnO) is a well-known n-type transparent conducting oxide that has attracted substantial research for photovoltaic and optoelectronic applications. While transparent and crystalline zinc oxide films are currently obtained by a wide variety of growth methods, black and amorphous zinc oxide films are not currently investigated although several recent studies on black zinc oxide have renewed its potential for photocatalytic applications. Among plasma-based techniques, pulsed electron beam deposition (PED) is a versatile technique for the growth of oxide thin films for applications in transparent electronics and photovoltaics [1].
We report on the tunability of oxygen deficiency in ZnO thin films grown at 300 °C on c-cut sapphire single-crystal substrates by PED through a slight variation in the argon pressure. At a pressure of 2 10^{-2} mbar transparent, stoichiometric and crystalline films ZnO were obtained, whereas at 9 10^{-3} mbar black and amorphous films with about 15% oxygen deficiency resulted. The composition, structural, electrical and optical properties of transparent and black ZnO thin films were comparatively investigated as a function of oxygen deficiency. Both films exhibit structural disorder (amorphous vs. polycrystalline) and a high carrier density, leading to a temperature-dependent resistivity behaviour specific to disordered metal oxide systems, which can be explained either by transport models of metallic conductivity and quantum corrections to conductivity or by the Mott variable range hopping model. The low mobility value of black and amorphous zinc oxide thin films could be due to both structural disorder and the presence of Zn clusters in the films. The stoichiometric films are transparent, as expected for zinc oxide, while the black films exhibit enhanced absorption in the visible and near-infrared due to oxygen deficiency, thus extending the range of applications of zinc oxide thin films from transparent electronics to solar absorbers and photocatalysis. 9:25 AM SF02/SF03/SF04/SF06/SF07.10
Flexible Laser-Induced Graphene Sensors for Next-Generation Soft Grippers Anna ChiaraBressi[1,1], AlexanderDallinger[2], GiovannaDe Luca[1,1], MatteoCianchetti[1,1] and FrancescoGreco[1,2,1]; [1]Scuola Superiore Sant'Anna, Italy; [2]Graz University of Technology, Austria

Laser Induced Graphene (LIG) is a three-dimensional carbon-based nanomaterial fabricated with single-step local pyrolysis. Commercial IR laser engravers are exploited to scribe conductive patterns onto different polymeric precursors without the use of chemicals or masks. LIG applications span different fields, including soft electronics, robotics and wearable electronics.[1–3] In the domain of soft robotics, robotic systems are designed and realized with flexible materials and structures. Therefore, it becomes crucial to incorporate soft and flexible sensors to adapt and conform to the deformable nature of the robots. Within this context, we propose the sensorization of a soft gripper with piezoresistive LIG tracks.
Soft grippers come in a variety of shapes, dimensions, and actuation mechanisms, tailored to the specific application and the properties of the objects to be grabbed. [4] To ensure secure and delicate grasping, the grippers must be designed with closed-loop control on deformation and force applied during the interaction with the target. Moreover, continuous feedback is a key aspect to allow for precise monitoring and adaptive real-time adjustment of the position.
This project aims to develop a novel method for extracting parameters from a finger-based pneumatic gripper, associated with its bending angle and contact pressure. Piezoresistive LIG

sensors have been scribed from polyimide with a CO_2 IR laser and then either embedded within the robot's soft materials or attached externally. Additionally, attention has been given to addressing stiffness mismatch between the sensor and the soft gripper and to ensuring robust integration in the device, to avoid causing interference during data collection. A comprehensive investigation has been conducted on the LIG materials to evaluate the influence of laser-scribing settings and track designs on the gauge factor of the sensors.
This study lays the foundation for future research and optimization of this promising solution, which combines lightness and flexibility with a cost-effective, simple and rapid fabrication process.

9:30 AM SF02/SF03/SF04/SF06/SF07.11
Designing Smart Metamaterials as Versatile Actuators by Halftone-Assisted Photo-Stereolithography ZhongkunZhao and HongtaoSun; Penn State University, United States

Metamaterials have gained significant attention in the field of structural engineering due to their unique mechanical characteristics and exceptional material properties arising from their structures. These metamaterials offer extraordinary opportunities for customizing overall physical characteristics, such as electromagnetic, acoustic, mechanical, and thermal properties, through the design and organization of their architectures.[1-6] Extensive research has been conducted to fabricate metamaterial as passive structures after manufacturing. To explore additional control over the metamaterials, the incorporation of intelligent materials, such as shape memory polymers (SMPs), into three-dimensional (3D) architectures holds promise for creating innovative multifunctional smart architectures with controlled responsive behaviors.
In this study, we introduced a photo-stereolithography-enabled 3D printing technique to fabricate two-dimensional (2D) or three-dimensional (3D) SMP metamaterials. These printed meta-structures can function as stimulus-responsive actuators, offering geometrically reconfigurable, functionally deployable, and tunable mechanical characteristics. With their unique reversible effects on highly deformable behaviors, SMP meta-structured actuators can be bent, compressed, stretched and twisted, enabling to store/release mechanical energies in different forms upon thermal responsive stimuli. By manipulating printing parameters such as exposure time, light intensity, printing layer thickness, significant changes in mechanical properties, including Young's modulus and toughness can be achieved, resulting in a wide variation in mechanical energy and responsive behaviors.
To explore versatile actuation behaviors within a single SMP metamaterial, we developed a halftone-assisted photo-stereolithography technique. This approach involves designing and encoding halftone patterns into metamaterials during the printing process to spatially control localized mechanical properties through tunable UV curing. This enables regulation of overall mechanical properties and stimuli-responsive behaviors. For instance, by incorporating various halftone patterns with controlled area percentage of curable pixels at specific triple intersections of re-entrant auxetic metamaterials, we can achieve versatile deformations, such as elongation ranging from 10% to 50% of the original length, and lifting loads 16-fold to 83-fold higher than their weight. Designing various halftone patterns in specific sites offers a new strategy to manipulate mechanical characteristics and stimulus-responsive behaviors within a single smart metamaterial, demonstrating great potential for multifunctional actuators.
In summary, our research demonstrates the fabrication of SMP metamaterials through a halftone 3D printing technique, providing stimuli-responsive actuators with tunable mechanical characteristics. The incorporation of halftone patterns offers precise control over localized properties, enabling versatile deformations and expanded functionality within a single metamaterial. This work contributes to the advancement of intelligent materials and their application in the development of multifunctional actuators.

Numerical Model to Predict The Electrical and Mechanical Behavior of Origami-Inspired Morphing Wing Actuator HannahNabavi, Jeong-HoLee and GraceGu; University of California, Berkeley, United States

The realization of flapping wings has been critical to the advancement of micro-aerial vehicles, accelerating aerospace and military applications. While flapping wings have been thoroughly studied in the literature, numerous models utilize mechanical power transmission systems that convolute wing motion, contributing added weight and increasing wear susceptibility. Piezoelectric materials exhibit unique bending characteristics that allow for prompt mechanical strains in response to an electrical potential. With their distinctive morphological properties, piezoelectric actuators are prime candidates for micro-aerial vehicles, providing enhanced sensitivity and lightweightness to flapping wings. Understanding their electrical and mechanical properties is critical to the design of small-scale wing systems.

In this research, we aim to predict the electrical and mechanical behavior of piezoelectric morphing wing actuators for micro-aerial vehicle applications. A numerical model of a piezoelectric tri-layer thin plate was constructed in a finite element toolbox. The mechanical tip displacement was investigated under an applied deformation-inducing electric field, and the Timoshenko-Ehrenfest beam theory was applied to mathematically validate the spatial displacement of the wing deformation. Origami folding methods were explored to inform future geometrical refinements that could facilitate enhanced wing motion performance.

Through this research, the approach illustrates the development of an accurate numerical model for a piezoelectric actuator system, which will be utilized in the wing structure optimization in future research. A physical wing prototype will be designed to confirm experimental validity. Moreover, the piezoelectric system will continue to be optimized to leverage origami-induced programmable surfaces, allowing for increased dimensionality and tunability for piezoelectric morphing wings. This work will open up new areas of study in flapping wing actuators and lay the groundwork for origami-inspired piezoelectric structural analysis to be completed in the future.

9:40 AM SF02/SF03/SF04/SF06/SF07.13
Photo-Stereolithography-Regulated Heterogeneity Domains in Fiber-Shaped Micromotors for Tunable Responsive Behaviors ZhongkunZhao and HongtaoSun; Penn State University, United States

Intelligent materials enable sensing and adaptive responses to various external stimuli. These active materials find applications in diverse fields such as soft robotics, actuators, biomedical devices, and sensors.[1-7] Among these smart materials, Shape Memory Polymers (SMPs) have shown promise as stimuli-responsive materials with distinctive reversible effects on highly deformable behaviors.[8-10] However, achieving precise control over responsive behaviors while concurrently modulating the mechanical properties remains a significant challenge. To address this challenge, we present a grayscale lithography-enabled printing process for fabricating fiber-based rotating micromotors using SMPs.
Our approach involves spatially manipulating the gradient and orientation of heterogeneity domains within our fiber-shaped SMP actuators through photo-polymerization. Compared to conventional layer-by-layer 3D printing of homogeneous fibers for the control over geometry only, our approach enables extensive tunability of crucial material and performance characteristics. This includes precis control over Young's modulus (ranging from 265 to 1208 MPa), thermal stimuli-responsive behaviors (with a maximum rotation rate varying from 169 to 441 rpm), and torsional mechanical energy (with stored energy ranging from 19 to 69 J kg^{-1}, and released energy from 3.9 to 9.5 J kg^{-1}). By incorporating stiff and soft domains with varying curing time, we engineered various interfaces into our fiber-shaped actuators, thus manipulating the stimuli-responsive performance. We also observed that the orientation of the heterogeneity domains played a significant role in the rotation performance of the fiber-shaped motor. More interestingly, introduction of a stiffness gradient through spatial heterogeneity designs between the stiffest and softest domains, enables the highest maximum rotation rate of 441 rpm. This improvement is attributed to the gradient feature between the stiff and soft domains, which synergizes the complementary properties between neighboring domains, which synergizes their complementary properties.
Furthermore, by controlling the size of heterogeneity domains, we can further tune overall material properties and performance. To gain insights into the underlying mechanism, we conducted a detailed analysis of localized mechanical behaviors in the SMPs using digital imaging correlation (DIC) methodology. This allows us to differentiate the heterogeneous properties and interfaces within the material and observe the strain variations in different regions. The localized stress-strain curves derived from the DIC analysis confirm the encoded modulus gradient within the heterogeneity domains, aligning with our design principles.
In summary, our approach of incorporating heterogeneity domains and interfaces, presents a novel method for the design and fabrication of smart materials and actuators with regulated performance. These findings hold significant implications for the advancement of intelligent materials and offer potential applications across various domains.

Developing 3D-Printable, Reactively-Formed Electrical Conductors ShaneQ. Arlington[1,2]; [1]Charles Stark Draper Laboratory, United States; [2]Johns Hopkins University, United States

Self-propagating high-temperature synthesis (SHS) in macroscale structures is an effective method of creating high-temperature materials directly. In nanostructured, micro-scale materials, SHS has been thoroughly explored for rapid liberation of heat, where short diffusion length-scales enable very low ignition thresholds. For instance, materials such as Al/Ni multilayers have been demonstrated to be extremely versatile micro-heat sources to enable *in situ* bonding, sealing, and ignition of additional energetic materials to name a few applications. As presented at previous meetings, Draper has developed a platform which harnesses both these aspects of SHS – using SHS to form a conductive, high-temperature, carbide, and harnessing the reaction heat to reflow a highly electrically-conductive matrix phase. Together, this enables the production of 3D-printed electrical conductors *in situ*. In this talk, we summarize the process by which material systems were considered, discarded, and selected; the development and fine-tuning of our reactive particles; and the ultimate performance (and limitations) of the final materials. We will delve into the serendipity of how an erroneous phase diagram played a crucial role in our development process, and the years-long, multi-continent process it took to uncover the flaw. Finally, we will cover future applications and pathways, both at Draper and beyond.

11:00 AM SF07.01.02
Curing Reactive Silver Ink using Intense Pulsed Light MorganMichael[1,2,3], AdriaKajenski[1,2,3], GuinevereStrack[1,2,3] and AlkimAkyurtlu[1,2,3]; [1]University of Massachusetts Lowell, United States; [2]Printed Electronics Research Collaborative, United States; [3]Raytheon UMass Lowell Research Institute, United States

Additive manufacturing (AM) covers a variety of techniques used to build up materials layer by layer. Direct ink writing is an AM technique used to selectively dispense the material directly onto a flexible substrate with high accuracy and precision. This technique enables rapid prototyping and produces low volumes of waste products. Materials used in AM are tailored for their respective printing methods and for targeted mechanical or electrical properties, ranging from dielectric materials for coatings to resistive inks for printed resistors and nanoparticle dispersion inks for conductive patterning. Reactive particle free inks are a competitive alternative to NP-based inks which provide numerous advantages. For example, the formation of continuous films vs. conductive barriers between nanoparticles can yield higher conductivities, while providing the capability of in-situ curing. In this work, we used a silver reactive ink, based on a silver complex, which upon curing, dissociates to silver ions that are subsequently reduced in situ by reducing agents in the solvent system.
Many inks used in AM require a curing step to initiate chemical reactions, drive off solvents, or sinter together nanoparticles. Photonic curing with IPL (Intense Pulsed Light) is a curing method that operates on the millisecond time scale, significantly reducing the overall manufacturing time and energy expenditure. This curing method is typically used to heat printed films of metallic nanoparticle inks that exhibit rapid thermal changes that can exceed the melting temperature of the nanoparticles. The application of IPL to liquid phase reactive inks is associated with silver (I) complex degradation and reduction, and eventually local heating once phase separation (nanoparticle formation) occurs. Photonic curing on Kapton and polyurethane (PU) coated nylon resulted in resistivity values as low as 6 and 12 μΩ cm, respectively. On average, photonically cured samples were 30% less conductive than samples cured thermally in a box oven. The utility of the ink was demonstrated by printing and photonically curing simple RF devices. Device functionality was assessed with measured scattering parameters that matched simulations.

11:15 AM SF07.01.03
Developing a High-Energetic and Fast-Response Ignitor by Integrating Reactive Inks on Semiconductor Bridges TaoWu, Maria-IsabelMendoza-Diaz, AlainEsteve and CaroleRossi; LAAS-CNRS, France

Due to the growing appetite for developing compatible miniaturized micropyrotechnics systems, the traditionally used electro-pyrotechnic initiators have been upgraded from a bridge wire to a semiconductor bridge (SCB) *via* microelectromechanical systems (MEMS) technology. As an innovative ignition device, SCB can generate heat and plasma upon an electrical input. With its superior properties in the ignition, such as rapid response, low energy input, and high degree of integration, SCB has been largely employed in various civilian and military applications. For the purpose of successful ignition, energetic nanothermites have been integrated into SCB (ESCB) based ignitors in order to enhance the energy output and flame size. Nanothermite reactions refer to a redox reaction between a physically mixed metal fuel and solid metal oxides and have been substantially studied due to their high energy densities, greater stabilities, and also high tunability in terms of particle size, composite composition, stoichiometry, and packing. Over the years, reactive multilayer films (RMF), mostly Al/CuO nanolaminates, have been integrated into microchip ignitors and achieved ignition in a time scale of μs with energy input as low as several watts. However, the fabrication process (mostly magnetron sputtering) of such RMFs suffers from drawbacks like low sample loading, long process time, delamination due to thermal shocks, etc, which limits the industrial application of ESCB. Thus, an alternative method is urgently needed to develop by withholding the advantages and discarding the disadvantages of RMF materials in ESCB-based ignitors. In the last decade, direct ink writing has gained much attention due to its facile manipulation, high adaptability, and scalability as well as tunability.
In this work, for the first time, we combined the direct ink writing technique and ECB chip to fabricate a novel ESCB ignitor that features better ignition performance than traditional ignitors but with much less cost in time and goods. Briefly, a 5×5 mm^2 sized SCB-based ignition chip with gold contact pads and titanium resistance is fabricated using a series of photolithography/lift-off processes and magnetron sputtering. Then a 250 μm high peripherical container was fabricated on top of the chip by lamination and photolithography processes and is

designed to controllably store the printed energetic materials. Moreover, the ignition behavior of such an ignitor can be easily tuned by changing the fuel/oxidizer/binder constituents to apply in different scenarios.

11:30 AM SF07.01.04
Recycling Iron Power as an Energy Carrier: Investigating Material Properties Through Cycles of Combustion and Reduction GiuliaFinotello, NicoleStevens and NielsDeen; Eindhoven University of Technology, Netherlands

The world's energy system is transforming from a fossil fuel-based energy infrastructure to a society supported by sustainable energy sources, like solar and wind energy. The production of sustainable energy is quite intermittent, causing a great demand for additional capacity of local energy storage. We propose a low-cost alternative for high density energy storage: iron powder. Recently iron powder has been proposed as an energy carrier for its high energy density, ease to be stored, and for its fully CO2-free combustion process. Renewable electricity can be used to reduce iron oxide powder into iron, which can be densely stored under ambient conditions and combusted whenever and wherever energy is needed, providing fully renewable heat. This research determines the potential of the entire iron fuel cycle, in terms of the material properties.
Iron oxide powder is combusted and reduced over 6 cycles, where each partial cycle had the same conditions. Reduction experiments are performed inside a lab-scale reactor using a hydrogen flow at elevated temperatures of 400 to 600 °C. High temperatures are beneficial from a kinetic point of view. However, previous studies showed de-fluidization due to sticking of the powder above 600 °C. The reactor and heating furnace are designed for a full control of operating conditions. The powder is assessed in terms of particle size, morphology, porosity, composition and reduction degree after each partial cycle. We observe that the particle size distribution shifts to larger size already after the first combustion process. Nevertheless, the size distribution remains approximately the same over multiple cycles. This indicates that the powder can be used in the cyclic process without intermediate treatments (e.g sieving).
A trade-off between a high reduction degree and absence of solid sticking behavior is identified at the temperature of 590 °C. The results of the XRD show that reduction conversion to iron is larger than 80% for each cycle. Sticking is observed in the powder after combustion, which is assumed to take place within the collection part of the process.The losses due to the handling of the powder through each step of the cycle is negligible. Iron powder is therefore a good candidate to be used as energy carrier in the iron fuel cycle.

11:45 AM SF07.01.05
Diborane Generation from Sodium Borohydride using Ionic Liquids for Air Breathing Propulsion Applications Ashvin KumarVasudevan, PrithwishBiswas, YujieWang and MichaelR. Zachariah; University of California, Riverside, United States

Sodium borohydride is a potential fuel source for air-breathing propulsion applications. However, sodium borohydride by itself is stable in air and primarily releases hydrogen on heating. Literature work suggests that a strong Lewis acid such as boron trifluoride (BF_3) is required to initiate decomposition into diborane and sodium tetrafluoroborate. Our current study shows that ionic liquids such as 1-Ethyl-3-methylimidazolium tetrafluoroborate, (EMIM BF_4) can act as good sources of BF_3 and bring about complete decomposition forming sodium fluoride and diborane. Accordingly, a molar ratio of 3:1 ($NaBH_4$: EMIM BF_4) is stoichiometric for complete conversion to sodium fluoride and diborane. Ignition of the mixture shows rapid reaction of diborane with air. Successful combustion even at low amounts of ionic liquid indicates a unique decomposition mechanism initiated by BF_3.
Analysis of evolved products using T-jump time of flight mass spectrometry shows consistent amounts of diborane release at all molar ratios tested. When very low amounts of ionic liquid (molar ratio 16:1) are used, diborane is accompanied by hydrogen evolved from excess unreacted sodium borohydride. The solid products comprise mostly sodium fluoride with some traces of sodium tetrafluoroborate as seen by XRD. Mass losses observed in the TGA further suggest complete conversion to diborane and sodium fluoride at all molar ratios. Analysis of the gaseous and solid products alongside combustion results with 3d printed samples to describe the flame propagation will be presented and a mechanism specific to sodium borohydride decomposition in ionic liquids will be discussed.
The use of thermally stable ionic liquids provides a unique avenue for generating diborane from borohydrides which can be incorporated to make air breathing propellants which have low ignition temperatures. Early results with potassium borohydride show that similar decomposition mechanisms are possible in other alkali borohydrides. Further work is needed to explore the potential of various hydrides and borohydrides for air breathing propulsion.

SESSION SF07.02: Simulations of Reactive and Energetic Materials
Session Chairs: Michael Abere and Jennifer Gottfried
Monday Afternoon, November27, 2023
Sheraton, Second Floor, Independence West

1:30 PM *SF07.02.01
Atomistic Simulations of Reactive Materials: Role of Microstructure and Defects Coupling Mechanics and Chemistry AlejandroStrachan; Purdue University, United States

Micro-, nano-structure, and defects play a dominant role in the kinetics and thermodynamics of reactive materials. This presentation will discuss molecular dynamics simulations of the chemical reactions of nanostructured Ni/Al and thermites subjected to thermal and dynamic mechanical loads. The simulations provide insight into the mechanisms through which convective transport accelerates intermixing and, consequently, exothermic chemistry. These mechanisms are controlled by the thermo-mechanical properties of the constituents (e.g. flow stress and melting temperature). The simulations will be contrasted to various experiments and the implications of accelerated chemistry for various applications will be discussed.

2:00 PM SF07.02.02
Fundamental Measurements of Plasticity in Energetic Molecular Crystals DavidF. Bahr and HughP. Grennan; Purdue University, United States

Plastic flow in crystalline solids most often occurs from the motion of dislocations. Accommodating general plasticity requires multiple slip systems, the ability to make new dislocations, and the existence of local stresses sufficient to move said dislocations. While the vast majority of plasticity studies are in atomic or ionic systems, the complex bonding in molecular crystals (exhibited by both pharmaceutical and energetic systems) opens up spaces in materials where it may be hard to make but easy to move, or hard to move and easy to make, the defects needed to accommodate plasticity. In this current study we examine the onset of plasticity in as-grown powder form (sub-mm) crystals and the hardness of these materials once plastic flow has been established using nanoindentation techniques. In systems ranging from RDX and HMX to PETN and CL-20 we find that the yield point phenomena appears when the maximum applied shear stress reaches between 2-7% of the elastic modulus of the material. The activation volume implied from a cumulative event analysis of approximately 20 yield-exhibiting indentations in each material is on the order of the molecular volume, but does not directly correspond to that across a broad range of space groups, suggesting that the process of nucleating dislocations in, in these molecular solids, more complicated than the atomistic processes often found in metallic or ionic systems. The hardness of these materials does not correlate well with the yield conditions, again showing the independence of the nucleation event and the subsequent mobility of the dislocations in crystals of limited slip condition. Finally, data where growth conditions were varied to create crystals of varying quality exhibited the same nominal activation volume, the same overall hardness, but different mean values for the yield point stresses, suggesting that the activation of plasticity processes in energetic molecular crystals can be directly correlated to defect density and these defects are not solely controlling the subsequent dislocation motion.

2:15 PM SF07.02.03
Multiscale Simulations of Non-Equilibrium Response in Determining Orientation-Dependent Property, Performance and Sensitivity of Faceted Molecular Crystals JankiBrahmbhatt and SantanuChaudhuri; University of Illinois at Chicago, United States

Energetic materials (EMs) are a subset of molecular crystals that serve a wide range of purposes. Given the nature of energetic materials, understanding how interfacial interactions contribute to overall crystal nucleation/growth with preference for certain facets, molecular packing, shock sensitivity, and material stability is crucial. EMs are often formulated as composites with polymeric binders and plasticizers to increase their stability and transportability. Despite the fact that the polymer/plasticizer matrix usually makes up about 7-8% of the total volume, the strength of adhesion between the polymer/plasticizer and the EM is an important consideration when formulating PBXs as incompatible formulations have an adverse effect on material performance—both in regard to shelf life and the possibility of unplanned detonation. Accurately modeling the degradation and delamination at binder-crystal interfaces facilitates mesoscale modeling of crystal behavior. At its core, adhesion is related to the free energies of the materials, but given the highly facetted nature of EM powders, pressing them into PBX composites results in irregular shapes with voids. Interfaces present in such composites play an outsized—though often difficult to quantify—role in controlling their properties, performance, and failure. At present, the adhesion between an EM and a polymer/plasticizer is primarily determined using cohesive models which notably lack orientation-dependent insight. However, for highly facetted molecular crystals, effectively understanding the interfacial adhesion requires examining the diverse interfacial molecular configurations. Experimentally, the work of adhesion can be indirectly calculated from the interfacial tension via various techniques, but they provide limited insight into the chemical interactions at the interface.

The prediction and modeling of these properties necessitates a systematic approach to quantify the Gibbs Free Energy at surfaces. Mesoscale models stand to benefit from atomic-scale insight

into interfacial phenomena. The surface free energy (SFE) provides vital insights into the mesoscale interfaces in granular composites often containing defects. The SFE allows us to predict theoretical crystal shape using Wulff Construction and the diversity of bonding environment in energetic crystals. Additionally, at interfaces, the SFE can be used as a metric to indirectly determine the compatibility between the EM and polymer. We have developed nonequilibrium methods to quantify the surface energy, SFE, and entropy for HMX. We contextualize these values in terms of strength of adhesion between HMX-Polymer (HTPB)/plasticizer (DOA). We will discuss the differences in bonding strengths for different HMX facets with HTPB, DOA, and a mixture of HTPB-DOA based on steered molecular dynamics simulations. HTPB appears to bond more strongly to some facets than others, and we will discuss the drastic differences in the work of adhesion between HMX facets, and how the addition of a polymer/plasticizer affects the shock initiation and reaction chemistry.

This knowledge from atomic-scale reactive molecular dynamics simulations allows us to examine the interfacial bonding environment in detail and can lead to better continuum models and better engineered stable crystal interfaces and PBX composites.

2:30 PM SF07.02.04
Plasticity in Energetic Molecular Crystal HMX: Physical Aspects and Constitutive Modeling ZhaochengZhang and CatalinR. Picu; Rensselaer Polytechnic Institute, United States

Plastic deformation plays a key role in the initiation of energetic materials at impact velocities below the hydrodynamic limit. However, the mechanisms of plasticity in low symmetry molecular crystals are much less studied than those governing the plasticity of monatomic crystals. In this work we investigate the physical basis of plastic deformation in HMX and develop mechanism-based constitutive models which are calibrated based on molecular simulations. The talk will outline several aspects of the physics of plastic deformation, including the mechanisms causing strain rate sensitivity, the pressure sensitivity and the mechanism of strain hardening. A constitutive model that accounts for this physics and which can be used in continuum simulations of shock and initiation will be introduced.

3:15 PM *SF07.03.01
***In Situ* Characterization of Ultrafast Reaction Dynamics in Energetic Materials**KatharineTibbetts; Virginia Commonwealth University, United States

Ignition of reactive materials initiates reactions on atomic length scales within femtoseconds, making these reactions difficult to capture experimentally. This presentation will discuss insights gained into sub-picosecond reaction dynamics of ionized energetic molecules using the technique of femtosecond time-resolved mass spectrometry (FTRMS). FTRMS is an optical pump-probe technique that can capture molecular rearrangement and bond-breaking events with sub-50 femtosecond resolution. Coupled with quantum chemical and molecular dynamics computations, FTRMS enables direct observation of initial reaction dynamics that contribute to ignition of reactive materials. Recent FTRMS results on isolated nitro-organic molecules and laser ablation methods to extend FTRMS measurements to molecular clusters and solids will be presented.

3:45 PM SF07.03.02
Investigating the Combustion Behavior of Reactive Composites with High-Speed Videography: Role of Heat Feedback YujieWang and Michael R. Zachariah; University of California Riverside, United States

Aluminum (Al) has been used as the primary fuel in solid rocket propellant due to its ready availability and high enthalpy. Al nanoparticles provide a greater energy release rate and a lower ignition temperature compared to conventional Al microparticles. However, the nanostructure of Al nanoparticles usually deteriorates quickly before and during combustion because of reactive sintering and agglomeration within the combustion process. Consequently, the effective size of aluminum particles increases during combustion. This phenomenon can have a significant impact on the combustion performance of the propellant. In this study, we use high-speed videography to study the effect of Al sintering and heat feedback on the combustion behavior of the high-loading energetic composite. We observe from microscopic imaging that for the composites of Al nanoparticles and ammonia perchlorate with different equivalence ratios, dramatically larger droplets are formed for equivalence ratio of 2 than equivalence ratio of 1. One expects that the burn rate of equivalence ratio of 2 should be lower than equivalence ratio of 1 due to its lower energy density. However, burn rate obtained from macroscopic imaging show that the burn rate of equivalence ratio of 2 is higher than equivalence ratio of 1. Analysis of agglomerate residence time indicates that droplets with an equivalence ratio of 2 have considerably longer residence times on the burning surface than equivalence ratio of 1. This phenomenon leads to a significantly greater heat feedback to the unburnt propellant, unexpectedly resulting in a higher burn rate compared to an equivalence ratio of 1. This result motivates us to explore methods for manipulating heat feedback. Silicon (Si) nanoparticles are added to the Al and potassium perchlorate composites. It is found that the size of agglomeration has minimal change when Si is added. However, the residence time is increased with Si addition, leading to a higher heat feedback to the unburnt composite. Consequently, the composite with Si has higher burn rate than the composite without Si. This study illustrates that it is possible to control the burn rate of an energetic composite by manipulating the heat feedback.

Revealing the Dynamics of Reactive Materials with Ultrafast Transmission Electron Microscopy VolkanOrtalan; University of Connecticut, United States

Recent developments in instrumentation have made it a very exciting time to perform both fundamental and applied research in the electron microscope. The development of nanosecond and faster photoemission electron sources offers the chance to move the high spatial resolution world of electron microscopy into the ultrafast world of materials dynamics. Reactive materials are known to release large amount of heat via rapid exothermic chemical reactions upon receiving an initiating energy input. Due to relatively fast propagating reaction fronts, Ultrafast Transmission Electron Microscopy (UTEM) has immense potential in discovering the fundamental processes leading to reaction initiation and evolution in reactive materials. In the UTEM, while samples are excited with a nanosecond pulsed laser to trigger reactions via photothermal processes, a second pulse with a known time delay is used to stimulate the photoemission of electrons from the cathode. This single-shot approach makes it possible to capture various stages of irreversible processes with high temporal resolution and understand how a dynamic process evolves in reactive materials. In this presentation, examples of single-shot UTEM studies of reactive materials will be presented. Short-lived transient processes involved in reactions and the evolution dynamics will be discussed to obtain new insights into the reaction processes.

4:15 PM SF07.03.04
Direct Imaging and Simulation of the Interface Reaction of Metal/Metal Oxide Nanoparticle Laminates HaiyangWang, PrithwishBiswas, MichaelR. Zachariah and YujieWang; University of California, Riverside, United States

One of the difficulties in understanding how powder composites of reactive fuel/oxidizer systems behave is the lack of control of the mixing length. In this study, we have prepared Al/CuO particle laminates using a direct writing approach. With as little as 10 wt% polymers we were able to obtain free-standing microscale particle-based laminates. Using these composites, we were able to image the cross-section of the laminates to directly probe the interface reaction with high-speed microscopic imaging and pyrometry. We show quantitatively how the burn rate can be altered by changing the layer thicknesses of the printed laminates and under high-speed microscopy imaging asymmetry heat transfer resulting in fingering in the temperature profiles in the reaction front. Numerical simulations of the heat and mass transport processes are able to reproduce the finger-structured reaction fronts. We find that for Al/CuO particle-based laminates the lateral O_2 diffusion rate from CuO to the Al layer appears to be rate-limiting. The finger-like profiles appear due to the combined effects from the faster propagation of the interfacial reaction over the bulk, and the thermal diffusivity differences between the Al/CuO layers. Interestingly we see no evidence of layer intermixing even on post-combustion inspection. These results are to our knowledge the first imaging of interface reactions between particle composites and provide a valuable testbed for probing mechanisms and validating models.

SESSION SF07.04: Multiscale Modeling of Reactive Materials
Session Chairs: Carole Rossi and Michael Zachariah

8:45 AM *SF07.04.01
Current Challenges and Perspectives in Modelling Multiphasic Thermite Reactions AlainEsteve and CaroleRossi; LAAS-CNRS, France

For three decades, significant research efforts have been devoted to thermites and nanothermites using different metal/metal oxide combinations and custom nanostructured architectures. Unlike explosives, these energy-dense materials undergo a rapid deflagration driven by a carbon free oxidation-reduction reaction, which forms stable reaction products (metal oxides or hydroxides). Moreover, these products have stronger mechanical strength and heat resistance than CHNO compounds. They are versatile, different combustion effects (in terms of pressure/gas development, temperature footage, initiation delay) can be obtained by manipulating the reactive system (metal and oxide powders) and their microscopic and mesoscopic morphology. Predictive simulations of the self-propagating reaction of thermite materials is one critical step to achieve their technological maturity and effective deployment into applications[1]. There is however a lack of fundamental understanding on the mechanisms occurring in thermites combustion due to the complexity associated with the material heterogeneities and multiphase (gaseous, condensed phases) and reactive (high energy reaction) flows. Thanks to the constant increase in computing power and progress in numerical methods and modeling techniques, we believe that the most efficient way to address these questions, is to establish a multi-scale modeling approach (nanoscale à cm-continuous scale). DFT based simulations help to decipher localized events (diffusion/reaction)[2] while molecular dynamics simulations mostly based on reaxFF allow exploring more collective phenomena in terms of both the system size (thousands of atoms) and time duration (nanoseconds)[3]. Microkinetic modeling[4,5] can describe the detailed surface and gas phase reaction mechanisms. Finally, the development of numerical CFD continuous models of the self-propagating combustion, is a key step to better test and confront simulations and experiments, to obtain deeper insights into the multiphase physics, thermal and transport processes[6]. The presentation will overview and discuss the multiscale modelling approach adopted by our team to better understand the combustion of Al/CuO thermites and simulate their self-propagating combustion, based on recent publications.

The Combustion Complex of Fine Iron Particles XiaochengMi[1], LeonC. Thijs[1], EfstratiosM. Kritikos[2], AkiFujinawa[3], AndreaGiusti[2], JeffreyM. Bergthorson[4] and Philipde Geoy[1]; [1]Eindhoven University of Technology, Netherlands; [2]Imperial College London, United Kingdom; [3]University of Cambridge, United Kingdom; [4]McGill University, Canada

The true reason underlying the energy crisis faced by our society is not the lack of renewables sources, but the mismatch between a continuous energy demand and a geographically scattered and temporally intermittent supply from these sources. To overcome this problem, the scientific community is in search of reliable and efficient energy storage alternatives. Metal-enabled Cycle of Renewable Energy (MeCRE***)*** has been proposed as a solution for sustainable, long-distance transport and long-term storage of clean energy. Owing to its high energy density, zero-carbon nature, and recyclability, iron powder is nowadays considered as the most promising energy carrier to realize MeCRE on a global scale. To build real-world power and heat generation systems, fundamental insights into the combustion properties of fine iron particles are required. Although a decent amount of knowledge in the combustion of conventional solid fuels is useful, numerous unique questions rooted in iron-powder combustion must be answered. These questions are mainly related to two unique features of iron-powder combustion: (I) The heterogeneous oxidation mechanism of individual iron particles and (II) the resulting laminar and turbulent flame dynamics with a spatially discrete heat release.

This presentation provides an overview of some theoretical efforts (supproted by experiemtnal evidence) made towards understanding the fundamenals of underlying in iron-powder combustion. The ignition characteristics of iron particles are analyzed consideirng solid-phase oxidation kinetics. After ignition, the rate-limiting mechansims govenring of an iron droplet at more elevated temperature (> 2000 K) is then examined using a single-particle combustion model informed by molecular dynamics (MD) simulations. This study reveals that the oxidation rate of an iron droplet is not solely controlled by the external diffusion of O_2, but an interplay among external diffusion, surface absorption, and internal transport. Euler-Lagrange CFD simulations are used to answer the question as to how the spatially non-uniform energy release from iron particles influences the flame dynamics under application-relevant conditions.

