+ JMR Distinguished Invited Speaker

SESSION BI01.01: Materials Research and Energy Justice
Session Chairs: Lauren Marbella and Michael Toney
Tuesday Morning, November28, 2023
Hynes, Level 2, Room 209

8:30 AM *BI01.01.01
Environmental and Social Justice Considerations in a Circular Economy TaylorUekert, HopeWikoff, JulienWalzberg, MeredithDoyle and AlbertaCarpenter; National Renewable Energy Laboratory, United States

A consideration of environmental justice (EJ) and social justice (SJ) is critical to minimize the impacts of technology deployment on local communities. SJ and EJ impacts occur in specific geographic locations but can cover a wide range of effects (e.g., air pollution, access to clean water, jobs, wages, and education), making it challenging to determine which metrics are appropriate to evaluate and which data are required for qualitative or quantitative analysis. This issue is only exacerbated when the technology in question is at an early technology readiness level (TRL) without community specific data. Here, we present a framework for evaluating the human health, local environment, and job implications of processes that are at early to middle TRLs. Using a case study on enzymatic polyethylene terephthalate (PET) recycling (middle TRL), we demonstrate how to qualitatively and quantitatively assess these EJ and SJ metrics for a circular economy context and how to communicate the results in a manner beneficial to both researchers and local communities.

9:00 AM *BI01.01.02
Developing & Evaluating Energy Justice Metrics for Early-Stage Materials Research NikitaS. Dutta, BettinaK. Arkhurst, ClaraHoughteling, KatherineAnderson and ElizabethGill; National Renewable Energy Laboratory, United States

Materials science is a central component of early-stage research and development of virtually all clean energy technologies. But as much as material breakthroughs often hold the key to high efficiencies, long lifetimes, and high stability in eventual devices, early-stage choices about material types, structures, and processing can also serve to lock in long-term social and equity impacts of deployed energy technologies. Thus, to achieve a just and sustainable energy transition, tools to assess the energy justice impacts of early-stage materials research are critical. Here, we discuss development of the Justice Underpinning Science and Technology Research (JUST-R) metrics framework—a suite of metrics targeted at early-stage researchers to assess energy justice considerations in their work. The framework is evaluated for its appeal to researchers and effectiveness at promoting integration of energy justice into research through case studies, which reveal its ability to broaden researcher perspectives and key avenues for future improvement.

9:30 AM BI01.01.03
Pathways for Incorporating Justice into Materials Science Research CaseyM. Davis[1], SashaNeefe[1], LaceyRoberts[1], RonanKennedy[1,2] and MichaelF. Toney[1]; [1]University of Colorado Boulder, United States; [2]University College Dublin, Ireland

As the climate crisis worsens, it becomes increasingly clear that solutions will be found at the intersection of science, policy, and community. Attracting and retaining graduate students who work to integrate energy justice into materials science will create a workforce with the tools to address climate change. It is important to consider energy justice when developing materials for a clean energy transition as marginalized communities that have been affected most by climate change tend to benefit least from new energy technology.

Scientists often exclusively receive scientific training, their research motivated by advancement of the field with little regard to societal needs. Graduate students who may take interest in supplementing their work with justice considerations frequently face resistance from advisors and delayed graduation. Energy justice in materials science at the academic level has only recently been garnering attention, so there are few studies in how to engage, retain, and train graduate students in this interdisciplinary field to employ just technologies. We propose a set of solutions at various levels aimed at enabling graduate students with existing interest in justice and engaging students who have not yet considered bringing this aspect into their graduate degrees.

In a doctorate degree, students are regularly discouraged from pursuing interests that do not directly relate to their PhD projects. If research students follow pursuits outside of conventional STEM research, they likely will face extra time in graduate school, which can be a significant deterrent. To address this, interdisciplinary PhD tracks can be created for the purpose of combining energy justice and materials science will explicitly train graduate students in this area. Additionally, adjusting departmental culture to encourage inclusion of justice in current materials science, chemistry, and engineering programs is a significant component. This shift can be partially accomplished by preferentially admitting students and hiring faculty who are committed to intersectionality, as well as encouraging students to include justice results in their dissertation alongside scientific development.

The participation of current graduate students who may not have previously considered societal implications in their degree is crucial. Education is a proven effective path to inspire interest. This exposure is possible through amending required course syllabi to include justice concepts, hosting speakers knowledgeable in these areas, and encouraging students to openly discuss ideas during prescribed meetings. Attracting and retaining researchers in this field will rely on conveying the benefits of environmental and justice work, which is often believed to be draining or even hopeless. Portraying the excitement of working in a cutting-edge field and seeing tangible positive impacts on communities will garner more interest.

Scientific journals are another important factor, as they shape the material that researchers are exposed to. Many journals consider pieces that discuss justice as less scientific and will even instruct authors to remove these components. However, by openly accepting papers which include a justice component related to the materials research, journals will not only educate readers about the societal context of researched technologies, but also encourage potential authors to include justice in their own work while acting as an example of how to do so. This prioritization can have a large impact on how academics view materials science.