9:30 AM *SF07.04.03
Mesoscale Modeling of Shock Waves and Intermetallic Reactions in Ni/Al Multilayer Thin Films with Explicit Non-Ideal Interfaces DavidKittell, PaulSpecht, KevinPotter, MichaelJ. Abere and DavidAdams; Sandia National Laboratories, United States

Solid heterogeneous materials exhibit a broad range of microstructural geometries when viewed at the meso(grain) scale. It is broadly recognized that these heterogeneous features play a role in the initiation and propagation of self-sustaining chemical reactions; however, layered reactive materials with a columnar grain structure have received less attention than for example granular/crystalline particle packs, porous materials with voids, and explicit particle size distributions, to name a few. In this talk, we will investigate shock induced reactions and phase change in Ni/Al reactive multilayers obtained from physical vapor deposition. These investigations are made via continuum-level simulations of thermal and mass transport, with explicit non-ideal interfaces.

While some shock-induced reactions have been simulated at the mesoscale for physical mixtures of nickel and aluminum powders (e.g., Austin and co-workers [1,2] and Xiong *et al*. [3]), the current talk will focus on advancements in three areas. (1) A new workflow is presented that is based on the Fast Fourier Transform, leading to an autocorrelation function which can mathematically generate multilayer geometries with non-ideal interfaces and columnar grain structures. This workflow is extended with machine learning; specifically, using style mapping and super resolution to combine features from the artificially generated layers and actual scanning electron microscope images. (2) Reaction is forced to begin at the Ni and Al interfaces by altering the thermal heat capacity of a small diffusion barrier that is present at the start of the simulations. Such diffusion barriers are observed in real reactive multilayers as a premix layer, following the physical vapor deposition process. (3) Arrhenius kinetics are used to propagate a reaction front following the arrival of a nonlinear shock wave. These (1)-(3) numerical methods are implemented and explored using Sandia National Laboratories' Eulerian hydrocode, CTH, and the results will be discussed and compared to the previous approaches.

Other topics covered may include homogenized models for shocks, as well as comparisons of the mesoscale results to experimental data obtained from gas gun impacts and laser-driver flyer impacts, which have been conducted at Sandia National Laboratories and the Advanced Photon Source at Argonne National Laboratory.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Microscale Techniques for Investigating the Chemistry and Energy Release of Reactive Materials JenniferL. Gottfried[1], ElliotWainwright[1] and CatherineDillier[2]; [1]U.S. Army Research Laboratory, United States; [2]Oak Ridge Associated Universities, United States

As an increasingly wide variety of novel synthesis approaches are being developed for reactive materials, e.g., unique alloys or core-shell structures and mechanically strained particles, microscale techniques for comparing the properties of these emerging materials to conventional or unmodified particles are desirable. Ideally, these techniques would enable relatively inexpensive, high-throughput investigation of the influence of the chemistry and nano- or micro-structural properties on the reaction mechanisms and energy release rates of reactive materials using minimal quantities of material. In our laboratory, we have developed several microscale techniques for evaluating the potential suitability of reactive materials in energetic formulations and increasing our fundamental understanding of the relationship between the structure and chemistry of reactive materials and their sensitivity or energy release behavior. The laser-induced air shock from energetic materials (LASEM) method enables us to compare the energy release of milligrams of material on the microsecond and millisecond timescales via high-heating rate excitation with a nanosecond-pulsed laser. Recent developments for the LASEM technique including new diagnostic capabilities, the incorporation of an environmental chamber to investigate the influence of atmosphere composition and pressure, and ongoing efforts to automate the data collection and analysis will be presented. To evaluate the influence of structural properties on the sensitivity of reactive materials, electrostatic discharge, impact, and friction tests with quantitative diagnostic measurements using an order of magnitude less material than military standard specifications have been developed. Finally, we report on recent efforts to develop a microscale technique for evaluating the impetus of novel materials.

11:00 AM SF07.05.02
Decomposition of a Sarin Gas Simulant DIMP with Combusting Metal Particles Evaluated with TDLAS and PRiMIRS – A High Throughput LWIR Spectrometer PreetomBorah, MiladAlemohammad, MarkFoster and TimothyP. Weihs; John's Hopkins University, United States

The use of chemical warfare agents (CWA's), particularly a nerve agent Sarin gas, is of growing concern. Due to their inevitable use, methods to effectively neutralize these weapons need to be further developed and improved. Composite metal powders have been effective in neutralizing biological warfare agents such as anthrax making them promising candidates for neutralizing CWA's. To understand the interaction between metal powders and a CWA simulant Diisopropyl-methyl phosphonate (DIMP), a two-fold decomposition pathway must be considered. DIMP can undergo homogeneous thermal defeat with exposure to moderately elevated temperatures to the surrounding gas as well as high temperatures local to the burning particles. Heterogenous chemical defeat can also occur with interactions between DIMP and generated metal-oxide species. To optimize metal powders towards effective neutralization of CWA's, the role of thermal and chemical defeat must be evaluated separately. Requisite diagnostic systems must be developed to perform at faster timescales (≥100 Hz) over shorter durations (≤5s).

A preheated stainless steel (SS) cell was used to generate DIMP vapor after liquid DIMP was inserted. Metal powders (Al8Mg:Zr) were held in a SS mount at one end of the cell and ignited with a resistively heated nichrome wire. The combusting metal particles then propagated across the cell containing DIMP vapor. A custom spectrometer (PRiMIRS) was used to monitor the concentration of DIMP during the experiment. The thermal contribution of the burning metal particles to the surrounding gas was measured using TDLAS at 1390 nm to probe H_2O spectra. Time resolved temperature profiles were calculated by running a minimization algorithm between experimentally obtained and simulated H_2O spectra. At faster timescales and shorter durations, DIMP decomposition products were not observed for temperatures up to 230C (homogeneous thermal defeat). The gas temperature contributions of combusting metal particles in the preheated SS cell remained below 230C. However, when these burning particles were introduced to the DIMP vapor, decomposition products isopropyl-methyl phosphonate (IMP) and isopropyl alcohol (IPA) were observed. To further investigate if decomposition is driven by thermal or chemical means, varying metal powder formulations were used such that certain chemistries generated nano-oxide species (vapor phase combustion) and other chemistries did not generate nano-oxides species (condensed phase combustion).

Effects of Interfacial Interaction on the Mechanical and Combustion Properties of Boron/HTPB Composites XiaolinZheng; Stanford University, United States

The development of high-performing solid fuels with superior mechanical and combustion properties is critical to future air-breathing propulsion systems for space exploration and hypersonic navigation. Boron (B)/hydroxyl-terminated polybutadiene (HTPB) composite has been studied for this purpose due to the high energy density of B and the appropriate processability and mechanical properties of HTPB. However, the weak interface between B and HTPB results in weakened mechanical properties, agglomerated B particles, and slow and inefficient combustion, especially for composites with high B loading (30 wt% and above). In this study, we investigated the effect of the interface between B and HTPB on the combustion and mechanical performance of high-loading B/HTPB composites by surface functionalization of B particles. We compared three interfacial characteristics: polar (pristine B)/nonpolar (HTPB), nonpolar (hydrocarbon-functionalized B)/nonpolar (HTPB), and covalently bonded (amine-functionalized B/HTPB) interfaces. We found that both covalently bonded and nonpolar/nonpolar interfaces effectively reduced the aggregation of B particles in the HTPB matrix, even with up to 45 wt% B loading, thus promoting the combustion efficiency and burning rate. Moreover, covalently bonded interfaces in B/HTPB composites led to strain-hardening behaviors, resulting in enhanced strength, ductility, and toughness. This work highlights the significance of interface engineering in B/HTPB composites for the efficacy and safety of future air-breathing solid-fueled propulsion devices.

2:00 PM SF07.06.02
Spherical Reactive Composite Powders Combining Boron with Polytetrafluoroethylene (PTFE) PurvamGandhi, AshleyCastillo, MirkoSchoenitz and EdwardL. Dreizin; New Jersey Indtitute of Technology (NJIT), United States

Different compositions of boron and polytetrafluoroethylene (PTFE) were prepared using emulsion assisted ball-milling. For each composition, porous spherically-shaped powders were prepared. Additionally, the size and porosity for the same composition powders were tuned selecting the milling parameters. The prepared powders were characterized using scanning electron microscopy. Particle sizes were measured using low-angle laser light scattering. The particle sizes of the prepared powders vary from 5 to 30 μm. Tests related to the reactivity of these powders were performed using Thermogravimetry (TG) and Differential Scanning Calorimetry (DSC). With an increase in the amount of fluorinated additive, PTFE, the temperature at which the onset of mass gain occurs becomes lower. However, the total mass gain at the end of the measurement (at 900 C) is greatest for the neat milled boron with no PTFE added. In DSC, several overlapping exothermic peaks were observed; the peaks shifted to lower temperatures as the concentration of PTFE increased. The strongest exothermic peak was observed for the composite containing 5 wt% PTFE. Prepared powders were placed on top of a flat, electrically heated filament, and their ignition temperatures were measured in air. With increase in the PTFE concentration, the ignition temperature of the composite decreases. Generally, the results suggest that addition of PTFE improves the reactivity of boron.

2:15 PM SF07.06.03
Transition Metal Catalysts for Boron Ignition and Combustion SaminaSarwar, Kerri-LeeA. Chintersingh, MirkoSchoenitz and EdwardL. Dreizin; New Jersey Institute of Technology, United States

Boron is thermodynamically advantageous as a fuel for explosives and propellants because of its high volumetric and gravimetric heating values. However, there are limitations with its practical use due to long ignition delays because of the inhibiting oxide layer and long combustion times. Previous studies indicate that boron particles burn at temperatures below its boiling point, and combustion is limited by heterogeneous surface reactions with air. One proposed solution to improve the reaction rate without compromising energy density is to include transition metal (TM) additives that can accelerate surface oxidation by different mechanisms. Specifically, Bi leads to favorable redox reactions; Fe, Co, and Ni act as oxygen shuttle catalysts; and Zr and Hf lead to exothermic formation of respective borides. Boron composites were prepared by combining 95% pure commercial boron powders with 5 wt% of a selected TM additive powders (Ni, Co, Fe, Bi, Zr, or Hf) using a planetary mill and 20 mL of hexane as the process control agent. The samples were milled for 4 hours with the ball-to-powder (BPR) mass ratio of 10 and at a rotation speed of 350 RPM. Scanning electron microscopy was used to examine the powder morphology and elemental distribution on the particle surface. The samples were also characterized using low-angle laser scattering to obtain particle size distributions. Low-temperature thermogravimetric (TG) measurements in O_2/Ar environment up to 700 C were used to obtain oxidation kinetics of the prepared samples and to examine the role of the additives and the effect of milling on oxidation of boron. TG results show lower-temperature oxidation onset for all milled samples compared to starting boron. Samples containing Bi and Co have the greatest and fastest mass gain. To explore the effect of TM additives on ignition and combustion, the

prepared powders were aerosolized, and single particles were ignited in room air using a 125-W CO_2 laser. The optical emissions of the burning particles were captured using photomultiplier tubes filtered at 700 and 800 nm to determine combustion temperatures and burn times as a function of the particle sizes. The kinetic model determined from low-temperature TG oxidation studies was used to estimate the particle combustion temperatures in air. The prediction was in agreement with experiment only for neat boron and B-Fe powders that burned at about 2500-3500 K. Selected samples of commercial boron, milled boron, and boron milled with Fe, Co, and Bi additives were also hand blended with 76 wt% potassium nitrate, KNO_3 to form pyrotechnic mixtures for larger scale ignition and combustion tests in room air. Approximately 10 mg of the B/KNO_3 powder samples were packed into an aluminum cavity with a 4.85 mm diameter and 1.41 mm depth. The powders were ignited using a 10-ms CO_2 laser pulse. The combustion event was recorded using a photodiode sensitive to emission with the range of wavelengths of 350-1100 nm, and using a high-speed monochromatic video camera equipped with a 0.7 – 4.5x Zoom Monocular lens. In addition a compact UV-VIS-NIR spectrometer (190-850 nm) set at 1000 ms integration time was used. The experiments determined the ignition delays, plume propagation rates, overall combustion times, and temperatures, for the ignited samples. Preliminary experimental data showed shorter ignition delays for B-Co composite, whereas B-Bi samples demonstrated shorter combustion times and faster plume propagation rates than other composites. Time-resolved spectra of the combustion events were processed assuming grey body emission and resulted in combustion temperatures above the boiling point of B_2O_3 and the melting point of boron. Commercial boron powders showed characteristic BO_2 emission peaks and burned at ~3000 K, while some samples like B-Co showed no clear BO_2 emissions and burned at lower temperatures of 2400 K, indicating changes in the reaction mechanisms due to different TM additives.

2:30 PM SF07.06.04
Effects of Boron in Ignition and Combustion of Al-B-Ti Mechanically Alloyed Powders MeganBokhoor, MichaelR. Flickinger, JohnFite and TimothyP. Weihs; Johns Hopkins University, United States

Aluminum powders are a common metal fuel for energetic applications but often cannot reach ideal combustion efficiencies. Creating composite powders with additional constituents has been shown to increase combustion efficiency and reduce the ignition threshold via an intermetallic reaction. Here, we explored the effects of adding titanium and boron to an aluminum matrix to produce mechanically alloyed Al-B-Ti powders. We compared sieved (<75 um) chemistries with constant Ti content while varying boron from 0 to 25 atomic percent. These powders were characterized using particle size analysis and large, stitched SEM cross-sections to define morphology and particle size distribution as well as wire ignition and differential thermal analysis (DTA) to evaluate their ignition and combustion properties. The composite powders showed a decrease in ignition temperature and increase in mass gain with increasing boron content. The combustion properties were analyzed using SHEAR to acquire temperature and spectral data.

2:45 PM SF07.06.05
Exfoliated Magnesium Diboride Nanosheets as Solid Fuels DongwonKa, YueJiang, AndyHuynh and XiaolinZheng; Stanford University, United States

Magnesium diboride (MgB_2) has been explored as an alternative fuel to boron (B) due to its high energy density and an additive effect of magnesium (Mg) to promote B combustion. However, in the oxidation process, MgB_2 has a relatively slow reaction rate and high ignition threshold compared to other metal or metalloid fuels. The primary oxidation of MgB_2 does not occur unless it decomposes at a high temperature (830 °C), and it still has slow heterogeneous oxidation of boron following the decomposition. Recently, two-dimensional (2D) exfoliated MgB_2 nanosheets have attracted increasing attention due to their unique properties and potential applications in various fields. In this work, we present the potential of 2D exfoliated MgB_2 nanosheets as solid fuels in overcoming the challenges of MgB_2 combustion. The oxidation behavior and energetic performance of MgB_2 nanosheets are studied through materials characterization and combustion tests under slow and fast heating conditions. The results show that the MgB_2 nanosheets oxidize from a lower temperature than bulk MgB_2 under slow heating conditions as the MgB_2 nanosheets oxidize without decomposition. At fast heating rates, the MgB_2 nanosheets exhibit a lower ignition threshold, higher combustion efficiency, and faster energy release rate than other B-based fuels. This study highlights the potential of MgB_2 nanosheets as promising solid fuels with superior energetic properties.

3:30 PM *SF07.07.01
Engineered Reactive Crystals and Structures for *In-Situ* DIMP NeutralizationTristanKenny, BrandilynnUkena and LoriGroven; South Dakota School of Mines & Technology, United States

Traditionally the destruction of CWA is thermally induced during the blast wave, however, it is highly desired to augment the neutralization by the intentional generation of metal oxide nanopowders during the detonation event. Metal oxide nanopowders are expected to act as catalytic adsorbents and can be generated in-situ via several routes including metal powder inclusion. However, with bulk metal powders there remains a diffusion and oxidation timescale limitation. To overcome the reaction timescale issues, this work focuses on the inclusion of engineered reactive crystals and the intentional design of architectures that can maximize dispersion. These engineered crystals are focused on ionic cocrystals composed of an organic solid (e.g. glycine, urea, hexamine) and a metal salt. The primary focus here is on generating magnesium oxide (MgO) and alumina (Al_2O_3). In the case of MgO, an ionic co-crystal of magnesium nitrate/glycine is generated through mechanochemical means and subsequently used in formulation. For alumina, both aluminum nitrate and perchlorate are assessed with hexamine to form reactive complexes that upon combustion generate high surface area alumina (> 200 m^2/g). These materials are further combined with an acrylate photopolymer to produce additively manufactured structures via DLP at solids loading exceeding 60 wt%. Detonation testing of generated materials was assessed in collaboration with UIUC (Prof. Glumac). For these studies, a surrogate CWA, diisopropyl methyl phosphonate (DIMP) was used, and It is shown that the inclusion of the ionic co-crystal magnesium nitrate/glycine to generate MgO in-situ decreases DIMP concentration significantly after just 1 ms. Product is collected from such tests and further characterized to help elucidate the decomposition mechanism.

4:00 PM SF07.07.02
Interaction of Hydrated and Dehydrated MgO with Disopropyl Methyl Phosphonate (DIMP) at Elevated Temperatures ElifI. Senyurt[1], SwapnilDas[1], LoriGroven[2], TristanKenny[2], MirkoSchoenitz[1] and EdwardL. Dreizin[1]; [1]NJIT, United States; [2]South Dakota School of Mines & Technology, United States

Condensed combustion products of reactive materials generated in a blast can serve to accelerate decomposition of toxic liquids, such as sarin, a chemical weapon agent (CWA). In particular, destruction of aerosols of CWA droplets can be augmented by inducing their interaction with a metal oxide smoke. The smoke particles are expected to adsorb and catalyze the decomposition of CWA. The mechanisms and rates of such adsorption and decomposition reactions are poorly understood and are expected to be different for various oxides. Experimental studies commonly use surrogates of CWA. Diisopropyl methyl phosphonate (DIMP), an organophosphorus compound often used as a surrogate of sarin, was used in this work. Its interaction with fine MgO powders representing a smoke produced by magnesium-bearing metal fuels, was studied experimentally. Different MgO powders were explored. In addition to two commercial (-325 mesh and nano-sized) MgO powders, several custom MgO powders synthesized from Mg(NO3)2*6H2O and C2H5NO2 (1:1 and 1:2 mole ratios) were used. Commercial MgO powders were found to be partially hydrated. To remove the hydroxide, all MgO powders were heated to 450 C in a furnace of a thermo-gravimetric (TG) analyzer in a mixed argon/oxygen flow. Further, as-received, as-prepared, and de-hydrated MgO powders were mixed with liquid DIMP in 0.7 ml open alumina crucibles. The DIMP/MgO mixtures were also heated to 450 C using the TG analyzer in a flow of mixed argon and oxygen. As expected, a first major mass loss step occurred while the liquid DIMP was evaporating. It ended before the boiling point of DIMP was reached. The residual mass represented DIMP adsorbed to the powder both physically and chemically. That mass was slowly reduced upon further heating for some samples. Certain residual mass was still retained by all powders even after their exposure to 450 C. A distinct second mass loss step was observed starting at ~250 C for the dehydrated commercial MgO powders, but not for the as-received and custom prepared powders. In separate experiments, all MgO powders were intentionally hydrated by mixing them with water. They were then dehydrated by heating them to 450 C in Ar/O2 environment. For all such hydrated and dehydrated powders exposed to DIMP and subsequently heated in TG, the second mass loss step was observed. This second mass loss step is qualitatively similar to that reported recently to occur when DIMP interacted with gamma alumina. The MgO powders exposed to DIMP and to the TG heating program were recovered and examined using FTIR-ATR analyzer. Clear signatures of DIMP molecule fragments adsorbed to MgO were observed. Such signatures were stronger for the dehydrated powders, which were initially hydrated. The results and possible mechanisms responsible for the adsorption and decomposition of DIMP by MgO surfaces will be discussed in this talk.

4:15 PM SF07.07.04
Laser-Induced Trapping of Metastable Amorphous-AlO_x /C (2.5< x ≤3.5) Nanocomposites Stabilized by Carbon Interfaces—Implications for Solid-Phase Gas Generator Additives ElijahM. Davis[1], GerdJ. Duscher[1], JianguoWen[2] and DibyenduMukherjee[1]; [1]The University of Tennessee, Knoxville, United States; [2]Argonne National Laboratory, United States

Tailored interfacial and metastable structures can effectively circumvent the diffusion limitations due to oxide shell formation in Aluminum (Al) nanoparticle (NP)-based energetic nanomaterials (ENMs). Yet, rational design and synthesis of metastable nanostructures via non-equilibrium routes remain largely unexplored. Specifically, non-stoichiometric/amorphous Al-oxide (a-AlO_x) structures in metastable states, albeit, theoretically predicted, are rarely reported in experiments due to the inability to kinetically trap and phase-stabilize such exotic out-of-equilibrium phases at nanoscale. We report a pivotal advancement in addressing this challenge by employing reactive Laser Ablation Synthesis in Solution (r-LASiS) as a one-step, one-pot non-equilibrium route to synthesize unusual metastable a-AlO_x NPs in hyper-oxidized states ($2.5<x\leq3.5$), phase-stabilized by interfacial C monolayers and dispersed in pyrolyzed-C matrices. Detailed characterizations from bulk and surface spectroscopic analyses as well as electron microscopy imaging reveal highly disordered a-AlO_x NPs (<5-8 nm sizes), remarkably stabilized by interfacial monolayer shells of ordered C-atoms. Using techniques such as Solid-state Nuclear Magnetic Resonance (SSNMR), X-ray Photoelectron Spectroscopy (XPS), and Electron Energy Loss Spectroscopy (EELS), we are able to establish the material's structure and composition in the hyperoxidized state. Interestingly, the a-AlO_x NPs of sizes less than 10 nm were stable even at elevated temperatures. At temperatures higher than 750 ºC, the a-AlO_x structures undergo a solid-solid phase transition that culminates in the formation of stable α-Al_2O_3 while releasing excess trapped gases. This talk will also present results for the detailed kinetic measurements carried out for the solid-solid phase transformation from metastable a-AlO_x to stable α-Al_2O_3 crystalline structures by using time-dependent high-temperature XRD analyses. The ability to kinetically trap such metastable nanomaterials in localized low-energy troughs, until their precipitous plunge to their global lowest energy state, has wide-ranging implications for their potential applications as solid-state gas generator additives that can bypass the diffusion limitations.

SESSION SF07.08: Poster Session: Advances in Reactive Materials Engineering

Enhancing the Reactivity of Boron Containing Complexes and Boron Nanoparticles as Fuels for Energetic Applications PrithwishBiswas, MichaelR. Zachariah and YujieWang; University of California, Riverside, United States

Despite its high gravimetric and volumetric energy densities, boron (B) particles suffer from poor oxidative energy release rates as the boron oxide (B_2O_3) shell impedes the diffusivity of O_2 to the particle interior. One way to alleviate this issue is to employ solid-state B-contiaining complexes such as ammonia borane (AB) which can potentially generate gas phase B-species, reactivity of which will be trivially affected by solid state diffusion limitation. However, the intrinsic thermochemistry of AB also makes its application as a fuel challenging, as it oligomerizes and gets kinetically trapped into boron-nitrogen-hydrogen clusters on thermal activation. Herein, we mitigate this challenge by selectively altering the thermal decomposition pathways of AB with the help of a) ammonium-ion based oxidizing salts and b) polymeric carbonyl groups. The dative B-N bond of AB is responsible for triggering its thermal oligomerization pathway and the oligomerization is initiated through the formation of an intermediate known as diammoniate of diborane (DADB), which is formed as a result of an intermolecular nucleophilic attack of the N on B simultaneously accompanied by an intermolecular hydride ion exchange between the B-atoms. We show that in the presence of NH_4^+ ions, AB forms an alternative intermediate, as the nucleophilic interaction between the N of NH_4^+ with the B of AB is more favorable. This inhibits the oligomerization reactions of AB, thereby leading to the rapid and complete oxidation of its energetic constituents resulting in a ~27x faster energy release in presence of an NH_4^+ ion containing oxidizer such as NH_4ClO_4. As an alternative approach, we also show that when AB is incorporated into polymer matrices containing carbonyl functional groups, thermal activation causes the carbonyl groups to engage in nucleophilic interactions with AB. Such interactions catalyze the lysis of the dative B–N bond resulting in the decomposition of AB to reactive fuels, NH_3 and B_2H_6, with no evidence of its oligomerization. We find that the carbonyl groups function as catalysts and do not participate in any net reaction. In situ high-heating rate (~10^5 K/s) characterizations demonstrate that AB/carbonyl-based polymer composites completely gasify to NH_3 and B_2H_6 at ~510 K, followed by spontaneous ignition in the air with negligible delay. This chemical pathway enables the solid-state storage of reactive fuels, NH_3 and B_2H_6, and their controlled on-demand release for high-energy applications. Alternatively, experiemental studies have shown that the addition of metals with lower free energy of oxidation such as Mg can reduce the oxide shell of B and enhance the energetic performance of B by ~30-60 %, however the underlying mechanism behind the reactivity enhancement is unknown. Through DFTB-MD simulations of the reaction of Mg vapor with B_2O_3 surfaces, we found that Mg become oxidized on B_2O_3 surfaces forming a MgB_xO_y phase. This induces a tensile strain in B-O bond at the MgB_xO_y-B_2O_3 interface and the interfacial B is simultaneously reduced resulting in the development of dangling bonds. The interfacial bond straining creates an overall surface expansion indicating the presence of a net tensile strain on the B_2O_3 surface. The B with dangling bonds can act as active centers for gas phase O_2 adsorption thereby increasing the adsorption rate and the overall tensile strain on the surface will increase the diffusion flux of adsorbed O through the surface to the particle core. As the overall B particle oxidation rate is dependent on both O adsorption and diffusion rates, the enhancement in both of these rates increases the overall reactivity of B particles.

8:00 PM SF07.08.02
Physicochemical Mechanisms Controlling the Energetic and Biocidal Performance of B and Al Composites YujieWang and Michael R. Zachariah; University of California, Riverside, United States

Boron is an attractive fuel in energetic materials due to its high gravimetric and volumetric energy content. However, boron often suffers from slow oxidation kinetics because its native oxide shell has low melting point and acts as a liquid barrier that retards its reactivity. We have studied a family of oxidizers with nearly identical chemistries to understand the controlling mechanisms of igniting boron. Boron nanoparticles with alkali metal perchlorates and iodates ($LiClO_4$, $NaClO_4$, $KClO_4$, $LiIO_3$, $NaIO_3$ and KIO_3) were investigated by temperature-jump (T-Jump) ignition and time-of-flight mass spectrometry (TOFMS) with rapid heating rates (~10^5 K/s). T-Jump ignition tests in inert environment show that B/$LiClO_4$, B/$NaClO_4$, B/$LiIO_3$, and B/$NaIO_3$ ignite while B/$KClO_4$ and B/KIO_3 do not, even though the chemistries are very similar. T-Jump TOFMS results demonstrate a significant increase of Cl and I containing species for Li and Na composites relative to K when B is introduced. Thermogravimetry/differential scanning calorimetry (TGA/DSC) analysis demonstrates the presence of a temperature gap between melting and decomposition onset of $LiClO_4$, $NaClO_4$, $LiIO_3$, and $NaIO_3$, respectively, whereas $KClO_4$ and KIO_3 melt and decompose concurrently. We find that the larger interval between melting and decomposition provides more time for the oxidizer to melt and surround/wet the B nanoparticles prior to decomposing, rendering better access to oxygen for B nanoparticles that results in more vigorous ignition. It demonstrates the significant impact of transport phenomena and physical properties of oxidizers on boron ignition. Metal iodates ($LiIO_3$, $NaIO_3$, KIO_3, $Mg(IO_3)_2$, and $Ca(IO_3)_2$) have high iodine and oxygen content and are therefore attractive oxidizers for energetic and biocidal application. We have investigated the iodine release and energy release of Al-iodate thermites via TOFMS and combustion cell tests, respectively. It is found that there is a trade-off between iodine release and reactivity among these thermites as Al-$Mg(IO_3)_2$, Al-$Ca(IO_3)_2$, and Al-$LiIO_3$ release more iodine but are less reactive than Al-$NaIO_3$ and Al-KIO_3. Free-standing composites containing 90 wt% loading aluminized metal iodate are assembled by 3D printing and their combustion behaviors are studied by high-speed videography and pyrometry. It is found that Al-$Mg(IO_3)_2$ and Al-KIO_3 cannot propagate while Al-$Ca(IO_3)_2$, Al-$LiIO_3$, and Al-$NaIO_3$ propagate. For the later three composites, molten droplets with similar size form on the burning surface, while Al-$NaIO_3$ has a propagation rate about twice of the Al-$Ca(IO_3)_2$ and Al-$LiIO_3$. Temperature profile from three-color (RGB) pyrometry demonstrates flame temperature of Al-$Ca(IO_3)_2$ and Al-$LiIO_3$ are similar and lower than Al-$NaIO_3$. It is concluded that Al-$Ca(IO_3)_2$ and Al-$LiIO_3$ composites have potential application as biocidal agent due to both heat and iodine release.

8:00 PM SF07.08.03
Intelligent Exploration of Thermite Design Space Through Active Learning Algorithms ClaudiaRamirez[1], YasserSami[1], DavidGauchard[1], NicolasRichard[2], MatthieuJonckheere[1], AlainEsteve[1] and CaroleRossi[1]; [1]LAAS-CNRS, France; [2]CEA-DAM, France

The reactive materials design space is prohibitively large as not only the chemistry (nature of fuel and oxidizer) but also the microscopic (size of the fuel and oxidizer particles, purity of the metal) and mesoscopic properties (powder density, stoichiometric conditions, binder or additives) influence their macroscopic combustion. For two decades or so, data-driven science is

considered as a new paradigm in materials discovery and design that has already achieved number of successes in accompanying and accelerating research and innovation beyond the "Edisonian" approach based on trial-and-error used in most research laboratories. The most used approach is the Bayesian optimization algorithms, which requires large data base for approximating the objective function which is totally not possible when working with reactive materials: each experiment is costly due to the complexity to capture the combustion process *in operando*, and, truly predictive models that can replace experiments are computationally costly.
In this work, we explore *active learning* algorithms to allow for a guided and intelligent generation of database starting from a very limited set of available data. As a case study, an Al/CuO powdered thermite (mixture of Al and CuO particles) is considered because it is well-documented from both theoretical and experimental perspectives and a model is available to simulate its combustion [1,2] in close vessels. A Gaussian process surrogate (GP) is used to approximate the target function in terms of the pressurization rate. Importantly, we explore different acquisition functions translating different exploration tradeoffs from the GP building block to guide the sequential sampling choice (Al/CuO sample) in the database. We study the impact on the quality of the database when prioritizing specific regions of the target space in the acquisition function, while maximizing the coverage of the features space. After presentation of the method and algorithms, we will discuss, (i) the benefit of the proposed algorithm compared to the brute force sampling (systematic sampling) of the Al/CuO design space through LHS technique (Latin Hypercube Sampling) and, (ii) physical aspects of interest of the design space of Al/CuO for gas generation applications.

8:00 PM SF07.08.04
Crystal Morphology in Ammonium Perchlorate Based Solid Composite Propellants MasonFreund, SumanKumari and VolkanOrtalan; University of Connecticut, United States

Reactive and energetic materials are used in a variety of fields and therefore must be able to perform at different operating conditions. Being able to alter and control the properties of these materials in terms of the burning rate, heat of reaction as well as the sensitivity will allow the tailoring of reactive materials to perform optimally in a variety of applications. The reaction properties, performance, and sensitivity will be influenced by both the chemical and physical characteristics of the energetic material [1]. A well-known and widely used oxidizer component in composite solid propellants is ammonium perchlorate (AP). AP composite propellant formulations using metal fuel particles and polymeric binders can contain as much as 70% AP [2]. Due to the large percentage of AP in these composites, the oxidizer's properties including the size, shape, morphology, and defects will have a large effect on the performance of the composite. Understanding the modification of the energetic crystal morphologies and structures and the influence on the reaction properties, pathways, and mechanisms is important to the overall performance and safety of the reactive material.
In this work, the preparation of microscale ammonium perchlorate crystals and under confinement of nitrocellulose is demonstrated. A focus is placed on AP concentration dependence of the crystal size and morphology as well as the different observed morphological regimes. Solutions from low AP concentration up to the solubility limit are observed in scanning and transmission electron microscopy to better understand the role of solute concentration on the final crystal physical characteristics. Additional crystals are also grown in the presence of metal nanoparticles to form a composite solid propellant.

8:00 PM SF07.08.05
Study on Energetic Reactive Plasticizers Utilizing Ring Strain Energy and Solid-State Copper-Free Azide-Alkyne Click Reactivity in GAP-Based Polyurethane Binders MingyangMa and YounghwanKwon; Daegu University, Korea (the Republic of)

Plastic-bonded explosives (PBXs) are energetic composites composed of highly energetic molecules bound together by polymers which can create void-free and protective matrix. As a processing aid in the manufacture of PBXs, plasticizers are usually added to ease the processibility of composite formulations, and tune the mechanical properties of cured polymer composites. Inert plasticizers like dioctyl adipate (DOA) find application in hydroxy-terminated polybutadiene (HTPB)-based cast-cured PBXs formulations. However, both DOA and HTPB are non-energetic to decrease the energetic performance of PBXs.
Energetic polymers and plasticizers functionalized with explosophore groups such as nitrate ester ($-ONO_2$), azide ($-N_3$), or nitro ($-NO_2$) group have emerged as a replacement to non-energetic ones. For instance, an energetic polymer, glycidyl azido polymer (GAP), is a hydroxy-terminated polyether which can form the polyurethane (PU) matrix with a suitable isocyanate. Plasticizers may readily migrate out of polymer matrix after certain periods of time even under the relatively mild storage condition, giving rise to the vulnerability of polymeric matrix leading to the energetic composites sensitive to impact, friction and heat. Series of energetic reactive plasticizers have been reported to prevent the migration problem of plasticizers within GAP-based PU binders by utilizing in-situ Cu(I)-free azide-alkyne Click reaction. Although explosophore groups of energetic polymers and plasticizers provide an improved energetic performance, disadvantages of the explosophore groups such as high impact sensitivity, instability at high temperatures and easy oxidation in air have been apparent.
In this study, ring strain energy of cyclic compounds is scrutinized to be an alternative, safe and reliable energy source for energetic reactive plasticizers instead of explosophore groups. Notably, the efficacy of ring strain energy is deemed to provide a relatively inactive energy bearing some immunity to impact and shock because the release of which is commonly initiated by ignition. The energetic reactive plasticizers are designed to have both "energetic" ring-strained cyclic moiety as a new energy source and "reactive" alkyne group for solid-state copper-free azide-alkyne Click reaction with azide groups of GAP-based PU binders. The energetic reactive plasticizers are synthesized via an esterification of ring-strained cyclic carboxylic acids and alkynols. The homodesmotic schemes designed for computing the intrinsic ring strain energy of the energetic reactive plasticizers are developed and those ring strain energies are predicted at B3LYP/6-31G* level of theory. The plasticization effect of the energetic reactive plasticizers on the GAP prepolymer in terms of miscibility and rheological behavior are evaluated respectively. The energetic reactive plasticizers are found to exhibit a distinct copper-free azide-alkyne Click reactivity toward the GAP prepolymer. The experimental determination for the Click reactivity is in good agreement with the theoretical prediction of frontier molecular orbital. The GAP-based PU binders chemically linked to the energetic reactive plasticizers impart an enhanced tensile properties and impact insensitivity due to the transformation from azide to triazole group. Additionally, heat of formation calculated from heat of combustion of energetic reactive plasticizer/GAP-based PU binders is also analyzed.

8:00 PM SF07.08.06
Preparation of Pure Ti Nanopowders by High-Energy Ball Milling and Dehydrogenation of TiH_2Eui SeonLee, Youn JiHeo and Sung-TagOh; Seoul National University of Science and Technology, Korea (the Republic of)

Due to the characteristics of a high strength-to-weight ratio, superior corrosion resistance, good specific strength, and forming a lightweight alloy of titanium (Ti), the fabrication of high-purity Ti has consistently attracted attention, which is technological importance for a wide range of applications such as the aerospace industry, orthopedic, and dental implant materials. However, its susceptible oxidative characteristics and high-yield strength restrict the manufacturing of pure Ti through casting and cold working. Therefore, the powder metallurgy process is widely used in the production of Ti, but it has been difficult to prepare a pure Ti powder with suppressed oxidation. In this regard, we focus on the production of ultra-fine and pure Ti powders with low oxygen content through milling and dehydrogenation using brittle titanium hydride (TiH_2). We perform a high-energy ball mill (HEBM) using a planetary system to refine micron-sized TiH_2 powders by varying the milling speed, ball size, and time. The optimum condition for TiH_2 milling is determined by analyzing the particle size and lattice strain of the milled powders. The effect of particle size on dehydrogenation is investigated by thermal analysis with a heating rate of 5°C/min under an argon atmosphere. In addition, the effect of the reducing agent added during the dehydrogenation heat treatment process on the change in oxygen content of the synthesized Ti powder was analyzed. By optimizing the milling conditions, TiH_2 particles with a minimum size of 195.9 nm were obtained, and the dehydrogenation temperature decreased up to 140°C as the particle size decreased. In this work, we provide a promising technique for synthesizing the ultra-fine pure Ti powder which is important for the military industry and precursor elements for alloys and compounds.

8:00 PM SF07.08.08
Examining the Aging Characteristics of Fluoropolymer-Coated Boron using Heat Flow Calorimetry SebastianQuek Yongsen[1,2], SreekumarPisharath[1,2] and HngHuey Hoon[1,2]; [1]Emerging Nanoscience Research Institute, Singapore; [2]Nanyang Technological University, Singapore

Boron (B) is a remarkable metal fuel offering significant potential in terms of both theoretical gravimetric and volumetric energy. However, realizing its complete experimental potential has been challenging due to the existence of a diffusion-limiting boric oxide layer. Consequently, numerous strategies have been devised over time, primarily aiming to disrupt the boric oxide shell and effectively activate boron for enhanced combustion reactions. Our approach relied on the application of a low molecular weight fluoropolymer (FP) coating, which we developed in-house, to enhance the combustion of boron to elevated levels. In this method, the activation process is initiated by the fluorination reaction, which leads to the disruption of the boric oxide shell. Additionally, the hydrophobic nature of FP is expected to provide a passivating effect on boron by preventing aging reactions caused by humidity and temperature. However, this aspect has not been thoroughly investigated yet. The present study focuses on examining the aging characteristics of FP coated B using heat flow calorimetry (HFC) experiments. We comprehensively investigate the aging process as a function of the percentage of FP coating, relative humidity, and temperature to gain a deeper understanding of the behaviour and stability of FP-coated B over time. We believe that this research will provide insights for optimizing the performance and utilization of activated boron as a metal fuel, thereby creating new possibilities for its practical applications.

8:00 PM SF07.08.09
Nanothermite Based Anti-Tamping Technology FlorentSevely, SandrineSouleille, LudovicSalvagnac, AlainEsteve and CaroleRossi; LAAS-CNRS, France

Security has become a vital part of electronic products that have being employed in critical data storage (personal, bank, etc) or critical equipment such as military systems. They not only handle sensitive data in uncontrolled environments, but also face intellectual protection issues or counterfeiting issues. Unfortunately, all current anti-tamping technologies, while being effective are susceptible to be cracked or bypassed, leaving the system vulnerable. That is why an ultimate action must be considered upon the detection of intrusion through irreversible destruction of the component being attacked. We developed a triggerable ultimate security device capable of physically destroying a memory chip that contains classified data, within a few milliseconds, upon the detection of intrusion. The developed device [1] is designed as an add-on module that can be positioned on any electronic chips, IC-circuit, or memory cards, without requiring any specialized chip design, substrate type or encapsulation solution. Its operation is simply based on the exothermic reaction of a solid-state printed energetic composite that physically disintegrate the sensible component in less than 1 ms. The solid-state energetic composite consists of a mixture of Al/CuO nanothermite with a copper ammine complex densely printed onto the chip that is meant to be destroyed. This energetic layer can be ignited through capacitance discharge in less than 50 µs. The poster details the fabrication of the device and demonstrates that 400 mg of energetic composite irreversibly destroys one silicon chips (~120 mm^3) in less than 10 ms.

8:00 PM SF07.08.10
Stoichiometry-Induced Control of the Reaction Front in Ni/Al Reactive Multilayers NensiToncich, FabianSchwarz and RalphSpolenak; ETH Zürich, Switzerland

Reactive multilayers are a class of metastable materials that exhibit remarkable thermal, chemical, and mechanical properties, making them highly versatile across diverse applications. One of the most intriguing aspects of reactive multilayers is their inherent ability to undergo self-sustained, exothermic reactions with high temperatures. This phenomenon arises from the stacking of alternating thin films of constituents with a large negative enthalpy of mixing. Leveraging this behavior, reactive multilayers find applications as intrinsic heat sources in many fields, including thermal batteries, biological hazard neutralization, joining processes, micro-propulsion, thin-film healing, and the microelectronic industry. Despite numerous investigations on the control of their reaction behavior, further studies are required to broaden the application and enhance the performance of reactive multilayers.
The objective of this study is to control and optimize the thermal management of Ni/Al reactive multilayers through the investigation of the impact of the stoichiometry on their reaction behavior. To this end, a wide range of Ni/Al ratios were fabricated and studied contributing to a substantial expansion of the current reported Ni/Al systems. Furthermore, the role of the bilayer thickness (B) was analyzed and batches of systems with 50, 70 and 90 nm-B were fabricated. This research focused on the evaluation of reaction kinetics and reached temperatures, characterizing alongside the mechanical properties, structure and composition of the systems through nanomechanical testing, differential scanning calorimetry (DSC), scanning transmission electron microscopy (STEM), and X-Ray Diffraction (XRD). MD simulations were conducted to investigate the kinetics and mechanical properties, revealing a consistent trend comparable to the experimental findings. When the concentration of Al exceeds the equimolar ratio with Ni, there is a noticeable decrease in the propagation rate. On the contrary, an increase in Ni concentration results in a reduction in the stoichiometry-dependent nature of propagation. The results obtained from this research will offer valuable insights into the design of Ni/Al reactive multilayers with customized thermal characteristics.

8:00 PM SF07.08.11
In-Detail Elaborating The Way of Titanium in Thermite Reactions TaoWu, VidushiSingh, AlainEsteve and CaroleRossi; LAAS-CNRS, France

In recent years, it has been reported that adding titanium into reactive thermite composites (such as Al/I_2O_5, B/CuO) can improve their combustion efficiency and lower their ignition temperature. However, these authors were only able to point out the complexity of the mechanisms governing ternary thermites reactivity but failed to answer the question of the exact role of the Ti reaction with oxidizers in such thermite composites. Due to the fast reaction rate and the difficulties in tracking elemental movements in Ti-based thermite nanoparticles, a full diagnosis from a fundamental standpoint awaits. In this work [1], we put our focus on in-depth understanding the reaction mechanism of Ti-based thermite by employing a magnetron-sputtering technique to grow high purity and well-defined CuO/Ti nanolaminates. Contrary to powdered nanothermites in which a thick titania oxide shell layer separates its pure fuel Ti core from the outer surface oxidizer particle, nanolaminates feature a very well-controlled interface (in thickness and structure) between the fuel and oxidizer. Furthermore, the multilayer system allows a full contact between the different species compared to particulate system showing random contact, which is crucial to clearly identify and rationalize the different mechanisms taking place during initiation/propagation of the reaction. This provides an ideal model-system to quantitatively describe the TiOx interfacial oxide growing using a host of characterization techniques including microscopy, thermal analysis, spectroscopy and X-ray diffractometric.
Results show that 70% of theoretical heat of reaction of the Ti/CuO system is released within a single strong exotherm at 430 °C, thus confirming the early and fast Ti oxidation. High resolution electronic microscopy reveals that the titania, terminal reaction oxide, is grown and propagates into the Ti layer, driven by the diffusion/reaction of oxygen atoms released by CuO at 300 °C. Spectroscopy measurements show that CuO/Ti redox reaction undergoes a two-step oxidation process: at 300 °C, Ti is first oxidized into TiO and further oxidized into crystalline TiO_2 at 500 °C. At a similar initiation temperature, the Ti-based sample supports more oxygen transport, thus a greater number of elementary exothermic reactions, causing a greater amount of heat per unit volume. In turn, this drives the system into the self-sustaining reaction mode where sufficient energy is present to activate mass transport across the continuously forming terminal oxide until the reaction is completed. This study confirms that Ti can be of great interest in addition or replacement of Al in nanothermites, for applications where it is desirable to lower the ignition temperature. Adding two CuO/Ti bilayers prior to the deposition of CuO/Al multilayers allows decreasing ignition time below the ms (200 µs) against 15 ms without CuO/Ti. Also, a burn rate enhancement factor of × 3, and a reduction of the ignition delay by × 700 is obtained when replacing Al by Ti in standard CuO/Al multilayers.

8:00 PM SF07.08.12
Decomposition of DIMP Vapors Interacting with Metal Oxides ElifI. Senyurt, MirkoSchoenitz and EdwardL. Dreizin; NJIT, United States

Finely dispersed metal oxide particles form as a result of combustion of many energetic formulations; such particles are expected to catalyze decomposition of toxic vapors of chemical weapon agents (CWA), such as sarin. The thermal decomposition of CWA vapors is very fast at high temperatures; however, as the temperatures approach the CWA boiling point (~200 C), the rate of thermal decomposition drops. Thus, for the temperature ranges of 200 – 500 C, the effect of condensed combustion products catalyzing CWA decomposition are expected to be most important. The reactions and processes involved are poorly understood. Here, such reactions are studied using DIMP as a surrogate of sarin. DIMP is introduced into a heated laminar flow system and interacts with a porous plate pre-loaded with fine powders of different metal oxides. The initial concentration of DIMP in air or in nitrogen is adjusted to 3 µmol/L. The concentration of DIMP in the flow passed through the plate is measured using a total gas analysis unit of an FTIR analyzer. Both flow system and the porous plate are heated to temperatures between 200 and 350 C; the flowrate of air is varied. Metal oxides exposed to DIMP-bearing flow are recovered and analyzed using FTIR-ATR. Results will be presented and discussed for several metal oxides typically generated by energetic materials, including gamma-alumina, magnesium oxides, etc.

8:00 PM SF07.08.13
Improved Energetic Performance of Graphene-Supported Aluminum Nanoparticles: Computational Materials Research Incorporated with Science Pedagogy PriyanshuLuhar[1], SungwookHong[1] and LexiHwang[2]; [1]California State University, Bakersfield, United States; [2]California State University, Los Angeles, United States

Aluminum nanoparticles (ANPs) have attracted a great amount of attention owing to their high energy density, high reaction rate, earth abundance, and low toxicity.[1] ANPs have been considered effective reactive energetic materials. Recent studies show that adding graphene oxide and graphene fluoride improves the combustion performance of ANPs.[2,3] This is mainly due to a synergistic effect between graphene sheets and ANPs. For example, oxygen molecules could be easily dissociated when they get closer to both graphene sheets and ANPs. As such, we hypothesize that graphene supported ANPs, which could be considered novel reactive materials, provide a remarkable combustion performance. Here we simulate the oxidation of graphene-supported ANPs using reactive molecular dynamics (RMD) simulations based on ReaxFF.[4] The students conducted this research trained under research module/program designed by a guided inquiry-based instruction framework and other evidence-based science strategies. Results indicated positive impacts of our pedagogical approached simulation training. In particular, our RMD simulations led by the trained student reveal atomic-level reaction mechanism for the improved oxidation process of graphene-supported ANPs. As such, we believe our approach will strengthen a diversity in the community of reactive materials research, also providing a valuable input for the experimental design of solid-fuel propellants.

Ignition Study of Copper Oxide Nanoparticle Coated Boron Micro Spheres using Shock Tube PrashantDeshmukh and Weon GyuShin; Chungnam National University, Korea (the Republic of)

Boron is an attractive solid fuel for propellants and explosives. But natural oxide layer on the boron surface hinders ignition and combustion of boron. The present work aims to improve the ignition performance of boron by coating the copper oxide nanoparticles on micro sized boron particles. Structural study shows the growth of nanocrystalline copper oxide particles on the surface of boron particles. Continuous and uniform distribution of copper oxide nanoparticles creating a continuous layer were observed from surface morphology. Further, it shows the size of copper oxide nanoparticles is less than 10 nm. The existence of elements viz. copper, boron and oxygen in the samples were confirmed by EDS and XPS analysis. Thermogravimetric analysis shows that the onset oxidation temperature of boron shifted to lower temperature after coated with copper oxide. This shift in temperature depends on the coating density of copper oxide nanoparticles. Maximum shift in onset oxidation temperature was 98°C compared with those of pristine boron. The shock tube examination reveals that the boron coated with copper oxide particles have a quicker ignition delay time than those of pristine boron particles resulting in a 6% decline in ignition delay time.

Microwave and Electrochemical Stimulation for Control of Ignition and Throttling of Energetic Materials KerenShi, PrithwishBiswas, AdridaAnis and Michael R. Zachariah; University of California, Riverside, United States

While thermal and mechanical means are the most common approach to stimulate energetic components, alternative methods are also available. Laser ignition in both the visible and IR have also been used. In this talk I will discuss using microwaves (MW) and electrochemical means (EC) to stimulate, and modulate the energy release process. Unlike surface stimulation of the bulk materials, microwave heating offers the potential to trigger energy release within the energetic spatially and temporally, thus enabling the in-operando spatially selective control of the throttling. We give examples of employing reactive microwave sensitizers, Ti and MnO2 to trigger the localized ignition of non-microwave sensitive energetic components. In addition we demonstrate that by embedding wires which can act as a microwave receiving antennas we can both initiate ignition locally, or alternatively accelerate the burn rate locally.
In a second approach we demonstrate a new concept through which the volatility of a high energy density liquid propellant can be dynamically manipulated enabling one to (a) store a thermally insensitive oxidation resistant non-flammable fuel (b) generate flammable vapor phase species electrochemically by applying a direct-current voltage bias and (c) extinguishing its flame by removing the voltage bias, which stops its volatilization. We show that a thermally stable imidazolium-based energy dense fuel, can be made flammable or non-flammable by application or withdrawal of a direct-current bias. This cycle can be repeated as often as desired. The estimated energy penalty of the electrochemical activation process is only ~ 4% of the total energy release.

Active Control of Energetic Material Decomposition GregYoung; Virginia Polytechnic Institute and State University, United States

In an effort to create safer and more mission flexible energetic materials, we are exploring the potential of using electrical stimuli to start, stop, restart, and throttle material decomposition/reaction. Specifically, we are examining the ability to actively control the ignition, combustion, and extinguishment of solid propellants. In the roughly 80 years since the first rubbery composite propellants emerged, relatively little has changed in terms of performance, or perhaps more importantly their functionality. Solid propulsion systems are still plagued today with very little operational flexibility. One recent concept for actively manipulating solid propellant combustion involves taking advantage of electrochemical processes with the application of electrical power to the condensed phase of the propellant. Questions linger as to whether electrochemical or thermal processes dominate in these environments. Whether ignition or extinguishment is the goal, the answer likely changes, and satisfying both is challenging. But, by targeting specific ignition and combustion mechanisms, new solid propellants which can be actively controlled are emerging.
Composite propellants at minimum comprise a polymeric binder and crystalline oxidizer but may also include additives such as metal powders to enhance performance. Typical properties that are desirable for binders and oxidizers may be different in electrically controllable propellants where responsiveness may be more important than metrics such as specific impulse. Performance based additives are generally selected to improve the caloric properties of the propellant, however, when responsiveness is desired, different additives may be considered to elicit a specific response designed to improve operability. Additives which allow us to optimize one response for ignition/combustion/or extinguishment are often in opposition to another desired response due to competing mechanisms complicating the situation. That is, materials which tend to promote ignition, tend to impede extinguishment, and vice versa. The role of each of these components, binder, oxidizer, and additives is explored in the development of electrically controlled solid propellants which can be ignited, stopped, and restarted with only the application or removal of electric power. The formulation, fabrication, combustion behavior and properties of propellants controlled by electrical power will be discussed under relevant operating conditions.

Preparing, Tuning and Characterizing Spherical Composite Powders of Reactive Materials EdwardL. Dreizin and MirkoSchoenitz; New Jersey Institute of Technology, United States

It was recently discovered that spherical composite powders with attractive mechanical and chemical properties can be prepared using emulsion-assisted milling. During milling, starting powders are simultaneously being refined, mixed, and packed inside droplets in the emulsion. In the produced powders, each particle is a spherical compact combining the starting material components mixed on submicron scale. The powders typically have narrow size distributions reflecting the size of droplets in the emulsion. Powders also have certain porosity. Both porosity and size can be controlled by the milling conditions. The emulsion-assisted milling was found to be a versatile material processing technique effective for making composite spherical powders of metals, ceramics, polymers and mixes thereof. Recent progress in preparation of such powders will be reviewed considering both metal-metal and metal-oxidizer compositions. Correlations between milling process parameters and morphological features of the produced powders will be considered. Separately, correlations will be explored between the powder's morphological features and energetic performance. It will be shown that the powders with improved metrics characterizing their sphericity also have a better mixing between components that leads to their enhanced reactivity.

11:00 AM SF07.10.02
Correlation of Structure, Morphology and Energetics for Gasless Reactive Composite Powders JonathanL. McNanna, EdwardL. Dreizin and MirkoSchoenitz; NJIT, United States

Metal based composite powders capable of highly exothermic, gasless reactions were prepared by mechanical milling, adjusting parameters to intentionally vary particle characteristics. Two material systems were explored. In Ni/Al composite, intermetallic phases form exothermically leading to self-heating and accelerated oxidation. In a self-contained fuel/oxidizer system, Al/Fe2O3, a classic thermite reaction occurs forming molten iron and aluminum oxide. For each composite material, fully-dense irregularly shaped powders, as well as porous spherically

shaped powders are prepared and compared to each other. Particle characteristics such as size, shape, and morphology are observed by electron microscopy and low-angle laser light scattering. Scale of mixing and inclusion size are observed through image analysis and correlated to results of thermal analysis and ignition experiments. Specifically for the case of spherical powders, which are of interest for additive manufacturing techniques, milling parameters are optimized and associated with target size, uniformity of size, and sphericity. Finally, correlations are sought between morphological and energetic characteristics of the prepared materials.

11:15 AM *SF07.10.03
Optical Ignition and Combustion Characterization of Metal Fluoropolymer Composites StevenF. Son; Purdue University, United States

The ignition of energetic materials, and specifically solid propellants, is a complex process that must be safe, consistent, and precisely controlled. There is a wide range of applications with specific ignition requirements for solid propellants including inflation of airbags, propulsion systems (including rockets), as well as arm and fire devices. Currently, electrical or percussion pyrotechnic igniters are most the commonly used ignition systems. These systems must be carefully designed to deliver the proper amount of energy to a specified surface area of the propellant. A photon light source (i.e., flash or laser-based, ranging from UV to IR wavelengths) can potentially be used to ignite energetic materials with lower input energy and more precise spatial and temporal control, thereby improving safety and reliability by eliminating electrical systems used in pyrotechnic igniters. In addition, they could be potentially safer from stray electrical charges causing unintentional ignition. Here, we further explore the potential of optical ignition for energetic systems and identify ideal materials that can be used for optical ignition. In order to identify optically sensitive materials, we will study ignition energies, ignition delays, flame temperatures, and other combustion characteristics for possible energetic materials. This research addresses a gap in understanding of optical ignition for energetic materials, as finding and integrating materials that are optically sensitive while still being practical can be extremely challenging. These challenges include: (1) a lack of absorptivity to optical wavelengths in the UV to low-IR range, and subsequently, a very high sensitivity to input energy at the absorptive wavelengths that makes sustained ignition difficult, (2) a need for full density materials in practical energetic systems, while optically sensitive materials are exceedingly difficult to ignite as packing density increases due to heat transfer, and (3) the lack of research regarding novel fuels/oxidizers for the specific purpose of optical ignition.

Metal/fluoropolymer energetic materials have been of interest to the energetic materials community for many years. Due to fluorine's excellent oxidizing ability, they can be used in composite materials with metal fuels to produce energetic materials for a wide variety of applications. Polytetrafluoroethylene (PTFE), polyvinylidene fluoride (PVDF), polycarbon monofluoride (PMF), and terpolymers such as tetrafluoroethylene, hexafluoropropylene, and vinylidene fluoride (THV) have already seen extensive use in applications ranging including protective coatings, strain gauges, and electronics. However, when combined with metals such as lithium, magnesium, aluminum, or titanium, they also present an opportunity for a wide variety of energetic materials. For this study, metal/fluoropolymer composites present a novel opportunity for exploring optical ignition of widely absorptive, full-density energetic materials. This work will characterize the combustion and sensitivity of metal/fluoropolymer composites to provide novel materials for optical ignition of energetics.

Specifically, this work will begin with finding a suitable energetic composite that is optically sensitive. Once this material has been identified, research will be done to thoroughly characterize the optically sensitive composite by looking at additive manufacturability, flame temperatures, and ignition sensitivities from various methods and formulations. Once the material has been thoroughly characterized, it will be implemented into solid propellants to test the feasibility of the material in practical energetic systems. Finally, the lessons learned from this work will be applied to novel formulations to identify new optically sensitive energetic composites.

SESSION SF07.11: Reactive Materials and Machine Learning
Session Chairs: Alain Esteve and David Kittell

1:30 PM *SF07.11.01
Sensitizing Reactive Materials to Shock using Porosity Siva KumarValluri and DanaD. Dlott; University of Illinois Urbana-Champaign, United States

Metal oxidization can produce perhaps twice the energy of molecular explosives, but because metal oxidization is a combustion process requiring mass transfer to mix fuel and oxidizer, it is generally too slow to support detonations. In collaboration with Prof. Edward Dreizin of NJIT, we have been using materials produced by arrested reactive milling (ARM) which creates metal/oxidizer microparticles that are mixed on the nanoscale. Since a large variety of metal composites can be produced by this method, we need high-throughput tabletop methods to screen candidate materials for fast energy release under shock compression. We have developed a method that requires only a few microparticles which can be embedded in a transparent polymer and shocked by a laser-launched flyer plate. Nanosecond thermal imaging and optical pyrometry allow us to correlate properties such as particle size and shape to shock response. Recently we studied a nanoporous composite containing Al and dual oxidizers MoO_3 and KNO_3. Studies of the particle structure showed a strong correlation between size and porosity, and shock experiments showed that increased porosity lowered the shock threshold for reaction. This material was shown to release energy at rates comparable to HMX.

2:00 PM SF07.11.02
Designing Metal Fuels for Custom Thermite Compositions MelissaMello, Kerri-LeeA. Chintersingh, MirkoSchoenitz and EdwardL. Dreizin; New Jersey Institute of Technology, United States

Thermites are combinations of metal and oxide powders that, when ignited, exothermically react to release tremendous amounts of energy that can be used in welding, pyrotechnic, and military applications. Past work explored thermites by altering the oxidizer, morphology, microstructure, or fuel to oxidizer ratio and typically used the traditional fuel of choice, aluminum. Recent research on combustion of various metals and the development of the machine learning (ML) algorithms enables one to accelerate design of custom thermites. Materials can be customized to increase the rate of energy release, target specific temperature, generate specific gases, or have a gasless reaction. This customization can be achieved by combining thermite and intermetallic reactions, generating tunable mixing scale distributions of fuel and oxidizer, and exploiting distributions of particle sizes, shapes, and porosities. Here, the effect of the combination of such metal fuels as aluminum and zirconium is explored on the microstructure and reactivity of thermites with CuO, Fe_2O_3, and TiO_2 oxidizers. Composite thermite powders are formed by arrested reactive milling, a high-energy ball milling technique. Materials are characterized through SEM imaging and X-ray diffraction to explore morphology, microstructure and phases to aid establishing structure-function-performance relationships. Differential scanning calorimetry is used to observe the low temperature reaction sequences and product phases that may be relevant to employ in the optimized ignition and combustion scenarios. Preliminary results show that in argon environments up to 1273K, samples with greater than 25 at% Zr have low-temperature exotherms likely due to the formation of aluminides prior to subsequent oxidation of aluminum. Prepared samples are ignited using an electrically heated wire in air. A 440-nm wavelength laser ignites small batches of the prepared thermites in a closed 17-mL chamber, operated from 1 to 760 torr. A CO_2 laser ignites similar samples in room air. Ignition delays, burn times, and pressures traces are recorded for the laser-ignited samples. Emission produced by the flame is explored spectroscopically. Condensed combustion products are collected and analyzed. This work will focus on tailoring thermite reaction by tuning metal fuel composition and microstructure. The key experimental data will be used by an ML algorithm to optimize the tunable material parameters and develop novel thermite formulations on demand.

2:15 PM SF07.11.03
Characterizing Combustion Behavior in Al-Based Composite Metal Powders using X-Ray Phase Contrast Imaging and Machine Learning MichaelR. Flickinger, DeeptiHedge, YunzheWang, VishalPatel and TimothyP. Weihs; Johns Hopkins University, United States

Al-based composite metal powders made through arrestive ball-milling and Physical Vapor Deposition have shown dual-phase combustion behavior where Al burns in the vapor phase and another element like Zr, or Ti burns in the condensed phase. These particles tend to microexplode which enhances overall combustion efficiencies. Acquiring a robust understanding of the mechanisms leading to particle microexplosions is of particular interest for researchers who seek to independently control the ignition and combustion properties of these powders.

X-ray Phase Contrast Imaging (XPCI) has previously been used to investigate the *in situ* internal bubbling of reactive powders that leads to microexplosions. Recently, a large amount of high speed videographic XPCI data was collected at the Advanced Photon Source to assess the role of composite chemistry on combustion characteristics. Here we present data comparing the combustion behavior of composite ball-milled powders made with aluminum and either a refractory element such as Hf, Ti and Zr or other additive (C or Mg) at varying stoichiometric ratios. In particular, the powders' bubble growth and microexplosion frequency was correlated with particle size, velocity and chemistry. Unlike previous work where XPCI videos were analyzed manually, we leverage various machine learning methods to extract meaningful information from hundreds of thousands of video frames. Additional experiments were performed in an Ar/O_2 (21% O_2) to assess the impact of nitrogen on internal bubbling and microexplosion frequency.

Hybrid Modeling for Decoding Reactive Materials SiliDeng; Massachusetts Institute of Technology, United States

The design of reactive materials with reliable and programmable performance fundamentally hinges on understanding their chemical kinetics and transport properties. Traditional characterization tools, such as differential scanning calorimetry and constant-volume combustion experiments, have offered valuable insights into ignition phases and energetic performance quantification. Additionally, recent advancements in diagnostic technologies like Laser-Induced Air Shock from Energetic Materials (LASEM) and in-operando microscopy measurements have unraveled time and space-resolved dynamical responses of energetic materials. These multi-scale, comprehensive observations have deepened our understanding of kinetic and thermal transport behaviors. However, a challenge persists: the translation of these rich data sets into an understanding of intrinsic chemical kinetics and transport properties. This hurdle largely stems from the absence of an inverse modeling approach that could tie data to these physically meaningful properties.

In this presentation, we delve into hybrid modeling techniques that bridge this gap, extracting intrinsic properties (chemical kinetics and transport properties) of reactive materials from diagnostic tool data. These hybrid models integrate physical laws as first-principle constraints, enabling the extraction of kinetic and transport properties via sensitivity analysis. We illustrate the applicability of this approach through three examples involving the Chemical Reaction Neural Network (CRNN) [1], a kinetic inference framework for constant-volume combustion tests [2], and an inference framework for one-dimensional flame propagation. Initially, we introduce the CRNN as a versatile inference model adept at discovering chemical kinetics from time-history species measurements. Next, we delve into a specially designed kinetic inference framework that decodes chemical kinetics from time-history pressure profiles captured in constant-volume combustion tests. Lastly, we explore the simultaneous inference of chemical kinetics and transport properties from temperature fields in 1D flame propagation tests. These three examples collectively demonstrate the potential of hybrid modeling in unearthing the intrinsic properties of energetic/reactive materials from varied types of measurements.

4:00 PM SF07.12.02
Self-Propagating Reaction Mechanisms in TiB_2 Integrated Al/CuO Nanothermites VidushiSingh, RichardMonflier, NicolasMauran, AlainEsteve and CaroleRossi; LAAS-CNRS, France

Unary nanoscale metallic fuels such as Al, Ti, Mg, Zr and B with an oxidizer have been massively explored in reactive energetic formulations commonly used in explosives and propellants owing to their high combustion energy. While Al has routinely been preferred, its low melting point and the resultant sintering effects curtail the reaction surface area. Despite the high gravimetric and volumetric enthalpies of B, low combustion rates and poor diffusion across the liquid boron oxide barrier restrict its use as a fuel. Although Ti oxidation can be induced at low temperatures, its high sensitivity limits the integration in nanolaminates. To overcome some of these common limitations imposed by single fuel thermites, binary fuel systems are seen as a very desirable strategy to prepare insensitive safe to handle nanothermites exhibiting fast energy release and high propagation rates.
Whereas TiB_2 may not be the most obvious choice of fuel, the fuel-oxidizer surface synergistic effects brought by its integration in Al/CuO nanolaminates resulted in enhanced reactivity characterized by relatively faster burn rate and shorter ignition delay [1]. Beyond the excellent heat conducting properties, TiB_2 demonstrated a strong affinity towards oxygen boosting low temperature CuO decomposition concomitantly forming TiO and boron oxide, following which Al underwent oxidation via both liquid boron oxide and vapor phase oxygen. There is however a lack of fundamental understanding of the self-propagating mechanisms in such ternary thermites due to the complexity associated with the material heterogeneities and multiphase flow occurring during combustion.
Herein, sputter deposited ternary Al-TiB_2/CuO nanolaminates are fabricated as model structures, and a high-speed imaging system is utilized to study the flame-front propagation at sub-millimeter scales. DC magnetron sputtering is specially chosen to obtain precisely controlled layer-by-layer structures. To assess the extent of variation in the combustion regime, TiB_2:Al molar ratio is varied between 0 and 1. We examine the entire material life cycle of Al-TiB_2 bi-fuel component comprising of microfabrication, placement of TiB_2 in Al/CuO multilayer stack as well as the individual effects of Al and TiB_2 on the self-propagating combustion mechanism. While the individual placement of TiB_2 nanolayer in the stack only slightly affects the ignition and the combustion properties, the measure attests to be critical in precluding nano-structural losses. Finally, various combustion stages and flame front behaviors are discussed, followed by a scenario of the combustion process.

Inferring Transport Properties and Chemical Kinetics of Reactive Materials from Flame Dynamics SuyongKim and SiliDeng; Massachusetts Institute of Technology, United States

Reactive materials exhibit self-sustaining reactions that generate energy in the form of heat, light, and pressure. These materials find applications in power generation, novel material synthesis such as explosives/propellants, micro-joining/welding, transient electronics, and space constructions, owing to their tunable reactivity, mixing length scales, and architectures. Understanding the fundamental processes governing flame propagation is crucial for designing materials with desired properties. Current methods extract chemical kinetics and transport properties from flame propagation measurements by simplifying mass and energy conservation laws and correlating measurable temperature data. However, these methods are limited to steady flame propagation and may underestimate activation energy. Moreover, they may not accurately reproduce flame propagation speed based on the inferred properties.
To overcome these limitations, we propose a new framework that accurately infers transport properties and chemical kinetics from dynamic measurements of flame propagation. Unlike existing methods, our approach utilizes flame structures and dynamics derived from first-principle models through sensitivity analysis of the dynamical system. This framework enables the understanding of both steady and unsteady flame propagation, including pulsating flame dynamics. We demonstrate the accuracy and capability of our model through examples of steady and pulsating flame propagations. Furthermore, we compare the inferred chemical kinetics and transport properties with those obtained using existing methods for various materials. Finally, we discuss the potential integration of our proposed framework with state-of-the-art imaging diagnostic techniques.

Interfacial Reactions and Energy Transfer in Sputter Deposited Mg/CuO Thermite Reactive Nanolaminates ChloeSkidmore[1], Jon-PaulMaria[1], ElizabethC. Dickey[2] and StephenFunni[3]; [1]Penn State University, United States; [2]Carnegie Mellon University, United States; [3]Cornell University, United States

Multilayered stacks of reactive nanolaminates (RNLs) with well-defined interfaces consisting of a metal fuel and oxidizer offer a streamlined process for observing energy transduction and chemical reactions between thermite reactants. This presentation explores oxygen transfer in magnetron sputtered Mg/CuO RNLs as a function of bilayer thickness and metal-oxide layering sequence. Energy production in stoichiometric Mg-CuO films with bilayer thicknesses between 170-1020 nm is examined via differential scanning calorimetry (DSC), while Kissinger analysis methods are implemented to determine effective activation energies (E_a). To elucidate structural evolution in the Mg/CuO system, select samples are analyzed via in-situ high temperature x-ray diffraction (HTXRD). Calorimetry data show exothermic maxima near critical temperatures reported in the Mg-Cu phase diagram, along with a decrease in reaction temperature and effective E_a values as bilayer spacing increases. The 1 BL Mg-CuO RNL demonstrates an onset temperature near the Mg melting point of 650 °C and has the highest effective E_a of 600 kJ/mol. The 2-4 BL Mg-CuO films exhibit effective E_a values of 138-162 kJ/mol and reaction temperatures between 511-548 °C, which is within the Mg_2Cu/liquid region of the binary phase diagram. At 5-6 BL, a solid-state reaction process emerges with samples showing exothermic maxima between 388-421 °C and effective E_a values of 102-106 kJ/mol. These data are further corroborated by HTXRD data on 1, 3 and 5 BL Mg-CuO samples, with Cu peaks forming at 640 °C, 530 °C, and 415 °C, respectively. Further film characterization and preliminary thermal analysis also suggests that the epitaxial relationship (or lack thereof) between the substrate and initial RNL monolayer impacts film crystallinity, grain growth and reaction onset temperatures. Mg films deposited on c-sapphire are highly crystalline and strongly (000*l*) textured, while depositing Mg on CuO results in a decrease in overall crystallinity and a less textured Mg film. Conversely, CuO deposited on the substrate results in poorly crystalline films, but CuO crystallinity increases when CuO is deposited on Mg. Preliminary DSC analysis on Mg/CuO

samples with different layering sequences also indicate that bilayer films with CuO deposited first have lower reaction temperatures and effective activation energies. These results are supported by HTXRD results for 3 BL Mg/CuO samples with opposing stacking sequences – when CuO is deposited first Cu peaks appear at ~ 475 °C, while a Cu peak does not appear until 540 °C when Mg is deposited on the substrate. It is proposed that the highly textured Mg layer has a lower defect density in comparison to more disordered layers, resulting in decreased diffusion and increased reaction temperatures. The above findings indicate that reaction properties such as energy release and onset temperature are not easily estimated by solid state reaction dynamics and enthalpies of formation alone. Factors such as bilayer thickness, oxide passivation and intermetallic formation significantly influence observed reaction pathways, while seemingly innocuous deposition decisions such as RNL stacking sequence effect crystallinity and grain growth, subsequently impacting mass transport and reaction onset temperatures.