In this work we put forth a set of solutions to be used as guidelines for academic departments and journals to teach students to be well-rounded scientists who develop technologies to equitably better all communities. Implementing these solutions will ultimately help create a workforce that has the tools to address the climate crisis in an effective and thoughtful manner.

9:45 AM BI01.01.04
Team Based Sustainable Nanotechnology Research for Energy Justice in Materials Science and Engineering ChristineC. Broadbridge[1,2], ThomasSadowski[1,2], SuzanneE. Huminski[2] and JustinLipe[3]; [1]Southern Connecticut State University, United States; [2]CSCU Center for Nanotechnology, United States; [3]Quantum Biopower, Inc., United States

Sustainable nanotechnology is an interdisciplinary field with potential to catalyze innovative solutions to global issues such as climate change and biodiversity loss in areas ranging from science, technology and environment to economics, education, and society. By introducing sustainable nanotechnology to students at many different levels, potential also exists to engage and educate a diverse STEM literate workforce better equipped to tackle society's most challenging problems. In this talk, a range of activities will be briefly described with focus on methods employing industry-motivated research with important implications for energy justice through technological advancement of sustainable products, and as an educational pathway prioritizing recruitment and training for groups traditionally underrepresented in STEM careers, including women and racial minorities. These activities leverage strong intra- and cross-institutional partnerships to beneficially impact participants at all levels with diverse backgrounds. In particular, the Werth Industry Academic Fellowship (IAF) program at Southern Connecticut State University (SCSU) will be discussed in detail to demonstrate how a tiered approach to mentorship with industry participation can be applied to optimize societal impact, including deployment of clean energy solutions that improve energy justice for groups disproportionately burdened with pollution or climate risk, *and,* strong minority recruitment and retention in a rigorous undergraduate and Masters level research training program. The core focus of the Werth IAF is team-based interdisciplinary and industry-motivated research through rigorous research experiences, as well as professional development in business and entrepreneurship topics. A fellowship team is composed of individuals with diverse but complementary interests and typically includes a STEM faculty researcher, a School of Business faculty and industry mentor, as well as undergraduate and graduate students (often pre-service teachers in a 7-12 STEM discipline). To date, 38 students have completed the IAF (31 undergraduate students and 7 graduate students), and the 2023 cohort is the largest to date. Half of all IAF fellows are minorities and 37% are female. Program cohorts are small, providing individualized attention, instruction, mentorship and support to IAF fellows to encourage them with sound preparation for their research journeys. SCSU has a Title III designation because of the large number of low-income students who attend. Current fellowship teams are addressing important sustainability questions from a variety of different avenues including renewable or low carbon energy generation, energy storage, carbon remediation. The primary focus of this presentation will be a well-developed multi-tiered SCSU collaborative partnership with Quantum Biopower – a local Connecticut company that is the first in the state and one of a few in the region to specialize in commercial scale anaerobic digestion of food scrap for producing biogas and sustainable landscape products. In addition to processing SCSU's food scrap from dining services, Quantum Biopower has partnered in a variety of sustainable nanotechnology research projects with SCSU since 2016. Using biochar as a through line, the collaborative team prioritizes research on a material that has been identified for its flexible application in many industries, and as one of only a small number of technologies with scalable global carbon sink potential necessary for avoiding the worst impacts of climate change. IAF research at SCSU is exploring biochar in applications ranging from water and nutrient retention in soil to supercapacitors, which has strong potential for Quantum Biopower's future growth as a company.

10:00 AMBREAK

10:30 AM *BI01.01.05
Sustainable Battery Chemistries and Materials for Next-Generation Battery Technologies ArumugamManthiram; The University of Texas at Austin, United States

The ever-increasing demand for energy and the rapidly escalating environmental concerns have created enormous interest in the development of affordable clean energy technologies. Renewable energies, such as solar and wind, offer an appealing solution, but they are intermittent. A widespread adoption and utilization of renewable energy sources will need an economic and efficient storage of electricity produced from them; storage is currently the bottleneck to utilize renewable energies. Rechargeable batteries are the most viable option to store and utilize the electricity produced from renewable energies. However, a widespread adoption of battery technologies for grid electricity storage as well as for electric vehicles requires optimization of several parameters, such as cost, energy density, power density, cycle life, safety, and environmental impact, all of which are directly linked to severe materials challenges. Among them, cost, sustainability, supply chain issues will be the single dominant factor as we move forward to establish energy justice. This presentation will focus on the development of sustainable next-generation battery chemistries and materials.