SESSION SF07.13: Tailoring Reactive Materials Performance II

Optimizing the Composition of Alloyed Metal Powders for Enhanced Ignition and Combustion TimothyP. Weihs; Johns Hopkins University, United States

Elemental Al or Mg powders are commonly used in high explosives, propellants, and pyrotechnics to enhance performance, yet in many cases combustion efficiencies are well below 100%. Recent closed-chamber detonation studies suggest that multi-element or alloyed metal powders ignite more readily and reach much higher combustion efficiencies than elemental Al powders. However, our community is just beginning to explore the many alloys that can be formed by mixing elements with high heats of combustion such as Al, Mg, Li, B, Si, Ti, and Zr. Given small variations in the atomic fraction of four elements in an alloyed powder generate over a million potential chemistries, we are leveraging a combinatorial process to rapidly screen the ignition and combustion properties of alloyed metal powders. We do so by sputter depositing ~ 30 micron thick coatings onto polymer meshes and then debonding the coatings to create elongated powders. In our first two combinatorial studies 1) we systematically vary the at% of Zr in Al-Zr and Al-Mg-Zr powders and 2) we vary the relative percentage of Al and B in Al-B-Ti powders. In this presentation we report on trends in ignition temperatures as a function of chemistry using hot wire experiments, and we describe their combustion temperatures, durations, and gaseous species using a novel, hyperspectral imaging system. Trends in the measured properties as a function of chemistry will be compared with those for elemental powders.

9:30 AM SF07.13.02
Reduction and Combustion of Iron Powder for Energy Storage: The Influence of Micro-Structure ConradHessels, GiuliaFinotello, XiaochengMi, RoyHermanns and Philipde Geoy; Eindhoven University of Technology, Netherlands

Cyclic reduction and combustion of iron powder is emerging as a promising method for seasonal storage and intercontinental transport of renewable energy. When renewable energy is in surplus, iron-oxide powder can be reacted with green hydrogen to produce “energized” iron powder. When the energy needed again, the iron powder can be reacted/combusted with oxygen in air, thereby releasing a tremendous amount of heat.
Both the reduction (in solid-state) and the combustion processes (in liquid state) result in changes in the micro-structure and morphology of the powder, which in turn influences the performance of the cycle. The reduction process produces porous particles (sponge iron), with a reduction-temperature-dependent pore size. The resulting effective surface area influences the ignitability and safety of the powder. The subsequent combustion process produces a combination of (1) spherical particles with hollow (open and closed) cores and (2) “tulip”-shaped hollow shells. The closed cores are likely the result of shrinkage cavities, while the “tulip”-shaped shells are most likely caused by micro-explosions observed during combustion. All combusted particles show cracks and preferred crystal orientations, in turn influencing the reduction process.
In this work combusted and reduced powder is analyzed using various material characterization techniques, such as scanning electron microscopy (SEM), X-ray diffraction (XRD), particle size analysis, and X-ray computed tomography (μCT). The micro-scale findings are coupled to macro-scale phenomena observed during the combustion and reduction processes.

9:45 AM SF07.13.03
Ignition and Combustion of Al/Zr Composite Powders in Varied Gas Environments MichaelR. Flickinger and TimothyP. Weihs; Johns Hopkins University, United States

It is well known that reactive metal composite powders can be ignited at relatively lower temperatures due to exothermic intermetallic formation reactions which help drive the particles to higher temperatures. This study systemically assesses the impact of intermetallic reactions contributing to particle ignition in three Al/Zr composite powders and differentiates its impact from oxidation and nitridation which may also influence ignition initiation.

Here we synthesized three different shaker milled Al/Zr composite powders with varying Zr at% content: 3Al:Zr, Al:Zr, and Al:3Zr. After sieving particles below 75 microns, powder samples were heated to different temperatures at a slow heating rate (20C/min) in Argon based on initial DTA traces done to 1000C for each powder. Those samples were then characterized via XRD, DSC, TGA, and SEM to explain wire ignition results. Wire ignition experiments performed at heating rates between 15-25,000 K/s revealed that increasing Zr at% decreased the overall relative ignition temperature rise as all the intermetallic heat was removed.

The combustion properties of the annealed powders were investigated to see if removal of the intermetallic heat affected the powder’s combustion behavior. A custom spectroscopy system called hyperspectral imager for emission and reactions (SHEAR) was used to gather key combustion data including combustion temperature profiles, burn durations and emission spectra. We relate this data to the microexplosion frequency and ignition delay of the three different powders.

Fabrication, Reactive Characteristics and Combustion Properties of Al Based Core-Shell Composite Particles JohnWen and AnqiWang; University of Waterloo, Canada

Metastable intermolecular composites (MICs) have shown promising characteristics in storing and supplying thermal energy to produce heat and power especially for propulsion and miniature systems. To improve their ignition and flame propagation properties, core-shell and other assembled structures are commonly fabricated as aerogels, thin films, multi-layers and powders with enhanced interfacial compatibility between reactive components. We developed wet-chemistry synthesis routes to fabricate a variety of spherical and colloid core-shell structured aluminum-based MICs including Al/CuO, Al/Fe3O4 and Al/NiO. Electron microscopies, X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS) were used to examine the geometry and microstructure of core-shell products. A good coverage of metal oxide nanoparticles has been achieved on aluminum micro- and nano-sized particles, as the crystallization of metal oxide or complex nanoparticles under controlled chemical environment was the key to homogeneously fabricated core-shell structures. The onset temperature, energy release and activation energy corresponding to the major exothermic events were found to be distinct yet comparable to physically mixed powders of aluminum and oxides nanoparticles due to the shortened diffusion distance between aluminum and oxidizer nanoparticles, evidenced by the thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) results.
Combustion of these core-shells, patterned as thin-films or loaded in a combustion chamber as loose powder, exhibited improved ignition and flame propagation characteristics. High-speed microscopic imaging and infrared thermography were utilized to reveal the mass and thermal transport phenomena near the flame front of a burning film composed of energetic particles. While the reactive sintering mechanism seems valid for both physically mixed and core-shell samples, the thickness of the flame front and its propagation speed demonstrated the competitive roles of the reactivity, sintering and heat conduction. The formation of standalone core-shell reactive structures reduced the role of reactive sintering of aluminum nanoparticles and generated

much finer hotspots along the propagation of flame front. Generally the global burning rates at different fuel/oxide equivalence ratios are determined by the reactivity and thermal transport. Near the stoichiometric condition, although reactivity is high, low thermal conductivity limits the thermal feedback, leading to non-uniform burning propagation on the thin film. On the other hand, at fuel-rich conditions, despite uniform burning propagation, the global burning rate is limited by low reactivity. During the combustion tests with loose powders, a two-stage combustion behavior has been observed as laser induced ignition was achieved first on the surface exposed to air before the combustion propagation swept through the entire sample volume. Such two-stage combustion behavior, being more commonly observed for physically mixed MICs, is less evident in core-shell structured MICs. The formation of individually reactive core-shell particles allows for enhanced condensed-phase reactions within a smaller zone which accelerates the propagation of combustion once the bulk reaction is initiated. While the ignition delay and burning rate of these powders are not necessarily corelated to the reactivation kinetics found from the DSC measurements, thermodynamic properties and energy transport paths within the packed sample play a more significant role in the combustion chamber tests.

Bridging the Gap between Improved Reactivity of Aluminum/Gallium Nanoalloy and Nanoscale Composition Variations via Advanced Microscopy Chi-ChinWu[1], ScottWalck[2], HenryJ. Hamann[3], MetinOrnek[3], StevenF. Son[3] and Padinjaremadhom.V. Ramachandran[3]; [1]U.S. Army Research Laboratory, United States; [2]Survice Engineering Company, United States; [3]Purdue University, United States

Aluminum/gallium (Al/Ga) nanoparticles were synthesized by reducing Ga (III) chloride to neutral Ga^0 on fresh surfaces of relatively uniform (~40 nm) aluminum nanoparticles (nAl), Results from thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) demonstrated improved reactivity relative to a commonly used commercial nAl without Ga coating. The Al/Ga nanoparticles displayed a sharp exothermic peak and single-stage oxidation significantly lower than aluminum (Al). Advanced transmission electron microscopy (TEM) techniques were exploited to fill the gap between the morphology and locally varying composition of Al/Ga nanoalloy and enhanced thermal behavior with capabilities that conventional laboratory scale tests and baseline material characterization could not. High-resolution TEM showed different shapes of Al cores surrounded by amorphous shells, depending on the wait-time of Ga addition. The low Ga concentration was confirmed by X-ray energy dispersive spectroscopy (XEDS) acquired from relatively large quantities of Al/Ga agglomerates. Electron energy loss spectroscopy (EES) and XEDS mapping were employed in scanning (STEM) mode to further investigate Ga and other trace elements. The results from only a few well-dispersed particles accurately revealed the nanoscale distribution of trace elements. Overlaid multivariate statistical analysis (MSA) quantitatively illustrated the nanoscale spatial variations and showed the presence of residual elements in shells. Gallium was found to be most concentrated at the core/shell interface for large particles, while small particles were composed of monocrystalline Ga surrounded by a thin oxide layer. Upon heating, the melting Ga underneath the oxide shell presumably facilitates shell fragmentation and exposure of active Al core for oxidation, leading to the improved reactivity observed by TGA/DSC. This work not only provides significant insights on evaluating the spatial distribution of Ga coating on nAl for bimetallic nanoalloy exploitation, but also underscores the critical value of advanced materials characterization to advance the understanding of novel energetics.

11:15 AM SF07.14.03
Improving the Morphology and Reactivity of Ball-Milled Aluminum Powders using Liquid Metal Embrittlement PurvamGandhi, MirkoSchoenitz and EdwardL. Dreizin; New Jersey Institute of Technology, United States

Liquid Metal Embrittlement (LME) is a process of modifying normally ductile/malleable solid metals, such as aluminum, with the help of liquid metals, such as gallium, in order to limit their elongation to failure. Recent studies have shown improvements in reactivity of aluminum-based thermites by mixing aluminum powder with a gallium alloy, galinstan, liquid at room temperature. Here, the LME approach serves to change not only the reactivity but also the morphology of aluminum powders used as fuels. Aluminum powders with tunable particle sizes and shapes are prepared by ball-milling. A Retsch PM 400 planetary mill is used. Emulsion-assisted milling is used to prepare porous spherical aluminum powders with narrow particle size distributions. Thin foils of gallium serve as additives mixed with the starting Al powder in a milling vial. Less than 5 % of gallium are added and milling is performed in agate vials with agate milling balls to minimize interaction of gallium with the milling media and vials. Powders prepared with and without addition of gallium are recovered and characterized using scanning electron microscopy, thermal analysis, and x-ray diffraction. Effect of gallium additives and milling conditions on the structure, morphology, and reactivity of the prepared powders will be discussed.

11:30 AM SF07.14.04
Using Low-Temperature Plasmas to Engineer Nano-Energetic Materials LorenzoMangolini, BrandonA. Wagner, EmmanuelVidales Pasos and MichaelR. Zachariah; University of California, Riverside, United States

Low-temperature plasmas are a versatile and effective tool for nanoparticle production. The presence of high-energy electrons in these systems is well-known to lead to the nucleation and growth of particles. While this is a major source of contamination in the semiconductor industry, the plasma community has now learnt to optimize low-temperature plasma processes for the deliberate formation of particles with desirable properties. For instance, low-temperature plasmas can produce particles sufficiently small to show quantum confinement effects [1] and localized surface plasmon resonance.[2] Due to their capability of producing particles with very small sizes (<10 nm), these systems are of obvious interest for application in energetic materials. In this talk, we will discuss two examples of how low-temperature plasmas can be used to produce magnesium-based and silicon-based energetic nanomaterials.
In a first example, magnesium nanoparticles are first produced via thermal evaporation of a bulk magnesium source. Following homogeneous nucleation, the particles are injected in a RF driven low-temperature plasma to which hydrogen is added. Optical emission spectroscopy is used to measure the atomic hydrogen density, which is found to be quite high (~10^{14} cm^{-3}). As a consequence, the magnesium particles are rapidly converted into magnesium hydride as they are aerodynamically dragged through the plasma, within a residence time of a few tens of milliseconds. XRD analysis confirms that the MgH_2 molar fraction can be as high as 25% after in-flight plasma processing. Characterization of the combustion properties confirms that the hydrogenated magnesium particles have a significantly lower ignition temperature compared to Mg particles of the same size, as confirmed by time-of-flight mass spectrometry. Modelling of the energy exchange between the plasma and the nanoparticles suggests that while in the plasma, the particles are sufficiently hot to desorb hydrogen, limiting the degree of hydrogenation to roughly 25% for our current reactor design. This insight provides guidelines towards the development of magnesium-based particles with a significant degree of hydrogenation.
In a second example, we will discuss the case of ultra-fine (<10 nm) silicon nanoparticles which can be easily grown by RF excitation of a silane-containing plasma. Due to their large surface area, it is necessary to carefully control the surface chemistry of these particles. One way to do that, is to utilize a two-steps plasma reactor in which the particles are grown in a first plasma and then passed onto a second flow-through reactor to which a fluorocarbon source is added. TEM analysis suggests that this approach leads to the growth of a highly conformal CF_x shell onto the silicon core. We have found that this approach is very effective at preventing the formation of a native oxide. The core-shell particles form a nanothermite structure, whose combustion leads to the formation of SiF_x gaseous species, as confirmed by time-of-flight mass spectrometry measurements.

Physics-Based Co-Design of Energetic Molecular Crystals using High-Throughput DFT and Generative AI SantanuChaudhuri[1,2], JankiBrahmbhatt[1] and XavierBidault[1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

The packing motif of molecular crystals and co-crystals is a delicate balance between many subtle factors. The observed properties are not a linear function of the sensitivity of molecular building blocks. The common belief that stability, sensitivity, shock response, and performance can be co-optimized by a combination of molecular building blocks can be a simplification due to many unknown couplings between long-range and short-range interactions. We will discuss genetic algorithms for crystal structure prediction (CSP), and how this leads to an ability to search the potential energy landscape of common energetic materials and their polymorphs. Energetic materials can have the same molecular building blocks in many different conformations such as in RDX. Therefore, the E-V curve of molecular crystals and co-crystals are crowded at the bottom of the potential well with many predicted phases containing subtle differences in bond angle and relative rotational orientations of molecules. Using our models for multi-phonon up-pumping for sensitivity and thermochemical property predictions, high-throughput DFT methods can be used for searching polymorphs and co-crystals. We find that cocrystal sensitivity and properties show highly non-linear behavior. The case of CL20:HMX co-crystals will be

discussed. In comparison to co-crystals, molecular modification using a Diffusion based neural network can be a promising route for co-design with multiple objectives such as performance, sensitivity, and a range of thermochemical properties. We will discuss our latest molecular design tool DiffLinker, and generative adversarial neural network (GAN) based assembly of molecular crystals. They still need DFT training sets to improve accuracy but scaling on tens of A100 GPUs renders them highly efficient in generating a much larger pool of structures. A simple density-based screening can identify 10X more stable crystal structures compared to a DFT-based genetic algorithm for CSP. A closed-loop approach between generative AI for modifying molecular building blocks, using GAN to assemble crystals, and a subsequent genetic algorithm based or pure DFT or tight-binding refinement of best structures can be a highly efficient strategy for co-design of new generations of energetic crystals. The AI-generated molecular building blocks can also be ranked with respect to their many physical properties and synthetic accessibility scores. We will conclude with a summary of new methods, their relative accuracy, and their potential to change the future of energetic materials engineering.

2:00 PM SF07.15.02
Formulation and Combustion of Al/CuO Nanothermites using Flake-Shaped Al Nanoparticles Pierre-HenryEsposito[1], PierreGibot[2], MarcComet[2], RenaudDenoyel[1], DenisSpitzer[2] and Marie-VanessaCoulet[1]; [1]CNRS-AMU, France; [2]CNRS- ISL, France

Aluminum powders are widely used as fuels in propellants or in pyrotechnic mixtures. It is now well established that size reduction of aluminum particles from the micrometric down to the nanometric scale improves the combustion rate [1,2]. In the case of Al-based nanothermites, several other factors are shown to affect the combustion properties. Among them, one can cite, the surface functionalization of Al nanoparticles [3], the use of core-shell fuel-oxidant particles [4,5], and the incorporation of porosity [6–8].

In this work, we highlight the influence of morphology and surface properties of aluminum nanopowders on the combustion properties of Al/CuO nanothermites prepared by physical mixing. A comparative study is performed between nanothermites formulated using commercial aluminum nanospheres and two kinds of aluminum nanoflakes synthetized using high-energy ball milling and with different surface properties.

We will first present a detailed characterisation of initial Al nanopowders in terms of texture and reactivity towards air and water. Secondly, we will focus on Al/CuO energetic compositions. We will demonstrate that, contrary to was is generally expected, the flake shape is not problematic for the nanothermites formulation. Then, we will show that higher sensitivity thresholds can be reached notably for friction and electrostatic discharge by modifying the surface properties. Such enhanced thresholds might be of interest for safer handling. Finally, combustion tests will be presented and correlations between flame propagation velocity, morphology and Al nanopowders reactivity will be proposed.

This work received support from the Direction Générale de l'Armement (DGA), Aix-Marseille Université (AMU) and the Region Sud (AENA Project).

Tailoring Energy Release and Improving Processes in Additively Manufactured Reactive and Energetic Materials DylanJ. Kline; Lawrence Livermore National Laboratory, United States

Additive manufacturing (or 3D printing) can be used to create complex parts with features that could not otherwise be made via traditional machining or casting techniques. For reactive and energetic materials, additive manufacturing opens new possibilities to architecture materials with unique features and then leverage those features to tailor energy release in an unprecedented way. However, reactive materials additive manufacturing is still in its infancy and is ripe with opportunities to investigate structure-function relationships and process improvements. To better understand the role of process on architecture and function, new tools must be developed to characterize the manufactured parts. Fortunately, additive manufacturing natively lends itself to in situ inspection and new diagnostics are being developed to probe the process and create "digital twins" of AM components. This presentation will begin with a general overview of additive manufacturing techniques employed in reactive and energetic materials with a specific focus on advancements made in pursuit of tailored energy release. We will then shift towards a discussion on in situ diagnostics developed for additively manufactured energetic materials and the impact on improving manufacturing processes and understanding phenomena in experiments.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory (LLNL) under Contract DE-AC52-07NA27344. LLNL-ABS-849970.

3:30 PM SF07.16.02
Influence of Different Nano Structure Densities on the Self-Propagating Reaction of Ni/Al Multilayer KonradJaekel, YeseniaH. Sauni Camposano, SebastianMatthes, MarcusGlaser, Jean PierreBergmann, PeterSchaaf, JensMüller and HeikeBartsch; Technische Universität Ilmenau, Germany

Reactive materials have garnered significant interest for bonding applications due to their ability to provide localized and rapid heating, thereby minimizing heat exposure to thermally sensitive components. The reaction parameters of these materials, such as velocity and temperature, are typically tailored through adjustments in layer spacing, total thickness, and atomic ratio of the involved elements. In this study, we consider the surface structures as an additional parameter for reaction tailoring and introduce a new aspect: adhesion of the formed compound without additional intermediate layers on silicon chips with a thermal oxide as heat barrier. Previous experiments involving Ni/Al multilayers on the thermal insulator SiO_2, revealed that the reaction led to substrate damage. The damage inflicted was substantial, as it also caused destruction in the Si layer beneath the thermally produced SiO_2 layer. Additionally, the Ni/Al compound was detaching during the reaction. The layer structure would therefore not be suitable for reactive chip bonding.

To mitigate this issue, we employed a reactive ion etching process to structure the surface, followed by oxidation, to create a thermal insulating layer. This SiO_2 layer not only facilitated self-propagating reactions, but it also additionally leads to an improved material bond. The oxidized nanostructures vary in density and have a height of approximately 1 µm. The nanostructure's densities range between 4 – 27 structures per μm^2, distributed across three wafer batches. The structure density of the first and second batch amounts to 3.55 - 6.23 structures per μm^2 and 7.22

- 14.64 structures per μm^2, respectively. The third batch has a much higher range counting 21.69 - 26.53 structures per μm^2. There is a process-related variation in structure density between the center and the edge. After separating and cleaning the samples, Ni/Al multilayers with a thickness of 5 µm, bilayer spacing of 50 nm, and an atomic ratio of 50/50 at.% were deposited onto the structured surfaces using direct current magnetron sputtering.

Upon electric impulse triggering, the multilayers underwent self-propagating reactions on all samples. Reaction propagation speed and surface temperature were measured by means of a high-speed camera and high-speed pyrometer. The data have shown that both values distinguish significantly for different nanostructure density. The first two batches showed lower velocities with increasing number of structures. The maximum temperature decreased as well between the first and the second batch. In contrast, the third batch has the highest temperature and propagation velocity as well as the highest structure density. These were results caused by the destruction of the substrate during the reaction, like on a flat SiO_2 surface. Only at the edges, where the structure densities were below 23 structures per μm^2 the compound stayed on the substrate like in the other two batches.

Since the layer architecture is the same, these differences in reaction propagation and maximum temperature, are attributed to an increased defect density which is a consequence of the growth characteristic of the sputtered layer on the structured surface. Flaking also depends on the structure density. This destructive behavior is mainly attributed to the volume change during the phase transformation. We observed that high structure densities lead to flaking, similar to the reactions on flat SiO_2 surface. In the range between 3 – 15 structures per μm^2 the layers adhere very well. The surface treatment is therefore proposed as an adhesion promoter for the reactive bonding of silicon chips as well as an additional parameter to tailor the multilayer reaction.

3:45 PM SF07.16.03
Large-Scale Periodic Modification of Reactive Multilayer Morphology by Direct Laser Interference Patterning of Growth Substrates ChristianSchäfer[1], VincentOtt[2], MichaelStüber[2], FrankMücklich[1] and ChristophPauly[1]; [1]Saarland University, Germany; [2]Karlsruhe Institute of Technology–Institute for Applied Materials, Germany

Reactive materials are a combination of two or more phases that can react exothermically in response to an external stimulus. The reaction behavior is determined by the transport of mass and heat and by the release of the latter. Therefore, the micro- and nanoscale morphology of the reactant phases plays a crucial role. A common arrangement of reactants is the sputter-deposited multilayer stack, where the bilayer thickness at a given overall composition is the main design parameter.
Deviations from the ideally flat binary layer stacking would provide an opportunity to modify the reaction behavior, but are usually not achievable by simply modifying the deposition process parameters. In this work, we present a method to modify the micro- and nanoscale morphology of magnetron sputtered Ni/Al multilayers using micrometer-scale, large area periodic surface patterning of the growth substrate.
Line structures with different periodicities have been created on thin Copper substrates by means of picosecond Direct Laser Interference Patterning (DLIP). Electropolishing has been utilized in a subsequent process to remove sharp asperities inherent to the laser processing, resulting in nearly ideal, smooth sinusoidal surface profiles. In the deposited Ni/Al multilayer stack, which retains the line structure even after detachment from the substrate, we found different changes in the layer morphology, depending on the structure period and depth. Shadowing effects during deposition caused by the substrate topography resulted in pores at distinct locations across the samples. In addition, the substrate pretreatment led to a local change in the interface roughness between the individual layers of the multilayer stack as well as to a periodic modulation of the bilayer thickness. It is discussed how the well-defined large-scale distribution of defects and the modified morphology can be used to quantitatively understand how pores inhibit heat and mass transport and thus affect the self-propagating reaction.

4:00 PM SF07.16.04
Self-Propagating Reaction of Reactive Multilayers Grown on Substrates with Designed Surface Topography YeseniaH. Sauni Camposano, KonradJaekel, SebastianMatthes, EminaVardo, MarcusGlaser, HeikeBartsch, Jean PierreBergmann and PeterSchaaf; Technische Universität Ilmenau, Germany

Reactive multilayer systems (RMS) consist of alternating layers of two or more components, which will react exothermically if the system is heated up locally, triggering a self-sustained and self-propagating reaction. Several studies were carried out with the aim of controlling the behavior of the reaction by changing the bilayer thickness or the atomic composition of the system. Moreover, recently the impact of the substrate and its surface topography on the propagation of the reaction has drawn attention. In previous studies, the influence of the surface topography of the substrate on the reaction behavior and on the phase transformation of the RMS during the reaction was revealed. However, the effect of surfaces with systematically distributed and defined structures needs to be further investigated.
In order to produce substrates with designed surface topography, silicon chips with a defined number of line/valleys structures in the surface were produced by lithography, reactive ion etching process and KOH etching. The KOH etching time was adjusted in order to produce valleys with different depths in the surface of the substrate. Sequentially, a SiO_2 layer of 1 µm thickness was produced on the surface by thermal oxidation with the purpose of ensuring the self-propagation of the RMS reaction. Al/Ni multilayers of 5 µm total thickness with a bilayer thickness of 50 nm was deposited on the Si/SiO_2 substrates by magnetron sputtering. The RMS were characterized before and after reaction. The analysis of the morphology exhibits the influence of the substrate surface characteristics on the growth of the Al/ Ni multilayers and on the formation of defects, which are located in the slopes between lines and valleys. It was shown that varying the number and depth of the structures in the substrate allows us to tailor the size and the number of defects in the RMS.
To investigate the impact of the produced defects and the new morphology on the behavior of the reaction propagation front, ignition experiments were carried out. The reaction was initiated by spark ignition, a high-speed camera and a high-Speed pyrometer were used to record the propagation front and to obtain the temperature/ time profile during the reaction. These results show the impact of the RMS morphology on the propagation front behavior, the velocity of propagation decreases exponentially in relation to the number of lines in the substrate surface, and the registered maximum temperature decreases as well for samples with a higher number of line structures. The calculated velocity varied from 11 m/s for the RMS deposited on flat substrates to 4.5 m/s for the RMS on substrates with line structures. Moreover, it was found that structures with a depth over 3 µm block the self-propagation of the reaction. Despite the difference in the propagation velocity and the temperature, the X-ray diffraction patterns of the reacted samples show the reflexes of the B2 phase AlNi in the different samples and no reflexes of Al or Ni can be observed, which suggests the complete reaction of the system.
These results show the possibility of modifying the self-propagation characteristics of the RMS reaction by using substrates with designed surface structures, where the depth of the structures can be adjusted to define the path of the propagation front, while the line/ valley structures systematically distributed allows to control the velocity and maximum temperature during the reaction.

Toward Precision Additive Manufacturing for Extremes—Opportunities and Challenges of ML-Enabled Closed Loop Approaches MitraL. Taheri[1,2]; [1]Johns Hopkins University, United States; [2]Pacific Northwest National Laboratory, United States

Extreme environments, including radiation, high temperature, and corrosion, present grand challenges for current materials systems. Novel materials to overcome these challenges have been discovered at a feverish pace in recent years, owing in part to high throughput and combinatorial approaches. Unfortunately, promising materials systems underperform due to processing and manufacturing limitations, as well as geometric and density constraints. Additive manufacturing promises the answer to many of these challenges, however control of build processes remains an elusive goal. This talk presents advances in precise additive manufacturing through closed loop processes, embedding artificial intelligence and machine learning approaches with computing and sensing hardware during the build process. Success in tailoring structures at the level of the meltpool, and below, is shown. The ability to design and tune alloys at a microstructural level is shown to be possible, and to be tailored toward specific extreme applications.

11:00 AM SF08.01.02
Development of TiAl Alloys for Gas Turbine Blades Seong-WoongKim; KIMS, Korea (the Republic of)

Research on developing new TiAl alloys for high temperature applications is introduced. At KIMS, we have developed new TiAl alloys which have excellent room temperature and high temperature properties. Especially, the new alloy showed excellent oxidation resistance in the temperature range from 900 to 1000ºC by forming stable Al_2O_3 oxidation layer. Process developement of casting, forging as well as 3d printing on the newly developed KIMS alloys was introduced. Especially, small size turbine wheel and blade were manufactured be centrifugal casting process. The results from the testing and validation of TiAl blade were shown that KIMS alloy can be used as a turbine blade above 900ºC. In addition, we proposed some underlying mechanism of high temperature strength of KIMS alloy from TEM and SEM observations. Finally, the operation test of micro gas turbine is now under examination to confirm the possibility of the application of the new alloy in the gas turbune engine.

11:15 AM SF08.01.03
Enhancing the Performance of Plasma-Facing Materials Through Additive Manufacturing HyejiIm, SamuelPrice and IanD. McCue; Northwestern University, United States

Tungsten-based alloys possess significant potential for enhancing the efficiency of a fusion system due to their attractive properties. In this study, we explore additive manufacturing (AM) as a viable processing route to tailor into fine-grained structures in tungsten alloys while mitigating the issues associated with laser printing of pure tungsten. To identify suitable alloying elements for tungsten-based alloys, we assessed hot cracking susceptibility and phase stability of the candidate alloys. By incorporating titanium and iron as alloying elements, we successfully fabricated fully dense tungsten-based alloys utilizing laser-powder bed fusion. We performed a comparative analysis of the density, microstructure, and mechanical properties of additively manufactured pure tungsten and tungsten-based alloys. Titanium and iron were melted during the printing process, effectively filling the gaps between un-melted tungsten powders and improving the relative density of the alloys. The utilization of titanium and iron as alloying elements not only enables the fabrication of fully dense alloys but also enhances material performance, making it feasible to produce intricate parts in the field of plasma fusion.

11:30 AM *SF08.01.04
Compositionally Graded Transition from Tungsten to Ferritic-Martensitic Steels via Directed Energy Deposition for Fusion Reactors IbrahimKaraman[1], DenizEbeperi[1], TimGraening[2], YingYang[2] and YutaiKato[2]; [1]Texas A&M University, United States; [2]Oak Ridge National Laboratory, United States

Nuclear fusion reactors utilize W and W-based alloys as plasma-facing components, which require joining into steel cooling structures based on state-of-art divertor designs. Direct joining between W and steels leads to the formation of brittle intermetallics. Joining with filler alloys is not compatible with high-temperature applications as the microstructure may degrade and promote a critical failure. The directed energy deposition technique enables the deposition of multiple pre-alloy or elemental powders simultaneously, in a layer-by-layer fashion, with precise control of the composition to avoid the formation of intermetallic or detrimental phases. In addition, its ability to fabricate compositionally graded transitions reduces the coefficient of thermal expansion mismatch between adjacent interlayer alloys. In this study, we demonstrated a framework to optimize the processing parameters for each alloy, generated processability maps, and successfully fabricated a dense, multilayered, linear compositional gradient from W to Gr91 steel, using V-based and Fe-based alloys as transition elements. Microstructure and mechanical properties of the interlayers and the thermal cycling response of the gradient structure will be presented.

Corrosion Behavior of Metals and Alloys in Selected Emerging Harsh Environments JohnScully, Ho LunChan and ElenaRomanovskaia; University of Virginia, United States

Corrosion of engineering alloys in selected emerging harsh environments can exhibit rates which differ by 6 orders of magnitude depending on regulating attributes of the alloy, its surface, physical conditions and the exposure environment. For instance, corrosion in ionic liquids can vary from passive dissolution regulated by a passive film to active dissolution at four to six higher electro-dissolution rate. Case studies presented include chromium and Ni-Cr alloys in FLiNaK molten salt versus aqueous solutions as well as various examples in ionic liquids where the conditions for passivation versus active dissolution are largely unknown. The kinetic and thermodynamic parameters that limit electro-dissolution are discussed.

2:00 PM SF08.02.02
Limitations of Equiatomic Refractory High Entropy Alloys: Role of Reactive Elements in Al-Containing HfNbTaTiZr Refractory High Entropy Alloy ElafAnber[1], DavidBeaudry[1], SebastianLech[1], Jean-PhillippeCouzinie[2], JamesM. Rondinelli[3], ChristopherWolverton[3], ElizabethJ. Opila[4] and MitraL. Taheri[1]; [1]Johns Hopkins University, United States; [2]University Paris Est Creteil, France; [3]Northwestern University, United States; [4]University of Virginia, United States

Refractory high entropy alloys (RHEAs) hold the promise of superior mechanical properties at high temperatures but are plagued by a lack of oxidation resistance. Efforts to improve the oxidation resistance of RHEAs by adding classical passivation elements, such as Cr and Al, have been unsuccessful, largely due to the inability to form a continuous protective oxide scale, or the formation of deleterious secondary phases. Here, we present a detailed analysis of the oxidation behavior in a HfNbTaTiZr-based RHEAs with Al additions. Our study presents a case for stable and uniform oxide growth through tuning of the base alloy chemistry, where we examine the limits of passivating element additions to equiatomic RHEAs. Using a combination of multiscale microscopy and thermodynamic calculations, we determined that despite the increase in Al content, metastable phases and discontinuous oxides were dominant over the composition range of $Al_xHfNbTaTiZr$ (x=0,0.25,0.75). As expected, the base RHEA (x=0) showed severe pesting after a one-hour exposure in ambient/atmospheric/etc air at 900° C, where HfO_2, ZrO_2, TiO_2 and $TiNb_2O_7$ were formed. The addition of Al improved the oxidation resistance of the base alloy and prevented pesting via promoting the formation of Al_2O_3. STEM chemical analysis revealed non-uniform enrichment of Zr and Hf near the metal/oxide interface that could block the diffusion of passivating elements, and thus, act against the formation of a uniform passivation scale. The addition of Al also induced the formation of the $ZrAl_2$ intermetallic phase that led to reduced density of Zr-rich oxides. We reach the conclusion that even if RHEAs contain enough Al to develop Al_2O_3 scale (i.e., 13 at. %), the passivation layer formed is still non-uniform with a high density of metastable oxides and intermetallic phases. This highlights the need for a passivating approach other than Al additions. Overall, this work provides insight into base alloy chemistry and its interplay with passivating elements as a key determining factor in passive film growth during high temperature oxidation.

.

2:15 PM SF08.02.03
Advanced Nanometer Resolution *In-Situ* Strain Mapping for Metal Oxidation by 4D-STEMYingHan[1], YongwenSun[1], DanZhou[2], Hugo PerezGarza[2], AlejandroG. Perez[3], ThanosGalanis[3], StarvosNicolopoulos[3] and YangYang[1]; [1]Pennsilyvinia State University, United States; [2]DENSSolution, Netherlands; [3]Nanomegas, Belgium

Metal oxidation is a paramount concern in the realm of metal material applications, leading to the degradation of metal surfaces, corrosion, and a decrease in the mechanical properties of the metal. To gain a comprehensive understanding of the strain anisotropy resulting from metal oxidation, the utilization of accurate strain mapping is invaluable, and it enables the advancement of oxidation mechanism theory. Here, we focus on Zr as an illustrative example due to its importance in architecture materials for fuel cladding and developed an in-situ strain mapping method to study the oxidation in metal, by integrating four-dimensional scanning transmission electron microscopy (4D-STEM), advanced gas-cell-holder, precession electron microscopy and direct electron detector. The key to successful strain mapping by our method lies in ensuring high signal-to-noise ratio in the nano-beam electron diffraction patterns. The effect of gas pressure, sample thickness and electron beam precession will be discussed. Our approach facilitates high-quality strain mapping across a large field of view during zirconium oxidation with nanometer resolution. This proposed technique has significant implications for a wide range of corrosion studies, enabling more insights into the chemo-mechanical evolutions in materials under extreme environments.

Preventing Aqueous Corrosion of Light Alloys (Al and Mg) for Engineering Applications SviatlanaV. Lamaka; Institute of Surface Science, Helmholtz Zentrum Hereon, Germany

The talk will present several approaches for preventing aqueous corrosion of aluminum and magnesium alloys used for engineering applications. Bulk or thin layers of electrolytes (300-30 micrometers) are considered. High-throughput robotic testing protocols of corrosion inhibition employ traditional or spatially resolved electrochemical methods, spectroanalytical methods but also recently validated image analysis approaches. These methods provide versatile and reliable data to train quantitative structure-property relationship (QSPR) models. Machine learning algorithms then identify hitherto untested potent corrosion inhibitors that are experimentally validated. Implementing identified inhibitors into industrial coatings and studying their inhibition mechanisms will be also presented. Applicability of specific data, e.g. generated by spatially resolved electrochemical methods for validating the finite element modeling of inhibitor leaching from the coatings will be also discussed.

Direct Ink Writing of Seeded and Fiber-Reinforced Silicon Carbide to Create Anisoptropic Microstructures RodneyW. Trice; Purdue University, United States

Silicon carbide (SiC) is a material of interest for many applications due to its mechanical properties, oxidation resistance, and high thermal conductivity. Colloidal processing and pressureless sintering can enable forming of complex shaped, dense SiC parts. Direct ink writing (DIW) is a colloidal processing technique where ceramic suspensions are extruded through a nozzle along a path, building up a part layer-by-layer. However, DIW is not only interesting for making complex shapes, but also for creating anisotropic microstructures by aligning particles or fibers via the forces in the print nozzle. In this work, SiC with anisotropic microstructure is created via the alignment of platelet seed particles or fibers in DIW and subsequent pressureless liquid phase sintering and annealing. The anisotropic microstructure and crystallographic texture of these materials will be explored with SEM, XRD, and EBSD. Mechanical properties of these ceramics will be explored via 4-pt flexural strength with Weibull analysis performed.

4:00 PM SF08.03.02
Mapping the Creation of Nanoporous Ultra-High-Temperature Ceramics CatherineB. Ott and IanD. McCue; Northwestern University, United States

Nanoporous materials have found use in a broad variety of applications ranging from sensing and actuation to catalysis and coatings. In the coatings space, nanoporous materials have generally been used as templates for thin networks, where the template is later dissolved away. However, nanoporous materials could themselves be used as part of a high-temperature coating, though the ligament coarsening rate must be controlled to retain integrity of the nanoporous structure at temperature. While nanoporous metals undergo curvature-accelerated surface smoothening, which leads to thickening of ligaments, increasing pore size, and decreasing surface-to-volume ratio, it has been proposed that this morphology evolution may be frozen by creating a nanoporous carbide/nitride ceramic due to the strong covalent bonding limiting surface mobility. The present work examines the conversion of nanoporous refractory metals to nanoporous ultra-high-temperature ceramics *via* gas-phase conversion at elevated temperature. Nanoporous Ta precursors were exposed to carburizing (methane-containing) and nitriding (ammonia-containing) environments over a range of temperatures for different lengths of time to examine the interplay between ceramic conversion and ligament coarsening rates. Kinetic models were developed for both degree of ceramic conversion and degree of coarsening to quantify the process for creation of a nanoporous ultra-high-temperature ceramics.

4:15 PM SF08.03.03
Preparation of Compositionally Complex Ultra-High Temperature Ceramics via Group IV Metal Functionalized Preceramic Polymers JamesPonder[1,2], HairaHackbarth[3], NicholasPosey[1,2], NicholasBedford[3], MatthewDickerson[1] and TimothyPruyn[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States; [3]University of New South Wales, Australia

Materials capable of withstanding ultra-high temperatures are becoming increasingly important for various aerospace applications, ranging from atmospheric re-entry shielding to aircraft brakes. While silicon-based ceramics have proven to be a key class of materials for these harsh applications, introduction of transition metals into these ceramics is required for ultra-high temperatures conditions. Preparation of ultra-high temperature ceramics (UHTCs) using traditional inorganic powder sintering methods limits the structural/compositional designs possible and is challenging for preparing composite components. Preceramic polymers (PCPs) have been used to address these challenges via the synthetic tunability and processing properties of polymers prior to pyrolysis. Following pyrolysis of the PCP, a polymer derived ceramic (PDC) is obtained. By tuning the PCP structure, curing/pyrolysis conditions, and pyrolysis atmosphere, the composition of the PDC can be manipulated for different properties.
Here we report that by functionalizing a commercially available polysilazane-based PCP with transition metal complexes, we have prepared polymer-metal complexes that convert to UHTCs composites when pyrolyzed. In addition to functionalization with the individual group IV metal (Ti, Zr, and Hf) complexes, a blend of the three metals was prepared to understand how the materials blend/separate in PDCs. Following ceramization at different temperatures, X-ray diffraction (XRD) and atomic pair distribution functional (PDF) analysis are used to understand the structural evolution of the material from amorphous to crystalline ceramics. A combination of quantitative energy dispersive X-ray spectroscopy (EDS) and selected area diffraction from transmission electron microscopy (TEM) was utilized to observe the distribution of atomic species within the ceramic. From these various methodologies, the compositions of the PDCs were found to consist of silicone and transition metal carbides, nitrides, and carbonitrides. Ultimately, we report a route to polymer derived compositionally complex UHTC nanocomposites suitable for various high temperature applications.

4:30 PM SF08.03.04
Active Oxidation in Nanocrystalline SiC Woven Fibers: Atomistic Simulation and High-Temperature Oxygen Plasma Experiment FredericSansoz and LucCapaldi; The University of Vermont, United States

High-temperature oxidation of nanocrystalline SiC fibers is critical for the deployment of advanced flexible thermal protection systems such as hypersonic inflatable aerodynamic decelerators developed for space exploration by NASA. Experimental evidence has shown that woven SiC ceramic fibers are prone to accelerated fiber embrittlement under high temperature oxidation in dynamic oxygen environments. The nanocrystalline structure of the constituent fibers impacts the reaction kinetics and phase transformations during active oxidation. However, our fundamental understanding and quantification of grain boundary effects on oxidation behavior in nanocrystalline SiC remain elusive when temperatures exceed 1500 K. In this talk, we will present large-scale molecular dynamics simulations with a reactive force-field, supported by direct observations from high-enthalpy oxygen plasma experiments, to elucidate the complex roles

of grain size on oxidation kinetics and the nature of oxides produced in both monocrystalline and nanocrystalline 3C-SiC between 1100 K and 2000 K. We find that nanocrystalline SiC samples exhibit two distinct oxidation kinetics with a transition point at 1500 K due to surface melting. The introduction of a grain-boundary network produces a two-fold decrease in oxidation activation energies compared to monocrystalline SiC below 1500 K. Above 1500 K, however, the activation energies rise substantially due to the formation of a liquid Si phase at the SiC/Si oxide interface. It is shown that the stability of the interfacial liquid phase is promoted by incoherent grain boundaries in the crystalline SiC.

4:45 PM SF08.03.05
Preventing Structural Collapse During Acceleration of Relativistic Lightsails for Interstellar Travel MarianneAellen, JohnE. Sader and HarryA. Atwater; California Institute of Technology, United States

Interstellar travel requires new propulsion mechanisms. Employing radiation pressure from a high-power ground-based laser is a conceivable route to accelerate an ultralight spacecraft to a significant afraction of the speed of light. To adhere to strict mass constraints, such a spacecraft can employ an ultrathin elastic membrane for its lightsail. During acceleration, a uniform membrane will deform significantly, potentially leading to its collapse. Here, we study the deformation of circular lightsails propelled by a Gaussian laser beam. We observe a significant change in scaling laws when increasing the lateral sail size from laboratory-scale (tens of micrometers) to mission-scale (several meters). A buckling analysis reveals critical accelerations and suggests design principles for hoop stiffening elements to increase the maximum acceleration. These findings serve as the basis to understand and prevent relativistic-lightsail collapse during acceleration.

5:00 PM SF08.03.06
Exploring SixCy Materials SakinehChabi; University of New Mexico, United States

Silicon and graphene are among the most critical research areas in nanotechnology, and any advancement in these areas can impact several scientific fields. The combination of silicon and carbon—or SiC—is yet another amazing material with a very bright future. Owing to its excellent thermal, mechanical, and semiconductive properties, SiC is a leading material for many strategic applications ranging from power electronics and high temperature applications to aerospace and structural applications. Additionally, multifunctional, and recoverable SiC structures can be designed by optimizing the design process e.g. via designing multidimensional SiC materials. Another potential design approach, which is the primary motivation behind this research, is to play with the composition and atomic percentage of Si/C materials and design Si_xC_y materials. Although a 1:1 composition or SiC is the most stable form of Si_xC_y, other compositions, are also found to be energetically favorable.
This works reports on the manufacturing of complex Si/C structures via a chemical vapor deposition method. The structure and properties of the grown materials were characterized using various techniques including scanning electron microscopy, aberration- corrected transmission electron microscopy, confocal Raman spectroscopy, and X-ray photoelectron spectroscopy. The spectroscopy results revealed that the grown materials were composed of micro/nanostructures with various compositions and dimensions. The coexistence of these phases and their interfaces can benefit several Si/C-based applications ranging from ceramics and structural applications to power electronics, aerospace, and high-temperature applications. In this talk, I will present our latest experimental efforts in the synthesis and characterization of SixCy material.

5:15 PM SF08.03.07
Poster Spotlight: Accelerated Assessment of Primary Radiation Damage using High-Throughput Methods ElenaBotica Artalejo, GregoryM. Wallace and MichaelP. Short; Massachusetts Institute of Technology, United States

In this project, we have developed a high-throughput approach using physical vapor deposition (PVD) to produce thick films with various compositions in a two-dimensional layout involving three different elements that form the alloy. Developing materials for plasma-facing components (PFCs) in fusion reactors is a difficult task, especially when additional functional requirements, such as electrical conductivity for radio-frequency (RF) antennas, need to be considered in addition to strength, heat tolerance, and radiation resistance. To complicate matters further, even trace amounts of certain elements (e.g. Nb) create an unacceptable amount of nuclear activation after neutron bombardment. Traditional approaches to determine suitable materials are time-consuming and involve numerous tests before and after irradiation to evaluate a limited number of alloy variations. However, our new approach allows us to simultaneously assess the evolution of properties in multiple compositions following consecutive radiation exposures, providing immediate insights.
To establish a baseline for the chemical composition, electrical properties, and thermo-elastic properties of the resulting thick film (measuring 3-4 µm), we employ rapid and non-destructive techniques such as electron dispersive spectroscopy (EDS), four-probe electrical resistivity measurement, and transition grating spectroscopy (TGS). Subsequently, we subject the sample to ion irradiation and reevaluate its properties to observe the relative changes created by the primary radiation damage. This iterative process is repeated until we reach the critical dose required for an RF antenna. By simultaneously evaluating hundreds of alloy compositions, our approach significantly accelerates the workflow compared to traditional methods, while maintaining the experimental reliability of radiation damage data. The extent of primary radiation damage is quantified by measuring the relative change in thermal conductivity using TGS, enabling us to correlate regions with better radiation damage resistance with their specific compositions. The decay of the TGS signal after irradiation directly corresponds to the presence of a greater number of vacancies in the microstructure. Additionally, we assess other properties relevant to an RF antenna, such as electrical resistivity at increasing radiation doses. Our study presents findings from the Cu-Cr-Nb and other Cu-Cr-X ternary systems, highlighting implications for the development of Nb-free Cu super-alloys in fusion environments.

5:20 PM SF08.03.08
Poster Spotlight: Design and Synthesis of Stabilized Nanocrystalline Vanadium Alloys DanielS. Ng, MalikWagih, TianjiaoLei and ChristopherA. Schuh; Massachusetts Institute of Technology, United States

A reduction in grain size is expected to convey several benefits to structural materials in nuclear fusion reactors, as grain boundaries can improve mechanical strength, as well as act as a sink for radiation-induced defects to avoid embrittlement. However, nanocrystalline structures contain a strong driving force for grain growth and tend to be thermally unstable. Selecting solutes with a thermodynamic preference to segregate to grain boundaries can stabilize smaller grains up to reasonable operating temperatures.

There are limited solute segregation data on candidate alloys for fusion applications such as vanadium, which is of interest for its low neutron activity and high thermal stress factor. A combined machine learning and molecular mechanics framework developed to calculate segregation energies from ab initio methods was adapted to BCC metals, allowing for the prediction of solute segregation strength in vanadium-base binary alloys across all transition elements. Select alloys were experimentally synthesized through powder metallurgy ball-milling, annealed, and characterized through transmission electron microscopy to validate the computational predictions of thermally stable solute segregation and nanocrystallinity. Mechanical testing demonstrated significantly higher strength in sintered powder compacts of vanadium alloys compared to their cast coarse-grained counterparts. Microstructures before and after ion irradiation experiments at elevated temperatures were examined to determine the extent of damage and radiation stability.

5:25 PM SF08.03.09
Poster Spotlight: *In-situ* High-Temperature Fracture Behavior of Polymer-Derived SiC Fibers for Extreme EnvironmentHyukJunLee[1,2], YoungJinShim[1,2], YoungKeunJeong[1], KwangYounCho[2] and YoungJunJoo[2]; [1]Pusan National University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Silicon carbide (SiC) fibers and its woven fabrics have been proposed as reinforcing materials of ceramic matrix composites (CMCs) for aerospace materials due to their excellent mechanical properties such as tensile strength (≥2.45 GPa) and tensile modulus (220 GPa) up to high temperatures above 1573K. In general, the high-temperature evaluation of polymer-derived SiC fibers proceeded at room temperature after heat treatment under inert gases or air gas, which does not reflect environments of space reentry or hypersonic impact. Therefore, in order to simulate and evaluate the extreme environment, the *in-situ* tensile strength of the SiC fiber was measured while a thermal-shock of Δ1773K in the air. The in-situ fracture behavior of polycrystalline SiC fibers was analyzed through the customized measurement equipment to investigate the effects of impurity phase or microstructure at high temperature. And the *in-situ* tensile strength was measured while thermal-shock to temperatures of 1273K, 1573K and 1773K in air without the heating rate. In addition, thermal-exposure time at a high temperature controlled from 5 to 120 min. The tensile strength of SiC single-filament measured by the *in-situ* measurement method was immediately decreased from 3.0 GPa to 2.45 GPa, 1.9 GPa, and 1.5 GPa after thermal-shock at 1273K, 1573K and 1773K, respectively. After thermal-exposure at 1773K for 120 minutes, the tensile strength of SiC single-filament was continuously reduced to 0.87 GPa. In the *in-situ* measurement method, the stress-strain curve of SiC fibers showed three-step behavior such as thermal expansion, elastic deformation, and ductile deformation compared to the general measurement method. In particular, the fracture surface in SEM images showed a sharp morphology like the tip of a pencil, indicating ductile deformation. In XRD and TEM, the crystal size of β-SiC was maintained up to 1773K, but the proportion of SiO_2 phase ratio increased gradually. In addition, the peak of SiO_2 was easily observed after thermal-shock at 1773K, but it began to form when thermal-shock at 1573K for more than 120 min. The formation of an oxide layer on the fiber surface did not have a significant effect on the high-temperature tensile strength, but the excess carbon present on the surface was a source of destruction because it formed a defect at the interface between the oxide layer and the fiber surface when exposed thermal-shock to high temperature. Consequently, it is expected that the *in-situ* high-temperature measurement method more closely simulates the environment in which polycrystalline SiC fibers are actually used in extreme environments and suggests the microstructural solution for next-generation polycrystalline SiC fibers.

Printable Electronics in Harsh Environments: Exploiting Silicon Carbide Nanowires for Solution Processed Schottky Diodes Kuan-YuChen and JosephAndrews; University of Wisconsin–Madison, United States

Printable electronics offer numerous advantages for flexible and large-area electronic device fabrication. Solution-processable nanomaterials have enabled the development of thin-film transistors and diodes with improved performance characteristics. However, sustaining device operation in harsh environments has been a challenge. This study explores the potential of Silicon Carbide Nanowires (SiC NWs) for enabling solution-processable electronics in harsh environments. The use of nanoscale SiC allowed us to disperse the material into liquid solvents while preserving its inherent resilience comparable to bulk SiC. SiC NWs possess superior physical properties such as a wide energy bandgap, high thermal conductivity, and high melting temperature. SiC NWs possess inherent flexibility and stretchability from the one-dimensional (1-D) nanostructures.
This work presents the fabrication of Schottky diodes using SiC NWs, with each diode comprising a single nanowire of approximately 160 nm diameter. The performance of the diodes is thoroughly analyzed, including their response to elevated temperatures and proton irradiation. We have detailed the utilization of a thermionic emission model in extracting the relevant parameters for solution processed SiC nanowire Schottky diodes. Furthermore, we have directly subjugated these devices to high temperature and high radiation environments, and analyzed their effects on the device's performance, demonstrating the resilience of the diodes upon elevated-temperature proton irradiation at a dose of 10^{16} particles/cm^2. The diodes maintain similar ideality factor, barrier height, and effective Richardson constant values. Our findings demonstrate the tangible merits of the solution-based process to utilize inorganic nanomaterials for use in challenging environments. Ultimately, this lays the foundation for the advancement of printed and flexible devices in harsh environment applications.

8:00 PM SF08.04.02
Evaluation of High-Temperature Wear Resistance of Explosively Welded Liner SiwookPark, Jung HyoPark, Kyu-SikKim, Sung HoYang and YoungmooKim; Agency for Defense Development, Korea (the Republic of)

In the case of Ni-Cr-Mo steel, it is widely used as a material for gun barrel due to its high hardness compared to other steel types, and is known to have excellent abrasion resistance at high temperatures. In thist study, the high-temperature wear resistance of Ni-Cr-Mo steel that meets the MIL-S-46119 standard was evaluated. In particular, a new characteristic evaluation device was developed and the behavior of temperature changem wear rate, and friction coefficient value was measured. In addition, by observing the microstructure, the research results necessary for the identification of the wear mechanism were obtained.

8:00 PM SF08.04.03
Enhanced Impact Energy Absorption of Aperiodic Nano Cellular Polymer Films Deposited by Self-Limiting Electrospray ZonglingRen[1], RobertGreen-Warren[2], NoahMcAllister[2], AraKim[1], AsaadShaikh[2], AssiminaA. Pelegri[2], JonathanP. Singer[2] and Jae-HwangLee[1,1]; [1]University of Massachusetts Amherst, United States; [2]Rutgers, The State University of New Jersey, United States

Micro/nano cellular materials have attracted significant attention recently due to their unique and tailorable mechanical characteristics originating from short-range phenomena and scale effects. With the periodic architecture, the effectiveness of energy absorption for micro/nano cellular lattice materials under mechanical stimuli of high strain rates (HSRs) has been demonstrated; the localized mechanical exchanges and responses allow them to outperform the conventional solid materials. In contrast, with the aperiodic architecture, the absence of lattice symmetry enables scalable additive manufacturing and ensures defect insensitivity in both performance and manufacturing, extending the application range.
In order to gain a deeper insight into the mechanical behavior of aperiodic nano cellular materials under HSRs and their energy absorption enhancement mechanism, we present the ultrahigh-rate mechanical study on the aperiodic polymeric films prepared by self-limiting electrospray deposition (SLED). The film comprises irregularly arranged hollow shells that are deposited on a silicon substrate. Polystyrene and its modified composites are used as the parent materials. The hollow cells possess a radius of approximately 2 microns, while the measured thickness of the shell walls is around 220 nanometers. For their HSR mechanical characterization, laser-induced projectile impact testing (LIPIT) is introduced in which solid silica microspheres having a diameter of 20 microns are used as standard impact-loading projectiles. The impact velocities range from 100 – 800 m/s. After impact data collection, the coefficient of restitution, specific energy absorption, and energy dissipation efficacy are calculated to quantify the energy-absorption ability and to identify the deformation mechanism. Based on the impact crater morphology observed in SEM images of target samples composed of homogeneous polystyrene, viscoplastic vertical densification without the Poisson effect is the dominant phenomenon. As both the increase of porosity and the decrease of film thickness can largely enhance the energy dissipation, by synergistically combining these two parameters, aperiodic cellular materials can attain comparable specific energy dissipation to that of lattice materials in the same scale. A comparison between HSR and quasi-static deformation reveals that significantly greater adiabatic thermal softening and plastic behavior in HSR deformation contribute to enhanced energy dissipation. The general design principle for energy dissipation enhancement in aperiodic nano-cellular materials is creating viscoplastic hot spots to promote adiabatic shear deformation. We further investigated the nano cellular samples with modified polymer chains. To introduce variations in the inter-chain connections, block copolymers were employed. In conjunction with the analysis of impact craters, the experimental data acquired through the LIPIT reveals a notable association between the existence of modified polymer chains and an intensified adiabatic shear deformation, which ultimately brings a substantial enhancement in energy dissipation. In summary, this study provides insights of the energy dissipating mechanism in aperiodic nano cellular materials and suggests its wider applications in scalable additive manufacturing.

* This collaborative research was supported by the National Science Foundation (Awards No. 2019928 and 2019849).

8:00 PM SF08.04.04
Lattice Boltzmann Method - Cellular Automata Method for Predicting Microstructural Evolution in Application to Tram Structural Steel WonjooLee[1], JinseongKim[2], SeunghoAhn[2] and JonghunYoon[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Railroad Research Institute, Korea (the Republic of)

Solidification is a phase transformation from a liquid to a solid. Most metallic materials are manufactured by the casting processes based on the principle of solidification because of its high productivity. Since the mechanical properties of as-cast products mainly depend on the microstructure characteristics such as primary dendrite arm spacing (PDAS) and second dendrite arm spacing (SDAS), the industries are trying to control the formation of microstructures. However, the dynamic evolution of the microstructure is hard to be observed experimentally and be predicted by only conventional macroscopic analysis. Therefore, many numerical models have been developed to predict and control of the microstructures formation in solidification. In this work, a lattice Boltzmann method (LBM) and cellular automata (CA) coupled model has been constructed to predict the microstructure formation during solidification.

8:00 PM SF08.04.05
Enhancing Interfacial Adhesion and Electrical Conductivity of Steel/Polymer Composites via Molecular Adhesion HyunjaePark[1], Hyung JunKim[1], Hye-jinYoo[2] and Cheol-HeeAhn[1]; [1]Seoul University, Korea (the Republic of); [2]POSCO, Korea (the Republic of)

The demand for steel/polymer composites (SPCs) is increasing in various industrial fields due to the need for weight reduction during the energy crisis. However, the development of SPCs faces a major challenge in achieving strong interfacial adhesion between heterogeneous materials like steel and polymer. Conventional physical adhesion methods, which rely on surface roughness, have drawbacks such as decreased durability and reduced interfacial adhesion under external conditions like temperature, humidity, and stress. Therefore, it is necessary to explore novel approaches to improve the adhesion of SPCs in practical applications.
In this study, we controlled the surface chemistry to enhance the chemical and physical interactions at the steel/polymer interface to improve interfacial adhesion. The materials used in the study include electro-galvanized steel, polyethylene (PE), acrylonitrile-butadiene-styrene (ABS), and Nylon 6, which are commonly employed in the automotive industry for interior components. We employed an organosilane coupling reaction to anchor primary amines on the steel surface, and introduced maleic anhydrides (MAs) onto the polymer film surface using a photo-initiated grafting method. The presence of amines on the steel plate and the amount of MA introduced onto the polymer surface were confirmed and quantitatively analyzed. The adhesive properties were evaluated using a lap shear test. The adhesion strength of PE increased from 0 to 11.5 MPa, from 1.5 to 11.1 MPa for the case of ABS, and from 12.7 to 14.1 MPa for Nylon 6. Notably, the adhesion strength of Nylon 6 was maintained at 89.0% even after 7 days of aging, in spite of the detrimental effect of moisture absorption on interfacial adhesion. This highlights the robust and sustainable nature of molecular adhesion, which can withstand changes in external conditions such as moisture.
Ensuring the in-process applicability is crucial for expanding the industrial application potential of SPCs. One important aspect in this regard is the feasibility of spot welding which is widely used in automated automobile manufacturing processes. In order to achieve the spot welding, we employed a conductive core layer. In order to achieve high conductivity, a network of conductive fillers was created within the resin. We prepared a polyketone composite by mechanofusion, where conductive fillers such as graphene nanoparticles were adsorbed onto the surface. The composite was then hot pressed to develop a conductive plastic with exceptionally high electrical conductivity of 207.5 S/cm. However, this high electrical conductivity was not sufficient to achieve an effective spot welding. We prepared conductive structure composite where steel fiber meshes incorporating into the plastic core layer. To ensure the steel fiber mesh

was embedded in the plastic without creating voids, an organosilane-based treatment was performed at the surface between the steel fiber mesh and the plastic via molecular bonding. Through this approach, we successfully produced a polymer/steel fiber mesh composite core layer that was void-free and capable of spot welding
In conclusion, this study successfully enhanced the interfacial adhesion in SPCs by improving the chemical and physical interactions at the steel/polymer interface. By employing molecular adhesion via precise control at the molecular level, the adhesion strength was significantly increased, and durability was improved, even in the presence of external factors such as moisture. Furthermore, for industrial application, we fabricated conductive SPCs which enabled spot welding by developing a conductive core layer and utilizing a steel fiber mesh. These findings is believed to contribute to the development of practical and effective SPCs, addressing the demand for weight reduction in various industries, particularly the automotive sector.

8:00 PM SF08.04.06
Parametric Study on the Rapid Electrical Discharge Machining of Explosively Welded Ta-W Alloy on the Gun Steel Tube Kyu-SikKim[1], Jung KyuSong[1], DonghoonKim[1], Sung HoYang[1], Si NamChoi[2] and SangbaeHan[2]; [1]Agency for Defense Development, Korea (the Republic of); [2]TMSys Inc., Korea (the Republic of)

Explosive welding is a solid-state metal joining process that uses explosive force to create a metallurgical bond between two metal components. This is a suitable method for joining dissimilar metals with high differences in melting points, such as Ta alloys and gun steels. The Ta-based alloy was explosively welded inside a gun steel tube in this study. Moreover, the effects of parametric electrical discharge machining (EDM) conditions for a non-machinable Ta-based alloy on the materials removal rate (MRR) and surface roughness were investigated. As a result of EDM tests, MRR could be accelerated by increasing current and pulse-on time. However, Ta-based alloys machined with high MRR showed relatively rough surfaces compared to slowly EDMed specimens. Surface characteristics were analyzed to evaluate the effect of the EDM conditions on the MRR and surface roughness.

8:00 PM SF08.04.07
Highly Elastic, Conductive and Reliable Nanolaminates with Nanocrystalline Cu/Metallic Glass Alternating Layers Gyeong-SeokHwang[1], Jae-YoungBae[2], Jun-WooKim[3], JeonghyunKim[3], Seung-KyunKang[2] and Ju-YoungKim[1]; [1]UNIST (Ulsan National Institute of Science and Technology), Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Kwangwoon University, Korea (the Republic of)

According to explosive commercialization of flexible electronics, stretchable electronics is also actively developing and researching for application and commercialization. In the case of bending deformation, the mechanically weakest material among many constituent layers can be protected from severe deformation by using structural design with the neutral plane concept. On the other hand, all constituent layer in which stretching deformation occurs should be uniformly stretched according to iso-strain condition. This characteristic of stretching deformation which is harsh environment limits further development in stretchable electronics. It is important to researching and combining not only design of highly stretchable structure but also highly stretchable material.
Among many kinds of stretchable electronics, it is known that an island-interconnect structure can easily enhance stretchability of electronic devices by using stretchable interconnection without degrading electrical performance. However, this type of structure requires high stretchability and mechanical reliability on structure and material of electrical interconnection. So far, copper and gold have been considered as common interconnect material due to very high electrical conductivity. However, crystalline metals have a very small elastic deformation limit (below 0.5% strain), and it is a critical shortcoming for highly stretchable and highly reliable electrical interconnection despite various stretchable structural designs. In this study, a solid metal interconnect with copper-like electrical conductivity and glass-like elastic deformation is investigated. This was obtained in the form of nanolaminates with alternating layers of nanocrystalline Cu and CuZrTi metallic glass. The mechanical, electrical properties and mechanical reliability with the stretchable substrate and the structure were evaluated depending on the thickness of the constituent layers. By using optimized nanolaminates, stretchable and wireless temperature monitoring sensors were fabricated and evaluated in various environments, such as physical workouts and harsh temperature conditions.

A Strategic Design Approach Controlling the B-Solubility in Transition Metal Nitride-Based Thin Films RebeccaJanknecht[1], KatharinaWeiss[1], RainerHahn[1], SzilardKolozsvari[2], PeterPolcik[2], DanielPrimetzhofer[3] and PaulMayrhofer[1]; [1]TU Wien, Austria; [2]Plansee Composite Materials GmbH, Germany; [3]Uppsala University, Sweden

Limited B-solubility in fcc-TiN poses significant challenges to the applicability of Ti-B-N-based hard coatings. In particular, excess B tends to segregate at the grain boundaries instead of being fully incorporated in the fcc lattice. Although increasing the B content enhances mechanical properties such as hardness, forming excess amorphous grain boundary phases can significantly reduce fracture toughness. Compared to TiN, we observed an increase of 10 GPa in hardness (up to 36.9±1.8 GPa) but a decrease in fracture toughness of roughly 25 % (down to 2.1±0.1 MPa*$m^{0.5}$). Assisted by ab-initio DFT calculations, we previously demonstrated that additional Ti (to deviate from the TiN–TiB tie-line) is required to fully incorporate more B (up to 8.7 at%) in the TiN lattice while minimizing B-rich amorphous phases. Here, we expand this research by adjusting the metal sub-lattice through Ti-, Cr-, Al- or Zr-addition to a Ti-B-N compound target (50 at.% Ti, 40 at.% N, and 10 at.% B). Our study highlights the key-role of kinetics in non-reactive deposition processes to overcome the thermodynamic limits of B-solubility in TiN. Through changing the stoichiometry by knowledge-based metal addition, we propose a general strategy to enhance the B solubility in transition metal nitride-based thin films.

8:00 PM SF08.04.09
Poster Spotlight: Design and Synthesis of Stabilized Nanocrystalline Vanadium Alloys DanielS. Ng, MalikWagih, TianjiaoLei and ChristopherA. Schuh; Massachusetts Institute of Technology, United States

A reduction in grain size is expected to convey several benefits to structural materials in nuclear fusion reactors, as grain boundaries can improve mechanical strength, as well as act as a sink for radiation-induced defects to avoid embrittlement. However, nanocrystalline structures contain a strong driving force for grain growth and tend to be thermally unstable. Selecting solutes with a thermodynamic preference to segregate to grain boundaries can stabilize smaller grains up to reasonable operating temperatures.

There are limited solute segregation data on candidate alloys for fusion applications such as vanadium, which is of interest for its low neutron activity and high thermal stress factor. A combined machine learning and molecular mechanics framework developed to calculate segregation energies from ab initio methods was adapted to BCC metals, allowing for the prediction of solute segregation strength in vanadium-base binary alloys across all transition elements. Select alloys were experimentally synthesized through powder metallurgy ball-milling, annealed, and characterized through transmission electron microscopy to validate the computational predictions of thermally stable solute segregation and nanocrystallinity. Mechanical testing demonstrated significantly higher strength in sintered powder compacts of vanadium alloys compared to their cast coarse-grained counterparts. Microstructures before and after ion irradiation experiments at elevated temperatures were examined to determine the extent of damage and radiation stability.

Multifunctional Polyethylene-Based Material for Radiation Shielding, Passive Thermoregulation and Onsite Fabrication in Space Exploration DuoXu[1], VolodymyrKorolovych[1], LembitSihver[2] and SvetlanaV. Boriskina[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Chalmers University of Technology, Sweden

Ionizing radiation sources, including primary particles such as energetic electrons, protons, and gamma rays, as well as secondary particles like thermal neutrons, are abundant at locations where space missions are often conducted, such as the low Earth orbit (LEO) and the Martian surface [1]. Space radiation could severely damage human tissues and electronic components, presenting a risk factor for space explorations [2]. Traditionally, high-Z number materials, primarily metals such as lead and aluminum, have been employed to attenuate space radiation. Due to the considerably high costs of transporting materials and equipment to space, low-density shielding materials based on polymer composites improve cost-effectiveness due to their lightweight nature, allowing for comparable radiation protection at a lower transportation cost [3]. Despite their advantages, polymer composites have their limitations, particularly their relatively low thermal conductivity [4], which can impact the performance of the electronic components protected by the shielding material, unless they are designed to operate at elevated temperatures. Consequently, a material design that achieves thermoregulation without compromising the radiation shielding performance is of paramount necessity.

Several materials have shown promising results in attenuating space radiation, providing a level of design flexibility in terms of structure and material composition. In this work, a polyethylene-based multifunctional material for space applications is proposed, with the target of providing radiation shielding, passive thermoregulation, and onsite fabricability simultaneously. The feasibility of onsite fabrication is demonstrated by the author's previous work, in which an optimized process of additive manufacturing via fused deposition modeling (FDM) is employed for polyethylene-based composite materials [5].

The radiation shielding performance of selected material structures and compositions is evaluated with a Monte-Carlo particle transport simulation tool PHITS, which calculates the total ionizing dose transmitted by the multifunctional material under specific radiation conditions. To evaluate the thermoregulatory performance of the material, we developed and employed a coupled thermal-optical model, which considers the extraterrestrial thermal environment and utilizes the material properties of each component, along with structural information, to estimate the temperature of the electronics that the material is designed to protect.

Preliminary experimental results reveal promising material candidates for this multifunctional material, and the structure could be further optimized for superior performance. The insights

gained from this study present significant opportunities for future research and developments in the field of space exploration with architectured materials tailored for specific applications.

This research is funded by the Cosmic Shielding Corporation (CSC), Altanta, Georgia and the MIT-Czech Republic Seed Fund. We also thank the Oak Ridge National Laboratory for the beam time for neutron scattering measurements (Proposal IPTS-28797.1 for NScD 2022-A) and William Heller (ORNL) for his help in running the experiment. We acknowledge Benoit Forget and Amelia J Trainer (MIT) for useful discussions.

Poster Spotlight: Accelerated Assessment of Primary Radiation Damage using High-Throughput Methods ElenaBotica Artalejo, GregoryM. Wallace and MichaelP. Short; Massachusetts Institute of Technology, United States

In this project, we have developed a high-throughput approach using physical vapor deposition (PVD) to produce thick films with various compositions in a two-dimensional layout involving three different elements that form the alloy. Developing materials for plasma-facing components (PFCs) in fusion reactors is a difficult task, especially when additional functional requirements, such as electrical conductivity for radio-frequency (RF) antennas, need to be considered in addition to strength, heat tolerance, and radiation resistance. To complicate matters further, even trace amounts of certain elements (e.g. Nb) create an unacceptable amount of nuclear activation after neutron bombardment. Traditional approaches to determine suitable materials are time-consuming and involve numerous tests before and after irradiation to evaluate a limited number of alloy variations. However, our new approach allows us to simultaneously assess the evolution of properties in multiple compositions following consecutive radiation exposures, providing immediate insights.
To establish a baseline for the chemical composition, electrical properties, and thermo-elastic properties of the resulting thick film (measuring 3-4 µm), we employ rapid and non-destructive techniques such as electron dispersive spectroscopy (EDS), four-probe electrical resistivity measurement, and transition grating spectroscopy (TGS). Subsequently, we subject the sample to ion irradiation and reevaluate its properties to observe the relative changes created by the primary radiation damage. This iterative process is repeated until we reach the critical dose required for an RF antenna. By simultaneously evaluating hundreds of alloy compositions, our approach significantly accelerates the workflow compared to traditional methods, while maintaining the experimental reliability of radiation damage data. The extent of primary radiation damage is quantified by measuring the relative change in thermal conductivity using TGS, enabling us to correlate regions with better radiation damage resistance with their specific compositions. The decay of the TGS signal after irradiation directly corresponds to the presence of a greater number of vacancies in the microstructure. Additionally, we assess other properties relevant to an RF antenna, such as electrical resistivity at increasing radiation doses. Our study presents findings from the Cu-Cr-Nb and other Cu-Cr-X ternary systems, highlighting implications for the development of Nb-free Cu super-alloys in fusion environments.

8:00 PM SF08.04.12
Effect of Temperature and Time on the Development of Hafnium Diboride (HfB_2) Coatings by Chemical Vapor Deposition (CVD) MeltemBolluk[1,2], OzdenKisacik[3], FurkanAkpunar[3], SerzatSafaltin[1] and IsmailDuman[2]; [1]University of Connecticut, United States; [2]Istanbul Technical University, Turkey; [3]TENMAK, Turkey

Refractory metal borides possess an array of impressive properties which has led to their categorization as advanced technology boron products. These properties include high refractoriness, wear resistance, corrosion resistance, high hardness, and high fracture toughness. HfB_2 is a remarkably high temperature ceramic material with features like its immunity to high temperatures and its power to remain steadfast in extreme conditions. This component is essential to various systems in the advanced technology and defense industries, and it plays a crucial role in them. HfB_2 has a wide range of applications, including aerospace, aviation, and metallurgy. (Kauffman, 1965). HfB_2 is an ideal material for high-temperature ceramics because of its elevated melting temperature, remarkable thermal conductivity, outstanding resistance to thermal shock, a low thermal expansion coefficient, high-temperature resistance, and the ability to remain stable in extreme environments. HfB_2 has many impressive characteristics that make it a practical solution to be used as a thermal protection system for mission-critical applications, which include hypersonic flights, atmospheric entry systems, and rocket thrusters (Sonber, 2011).
This research implemented a CVD-based gas phase coating technique, designed for the purpose, to produce HfB2 coatings on copper (Cu) substrates at various temperatures and time. CVD is a low-temperature process used for coating and powder production and can create pure products that other techniques cannot. Chlorides and hydrogen gases are among the most preferred reducing agents in CVD systems. The gas phase reactants were selected as in Reaction 1 (Pierson, 1999).
$HfCl_4 + 2\ BCl_3 + 5\ H_2 \rightarrow HfB_2 + 10\ HCl$ (1)
In the present study, HfB_2 refractory boride coatings were produced as a high purity coating from the gas phase using a specially developed reactor and process design (Bolluk, 2015).

We performed structural analysis methods in order to examine the coatings. According to the XRD results, high purity HfB_2 polycrystalline coatings were obtained. The SEM-EDS analysis was used to evaluate the impact of reduction temperature on crystallite size and to examine the effects of different reduction temperatures on nucleation, grain growth, and morphology. The X-ray photoelectron spectrometry (XPS) technique applies to examine the surface characterization, bond structure and elemental distribution of refractory boride coatings.

Fluorinated Omniphobic Coatings for Low-Surface-Tension Liquids ShashwataMoitra and ConstantineM. Megaridis; University of Illinois Chicago, United States

There has been extensive research on repellency and capillary-driven transport of high surface tension liquids (e.g., water, glycerol, etc.), but only limited attention has been given to contact-line confined transport of liquids with low surface tension (e.g., oils, alcohols, etc.) and oleophobicity. When the fluid surface tension drops below 40 mN/m, repellency becomes extremely difficult. This situation is encountered in many engineering applications and thus is of high technological importance. In this work, we use a fluorinated nanocomposite coating material deposited on a surface textured by laser etching, a scalable technique that requires no lithography implementation. The approach results in the repellency of liquid hydrocarbons with surface tensions as low as 20 mN/m. The repellency of several liquids with surface tensions in the range of 20-72 mN/m is experimentally investigated. Comparisons are performed between the velocities acquired by fluids transported pumplessly on a wedge-shaped wettability-patterned track, due to confinement imposed by the superomniphobic background surrounding the wettable track. Finally, travel distance and velocities of low-surface tension liquids transported on inclined ramps against gravity on similar wedge-shaped wettability-patterned tracks are compared.

Defect-Induced Strengthening of Carbon Nanotube Fibers YongKim[1,2], Seung-YeolJeon[2], Woong-RyeolYu[1], Hyeon-SuJeong[2], Seon-YeonKim[2], Ha-YoungYu[2] and Bo-KyoungChoi[2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

The mechanical capabilities of CNT fibers are impeded by their irregular internal structure, which gives rise to diversely sized CNT bundles that are unable to evenly distribute forces, resulting in slippage of CNTs and lowered mechanical properties. Despite various efforts to enhance the internal structure of CNT fibers, such as polymer infiltration, super-acid treatment (e.g., CSA) for densification, and mechanical compression, the formation and pulling out of uneven bundles has not been avoid yet. In this study, bundle formation was hindered by introducing defects on the surface of CNTs, consequently reducing the van der Waals interactions among individual CNTs. We introduced surface defects on the wall of single-walled carbon nanotubes (SWCNTs), such as oxygen containing functional groups or vacancies using diverse techniques, e.g., heat treatment in air environment followed by different acid treatments. Then, SWCNTs with different type of defects in CSA were dispersed and spun into fibers, and their mechanical properties were evaluated. Our study demonstrated that oxygen-containing defects on CNT fibers progressively increased the modulus as the strain increased before failure, resulting in an approximately 40% increase in strength compared to non-treated fibers.

Molecular and Nanoscale Investigations on Ultraviolet-Degraded Polyurea AmriteshKumar, MaryamGhorbani and GeorgeYoussef; San Diego State University, United States

Polyurea, an elastomer synthesized by the polyaddition of amine and isocyanate, is an emergent engineering material, offering impact mitigation, chemical and moisture resistance, and large tearing elongation. Polyurea-coated structures are often deployed in harsh and extreme environmental operating conditions; hence, extended exposure to natural ultraviolet (UV) radiation might influence the overall mechanical and structural behaviors. However, the state-of-the-art has been limited to macroscale investigations, encompassing the dynamic, micromechanical, viscoelastic, and hyperelastic responses of polyurea. This research aims to extend the current understanding of the influence of UV radiation on polyurea elastomers at various spatiotemporal scales as a function of artificial weathering, ranging from 0 to 15 weeks. Therefore, the current research presents a threefold novel approach to decipher the spectro-mechanical properties of UV-exposed polyurea in two environmental conditions: oxygen-rich and oxygen-deprived. Firstly, nano-indentation and nano-impact characterizations were performed on virgin and exposed samples to quantitatively determine the UV effects on the mechanical properties, including the elastic modulus, hardness, and impact resiliency. A notable by-product of the indentation measurements is revealing the degradation depth, delineated as the transition between exposed skin and virgin core as a function of exposure duration. The nanoscale indentation-induced topological changes inferred the fracture and failure behavior of UV-exposed polyurea samples. Secondly, the UV-exposed samples were submitted to laser-induced shock waves to report their response at ultrahigh strain rate (10^6 s^{-1}) loading conditions. The intensity of the stress waves was tuned by changing the size of the illumination area and the laser energy, where unique locations on the samples were loaded only once to evade the effects of time-dependent deformations. Subsequently, the responsible shock-failure mechanisms were discerned using post-mortem optical and electron microscopy. Finally, spectroscopic analyses using infrared techniques (FTIR, Raman, and terahertz) construed the conformational evolution of the macromolecule in UV-exposed polyurea, elucidating the effects of photodegradation and photo-oxidation mechanisms. Thus, this research provides holistic, multiscale, and mechanistic insights into the effect of extended ultraviolet exposure on polyurea elastomers, potentially leading to improved shock tolerance of polyurea-coated civilian and military installations.

High-Temperature Nanomechanical Behavior of Polymer Films Produced via Self-Limiting Electrospray Deposition (SLED) RobertGreen-Warren, NoahMcAllister, IshaShah, AdrewHuth, JonathanP. Singer and AssiminaA. Pelegri; Rutgers University, United States

Advanced polymer coatings are gaining prominence due to the increasing requirements for high-performance materials that also minimize environmental impact and cost. These coatings are increasingly relevant across numerous industries including aerospace, automotive, biomedical, and mobile devices. The objective of this work is to investigate the influence of porosity on the creep response of the resultant porous polymer films. This study delves into the behavior of polymer composite films fabricated using a novel Self-Limiting Electrospray Deposition (SLED) process. SLED makes use of the buildup of charge in a glassy polymer film to create conformal highly porous microcoatings on flat, templated, or 3D surfaces. Lowering the glass transition temperature of the material reduces both the charge build-up, resulting in more areal mass in the resulting coatings, and the porosity of the films as they densify. Further, the selection of carrier solvent and spray flow rate can alter the characteristic length scale of the coatings by changing the droplet size. Here, we study porous polyimide (PI) coatings, which are valued for their dielectric and chemical barrier properties coupled with high thermal stability, with applications ranging from hermetic seals to battery separators. Samples ranging from 0-70% porosity are deposited via SLED and observed using a combination of optical microscopy and spectroscopic microreflectomery to evaluate film thickness and porosity. Each sample is then characterized mechanically via time-dependent nanoindentation with in-situ heating up to 400C to measure the effects of porosity on the creep response of the polymer films.

Crystallographic Orientation Effect of Substrate Grain on the Oxidation Behavior of Ferritic Stainless Steels for Solid Oxide Fuel Cell Interconnects Yoon SeokKo[1], Min-SeongKim[1], Heung NamHan[2], JinwooKim[2] and Dong-IkKim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Hydrogen has been paid great attention to be the future energy carrier because of the demand for alternative clean and renewable power generation. For the utilization of hydrogen, the hydrogen storage system must be developed, and this stored hydrogen energy should be converted to electricity by fuel cells with high efficiency. From this point of view, metallic materials can serve an essential role. Hydrogen storage alloy has attracted much attention because of its high volumetric energy efficiency for hydrogen storage systems, and metallic interconnects for the stacked fuel cell system have altered the ceramic interconnects because of their low cost and good formability. However, the oxidation of the metallic materials can be a problem. In the former case, the surface oxide layer was reported to be the main factor affecting the alloy's activation characteristic and delaying the hydrogen charging. In the latter, the oxide layer on the metallic interconnects degrades the power generation efficiency of the fuel cell system because of its high electrical resistivity. Therefore, controlling the oxidation behavior of metallic materials is important. From a practical point of view, compositional change of the metallic materials has been discussed in depth to control the oxidation behavior. In contrast, the orientation effect of the substrate grain on the oxidation behavior of metallic materials has not been well discussed.
Therefore, the aim of this study is to investigate the effect of crystallographic orientation on oxidation behavior. For this purpose, the electron backscatter diffraction method (EBSD) was used to observe the orientation of the ferritic stainless steel, which was designed to apply the metallic interconnect for a solid oxide fuel cell (SOFC) system. Three substrate grains with <111>, <110>, and <001> parallel to the plane normal direction of the specimens were marked using the focused ion beam (FIB) and tracked during the oxidation test. The temperature was set to 800 Celcius degree to simulate the operation temperature of the SOFC. After the oxidation test, three lamellar specimens were preared from each substrate grain, and the transmission electron microscope (TEM) and the transmission Kikuchi diffraction (TKD) analyzed the orientation relationship between oxides and the substrate. Based on these findings, the texture of the ferritic stainless steel was carefully designed, and the oxidation behavior was successfully controlled.

8:00 PM SF08.04.18
Poster Spotlight: *In-situ* High-Temperature Fracture Behavior of Polymer-Derived SiC Fibers for Extreme EnvironmentHyukJunLee[1,2], YoungJinShim[1,2], YoungKeunJeong[1], KwangYounCho[2] and YoungJunJoo[2]; [1]Pusan National University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Silicon carbide (SiC) fibers and its woven fabrics have been proposed as reinforcing materials of ceramic matrix composites (CMCs) for aerospace materials due to their excellent mechanical properties such as tensile strength (≥2.45 GPa) and tensile modulus (220 GPa) up to high temperatures above 1573K. In general, the high-temperature evaluation of polymer-derived SiC fibers proceeded at room temperature after heat treatment under inert gases or air gas, which does not reflect environments of space reentry or hypersonic impact. Therefore, in order to simulate and evaluate the extreme environment, the *in-situ* tensile strength of the SiC fiber was measured while a thermal-shock of Δ1773K in the air. The in-situ fracture behavior of polycrystalline SiC fibers was analyzed through the customized measurement equipment to investigate the effects of impurity phase or microstructure at high temperature. And the *in-situ* tensile strength was measured while thermal-shock to temperatures of 1273K, 1573K and 1773K in air without the heating rate. In addition, thermal-exposure time at a high temperature controlled from 5 to 120 min. The tensile strength of SiC single-filament measured by the *in-situ* measurement method was immediately decreased from 3.0 GPa to 2.45 GPa, 1.9 GPa, and 1.5 GPa after thermal-shock at 1273K, 1573K and 1773K, respectively. After thermal-exposure at 1773K for 120 minutes, the tensile strength of SiC single-filament was continuously reduced to 0.87 GPa. In the *in-situ* measurement method, the stress-strain curve of SiC fibers showed three-step behavior such as thermal expansion, elastic deformation, and ductile deformation compared to the general measurement method. In particular, the fracture surface in SEM images showed a sharp morphology like the tip of a pencil, indicating ductile deformation. In XRD and TEM, the crystal size of β-SiC was maintained up to 1773K, but the proportion of SiO_2 phase ratio increased gradually. In addition, the peak of SiO_2 was easily observed after thermal-shock at 1773K, but it began to form when thermal-shock at 1573K for more than 120 min. The formation of an oxide layer on the fiber surface did not have a significant effect on the high-temperature tensile strength, but the excess carbon present on the surface was a source of destruction because it formed a defect at the interface between the oxide layer and the fiber surface when exposed thermal-shock to high temperature. Consequently, it is expected that the *in-situ* high-temperature measurement method more closely simulates the environment in which polycrystalline SiC fibers are actually used in extreme environments and suggests the microstructural solution for next-generation polycrystalline SiC fibers.

8:00 PM SF08.04.19
Computational Fracture and Thermal Analysis of Glass-Ceramics under Extreme Conditions DomenicaRodriguez[1], SujinKim[2], Sung-YupKim[3], Hyung SubSim[2] and SungwookHong[1]; [1]California State University, Bakersfield, United States; [2]Sejong University, Korea (the Republic of); [3]University of Illinois Chicago, Korea (the Republic of)

The research on a wide range of glass-ceramics has gained a great attention in the areas of nanotechnology and materials science. In particular, lithium disilicate, aluminum silicates, lithium aluminum silicate glass-ceramics have been successful in many industry applications, owing to their generally superior mechanical properties such as high flexural strength and fracture toughness. As such, it is virally important to obtain fundamental understanding of mechanical/thermal characteristics of the glass ceramic materials to be extended to other commercial applications like display glasses and heat exchangers. However, the mechanical/thermal properties of those materials still remain elusive because of the lack of computational effort to model such a complex system. Here, we perform reactive molecular dynamics (RMD) simulations to reveal mechanical behaviors of glass-ceramics under tensile conditions. We also identify thermal behaviors of the glass-ceramics to better understand materials behaviors at extreme conditions. Our work will make a reasonable contribution to the scalable and reliable synthesis of glass ceramics-based composites at extreme conditions.

8:00 PM SF08.04.20
Recycled Wood-2D Material Composites: A Potential Structure Alternative for Extreme LEO Environments BaselR. Altawil, RamiA. Elkaffas, YarjanAbdul Samad and Seanswei; Khalifa University of Science and Technology, United Arab Emirates

The rapid proliferation of space structures predominantly composed of aluminum has engendered critical challenges in space exploration. The aftermath of space missions leaves behind aluminum debris, which poses not only an imminent threat to other space assets but also when these remnants re-enter the Earth's atmosphere and combust, exposes our environment to potential health hazards. This growing concern necessitates a shift towards environmentally benign materials for space applications.

Our research proposes a pioneering approach: integrating recycled wood with graphene using advanced fusion techniques. This composite targets the pressing challenges faced by the prevalent use of aluminum in space structures. Leveraging the ecological attributes of wood and the remarkable properties of graphene, our novel composite aspires to be suitable for the harsh Low Earth Orbit (LEO) environment.

To ascertain the viability of this material for space applications, extensive environmental tests encompassing thermal cycles, vacuum conditions, and rigorous vibrations were executed. Preliminary results are promising, showcasing potential benefits like significant mass reduction, enhanced radiation shielding, superior thermal insulation, and improved damping during launches.

8:00 PM SF08.04.21

Advanced X-Ray Characterization of Fusion Materials AnthonyZhu[1], MichaelZhang[2], RyanKim[3], TakaakiKoyanagi[4], WeichengZhong[4], LanceSnead[5], DavidSprouster[5] and MiriamRafailovich[5]; [1]Barrington High School, United States; [2]Livermore High School, United States; [3]Thomas Jefferson High School for Science and Technology, United States; [4]Oak Ridge National Laboratory, United States; [5]Stony Brook University, United States

In the present work, we describe our efforts employing advanced non-destructive X-ray-based characterization to support the fabrication and post-irradiation examination of materials for advanced fusion energy systems. Specific material systems include castable nanostructured alloys (CNAs) and neutron irradiated tungsten. We quantify the microstructural and atomic properties of advanced first-wall materials through two-dimensional mapping and high-throughput X-ray diffraction (XRD). X-ray-based characterization techniques provide complimentary quantitative insights across multiple length scales needed to fill critical knowledge gaps and predict long-term behavior and performance.

CNAs have been under development by the fusion program over the last decade and are meant to provide enhanced elevated temperature performance as compared to reduced activation ferritic martensitic steels through the internal formation of irradiation-stable and dislocation-pinning precipitates. In this way, CNAs are a potentially more practical high-temperature option for high-heat-flux or other challenging fusion applications. The uniformity of the microstructure and engineered precipitates through various cast plates are investigated here by constructing 2D microstructural maps from XRD analysis.

Tungsten is presently the leading plasma-facing material candidate due to its high melting point, resistance to sputtering, and chemical compatibility with tritium. However, extended exposure of W to fusion plasmas and intense 14 MeV neutrons, resilience against plasma-induced surface damage (cracking, erosion/exfoliation, and fuzz formation), and degradation of bulk mechanical properties due to neutron irradiation raise significant concerns about its stability. We performed XRD experiments of unirradiated and neutron-irradiated polycrystalline W alloys after low-dose irradiation at 800°C (0.1 dpa) and after high irradiation temperature (>800°C).

XRD patterns were collected for fifty neutron irradiated W, and 2D XRD mapping data for six CNA alloy plates were performed at the PDF beamline at the National Synchrotron Light Source-II. Analysis of the XRD patterns allows the determination of the lattice strain, change in microstructure parameters, and formation of secondary phases. We developed a high-throughput quantitative XRD analysis routine to generate microstructural data of both sets of specimens. Using Perl and Python scripts, we ran batch analysis of our data through the Materials Analysis Using Diffraction software and then generated heatmaps that plot our collected data in 2D mappings.

The quantitative XRD analysis of the exposed CNA samples show a complex hydrogen uptake in the metal carbide crystallites, and the lattice expansion and crystallite size reduction will have non-negligible implications on the mechanical properties and retention of transmutation products within this important structural component. The heatmaps visualize microstructural features (carbides) that provide strength to the steel and are trapping sites for radiation-induced gaseous products. The steels are strangely affected by the exposure and expand (lattice expansion).

Our initial success in demonstrating the effective characterization of fabricated and as-irradiated materials supports our goal of fabricating functionally graded or composited first wall tile structures (i.e., W-CNA), which may be essential to mitigate the very high heat flux loading anticipated as we move beyond ITER towards DEMO-like fusion systems.

AZ, MZ, and RK acknowledge the Garcia Research Program and the Morin Charitable Trust for their contributions to making this work possible. These experiments and analysis were supported by the U.S. Department of Energy Office of Fusion Energy Sciences under contract DESC0018322 with the Research Foundation for the State University of New York at Stony Brook and DE-AC05–00OR22725 with UT-Battelle LLC.

8:00 PM SF08.04.22

Graphene-Enhanced Wood: A Lightweight and Sustainable Material for Spacecraft Structures AfnanS. Malik[1], RamiA. Elkaffas[1], BaselR. Altawil[1], BlaiseTardy[1], Seanswei[1], YarjanAbdul Samad[1,2] and OmniaKhattab[1]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]University of Cambridge, United Kingdom

Laser ablation debris removal is a promising means of achieving sustainable space operations [1,2]. However, conventional metals in spacecraft ablate into spallation particles [3] that may harden and impact spacecraft or oxidize and deplete the ozone layer [4,5]. Wood is a candidate space structural material since it is 84% less dense than conventional metals such as Aluminium alloys and does not produce polluting spallation particles such as alumina (Al_2O_3) [3,6,7]. Another candidate material is Graphene, which maintains an electric conductivity of 350,000 cm^2/V s [8], mechanical stiffness of 1 TPa [9], and EMI shielding efficiency of 90 dB [10] in space conditions [6].
This study proposes graphene-enhanced wood as a novel space material harnessing both those materials' properties, made through the procedure illustrated in Fig. 1. Delignification creates micropores that enhance flexibility and formability [11]. Graphene, produced through microwave-assisted exfoliation of thermally expanded graphite obtained from treating graphite flakes with perchloric acid [12], is then infused into the wood, coating inner cell walls and pores [13]. Finally, densification through air-drying or oven-drying at 60 °C for 12 hrs, or hot-pressing under 4 MPa pressure for 12 hrs at 80 °C, produces the final rigid form [11,14,15].
Our initial results demonstrate significant enhancement of the wood's tensile strength (up to six times), electrical conductivity (up to 35 S/m), EMI shielding efficiency (up to 16 dB), and laser ablation performance. Through an ongoing optimization process, these parameters will be further improved, and the final results will be presented in the final manuscript.

8:00 PM SF08.04.23

Evaluation of an Potential Application of Epoxy Resin as a Concrete Binding Adhesive DouglasX. Shattuck[1,2], EthanShan[3,2], CurtisSung[3,2] and SamanAbbas[3,2]; [1]St Joseph School Wakefield, United States; [2]National STEM Honor Society, United States; [3]Malden Catholic High School, United States

Due to the challenging assignment of finding water sources and producing cement on the moon, we have found that epoxy resin may be a possible solution for lunar building adhesives. Our goal is to explore and research the application of epoxy resin as an adhesive in the physical and functional testing of lunar soil models. We have made multiple compressive tests on the mixture and plan to conduct more tests in future research, including the synthesis of this material with simulated lunar regolith to further explore its potential in constituent lunar habitats.

Epoxy resin is widely used in engineering fields such as architecture, aerospace, and electronics. After chemical reactions between the epoxy resin and its hardener, it will solidify and have good chemical corrosion resistance. Meanwhile, the advantage of epoxy resin (1.1~1.2 g/cm^3) is its lighter density, including its hardener (0.9~1.1 g/cm^3), which is lighter than the combination of water (1.0 g/cm^3) and cement (1.4~3.0 g/cm^3).

Except for epoxy resin, hardener, and borosilicate glass (glass were completely invariant value in the first round), which are different from common cement concrete. The remaining mixture materials used in this experiment are common concrete materials: sand mixtures, metal powder (Al), and aggregates.

We believe that epoxy resin has great potential as an adhesive for lunar construction, as it has relatively light density and excellent chemical corrosion resistance and strength. With further research, it will contribute to the application and production of this material in extreme environments.

The Potential for Solar Vitrificarion of Martian Regolith for The Production of Building Material DouglasX. Shattuck[1,2], HaleyTalbot[3], LeoChen[3,2] and SamanAbbas[3,2]; [1]St Joseph School Wakefield, United States; [2]National STEM Honor Society, United States; [3]Malden Catholic High School, United States

Our study delves into the pragmatic utilization of vitrified Martian regolith as a key building material for prospective Martian habitats. We explore the feasibility of harnessing a specialized solar collector, tailor-made to amplify sunlight, in the pursuit of achieving the optimal temperature required to transmute Martian soil into glass. Our approach underscores the importance of employing readily accessible resources, thereby ensuring the viability of future Mars missions.
The Solar Collector design has been ingeniously streamlined, featuring a straightforward space frame crafted from commonplace 2x4's, securely joined together via screws. The innovative lens attachment relies on friction for stability, simplifying the construction process and diminishing the need for advanced equipment. Furthermore, the requisite water for the lens can be

sourced locally on Mars, substantially reducing dependence on Earth-based supplies.
The incorporation of screws into the design has markedly fortified the frame's structural integrity in comparison to prior iterations, obviating the necessity for supplementary support structures. Consequently, the entire assembly, including the solar collector, can be erected within a remarkably efficient timeframe of approximately four hours.
While the initial lens design successfully achieved temperatures of up to 200°C, it grappled with precision in focal point control. Consequently, we developed a secondary lens design, vastly enhancing its focusing capabilities. An in-depth analysis of the relationship between lens volume and maximum attainable temperature unveiled a temperature spectrum spanning from 136°C to a pinnacle of 665°C. It is noteworthy that while higher temperatures remain theoretically attainable, expanding the lens volume raises concerns about the structural integrity of the lens.
A noteworthy observation pertains to the linear correlation between lens area and temperature, indicating that larger lenses have the potential to deliver superior performance, extending their capabilities without compromising structural stability. Furthermore, augmenting the volume of fluid within the lens emerged as a promising strategy to enhance light focusing.
Our prototype successfully achieved elevated temperatures using commonplace materials, yet it faces inherent challenges, including a limited operational window and vulnerability to debris interference. Additionally, the positioning of the sun can impede its ability to consistently attain and maintain adequate temperatures. Consequently, these limitations underscore the necessity for further refinement and comprehensive testing to enable practical application in the construction of Martian habitats.

SESSION SF08.05: Atomic-Scale Mechanisms for Extremes

***In Situ* Mechanical Analysis of Hierarchical Nanoporous Metal-Conductive Polymer Hybrids in Electrolyte Environment**OlgaMatts and NadiiaMameka; Helmholtz-Zentrum Hereon, Germany

Recent progress in material design strategies towards hierarchically porous metals enable unique bicontinuous microstructures that combine desired, but conflicting, properties, namely, a large specific surface area and rapid mass transport [1]. Furthermore, because of the open porosity, these three-dimensional architectures provide access of chemical species and surface state modification of the inner surfaces via external control variables – surface charge density or adsorbate coverage. The nanoporous metals with structural hierarchy, thus, offer ample opportunities for design of multifunctional hard-soft hybrids as sensor and actuator materials [1] as well as various electrochemical energy systems [2]. Despite significant developments in the fabrication of hierarchical nanoporous metals so far, studies of their mechanical and functional behaviour in electrolyte environment, in which they can operate, are scarce.

Here, we explore an impact of the unusual morphology on the functionality of nanoporous metals by probing an influence of a conductive polypyrrole nanocoating (PPy) on the mechanical response of a nanoporous gold (npAu). Bulk hierarchical nanoporous gold (hc npAu) with two distinct and well-defined length scales has been formed by selective dealloying process [3]. The larger pores at the higher hierarchical level (characterized by diameters around 150 nm) of the hc npAu provide unhindered transport pathways, while nanopores at the lower hierarchy level (below 30 nm) supply a large fraction of surface sites. The pore sizes at both scales can be adjusted via fabrication conditions, whereas various PPy fractions in the pores are tailored during electrochemical polymerization of pyrrole [4]. Actuation, elastic and plastic behavior of the PP-coated hc npAu were then analyzed in situ upon potential cycling in an aqueous electrolyte. We revealed pronounced variations in the macroscopic length change, Young's modulus, and plastic flow in response to the voltage-induced redox reactions of the polymer films at the nanoporous electrodes. In the contribution, we discuss the origin of the observations and compare the functional performance of hc npAu/PPy with unimodal npAu/PPy hybrids.

Understanding the Role of Intermetallic Interface Contributions in Al – Ni Layered Systems RuthSchwaiger, Nicolas J.Peter, XiLi and MarilaineMoreira de Lima; Forschungszentrum Juelich GmbH, Germany

Nanometallic multilayer systems with designed micro- and nanostructures offer great potential to sustain extreme conditions, such as high temperature, corrosive environments, or radiation. The internal interfaces of such material systems include grain boundaries and interphase boundaries and can be tailored with respect to composition and morphology to achieve properties that cannot be achieved by conventional materials. Understanding the role and behaviors of the different interfaces is thus critical to developing materials suitable for extreme conditions. Most studies of layered systems focused on elements with a positive enthalpy of mixing to create almost atomically sharp interfaces. By contrast, only few studies investigated the interface morphology for systems with negative enthalpy of mixing, which offers additional degrees of freedom regarding materials design.
We investigated the Ni-Al multilayer system with varying layer thicknesses between 5 and 250 nm to understand the effects of the layer structure on the mechanical behavior and the stability of the microstructures not only at elevated temperatures but also after severe deformation. The microstructure characterization with TEM and STEM-EELS indicates wide interdiffusion at Al/Ni interface and formation of intermetallic bonding at interfaces and grain boundaries in Al/Ni multilayer. We measured a peak hardness of 9.03 ± 0.14 GPa, which is the highest measured so far for fcc-fcc layered systems and shows the potential of this interface engineering route. Our findings demonstrate that the intermetallic formed at Al/Ni multilayers contributes to a strong interface strengthening effect and compensates the weakening from interface diffusion. In this presentation we will discuss the role and potential of the interfaces and interphase boundaries for materials under extreme conditions.

8:45 AM SF08.05.03
Probing Residual Stresses and Dislocation Dynamics by Combining X-Ray Nano-Diffraction and Micropillar Compression Testing RebeccaJanknecht[1], RainerHahn[1], AntonDavydok[2], SzilardKolozsvari[3], PeterPolcik[3] and PaulMayrhofer[1]; [1]TU Wien, Austria; [2]Helmholtz-Zentrum Hereon, Germany; [3]Plansee Composite Materials GmbH, Germany

Architecting materials for extreme environments requires a comprehensive understanding of their behavior under challenging conditions. This study introduces a novel approach that combines micropillar compression testing with X-ray nano diffraction to in-situ investigate strains within TiN-based physical vapor deposited (PVD) thin films during loading. The micropillar compression testing induces and moves dislocations within the coating material. The simultaneous X-ray nano diffraction with a focused beam of 250 nm in size allows to capture detailed information about changes in strain as well as structure. Nanocrystalline Ti-B-N coatings with boron contents up to 40 at.% and ceramic-metallic TiN-Nb multilayers with different modulations served as model systems. The nanocrystalline Ti-B-N exhibits significant differences in deformation and fracture behavior, depending on the amorphous grain boundary phase fraction. The stresses needed to move dislocations within the metallic Nb layers of the TiN-Nb multilayers, depend on the Nb layer thickness and varies between ~3 and 10 GPa.

These comprehensive investigations allow to extract information on the predominant strength, ductility, and failure mechanisms active in nanocomposite or multilayered PVD materials. Based on these, PVD thin films with exceptional resilience and damage tolerance, making them suitable for high-stress applications, can be designed.

9:00 AM SF08.05.04
Mechanistic Study of Superlattice Effects on the Example of Hexagonal Diboride Coatings RainerHahn[1], ArnoldTymoszuk[1], TomaszWojcik[1], EleniNtemou[2], OliverHunold[3], PeterPolcik[4], SzilardKolozsvari[4], DanielPrimetzhofer[2], PaulMayrhofer[1] and HelmutRiedl[1]; [1]TU Wien, Austria; [2]Uppsala University, Sweden; [3]Oerlikon Surface Solutions AG, Liechtenstein; [4]Plansee Composite Materials GmbH, Germany

Coherently grown nanolayered PVD thin films, referred to as superlattice thin films, are known for their superior hardness compared to monolithically grown constituents. By employing in-situ micromechanical cantilever bending tests, we have shown that the fracture toughness also shows a significant bilayer period-dependent behavior. While mechanisms based on dislocation activity explain the hardness peak, the linear elastic deformation of the microcantilever during the fracture experiments suggests that these explanations are not directly applicable to describe the enhancement in fracture toughness. Consequently, an underlying, bilayer-period-dependent intrinsic property is responsible for this behavior.
This contribution presents an overview of the ceramic superlattice systems deposited so far, their increase in hardness and fracture toughness, and a mechanistic consideration of the increase in these properties. For this purpose, we selectively deposited systems, which differ in the two decisive factors for increasing the mechanical properties, the shear modulus difference ΔG and the

difference in the lattice parameters Δa. While our TiB_2-WB_2 systems show a pronounced difference in G, their lattice parameter is very similar, contrary to our TiB_2-ZrB_2 systems, having similar elastic properties while showing a pronounced difference in their crystallographic properties. We unravel the active mechanisms responsible for the respective increases in H and K_{IC} by performing the same micromechanical tests on these novel diboride coatings. Specifically, the TiB_2-ZrB_2 coatings showed an increase in K_{IC} up to 3.7 $MPa*m^{0.5,}$ while the TiB_2-WB_2 system experienced an increase in hardness to 45.5 GPa, both without a significant increase of the other mechanical properties. These results and investigations, especially the systematic design of the study, allow a targeted development of protective coatings.

Reactive Sintering of Oxide Dispersion Strengthened Nanoarchitectured Aluminum Alloys JasonR. Trelewicz; Stony Brook University, United States

High specific strength materials are critical for enhancing performance and efficiency in a broad range of applications such as next generation aerostructures and hypersonic vehicles but are often limited by the low relative strength often accompanying the reduction in density. For example, most aluminum (Al) alloys have yield strengths that are at most a few hundred megapascals while the yield strength of a common structural steel can exceed a gigapascal, albeit at the expense of density. One pathway for enhancing a material's strength is to reduce its grain size following the classical Hall-Petch relationship, and nanocrystalline materials containing grain sizes generally less than 100 nm occupy the lower limit of this approach. While nanocrystalline Al has been demonstrated with exceptionally high yield strengths of 400-600 MPa, grain size refinement for strengthening produces intrinsically unstable microstructures where thermodynamics favor grain growth. In this work, we combined targeted alloying for stabilizing nanocrystalline grains in Al with powder metallurgical processing advances that trigger an exothermic reaction during sintering to facilitate densification at low homologous temperatures and the formation of a distributed nano-oxide phase. Based on thermodynamic modeling, magnesium (Mg) was selected as the primary solute addition and mechanically alloyed with Al through high energy ball milling to produce a series of nanocrystalline Al-Mg alloy powders. Reaction of Mg with oxygen (O) during the decomposition of a byproduct of the selected process control agent provided the exothermic reaction required to enhance the sintering kinetics at low homologous temperatures. The resulting bulk nanoarchitectured alloy is shown to contain nano-oxides dispersed in a nanocrystalline Al-Mg matrix with a highly stable grain size of < 50 nm up to 500 °C and a strength double that of the aerospace grade Al alloy 7075-T6. In a broad sense, this reactive sintering technology enables the production of bulk, thermally stable nanoarchitectured alloys with amplified strengthening due to a confluence of mechanisms involving extreme Hall-Petch strengthening from the stabilized nanograins and matrix dispersion strengthening from the distributed nano-oxide phase.

Multiscale Microstructure Architecturing Protects Advanced High Strength Steel against Hydrogen Embrittlement DierkR. Raabe, DirkPonge and BinhanSun; Max Planck Institute for Iron Research, Germany

Advanced high-strength steels exhibit structural and chemical ordering and patterning phenomena across multiple length scales. These include short and medium-range chemical ordering, complex nanoprecipitate patterns, and coupled mesoscopic chemical-structural-mechanical partitioning effects. These phenomena can arise from kinetic freezing, chemical decoration of lattice defects, locally confined phase transformation effects, or chemical container phases that trigger local phase transformations.
Heat treatment can be used to architect these features in a hierarchical manner at bulk scale in medium and high manganese steels with lean chemical compositions [1,2]. These hierarchical ordering effects that involve different chemical and structural features across several length scales can be used to design a complex strain hardening behaviour and can help to enhance the materials' resistance to hydrogen embrittlement.

Strengthening of Eutectic Alloys with Mille-Feuille Structure Accompanied by Kink-Band Formation TokoTokunaga[1], KojiHagihara[1,2], ShuheiOhsawa[1], TakuyaYonemura[1], DaisukeEgusa[3] and EijiAbe[3]; [1]Nagoya Institute of Technology, Japan; [2]Osaka University, Japan; [3]The University of Tokyo, Japan

Application of the lightweight metal materials to the automobile components has been gaining attentions to mitigate the global warming problems by reduction of CO_2 emissions. Recently, Mg alloys with Long Period Stacking Ordered (LPSO) phase have been gaining attentions because they achieved high strength and high ductility simultaneously by the introduction of characteristic deformation bands; i.e., kink bands. To introduce the kink bands during deformation, the macroscopic shear direction must be restricted along the direction parallel to the loading orientation. Since the LPSO phase consists of periodic stacking of soft Mg layers and hard Y/Zn segregated layers, i.e., mille-feuille structure, it has been considered that this structure brings the strong plastic anisotropy and restricts the shear direction. Thus, by controlling the loading orientation, the kink-bands are expected to be obtained. This microstructure control using mille-feuille structure can be one of the effective ways to achieve high strength and high ductility materials.
In the present study, we have focused on Al-Al_2Cu and Ti-TiFe eutectic alloys to obtain the "micro-scale" mille-feuille structured materials. For the Al-based alloy, to achieve highly-aligned lamellar structure, the directional solidification with growth rates in a range of 5 to 300 mm/h was conducted. On the other hand, for the Ti-based alloy, we made use of the heat flow in the arc melting process to align the lamellar structure. We basically obtained a lamellar microstructure aligned parallel to the growth and heat-flow directions in both alloys. However, in the directionally-solidified Al alloys, as the growth rate increased, the alignment of the lamellae was gradually disturbed and the lamellae tended to incline against the growth direction. Moreover, the thickness of the lamellae and size of the colony, which is the group having the same lamellar orientation, decreased as the growth rate increased.
In the compression tests of the Al-based alloys, for the alloys with large colony diameters, large kink bands formed, which induces buckling of the specimen. On the other hand, it was found that a decrease in the colony diameter induces the homogeneous formation of tiny kink bands, leading to the drastic increases in the yield stress while maintaining ductility as observed in the Mg-based LPSO phase alloys. Moreover, it has been systematically demonstrated that the yield stress proportionally increases as the inverse of the square root of the colony diameter increases. This can be considered because the colony diameter affects the formation stress of the kink bands. From the obtained results, it has been demonstrated that control of the colony size and the alignment of lamellae are the key factors for achieving superior mechanical properties of the mille-feuille structured alloys with homogeneous formation of tiny kink bands.
In the compression tests of the Ti-based alloys, they showed extensively high strength over 2 GPa at room temperature, and kept the high strength at 400ºC. However, the strength decreased drastically at and above 600ºC. In the specimen deformed at 800ºC, the specimen deformed with formation of tiny kink bands. By the crystallographic analysis, rotation axises for the kink-bands formation were different in β-Ti and TiFe phases. This implies that the mechanism of the kink-bands formation in the present eutectic Ti-TiFe alloy was different from the conventional model for the kink-bands formation. In the presentation, the kink-bands formation behavior of the present Al and Ti alloys are presented in detail.

10:45 AM SF08.05.08
Entanglement of Ordered and Disordered Structures Enables Supercritical Elasticity YangRen[1], HaiyangChen[2] and Yan-DongWang[2]; [1]City University of Hong Kong, Hong Kong; [2]University of Science and Technology Beijing, China

Superelasticity associated with the martensitic transformation has a broad range of applications. However, the intrinsic hysteresis and temperature sensitivity of the first-order phase transformation significantly hinder their usage in many critical areas. We recently discovered that the first-order stress-induced martensitic transformation (SIMT) of a large class of shape-memory-alloys can be completely diminished by appropriate material design and thermal treatments to bring the transformation to a supercritical region [Chen et al., Nature Materials, 19, 712 (2020). https://doi.org/10.1038/s41563-020-0645-4]. In this talk, we will present a new type elasticity: supercritical elasticity (SCE), in NiCoFeGa single crystals which exhibit a large elasticity up to 15.2% strain, with non-hysteretic mechanical responses, a small temperature dependence and high-energy-storage capability and cyclic stability over a wide temperature and composition range. In-situ synchrotron X-ray diffraction shows that the SCE is correlated with a stress-induced continuous variation of lattice parameter accompanied by structural fluctuation. Neutron diffraction and electron microscopy observations reveal an unprecedented microstructure consisting of atomic-level entanglement of ordered and disordered crystal structures, which can be manipulated to tune the SCE. The alloys are very promising for high-performance engineering applications, ranging from deep-space and deep-sea exploration to intelligent robotics.

11:00 AM *SF08.05.09
Tailoring Structure and Properties of Architectured Metastable Alloys JurgenH. Eckert[1,2]; [1]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria; [2]Montanuniversitaet Leoben, Austria

Significant progress has been made in recent years in how to optimize processing conditions for metastable alloy and composite formation, microstructure design, net-shape forming and property adjustment of architecture metallic materials. However, the details of the correlation between composition, atomic structure, hierarchy of the microstructure, defects and thermo-mechanical treatments employed for structure modification and their impact on deformation and failure mechanisms for achieving tailored properties are still not well understood.
Recent work suggests that not only the intrinsic properties of metastable metallic alloys and composites are strongly affected by the details of atomic arrangements including short- and

medium-range order cluster motifs in amorphous solids and high-entropy alloys but also their response to external fields like mechanical deformation or temperature cycling largely depends on often complex local atomic rearrangements triggered by or causing heterogeneous stress and strain variation on different length-scales. This – together with microstructure modulation through tuning of architecture and length-scale of phases as well as the use of non-equilibrium processing techniques for phase and structure design – yields unique prospects for developing architectured materials for extreme conditions or environments.
This talk explores the diversity that can be achieved in metallic glasses, chemically complex alloys and composites considering structure changes, recovery and rejuvenation mechanisms, clustering, segregation as well as phase separation or nanocrystallization phenomena when the materials are subjected to different solidification conditions, mechanical deformation, thermo-mechanical cycling, or net-shaping. The findings from experiments and simulations will be discussed with respect to atomic rearrangements, short- and medium-range order modulation, local stress and strain states, defect generation and annihilation, nanoscale clustering or segregation and precipitation of secondary phases. The structure changes will be correlated with plastic deformability and failure mechanisms, and the effectiveness of composition and microstructure tuning and thermo-mechanical processing for materials design will be discussed to derive guidelines for processing and property optimization.

11:30 AM *SF08.05.10
Dissimilar Joining using Dealloying HidemiKato, KotaKurabayashi and TakeshiWada; Tohoku University, Japan

Liquid metal dealloying (or solid metal dealloying) can produce distinctive bicontinuous nano- and microcomposites with immiscible metals such as Ta-Cu[1], FeCr-Mg[2,3], and Ti-Mg[4]. These immiscible metal composites are not expected to have strong chemical bonding between the constituent metals, but they exhibit excellent strength and ductility. In particular, FeCr-50%Mg with a few μm ligaments exhibited a tensile strength of 191.9 MPa and a tensile elongation of 15.0%. These results led us to believe that LMD (or SMD) are effective as dissimilar materials joining techniques, especially between immiscible metals. Actually, in these years, multi-material structures that combine steel with lighter materials, such as magnesium alloys, have received wide attention in the field of welding engineering. In this paper, dissimilar joining of immiscible metals is discussed, then, as a simplified model, joining of pure Fe and Mg using Solid metal dealloying technique is demonstrated[5].

New Methods for Testing Materials under Extreme Conditions KeithA. Nelson; Massachusetts Institute of Technology, United States

The design of architected and other advanced materials to withstand extreme conditions has heightened the need for facile tests under such conditions that can be applied to small amounts of materials that may be in early developmental stages. Three recently developed and refined methods for materials testing under extreme conditions will be discussed.
In the laser-induced particle impact test (LIPIT), small (~5-50 μm) particles of various types are launched by laser ablation of a supporting layer. Camera images record a trajectory before, during, and after impact with a target material in order to determine particle speeds (~50-1200 m/s) before and after impact and to observe details of the particle and target material responses to impact (*Appl. Phys. Rev*. **8**, 011319). Target materials have included soft materials such as polymers and gels as well as hard materials including metals and ceramics. Architected materials and ultrathin layers have been studied.
Two methods involve laser-driven shock waves. In one, an intense laser pulse is directed to a circular-shaped “ring” pattern at the sample. Absorption in a 10-50-μm thick material leads to rapid melting and evaporation which launches a quasi-2-dimensional focusing shock wave. In opaque materials with strong near-surface absorption, a focusing surface acoustic wave (SAW) shock is launched. In both cases, pressures of several tens of GPa can be reached at the shock focus with only a few millijoules of laser pulse energy (*Rev. Sci. Instr*. **91**, 033711). Shock-induced chemical and structural transformations have been studied.
A very recent development (*arXiv*:2209.13897) has permitted ***laser generation of shock waves without damage to the optically irradiated region of the sample***. Instead of an intense laser pulse directed at a single sample region, many cylindrically focused pulses reach parallel “lines” at the sample in succession, with temporal and spatial shifts adjusted to move across the sample at a speed that matches the acoustic velocity. The shock wave is built up gradually by the successive pulses, each of which is below the optical damage threshold of the sample. This enables repeated shocks (up to ~10 GPa pressure to date) to be delivered to the same sample region so that cumulative effects of shock can be assessed. In an initial study, thousands of SAW shocks that reached strain levels of 1% (3 GPa pressure) in $SrTiO_3$ were launched. Typically, there was no visible damage to the sample until ~1000 shocks, after which severe damage (material ejection several microns deep) occurred and gradually spread during the next 1000-2000 shocks. The nondestructive shock generation method will enable detailed study of fatigue in many material classes. X-ray imaging methods may permit characterization of the nanoscale defects that accumulate prior to catastrophic damage.
The nondestructive shock generation method is being extended to focusing shocks generated by a succession of pulses directed to concentric circular regions of the sample, with the diameter gradually reduced from one pulse to the next to match the acoustic velocity. Initial tests with just two pulses have enabled shock pressures to be reached nondestructively that are comparable to those reached by many pulses in the method described above, due to the increase in shock pressure at the focus. The combination of approaches is useful to permit testing under compressive stress only (in a quasi-bulk compressional wave), tensile stress (which follows compression in the focusing shock, upon divergence from the focus), and significant shear stress (in SAW shocks several microns beneath the sample surface, where the SAW has a large shear component).
Finally, the methods involving multiple “lines” or “rings” of pulsed laser light are not restricted to the optically nondestructive regime. We hope to reach extreme pressures (> 100 GPa) by directing intense pulses to multiple concentric rings.

2:00 PM SF08.06.02
Observing High Strain Rate Compression of Gradient Density Octet Lattices using Ultrafast X-Ray Imaging AbhinavParakh[1], JonathanLind[1], AnnaGuell Izard[1], JohnKulikowski[2], WendyGu[2] and XiaoxingXia[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Stanford University, United States

Architected materials are a new class of engineered materials with controlled internal structures that give rise to properties that differ or surpass those of their constituent materials. Micro- and nano-structured lattices have demonstrated superior quasi-static mechanical properties compared to traditional materials or composites but, their dynamic mechanical behavior under high strain rate conditions is poorly understood. Here we compressed gradient density octet lattices fabricated using Nanoscribe under high strain rates and observed the deformation behavior using ultrafast X-ray imaging at Argonne National Lab. We used high fidelity hydrocode modeling of the lattices and utilized X-ray imaging to directly relate the measured in-situ compressed lattice to the model predictions for the expected output ramp profile. We observed that the direction of increasing density profile (higher density at the substrate compared to lower density at the substrate) affected the onset of acceleration and the compression profile at the backend of the substrate. We show that micro-architected lattices with smoothly varying density gradients have a great potential for creating tailored ramp compression profiles.

2:15 PM *SF08.06.03
Energy Absorption in the Gigapascal Range – Methods to Absorb Energy for Extreme Mechanical Loads JeffreyLloyd; DEVCOM Army Research Laboratory, United States

Design of architected structures and materials for energy absorption is straightforward – choose a solution that maximizes specific energy absorption for a given loading amplitude while keeping below some maximum allowable threshold stress. Novel materials and architectures of lattices and foams have increased the specific energy absorption capacity and threshold stresses

that can be tolerated, but these structures are generally dominated by the densification phase for loads exceeding hundreds of Megapascals. In this talk we examine the potential for volume-reducing phase transformations to manipulate waves with amplitudes up to tens of Gigapascals. As an example, the ability for the ��→�� transformation to absorb shock waves in Fe and its alloys is studied for monolithic and hierarchically structured materials using both experiments and computer simulations. Methods are presented for designing new metal alloys, both monolithic and graded, that can achieve high specific energy absorption.

2:45 PM SF08.06.04
Material Properties of Aerogel Measured using Bow Shock Induced by Supersonic Particle Impact YunKai and KeithA. Nelson; Massachusetts Institute of Technology, United States

Aerogels are lightweight materials with a nanoporous structure that captivate the interest of researchers in various fields of science and technology. They possess numerous exceptional characteristics and find applications in a wide range of areas, including thermal and acoustic insulation and kinetic energy absorption. Typically, the mechanical properties of aerogel were measured using uniaxial compression, three-point bending, ultrasonics, and atomic force microscopy. However, accurately measuring the mechanical properties of aerogel can be challenging due to its low density, high porosity, and brittleness. Aerogels, especially silica aerogel, are known to be fragile and brittle. This makes them inapt for load-bearing testing methods.
In this study, we utilize a method called laser-induced particle impact testing (LIPIT) to investigate the properties of aerogel materials. Specifically, we report on the observation of bow shock generation during supersonic particle impacts. It is worth noting that previous works did not report the occurrence of bow shocks, as solid or liquid samples in those studies typically possess higher acoustic speeds compared to projectile speeds. However, aerogel, an air-like material with intricate foam structures, may exhibit a significantly lower acoustic speed (around 100 m/s) than our typical projectile speed (approximately 1000 m/s). This characteristic facilitates the generation of bow shocks. We can accurately extract material properties by performing aerodynamic analysis on bow shocks. The advantage of our bow shock-based study is that it eliminates the risk of altering the material properties before the measurement takes place since the bow shock is the fastest event in the system. Moreover, our approach not only allows for the determination of material properties such as acoustic speed and bulk modulus but also enables the calculation of the previously unreported drag coefficient. Our results have implications for the design of aerogel-based materials for various applications, including impact protection and shock mitigation.

Assessing the Design Space for Architected Materials in Extreme Loading Scenarios MukulKumar, BrandonZimmerman and JonathanLind; Lawrence Livermore National Lab, United States

Owing to the tunability of mechanical response for structural applications, additively manufactured lattice structures are increasingly being studied to elucidate their response to static and dynamic loads. However, these roles are typically in opposition: static loads must be supported sufficiently far away from the onset of buckling or yielding, whereas dynamic loads are typically ameliorated by crushing of the lattice, which provides excellent energy-absorption due to the large plastic deformation accompanying densification. Moreover, emergent behavior, such as material jetting and elastic wave propagation, arising from the open architecture has been observed in situ under dynamic loading conditions. In this work we will outline a design scheme for lattice structures that must simultaneously support static loads while enduring high-amplitude impulsive loads. For a class of impulse shapes associated with laser-based shock compression, our key findings show that the static and dynamic responses of the lattice can be uncoupled and linked by a strength model that accounts for variability in the additive manufacturing process. Moreover, costly global search optimization can be replaced by sequential one-dimensional optimization following the direction of the wave propagating through the lattice. The design rules developed in this study expand the domain of applicability of lattice structures to challenging dual-loading regimes spanning decades of strain rates.
This work was performed under the auspices of the US Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Temperature- and Rate-Dependent Deformation of Additively Manufactured Copper Microlattices Sung-GyuG. Kang[1], BárbaraBellón[1], Lalith KumarBhaskar[1], DipaliSonawane[1], JanisWirth[2], AlexanderGötz[2], BenjaminA. Zubiri[2], ErdmannSpiecker[2], GerhardDehm[1] and RajaprakashRamachandramoorthy[1]; [1]Max-Planck-Institut, Korea (the Republic of); [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The deformation behavior and mechanical properties of architected materials are determined not only by their geometry but also by the intrinsic mechanical properties of the constituent materials. In this study, we investigate the temperature and strain rate responsive deformation behavior of a 3-dimensional microarchitecture by examining the material's intrinsic deformation mechanism.
We fabricate copper microlattice architectures using an additive micromanufacturing process based on localized electrodeposition in liquid. The microlattices are characterized using nano X-ray computed tomography (nano-CT), which confirms the near-ideal connectivity between nodes and struts. Microstructural characterization is performed using electron backscatter diffraction (EBSD) and transmission electron microscopy (TEM), revealing that the microlattices are microcrystalline with a high fraction of twin boundaries.
Furthermore, we investigate, for the first time, the mechanical properties of the copper microlattices under a wide range of strain rates (from 0.001/s to 100/s) and at various temperature conditions (cryogenic -150°C and room temperature) using a piezo-based *in situ* micromechanical testing setup inside scanning electron microscopy (SEM). The unique temperature- and rate-dependent deformation behavior of the copper microlattices is observed and explained based on the intrinsic deformation behavior of the base material (copper) obtained from micropillar compression tests performed under the same loading conditions of high strain rates and non-ambient temperatures. Notably, it is found that depending on the temperature, copper accommodates plastic deformation through either dislocation slip or mechanical twinning.
This study demonstrates that complex 3-dimensional full-metal architectures can be successfully fabricated in an additive fashion at the micron scale. Furthermore, depending on the design of the architectures and their testing conditions of temperature and strain rate, these architectures exhibit unique deformation behavior that is suitable for dynamic and harsh applications.

Decomposing Contributions to Energy Dissipation in Impact of Architected Materials ThomasButruille[1], JoshuaCrone[2] and CarlosM. Portela[1]; [1]Massachusetts Institute of Technology, United States; [2]U.S. Army Research Laboratory, United States

Ultralight mechanical metamaterials enabled by advanced manufacturing processes have previously achieved density-normalized strength and stiffness properties that are inaccessible to bulk materials, but the majority of this work has focused on static loading while the mechanical properties of these metamaterials under dynamic loading conditions have remained largely unexplored. Properties such as energy absorption of these metamaterials are of high interest for protective applications and recent works on their dynamic response have demonstrated the benefit of architecture for impact mitigation.

Here, we systematically study the response of periodic mechanical metamaterials under microprojectile impact using two-photon lithography as a rapid prototyping technique for microscopic polymeric microlattices. We fabricate suspended thin-plate lattice architectures of varying thicknesses and morphologies to characterize their response to microparticle impact. We employ the laser-induced particle impact test method to accelerate ~30 μm-diameter microparticles to velocities of up to 900 m/s, and use ultra high-speed imaging of the impact process to measure impact energetics across multiple architectures and varying lattice plate thicknesses. We compare impact performance to an array of quasistatic uniaxial compression experiments to decompose the effects of lattice compaction and fracture on energy dissipation during impact. Additionally, we analyze our experiments in a dimensionless framework to provide a first-order estimate of impact response across materials and length scales and investigate how the energy dissipation components scale with the regime of impact. Lastly, we study the impact response using an explicit dynamics finite-element representation to provide insight on the impact mechanisms. This investigation provides a framework for the rapid design and characterization of future mechanical metamaterials for a variety of energy absorption applications.

4:30 PM SF08.07.04
Fabrication of Solid-Liquid Composite Micro-Architecture and Their Deformation Behavior Sung-GyuG. Kang[1], BárbaraBellón[1], Lalith KumarBhaskar[1], Leonardo ShojiAota[1], Se-HoKim[1], AlexanderGötz[2], ErdmannSpiecker[2], BaptisteGault[1], GerhardDehm[1] and RajaprakashRamachandramoorthy[1]; [1]Max-Planck-Institut für Eisenforschung GmbH, Germany; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Architected materials, composed of solid materials with pore channels, exhibit unique deformation behavior and mechanical properties. By altering the composition of the solid material or introducing different materials, the properties of architected materials can be further tuned. However, the introduction of liquid materials to architected materials has not been investigated due to intrinsic fabrication constraints in the widely used additive manufacturing processes. In this study, we demonstrate the feasibility of solid-liquid composite micro-architectures using a recent additive micromanufacturing technique based on localized electrodeposition.
As a case study, we designed and fabricated simple pure copper (Cu) micro-vessels containing pico-liters of liquid. The existence of the liquid was confirmed through cross-sectional analysis using cryogenic-focused ion beam microscopy. Atom probe tomography was employed to measure the chemical composition of the pure copper and the encapsulated liquid. Nano computed tomography (NanoCT) results confirm the dense pure copper vessel walls with the liquid confined inside the vessel. Importantly, we investigated the effect of the liquid on the deformation behavior and mechanical properties of the micro-vessels using a *in situ* micromechanical testing system capable of metrology at high speeds and sub-ambient temperature conditions. The micro-vessels exhibited significantly different stress levels and strain rate dependencies depending on the phase (water to ice transformation under cryogenic conditions).
In addition to the microstructural and mechanical characterizations, we will discuss the feasibility and potential of solid-liquid composite architectures at the microscale as novel structural and functional materials.

4:45 PM SF08.07.05
Synchrotron Radiation-Based Far-Infrared Spectroscopy under Extreme Conditions at the Canadian Light Source JianbaoZhao; Canadian Light Source, Canada

The study of materials under extreme conditions, such as high-pressure or low-temperature, is essential in understanding a broad range of problems in physics, chemistry, geology, and materials science. Extreme conditions can cause significant changes in the physical and chemical properties of matter, such as structural phase transitions, alterations in chemical bonding, and the emergence of new properties. Consequently, there is considerable research interest in studying materials under such conditions.
A synchrotron radiation-based infrared source is an ideal tool for investigating microscopic samples under extreme conditions due to its high brightness. The Far-infrared beamline at the Canadian Light Source (CLS) is a state-of-the-art synchrotron facility that offers significantly more brightness than conventional sources. The high brightness of the synchrotron radiation allows for the acquisition of Far-infrared reflectivity or transmission spectrum on small samples with greater throughput than with conventional sources. This capability is ideal for high-pressure studies using the Diamond Anvil Cell (DAC).
A synchrotron radiation-based Far-infrared spectroscopic experiment is particularly crucial for studying the lattice modes of materials as they typically appear in the Far-infrared region. Additionally, Far-infrared spectroscopy provides detailed information on the electrical transport properties of metallic materials, the bandgap of semiconductors, and the chemical bonding properties of materials.
This presentation will provide a brief overview of the capabilities of the Far-infrared beamline at the CLS. It will also highlight the Far-infrared equipment used for solid-state experiments, especially for Far-infrared transmission and reflectivity measurements under high-pressure using the DAC. The CLS provides a custom-made horizontal microscope for Far-infrared microscopy during high-pressure studies. The optical set-up allows for transmission and reflectivity measurements, and two infinity-corrected long working distance Schwarzschild objectives (working distance-47 mm; numerical aperture-0.5) are suitable for high-pressure infrared studies using the DAC. The CLS records synchrotron radiation-based Far-infrared Fourier transform spectrum in the low-frequency region (30-600 cm^{-1}) and the high-frequency region (300-1300 cm^{-1}) using the liquid helium free detector system manufactured by QMC Instruments Inc. Moreover, the homemade ruby fluorescence spectrometer is available on-site at the CLS to measure the sample pressure inside the DAC. The Far-infrared beamline of the CLS is open to users through peer review, with calls for proposals issued twice per year for experimental beam time.

SESSION SF08.08: Evolution at Thermal Extremes

Analysis of Heat Transfer Performance for Nanomaterial Composite Electroless Coating Utilizing Spray Cooling Technique SuparnaBhattacharyya, SuryaK. Pal and SudiptoChakraborty; Indian Institute of Technology Kharagpur, India

Heat Exchangers are the most common devices for chemical industries, pharmaceutical firms and petrochemical refineries. The basic structural material used for manufacturing this high end engineered machine is mild steel due to its easy availability and vast range of usage. But the material itself is also very much susceptible to atmospheric corrosion, industrial fouling and microbial attacks. The technique of electroless coating plays a very crucial role in minimizing the above disadvantages of the material thus increasing the product value in long run. The present study gives a comparison between heat transfer experiments of electroless Ni-P-TiO2 (ENP-TiO2) coated mild steel comparing them with the uncoated and Ni-P coated mild steel samples. An optimisation of the best suit is the main focus of the given study. The heat transfer analysis is carried forward using spray cooling setup. SEM, EDX and XRD analysis of all the sample showcases the surface morphology and phase structure analysis. A brief overview on surface roughness study predict the suitability of surface modification for the required research objective. The microhardness of all the sample has been analysed and reported. An in-house spray cooling setup has been used to analyse the heat transfer analysis using INTEMP software. Scaling up the analysis for industrial purposes specifically in shell and tube heat exchangers is a potential future scope of the current analysis.

8:15 AM SF08.08.02
Strong, Stable and Multifunctional Polyimide-CNT Network Composites via *In-Situ* Solvothermal PolymerizationMichaelN. Durso and A. JohnHart; Massachusetts Institute of Tehnology, United States

To maximize the mechanical properties of aligned carbon nanotube (CNT) networks, researchers have synthesized increasingly densely-packed yarns by direct synthesis and wet chemical approaches, such that macroscopic CNT yarns can now exceed 60 to 80% of their theoretical fully-packed density. However, the weak intermolecular attraction between CNT bundles continues to limit their mechanical properties, and while increasing CNT packing density increases the density of contacts, it also acts as a barrier to infusing a reinforcing polymer phase to create stable, dense CNT-polymer composites. Our team has explored these factors which govern nanoporous network infusion and developed a one-pot, green chemical route to synthesizing high-performance aromatic polymer reinforcement in-situ in CNT materials in superheated aqueous and alcoholic solutions, exploiting their novel physicochemical behavior under these conditions.

We demonstrate the synthesis of aromatic polyimide reinforcements to create composites which are mechanically stiff and strong and inherently resilient in extreme environments. By tailoring our chosen monomers, we show the broad applicability of the technique to generate linear and hyperbranched copolymers with CNT-specific interfacial interactions facilitated by hydrogen bonding. The aromatic backbone of these polymers affords composites with exceptional thermal stability and char formation compared to common CNT reinforcements, such as polyvinyl alcohol or epoxy resins; polymer decomposition onsets exceed 500°C and can encapsulate the subsurface CNTs from reactive species. Whereas traditional approaches of heated and solvent-diluted infiltration of high molecular weight polymers are challenged by the tortuous nanoscale pathways between densely-packed CNTs, our in-situ polymerization occurs within a highly-diffusive, low viscosity environment, enabling demonstrably-deep infusion through the nanoporous network.

The high stability and specific strength and stiffness of these composites makes them promising structural materials for extreme aerospace applications, where weight savings are critical to improve performance. Further, we demonstrate that these same polymers, as coated on the CNTs, exhibit multifunctional, synergistic behavior: simultaneously acting as the reinforcing phase of a strong composite and as organic redox-active material to form a free-standing battery electrode, avoiding additional conductive and binder additives. Such composites could help to enable new structural battery designs with greater flexibility than carbon fiber-based scaffolds, which lack the intrinsic flexibility of CNT materials.

8:30 AM SF08.08.03
Solutes at Triple Lines in Al-Based Nanostructured Alloys NutthTuchinda and ChristopherA. Schuh; Massachusetts Institute of Technology, United States

Interface volume fractions increase with decreasing characteristic length scales in materials, and understanding the stability of such structural features is therefore critical for fine structures. For nanostructured materials, this effect becomes even more complicated as higher-order defects such as grain junctions become relevant. Here we calculate the substitutional solute segregation of several Al-based systems at triple junctions and show how we can apply the dataset to better understand solute chemistry at both grain boundaries and triple lines. The results from classical embedded atom potential models are compared with a hybrid first-principles dataset, highlighting potential drawbacks of the classical interatomic potentials in capturing the full physics of grain junctions. The method and dataset can be applied in the design of nanocrystalline alloys at their finest grain sizes.

8:45 AM SF08.08.04
Interfacial Instabilities of Nanoscale Architectures Under Elevated Temperatures FadiAbdeljawad[1], OmarHussein[2], KhalidHattar[3] and ShenDillon[4]; [1]Lehigh University, United States; [2]Clemson University, United States; [3]The University of Tennessee, Knoxville, United States; [4]University of California, Irvine, United States

Recent advances in additive manufacturing have enabled the fabrication of architectured materials with intricate nanoscale features. Examples include nanolattices, nanoporous materials, and stochastic nanostructures. However, the microstructural stability of such morphologies under high temperature environments is not well understood. Using theoretical, experimental, and computational studies, we examine the stability of nanostructured rod geometries. Our in-situ annealing studies of polycrystalline alumina rods demonstrate a pinch-off instability in which the rod breaks up into spatially isolated domains, a phenomenon reminiscent of the Plateau-Rayleigh instability in liquids. We develop a theoretical model to investigate the role of grain boundaries (GBs) in the morphological instability of rod geometries. Our analysis shows that GBs play a destabilizing role in which the critical wavelength for the instability decreases with increasing the GB energy. We complement our theoretical model with phase field simulations, which reveal that the time to pinch-off decreases with increasing the GB energy. On the whole, our approach provides avenues to explore microstructure evolution of high surface-to-volume materials under extreme environments.

9:00 AM SF08.08.05
Anti-Icing Properties of Polar Bear Hair JulianT. Carolan[1], RichardHobbs[1], BodilHolst[2], ØyvindHalskau[2], ManishTiwari[3], VikaramjeetSingh[3], MartinJakubec[4], JonAars[5], MagnusAndersen[5], MarcoSacchi[6], NeubiXavier[6], AdamPestana Motala[6], EspenWerdal Selfors[2], ShaneO'Reilly[7], Anne LisbethSchmidt[8], ErsiliaBifulco[2], Paula E.Colavita[1] and MarcBrunet Cabré[1]; [1]Trinity College Dublin, Ireland; [2]University of Bergen, Norway; [3]University College London, United Kingdom; [4]University of Tromsø, Norway; [5]Norwegian Polar Institute, Norway; [6]University of Surrey, United Kingdom; [7]Atlantic Technological University Sligo, Ireland; [8]National Museum of Denmark, Denmark

This work examines the natural ability of the polar bear (*ursus maritimus*) to prevent ice accumulation on their fur. Unlike other mammals, polar bears thrive in extreme environmental conditions, enduring air temperatures as low as -40°C and extended periods in water. Despite these conditions and unlike humans and other non-Arctic mammals, polar bears do not seem to experience accumulation of ice on their fur. In this study, we investigate the anti-icing properties of polar bear hair, including measurements of hydrophobicity, freezing delay time, and ice adhesion strength. We measure these properties on samples with and without the presence of hair oils (sebum).

We compare polar bear hair to human hair and synthetic ski skin samples. Ski skins are pads of aligned fibers attached to skis that support ascents while wearing skis by providing directional friction to support climbing. The ice adhesion strength of polar bear fur was found to be comparable to state-of-the-art racing ski skin technology and lower than non-race cross-country ski skins. However, when the hair oils were removed, the ice adhesion strength of polar bear fur increased significantly, suggesting the oils play a crucial role in preventing ice accumulation in a manner similar to SLIPS (Slippery Liquid Infused Porous Surfaces) [1].

Differences in the results for hydrophobicity and freezing delay time measurements on washed and unwashed hair were less pronounced. The presence or absence of oils had little effect on these measurements, with minimal variation across the hair samples. Microscopic analyses support these findings, indicating that the removal of oils did not affect the surface roughness of the hairs, a crucial parameter for both hydrophobicity and freezing delay time [2, 3].

This work employs a multidisciplinary approach, encompassing chemistry, physics, biology, and engineering. Through microscopic and spectroscopic techniques, we aim to understand the specific properties of polar bear fur that provide an advantage in the Arctic climate compared to other mammals. The insights gained from this study may guide the development of future bioinspired materials for anti-icing applications.

9:15 AM *SF08.08.06
Flame-Made Metal Sulfide Nanoparticles in Chemically Aggressive and Reducing Conditions SumanPokhrel[1,2,1], JakobStahl[1,2], JanD. Groeneveld[1,2] and LutzMädler[1,2,1]; [1]University of Bremen, Germany; [2]Leibniz Institute for Materials Engineering IWT, Germany

The flame made particles especially metastable materials are key to many applications with enormous societal and economic impact. These applications include such as but not limited to catalysts, energy concepts, electrode fabrication procedure for batteries, fuel cells, and chemical sensors. The transformation of a materials from a laboratory use to large scale technological application require (1) large specific surface area for transfer of mass, charges and energy while the specific success lies in an individual chemical nature of the materials and process design rules for particle synthesis (2) robustness during the material evaluation although they are specific in their functionality. Based on all the attractive properties of the oxide materials, key to their success is an economical and sustainable synthesis. The availability of multiple synthesis techniques (*e.g.* solid-state reactions, precipitation in aqueous and non-aqueous media, aerosol and plasma synthesis), produce specific oxide materials that are unique with respect to their physicochemical properties. However, for sulfide materials only few high temperature synthesis pathways are known due to unresolved challenges including inert atmosphere requirement, easy oxidation, endothermic conditions and low scalability. In the present work we have exploited thermodynamically driven organic gas phase combustion in reducing spray generated through fuel/oxygen ratio. The knowledge acquired from non-aqueous precursor-solvent combinations, high temperature aerosol chemistry and single droplet combustion (copper naphthenate-tetrahydrothiophene as model example) was used to establish process windows for reducing flames able to produce ultrafine metal sulfides (Cu_2S, In_2S_3, SnS_2, ZnS, Bi_2S_3, CoS, MnS, Ag_2S) with high stability and crystallinity.[1,2] The reducing flame spray pyrolysis will now be able to drive process engineering to the next level producing binary metal sulfides for the earlier mentioned applications that will go far beyond the present state-of-the-art.

Dynamical Grain-Boundary Phase Diagrams in Irradiated Alloys PascalM. Bellon, GabrielBouobda Moladje, SouravDas, AmitVerma and RobertAverback; University of Illinois-Urbana-Champ, United States

Past modeling and experiments have established that irradiation can induce the self-organization of phase-separating alloy systems into nanoscale compositional patterns (CP) owing to the competition between finite-range ballistic mixing and thermodynamically driven decomposition. We extend these results to self-organization reactions that include both grain interiors and grain boundaries (GBs). We introduce a phase-field model to investigate this coupled self-organization in model phase-separating A-B nanocrystalline alloys. GBs, described as arrays of dislocations, act as defect sinks where solute segregation and precipitation can take place owing to vacancy-induced solute drag. We show that this solute convection, even in the absence of ballistic mixing, can lead to arrested coarsening of GB precipitates. In the presence of ballistic mixing, GB precipitates can become global steady states thus extending the phenomenon of CP

originally identified for grain interiors. Steady-state phase diagrams predicted by the model determine the irradiation parameters required for the stabilization of such nanostructures. These predictions are tested on Al-base and Ni-base alloys subjected to ion irradiation.

10:45 AM SF08.09.02
Irradiation-Induced Softening in Nanotwinned Copper DaehyeokAhn and DongchanJang; KAIST, Korea (the Republic of)

Crystalline metals usually become hard and brittle after being exposed to high-flux radiation. This degradation of mechanical properties compromises the stability of structural metals when used in various industrial applications exposed to irradiation. Recently, nanostructured materials such as nanocrystalline, nanolayered, or nanotwinned metals have been widely investigated as they may have the capability to mitigate radiation damage. The internal interfaces in those materials may serve as defect sinks into which radiation-induced crystallographic defects can be absorbed. In this study, we propose an ingenious approach not just to alleviate the conventional radiation-induced hardening but also to facilitate plasticity upon irradiation in crystalline metals. This unique behavior takes place in the nanotwinned metals because the highly-populated coherent interfaces, i.e., nanotwin boundaries, act as a site in which radiation damage sink and dislocation nucleation occur simultaneously. We conducted in-situ nanoscale tensile tests on single-grain nanotwinned copper and compared the difference in their mechanical behavior before and after irradiation of a 180 keV proton beam. Microstructure analysis of tested specimens reveals that irradiation-induced softening can be attributed to the increased roughness of the interfacial planes after absorbing the radiation damage, which in turn assists nucleation of dislocations. The results of this study suggest a new opportunity to develop intrinsically-tolerant materials against irradiation through the proper design of nanotwin microstructure.

11:00 AM SF08.09.03
Helide Formers Mitigating Helium Embrittlement of Polycrystalline Materials So YeonKim[1], SinaKavak[2], KübraBayrak[3], ChengSun[4], HaoweiXu[1], Myeong JunLee[5], DiChen[6], YongZhang[1], EmreTekoğlu[1], DuyguAğaoğulları[2], ErhanAyas[3], Eun SooPark[5] and JuLi[1]; [1]Massachusetts Institute of Technology, United States; [2]Istanbul Technical University, Turkey; [3]Eskisehir Technical University, Turkey; [4]Idaho National Laboratory, United States; [5]Seoul National University, Korea (the Republic of); [6]University of Houston, United States

Fusion power holds great promise as the ultimate energy source. However, achieving true sustainability in civilian fusion requires addressing the embrittlement of polycrystalline materials used in fusion reactors, which is caused by transmutation helium and leads to premature materials failure often within a year. Here it is experimentally demonstrated that nanodispersions with constitutional vacancy-like atomic-scale free volume can divert and securely store helium within their “bulk lattices,” significantly delaying critical helium damage in polycrystalline matrices. The selected nano-phase possesses a moderately large atomic-scale free volume to store helium while undergoing lattice distortions upon helium absorption. These distortions cause observable changes in X-ray diffraction (XRD) patterns, distinct from changes resulting from other factors like radiation damage. By comparing grazing incidence XRD patterns with *ab initio* computed patterns, it is shown that the added nano-phase can store helium up to ~10 at% within its bulk lattice, forming a “helide compound.” Incorporating just 1 vol% of the nano-phase reduced helium bubble size and number density by >20% and >50% respectively. These findings suggest that 1–2 vol% of similar nano-phases can effectively accommodate a few thousand appm of bulk helium, expected to be generated over a 10-year operational period.

11:15 AM SF08.09.04
Twinning Induced Dynamic Recrystallization of CP-Ti During Cryo Compression UmerMasood CH[1,1], Chung-SooKim[2] and T.S.Jun[1,1]; [1]Incheon National University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

Commercially pure titanium (CP-Ti) has been widely utilized in automobiles, aerospace, biomedical and chemical sectors owing to its low density, high specific strength, excellent corrosion resistance, and good biocompatibility. Despite having tantalizing properties, the poor formability of titanium due to insufficient slip systems poses a bottleneck to its extensive industrial applications. Due to the absence of enough slip systems, twinning becomes a major contributor to accommodate the <c> axis shear strain in hexagonal close-packed (hcp) metals, whether it be magnesium or titanium. Of the twinning systems, {10-11} <10-12> contraction twins are activated at high temperatures while {10-12} <-1011> extension twins (ETWs) and {11-22} <-1-123> compression twins (CTWs) can be profusely activated at ambient and low temperatures. Apart from accommodating plastic deformation, twinning modifies the texture by reorienting the crystallographic lattice and can also lead to grain refinement via dynamic recrystallization (DRX) by the multiple twin boundaries. In this study, a systematic investigation of the twin-induced dynamic recrystallization (DRX) of commercially pure titanium was carried out under uniaxial compression test at room (RT) and cryogenic (CT, -150 oC) temperatures. The compression tests were intentionally interrupted at 2%, 5%, and 10% strain levels at both deformation temperatures to examine the progressive evolution of microstructure. The detailed post-mortem analysis was performed using electron backscattered diffraction (EBSD). The results revealed that two major types of twins i.e. {10-12} extension twin (ET) and {11-22} compression twin (CT) were effectively activated at both deformation temperatures. During RT deformation, increased strain levels resulted in the higher evolution of ETs and CTs, where numerous twin lamellas, lateral twin thickening, and twin-twin (ET-ET, ET-CT) interactions were observed. On the other hand, only 2% strain at CT activated high-density of deformation twins (~equivalent to 10% strain level at RT) leading to higher strain energy stored in the material which can provide the preferential sites for the recrystallization nucleation. At higher strain levels during CT compression, the twinning intensity of ET and CT kept on diminishing while the fraction of low-angle grain boundaries considerably increased indicating the initiation of DRX. The DRX mechanism was identified to be twinning-induced dynamic recrystallization (TDRX), where {11-22} CTs and {10-12} ETs contributed significantly to DRX due to twin dislocation interactions. TDRX leads to a substantial grain refinement from 35 µm to 3 µm during CT deformation.

11:30 AM *SF08.09.05
Deformation Induced Phase Transformations in Hierarchically Microstructured Alloys JanelleP. Wharry[1], CalebClement[1,2], ChaoYang[1,3], HaozhengJ. Qu[1,4], PatrickH. Warren[1,5] and KeyouS. Mao[1,6]; [1]Purdue University, United States; [2]Westinghouse Electric Company, United States; [3]Rensselaer Polytechnic Institute, United States; [4]GE Global Research, United States; [5]The University of Texas at San Antonio, United States; [6]Florida State University, United States

The objective of this talk is to understand the influence of hierarchical microstructures – such as those created by irradiation, corrosion, or extreme mechanical strains – on deformation-induced phase transformations in structural alloys. Concentrated solid-solution fcc alloys form the basis for the most ubiquitous structural materials used throughout society (e.g. stainless steels, Ni- or Ti-based alloys), and for novel alloy concepts such as high entropy alloys. When these alloys are exposed to far-from-equilibrium extremes such as irradiation or corrosion, they may evolve hierarchical defect structures spanning multiple length scales – ranging from a complex distribution of point defects (vacancies and interstitials), extended defects such as dislocation loops and cavities, and mesoscopic defects such as cracks and pores. These hierarchical microstructures have historically been associated with localized deformation modes such as dislocation channeling. However, the role of these defects on activating less widely-understood deformation mechanisms – specifically diffusionless, deformation-induced martensitic phase transformations – have only recently been brought to light. Our recent studies have suggested that irradiation or irradiation-like defects can activate martensitic phase transformations over a wider range of loading conditions (i.e. higher temperatures, lower strain rates) than previously thought. The present study uses simulations to reveal how point defects and extended defects control the deformation mechanisms, and complementary experiments will illuminate defected + deformation microstructures.

Work will focus on four major alloys: fcc austenitic stainless steel, bcc ferritic steel, Ni-20Cr (in at%), and Ti. We will first demonstrate the role of point defects, extended defects, and cracks, in activating martensitic transformations in fcc steel, using a series of *in situ* and *ex situ* small-scale mechanical tests with *post mortem* dissection and characterization. Complementary molecular dynamics (MD) simulations demonstrate the fundamental role of defects on the deformation mechanisms. This understanding from fcc steel will then be extended to the bcc steel system, then to Ni-20Cr, which is a high stacking fault energy (SFE) alloy not expected to exhibit deformation-induced martensitic transformations. But again using a series of *ex situ* nanoindentation with *post mortem* characterization together with MD simulations, we reveal the role of a hierarchical microstructure on activating martensitic transformations. Finally, we will leverage these findings to intentionally engineer architected Ti with hierarchical structures that will promote deformation-induced beta-alpha phase transformations.

Dynamic Response of Additively-Manufactured Polymer Structures DanaDattelbaum[1], BriannaMacnider[2], BrianPatterson[1] and AxinteIonita[1]; [1]Los Alamos National Laboratory, United States; [2]University of California, San Diego, United States

Additive manufacturing (AM) has created a new paradigm in control of structure-property relationships for a wide variety of material classes and applications. The promise of AM lies in tailoring properties through this exquisite topological design and fabrication, and the possibility of "metamaterial" properties not possible through conventional manufacturing. For example,

additive manufacturing (AM) techniques have enabled topological tailoring of polymeric structures at the micrometer scale, producing new classes of materials with exquisite control of structure-property relationships. Relevant to mechanical properties under quasi-static (low strain rate) deformation, AM has produced many examples in which control of deformation mechanics and structural instabilities have led to novel properties, such as high strength-to-weight ratios, tailored thermal management, and auxetic deformation behaviors.
Dynamic loading generally refers to loading at intermediate to high strain rates, including high pressure, high strain rate regimes accessed by shockwave compression from high velocity plate impact, blast wave loading, explosive loading, and fragment impact. While many of the applications involving AM materials exploit novel deformation mechanisms at lower rates, such as designed bending or buckling deformations in the case of ligament structures, many of these mechanisms become "overdriven" at the higher strain rates and pressures found in dynamic experiments. One of the aims of our work is to better understand the transition(s) from controlled structural deformation at lower strain rates to dissipative mechanisms at play under shockwave loading.
Here, we will provide a summary of recent experimental examples of the dynamic responses of polymer-based AM structures. This summary will include examples of optimization of shockwave propagation through control of wave interactions at the micrometer-to-centimeter length scales. For example, we recently demonstrated that unprecedented shockwave dissipation could be achieved in fractal-based AM structures which introduce free surfaces, or interfaces, within a critical spacing (or timescale $t \sim L/2c_l$) that is determined by shock strength, and rarefaction (fan) or release wavespeeds; *e.g.* the material's sound velocity (c_l) at pressure. The dissipative effect is similar to localization phenomena related to "hot spots" in the shock initiation of explosives, but instead of energy localization leading to reactive burn, rarefaction interactions and material deformation can lead rarefaction interactions and reduction of the shock front. Experimental methods like high velocity optical imaging, surface-based optical digital image correlation (DIC), and time-resolved X-ray phase contrast imaging have been used to capture the features of polymer AM structures under dynamic loading. The structural features in the AM materials can themselves be used as Lagrangian tracers for analysis of material strain, localization, and material flow (material velocities, etc.). This allows for direct, quantitative comparison with simulation.
Investigations of the dynamic responses of AM polymers structures have increased measurably over the last 5 years, due in part to the availability of time-resolved *in situ* measurements such as X-ray phase contrast imaging, and advancements in AM manufacturing techniques. There are opportunities in this area for quantitative analysis of deformation under a range of strain rates, and improved understanding of the regimes where different structural deformation mechanisms are important. There is also a need for approaches to topological optimization for dynamic contexts, such as blast, shock, and fragment impact.

3D Auxetic Two-Phase Mechanical Metamaterial with High Impact Resistance TiantianLi, AmmarBatwa and YaningLi; Northeastern University, United States

New 3D mechanical metamaterials with a soft phase and a hard phase are designed. The new designs are fabricated via multi-material polymer jetting. Both quasi-static, low strain rate, and high-rate impact experiments are performed on the 3D printed specimens. Systematic finite element (FE) simulations are performed to evaluate the deformation mechanisms and the rate dependence of the designs at different stages of deformation. For comparison, both static and impact experiments on 3D printed single material specimens with the same geometries are also performed.
Interestingly, the two-phase designs show negative Poisson's ratio under large deformation. While, the single material designs show positive Poisson's ratio. More interestingly, the two-phase design show a significantly higher impact resistance than the single material design. The two-phase design survives after multiple strikes while the single material design fails catastrophically after one strike. To further explore the energy dissipation mechanisms of the two-phase design, specimens with different soft phase geometries are fabricated via 3D printing. Cyclic loading-unloading compression experiments are performed on the designs. The results are compared to reveal the mechanisms for high energy dissipation capability of the designs.

2:15 PM SF08.10.03
Mechanical and Thermal Responses of Hybrid Chiral Mechanical Metamaterial SiyaoLiu and YaningLi; Northeastern University, United States

Both 2D and 3D Hybrid chiral mechanical metamaterials with widely tuned overall thermal expansion coefficients (CTEs) are designed. Mechanical properties of the new designs are characterized by both finite element simulations and experiments. To achieve the desired CTEs, both bi-layer Strips (Bi-Strips) with patterned interfaces and shape memory effects of 3D printed materials are utilized. Due to the thermal mismatch, shape memory effects of materials, and the chirality-induced rotation, the designs will undergo either thermal expansion or shrinkage under constant temperature increase, resulting in widely tuned overall thermal expansion coefficients (CTEs) for the chiral mechanical metamaterials. Analytical models are developed to predict the overall CTEs of the chiral designs. The models are verified via systematic finite element (FE) simulations and experiments on 3D printed specimens. The 3D designs are able to achieve both negative Poisson's ratio and negative CTE. This investigation enlarges the design space of chiral mechanical metamaterials for achieving desired CTEs in a wide range.

2:30 PM SF08.10.04
Designing Nanoarchitecture Glasses with Tunable Mechanical Properties for Extreme Environments YuanchaoHu; Songshan Lake Materials Laboratory, China

Glassy materials usually show outstanding mechanical and physical properties than their crystalline counterparts. They are promising applicable materials in various fields. However, the lack of tensile ductility, which is universal across all types of glasses, strongly restricts their capability, especially for metallic glasses. In this talk, I will present our five years of work on the computer simulation design of glassy solids with various types of nano-architectures by millions of atoms. It is interesting to find that these nanostructured glasses show unique and record-breaking mechanical properties under tensile stress, which distinguishes them from bulk materials. This superior performance originates from the suppression of shear band-induced catastrophic failure at different length scales. More significantly, their mechanical response can be widely tuned by the designed nanoarchitecture. Contrary to the common belief, this work opens a new avenue to tailor the properties of the glassy materials in a broad range, similar to their crystalline counterparts. These optimized glassy materials are potentially useful in some extreme environments. Our finding may provide insightful guidelines for experimental glass design for various purposes by 3D printing

Electrochemically Programming the Stiffness of Metal Lattices JungtaekKim, ZakariaHsain and JamesH. Pikul; University of Pennsylvania, United States

In most engineering systems, stiffness is a single fixed value as a result of finding balance between soft and rigid components. There are an increasing number of applications, however, that benefit from materials whose stiffness can be programmed, including robotics, aerodynamics, haptics, and biomedical devices. This stiffness change can be easily implemented by using electrical stimuli which is compatible with electronic systems in robots and autonomous devices. Although there are many examples of soft materials with programmable stiffness, a large degree of stiffness change has not been achieved for materials which require GPa-scale moduli.

Here we present a novel mechanism for changing the stiffness of a structure by connecting and detaching nodes of a metal lattice through electrochemical deposition and etching. This approach is inspired by the chemical hardening of the spike joint in sea urchins, which is used to resist external forces. Here, however, we implement electrochemistry so that the chemical hardening can be electrically programmed. By selectively depositing metal to mechanically bridge the gap between struts of lattice, we can transition the lattices from a compliant state, where it undergoes bending dominant deformation, to a rigid state, where it bears the external load by axial elongation and stretching dominant deformation. Using spring models, we can design the desired range of stiffness changes. We demonstrate that a single stainless steel unit cell can transition from 7.6 MPa to 2.6 GPa, a 350 times change. This large change can be achieved under 0.3 V of electrical potential with a charge input of only 60mAh, which is small compared to the capacity of mobile devices, ~3000 mAh. In addition, we minimized the transition time between states to several hours by optimizing the electrolyte composition. We also used a single electrolyte for the etching and plating of copper. This approach to programable stiffness change can be widely applied for the robot and transportation in weight and energy-constrained situations such as aerospace and space missions by utilizing the advantages of precise electrochemical reactions with minimal energy consumption.

Lunar Dust Mitigation: On the Development of Materials and Coatings for ARTEMIS Mission RonaldH. Freeman[1,2]; [1]Journal of Space Operations & Communicator, United States; [2]American Institute of Aeronautics and Astronautics, United States

Background. One of the most restricting facets of lunar surface exploration was experienced by Apollo landed-lunar missions between 1969 and 1972: the dust problem. Valuable astronaut time was spent in manual brushing to remove dust from spacesuits and equipment [1]. Lunar surface operations were hindered by levitated fine lunar dust for which considerable unknowns remained unexplained [2]. Introduction. An optimal solution to mitigate dust adhesion identifies the dominant components of the adhesive force and reduces that force by surface modification. Coating method, used to protect the substrates from environment, changes surface properties of the substrates, such as adhesion, corrosion resistance, and wear resistance. Select coatings applied to component-, subsystem-, and system- exteriors, made of the most traditionally used substrate-serving material---Aluminum. Dust adhesion force of the Al substrate, for example, was significantly reduced by 80% from 45.53 to 8.89 nN.The lunar dust coverage (2.19%) of the Al substrate modified by composite etching to a 4-fold lower than that of the pristine Al substrate (9.11%), indicates excellent lunar dust repellence [3].Air plasma spraying ceramic coating composed of aluminum oxide results in a bond coat that promotes adhesion and oxidation resistance with the substrate and improves its durability [4].The Dust Solution Testing Initiative (DuSTI) project comparatively demonstrates effective lunar dust mitigation with different coatings in dusty environments. Purpose. NASA is working with five commercial companies to mature vertically deployable solar array systems for the lunar surface: Astrobotic Technology, ATK Space Systems, Honeybee Robotics, Lockheed Martin, and Maxar Technologies. The DuSTI project included several adhesion and abrasion tests on various substrates.Testing results provided data recommendations on coatings to use for adhesion and abrasion mitigation for lunar dust and their increased TRL Cost-effective capabilities developed in partnership with industry provide economical, operational services for small-scale lunar missions. Technologies that are appropriate for certain (smooth) surfaces (e.g., photovoltaic panels and optical components) may be unsuitable for other applications (soft and flexible materials) such as cleaning spacesuits [5]. With proper planning, this component of the integrated strategy should prove most cost effective. An example of an architecture and operational consideration is lessening the risk of astronauts falling on the lunar surface through changing EVA procedures and adjusting tool design to accommodate better balance. Active and passive technologies can be used to close the gap between expected dust exposures and system dust tolerance limits.The aim of this paper is expore different models of how surface modications function in spacesuit-, PV solar array-, and radiator- technologies. 4:00 PM SF08.11.03
Bio-Inspired Auxetic Chevron Mechanical Metamaterial under Thermal Loads and Impacts AmmarBatwa, YaningLi and SiyaoLiu; Northeastern University, United States

Inspired by plant leaves with various chevron patterns, a family of chevron mechanical metamaterials are designed. The designs are fabricated via multi-material polymer jetting. Systematic finite element (FE) simulations are performed to explore the effective mechanical properties of the designs including the effective stiffness and effective Poisson's ratio of the designs. Interestingly, it is found that by varying the fiber orientation at different levels, the effective stiffness and the effective Poisson's ratio can be tuned in a very large range. Especially, the effective Poisson's ratio can change from positive to negative. Also, designs with functionally graded fibers can further increase the auxetic effects. FE models of the representative volume elements (RVEs) of the designs are developed, and extensive parametric study is conducted under in-plane tensile loadings in two orthogonal directions. The design space for auxeticity in both directions are identified.
In addition, the mechanical behaviors of the design under thermal load and impact loads are also evaluated. Designs with positive and negative Poisson's ratios are selected. The thermal stress generated via temperature change of the selected designs are evaluated and compared via both FE simulations and mechanical experiments in a thermal chamber. To explore the impact resistance of the designs, impact experiments are also performed on the selected designs. The results show the auxetic designs have higher ductility and toughness, impact resistance and lower thermal stress.
Different from cellular auxetic mechanical metamaterials, the designed chevron mechanical metamaterials have no pores or voids and can achieve negative Poisson's ratio without sacrificing stiffness. The new designs show great potential in developing new materials to resist extreme thermal and impact loads.

4:15 PM SF08.11.04
Exploring Pristine Graphene as a Solid Lubricant Coating Film for Its Macroscale Application under Various Environments Min GiChoi[1], Won-SeokKim[1,2], Young-JunJang[2] and SongkilKim[1]; [1]Pusan National University, Korea (the Republic of); [2]Korea Institute of Materials Science, Korea (the Republic of)

Solid lubricants have been used not only as an alternative to liquid lubricants under extreme environments such as extremely high and low temperatures, and vacuum environments but also for applications to mechanical systems under ambient conditions at the macroscale. Graphene, one of the representative two-dimensional nanomaterials, has been extensively explored as a solid lubricant due to its excellent tribological properties from the nanoscale to the macroscale. However, since graphene has its own unique properties under various conditions, it is essential to investigate its tribological performance under various conditions. Also, although several researchers have attempted to achieve a super low coefficient of friction at the macroscale tribo-test, achieving low COF doesn't always correspond to good tribological performance. In real mechanical applications, the service lifetimes of the coating film can be more important. For achieving prolonged service lifetimes of the solid lubrication coating film, it is essential to form the rigid and stable transfer layer onto the counterpart surface after sliding. However, since pristine graphene has a chemical inertness, it cannot easily form the transfer layer, leading to its poor durability. In this study, we provide a material design strategy to realize the graphene-based solid lubricant to prolong the service times and a low COF simultaneously for applications to both ambient and extreme conditions. We simply stacked the graphene oxide on the pristine graphene film using a drop-casting method and achieved the formation of the transfer layer on the counterpart contact surface which can lead to an enhanced tribological performance under ambient conditions. In addition, to explore the tribological performance of graphene-based coating film under space environments where no oxygen exists, we conducted the tribo-test with the introduction of argon gas to mimic the space environments. Finally, we provided a possible strategy for the application of solid lubricants under various environmental conditions by unveiling the lubrication mechanism of the graphene-based heterogeneous solid lubrication coating film.

4:30 PM SF08.11.06
Bio-Inspired Irregular Architected Materials: From Citrus Pericarp to Energy Absorbing Lattices ChelseaFox[1], TommasoMagrini[1], AlexanderGroetsch[2], JungyunLim[2], LorenzoValdevit[2] and ChiaraDaraio[1]; [1]California Institute of Technology, United States; [2]University of California, Irvine, United States

Irregular architected materials offer a wide design space of mechanical properties such as strength, stiffness, strain-to-failure, and energy absorbed during fracture [1], but their design is a complex challenge. However, biological materials have developed a variety of irregular architectures evolved for impact protection and energy redistribution, such as the citrus fruit pericarp. The irregular structure of the citrus fruit pericarp is composed of a functional lattice-like arrangement of tissue, which protects the ripe fruit upon impact with the ground. In my talk, I will explain how we can examine the morphology of the pericarp lattice to extract general biomimicry design parameters, such as lattice beam density and concavity, which can be used to design lightweight materials with high strength and high strain-to-failure, particularly under dynamic loading. Furthermore, I will describe how computer-aided virtual growth algorithms can be used to design and fabricate lattice samples that mimic the citrus fruit pericarp, with spatially determined density and local coordination. Finally, through both quasi-static and dynamic drop tower testing, I will show how the lattice architecture influences the mechanical performance of the materials, making them optimal candidates for dynamic structural applications in extreme environments.

Surface Modification of Carbon Fiber by Polymer Derived Ceramic to Strengthen the Ceramic-Based Carbon Fiber Composite Lung-HaoHu; National Sun Yat-sen University, Taiwan

In this study, the surface of carbon fiber is sprayed with "polysilazane preceramic precursor" and pyrolyzed at different pyrolytic temperatures for coating a dense layer of amorphous SiCN ceramic film, which can be used as a surface reinforcing and protective coating. Polysilazane preceramic precursor can transform from a liquid polymer phase to silicon-based ceramic, which

is called polymer derived ceramic (PDC), at high temperatures. The microstructure and chemical composition of the coatings are characterized by field emission scanning electron microscope (FESEM), energy dispersive spectrometer (EDS), and Raman scattering spectrometer. Mechanical properties, Young's modulus and tensile strength, are measured by tensile test. Electrochemical properties are investigated by electrochemical analyzer for potentiodynamic polarization, electrochemical impedance spectroscopy and chronoamperometry. Finally, the experiments are repeated with adding graphene to the polysilazane preceramic precursor to form graphene-reinforced ceramic fiber composite (GRCFC) and compared with the original data. The experimental results show that the specific strength and modulus of the ceramic-based carbon fiber composite (CCFC) are enhanced 44.26 % and 15.37 % with spraying 40 wt.% polysilazane preceramic precursor in acetone on its surface as well as pyrolyzing at 450 °C. The results of potentiodynamic polarization experiment reveal that the corrosion potential is increased from -0.0971 V to 0.5862 V, the corrosion current density is decreased from 1.72×10^{-2} mA/cm^2 to 1.32×10^{-7} mA/cm^2, and the corrosion rate is extremely decreased from 9.98×10^{-2} mm/year to 9.54×10^{-7} mm/year. Therefore, it can be shown that the PDC coating can improve the mechanical properties of carbon fiber and have good protection. The GRCFC coated with 20 wt.% polysilazane preceramic precursor mixed with 0.5 wt.% graphene in acetone with pyrolyzing at 450 °C can achieve better specific strength (enhanced 73.15 %) and specific modulus (increased 41.15 %). The results of potentiodynamic polarization experiment reveal that the corrosion potential is increased from -0.0971 V to 0.5873 V, the corrosion current density is decreased from 1.72×10^{-2} mA/cm^2 to 3.61×10^{-6} mA/cm^2, and the corrrosion rate is extremely decreased from 9.98×10^{-2} mm/year to 2.88×10^{-5} mm/year. Therefore, it can be concluded that the PDC coating incorporated with additional graphene can significantly enhance the mechanical properties and corrosion resistance of the commercial carbon fiber.

8:15 AM SF08.12.02

Design of Refractory High Entropy Alloys for Extreme Environment by using CALPHAD YukiKomiya, AraiYutaro and YasuoKogo; Tokyo University of Science, Japan

High-temperature structural materials for a combustion region of gas turbine engine, such as turbine blades and liners have been researched continuously to increase their heat resistant temperature during operation. Ni-based superalloys are a typical conventional material, and a heat resistance temperature of 1100 degrees Celsius has been achieved in a Ni-based single crystal superalloy (TMS-238). Although Ni-based super alloys are sophisticated materials and a still candidate for advanced heat resistant components, the melting point of Ni is 1455 degrees Celsius, and the improvement of the applicable temperature of Ni-based superalloys is approaching its limit. Therefore, a new concept of material is needed to further improve the operating temperature.
We are focusing on High-Entropy Alloys (HEAs) composed of refractory metals (hereafter denoted as RHEAs). High-Entropy Alloys are composed of 5 or more elements and their configuration entropy exceeds 1.5R (R: Gas constant, 8.314J/mol K). Since lattice distortion and unexpected interactions occur, it is expected that HEAs has unique properties compared to conventional alloys.
We have designed and fabricated TiZrHfNbX (X = Ta, Cr) alloys (hereafter denoted as based-RHEAs) and evaluated their oxidation behavior. It was found that the fabrication of the alloys by arc melting resulted in a single phase of Nb remaining in the alloys, and the remining of Nb caused rapid oxidation of alloys. Based on these evaluation results, we performed a thermodynamic equilibrium simulation (by FactSage 8.1) and succeeded in increasing the homogeneity of the alloy by preparing a Ti1.25ZrHfNbCr2 alloy with an increased Ti and Cr content.
The Ti1.25ZrHfNbCr2 alloy was fabricated using the arc melting method by the same condition for based-RHEAs. Oxidation behaviors were evaluated and compared to the result of based-RHEAs. Thermogravimetric analysis (TGA) and isothermal oxidation tests at ~1200 degrees Celsius in air showed that the weight gain and the thickness of oxide scale for Ti1.25ZrHfNbCr2 were smaller than those of based-RHEAs which is equimolar composition with the highest entropy in the same element system.
Observation of the oxide scale revealed that it was divided into two layers. In the outermost layer, multiple complex oxides (e.g., CrNbO4-like structure, Zr6Nb2O17-like structure (from the result of X-ray diffraction)) were densely intermingled. Similarly, complex oxides (e.g., Hf6Nb2O7-like structure) were formed in the inner layer. These results suggest that the formation of these complex oxides and the structure of the scale probably have acted as a barrier to oxygen diffusion, leading to the suppression of oxidation.

8:20 AM SF08.12.03

Experimental and Analytical Evaluation on an Aerospace Thermal Protection System: Carbon Monolith Ablator RinaOno, KenjiroTsukamoto, AraiYutaro and YasuoKogo; Tokyo University of Science, Japan

Re-entry vehicles are exposed to high temperatures during re-entry owing to severe aerodynamic heating. Therefore, thermal protection systems (TPS) are important to protect the aircraft from heating. Ablator is a typical TPS used as high-speed re-entry vehicles. Generally, Ablator is a carbon-based material impregnated with resin that protects the vehicle from heating through thermal decomposition and ablation because the decomposition of resin is an endothermic reaction and gas evolved by the decomposition of resin prevents aerodynamic heating of the surface. Phenolic Impregnated Carbon Ablator (PICA) is a thermal protection system with used successfully on missions to the Moon and Mars. On the other hand, compressive strength of PICA is low and mechanical erosion occurs because substrate of PICA is a carbon felt. In addition, it is not possible to use resin with a low residual carbon content because a carbon felt cannot bear the load during operation. The use of a resin with a low residual carbon content is expected to increase the prevention of recession by the decomposition of resin. In the previous study, Three-dimensional Networked Porous Carbon (TNPC), which has approximately 25 times higher compressive strength than PICA and was used as a substrate for an ablator. Since TNPC has a continuous structure, we developed and evaluated Porous Carbon Ablator (PCA) by impregnating TNPC with acrylic resin that has a residual carbon content of ~0%. As a result, the recession characteristics of PCA were comparable to those of PICA due to oxidation and sublimation of the struts of TNPC.
In this study, we have developed a carbon monolith with a three-dimensional network structure by the carbonization of phenol monolith with a three-dimensional network structure. Although it is denser than TNPC, it can be easily fabricated by phase separation of phenolic resin and carbonization. Furthermore, the pore size can be controlled by the condition of phase separation because three-dimensional network structures of phenol monolith are maintained after carbonization. Since the recession of carbon monolith is smaller than that for TNPC, it is expected that ablator with carbon monolith substrate realizes the improvement of ablation behavior compared to PCA. Therefore, Carbon Monolith Ablator (CMA) was prepared by impregnating carbon monolith with acrylic resin, and its recession behavior and thermal properties were evaluated in an arc-wind tunnel test. The amount of recession was calculated based on the test conditions. To evaluate thermal conduction and temperature distribution of ablator during test, an analytical model simulating an arc-wind tunnel was created by conducting a heat conduction analysis using the finite element method. The thermal stresses were also evaluated using the temperature distribution obtained from the model. In this presentation, design guidelines and optimal analytical models for ablators using porous materials as substrate will be discussed based on the experimental and analytical results.

8:25 AM SF08.12.04

Carbothermal Synthesis of Borides in Air: A Cost-Effective Approach for High-Melting Point Functional Materials MiaMerritt[1], GraceFarrell[1], ZheChen[2], SarojPramanik[1], HertantoAdidharma[2], MaohongFan[2] and YuchengLan[1]; [1]Morgan State University, United States; [2]University of Wyoming, United States

Metal borides have gained significant attention in recent years due to their unique physical and chemical properties, including high melting points, excellent wear resistance, and chemical inertness. These properties make them highly suitable for various applications, such as catalysts and thermoelectric materials, under extreme environments. However, the synthesis of boride compounds typically requires extremely high temperatures, posing challenges in terms of energy consumption and equipment setup. In this study, we present a cost-effective method for the synthesis of borides using carbothermal synthesis in ambient air. This approach offers several advantages, including simple equipment setup, low energy costs, and minimal maintenance requirements. We systematically investigated the synthesis conditions to optimize the process and enhance the efficiency of boride production. The synthesized boride compounds were thoroughly characterized using techniques such as X-ray diffraction, UV-vis spectroscopy, and electron microscopy. These analyses provided insights into the crystal structure, optical properties, and morphology of the synthesized borides. Additionally, we explored the synthesis mechanism to gain a better understanding of the reaction pathways involved. The carbothermal synthesis method proposed in this study holds great promise not only for boride synthesis but also for other high-melting point materials for extreme environments.

8:30 AM SF08.12.05

Cold-Rolled 3D Printed Graphene Sheet as a Protective Material Against Fluorocarbon Plasma Etching Vamsi Krishna ReddyKondapalli, KyleBrittingham, GuangqiZhang, MahnooshKhosravifar and VesselinShanov; University of Cincinnati, United States

Various parts of processing chambers for dry etching like chamber walls, windows, cover baffles, rings, etc., are manufactured from chemically stable materials such as polycrystalline Si, SiO_2, or Al_2O_3. The interaction of these materials with ionized fluorocarbon gases causes chamber contamination due to corrosion, erosion, and particle generation. As a result, the processed semiconductor wafers may become contaminated. Carbon materials like diamond-like carbon (DLC) and graphene have been studied as protective materials to prevent the deterioration of the chamber parts. Here we report cold-rolled 3D printed graphene (3DPG) as a reusable protective barrier against fluorocarbon plasma etching. 3DPG was synthesized by combining 3D printing with atmospheric pressure chemical vapor deposition (CVD). This novel process enabled fabricating of 3DPG with a wide variety of shapes and structures. A simple procedure was used to cold roll the obtained 3DPG. The conducted characterization of this sheet-like material demonstrated enhancement of graphene flake alignment and stacking with increased gravimetric density due to the applied compression. Cold-rolled 3DPG can easily adhere conformably to solid surfaces and has a thin and flat profile. When exposed to a CF_4 plasma environment at a power of 100-300W and pressure of 200mTorr this material is etched at a significantly lower rate compared to silicon. These qualities make the cold-rolled 3DPG attractive for the protection of dry

etch chamber parts, and also as a hard mask used in reactive ion etching (RIE).

8:45 AM SF08.12.06

Graded Nanomaterial Architectures for Enhanced Fretting Wear Resistance of Surfaces Exposed to Extreme Conditions in Nuclear Reactors TingYang[1], T. A.Venkatesh[2] and MingDao[1]; [1]Massachusetts Institute of Technology, United States; [2]Stony Brook University, United States

The materials used in several parts of a nuclear reactor experience a combination of extreme conditions, i.e., mechanical stresses, radiative conditions and corrosive environments. For example, the pressurized water nuclear reactors typically contain a large number of fuel rods (about 50,000). These fuel rods are cylindrical in shape, contain radioactive material in their cores and are surrounded by a cladding layer. These fuel rods are kept in place with spacer grids such that there is space between the fuel rods for water to flow through and absorb the heat from the fuel rods, which can then be used to produce power. At the regions where the spacers are in contact with the exterior of the fuel rods, (i.e., the surface of the cladding that surrounds the radioactive fuel rod core), vibrational loads caused by turbulence in the water induces fretting damage which can lead to cracking and deterioration of the cladding layer, resulting in serious radioactive leak issues. It has been reported that, of all the causes of such leaks, grid-to-rod contact fatigue damage is the most prominent, accounting for more than 70% of the problems.

In such nuclear fuel rod applications where high cyclic loads are involved, surfaces with high yield strength and wear resistance are required. As surfaces with nanograins have been shown experimentally to significantly increase yield strength and enhance surface wear resistance, in this work, the potential for graded nanomaterial architectures for nuclear fuel-rod applications is systematically investigated. A three-dimensional finite element model is developed to analyze the characteristics of fretting sliding and shakedown behavior, considering different levels of contact friction and gradient layer thicknesses. The results obtained using 304 stainless steel as a representative model material demonstrate that metallic materials with graded nanostructured surfaces exhibit a significant reduction of over 80% in plastically deformed surface areas and volumes. This reduction significantly enhances the material's resistance to fretting damage when compared to homogeneous coarse-grained metals. It is noteworthy that the graded nanostructured material can exhibit either elastic or plastic shakedown behavior, depending on the contact friction coefficient. By reducing the friction coefficient (e.g., from 0.6 to 0.4 in 304 stainless steel), the graded nanostructured material achieves optimal fretting resistance, resulting in elastic shakedown behavior. This behavior is characterized by the absence of any increment in the accumulated plastic strain in the plastically deformed volume and area during subsequent sliding. These findings, derived from the investigation of graded nanostructured materials using 304 stainless steel as a model system, can be further refined to engineer optimal fretting damage resistance in nuclear fuel-rod applications.