The lithium-ion battery technology is currently dominated by layered oxide cathodes with expensive cobalt and nickel and graphite anode, which have supply chain challenges. In essence, cobalt is a problem today, nickel is a problem tomorrow, and lithium could become a problem day after tomorrow. This presentation will center on a path forward to eliminate cobalt first, followed by progressively eliminating mined transition metals, lithium, and finally any mined metal altogether. However, the task is met with fundamental materials science and engineering challenges. This presentation will focus on delineating the intricacies involved with them and the progress made in the following battery chemistries: cobalt-free lithium-ion, cobalt- and nickel-free lithium-ion, lithium-sulfur, sodium-sulfur, and sodium-organic batteries as an illustration to realize a sustainable battery technology future. For example, sodium is plenty in the ocean and sulfur is a byproduct in petrochemical industry, and both of them are mining-free. Specifically, innovative materials design, novel chemical synthesis, advanced materials characterization, prototype device assembly, and an establishment of the structure-property performance relationships will be presented to illustrate the progress.

11:00 AM *BI01.01.06
Advancing Energy Equity Through Distributed Energy Resources (DERs) BethelTarekegne; Pacific Northwest National Laboratory, United States

Energy justice and equity examinations uncover the reality that not all customers have the same needs of the energy system. For example: Elderly and disabled populations use energy in different ways and have different vulnerability profiles. Low-income households spend a higher percentage of their income on energy bills, relatively three times higher than affluent households (i.e., 6% of income on energy bills is a high energy burden and 10% is a severe energy burden). There is a clear demand for explicit work on energy equity and stakeholder engagement. More analysis can be done around: differentiating needs & interactions by demographics (age, race, health, rural, deep poverty) and compound, cumulative effects; understanding the relationships between policies and grid futures and the impact on people; designing technologies to be safer, to support well-being, and to include life-cycle implications; and recognizing the procedural limitations of energy system decision-making.

11:30 AM BI01.01.07
Community-Engagement in Clean Energy: 15 Years of Tribal Partnerships in the Pacific Northwest DanielT. Schwartz; University of Washington, United States

The U.S. Inflation Reduction Act (IRA) and Bipartisan Infrastructure Law (BIL) will mobilize unprecedented capital investments in clean energy technologies that can demonstrate tangible benefits to underserved and overburdened communities. In this era of clean energy development, the most successful scientists and engineers will need the ability to formulate scholarly questions and develop practical strategies that are informed by an understanding that clean energy is a socio-techno-economic grand challenge. Consequently, early in any scientific or technical advance, questions of material supply chains, life-cycle impacts, and the need for authentic community-engagement will be deemed an essential preliminary step toward scaling. Trainees able to balance the social, technical, and economic dimensions of clean energy will be ideally prepared to succeed in the Professional, Scientific, and Technical Services (PSTS) sector of the economy, where materials science and engineering job growth is projected to be more than double the rate of manufacturing employment over the next decade.[1-2]

The Northwest U.S. has a hundred-year legacy of major federal investment in clean energy infrastructure, but is widely acknowledged as a cautionary tale for the consequences of inequitable and unjust energy development.[3] With this as place-based context, the author will discuss lessons learned from 15 years of community-engaged clean energy research and educational activities with Northwest tribal nations supported through NSF IGERT, USDA CAP, and State of Washington funding that has involved students (undergraduate and graduate) and professional staff. Using a variety of bioenergy, wind, and solar-related education, research, and demonstration projects as tangible examples, we will describe a common trajectory our community-engaged clean energy projects have taken, typically starting as "technical assistance" questions that community decision-makers and influencers (such as elders) want addressed by an arms-length third party, and evolving to more scholarly questions. The training elements of community-engaged projects are ideal for PSTS careers, and participation in year-long tribal partnership projects was cited as a primary reason 9 Native American students chose to return to graduate school as part of a NSF IGERT training program led by the speaker. Other research and student outcomes will be documented, as well as professional challenges associated with community-engaged research and education given that this scholarly model remains fairly uncommon in the physical sciences and engineering.

SESSION BI01.02: Justice Considerations in Sustainable Energy
Session Chairs: Casey Davis and Michael Toney
Wednesday Morning, November29, 2023
Hynes, Level 1, Room 111

8:30 AM *BI01.02.01
A Molecular View of Social and Environmental Justice JeffreyA. Reimer[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The deposition of human waste carbon into the atmosphere, oceans, and lands is changing the planet. Indeed, the practice of extracting hydrocarbons from the earth and then littering it with artificially produced polymers and plastics not only fails to economically uplift local communities (an environmental justice issue) but also disproportionately impacts communities that are not equipped to handle these consequences (a climate justice issue). The absence of environmental and climate justice represents a legal and governance issue, and is an ethical lapse that affects all of humanity. Additionally, the inability to support underprivileged communities, and the creation of conditions that worsen their disadvantage, is a moral failure. Consequently, there's an increasing demand for the materials research community to conduct comprehensive research that addresses these justice concerns. Specifically, those in influential research roles are urged to ensure their work meaningfully connects to these ethical dilemmas.
Herein I will discuss two research agendas my group is undertaking that aim to link the molecular level to the macroscopic, and the macroscopic to process scale systems that reduce our carbon waste. The first involves a mechanistic exploration of carbon capture by porous materials, such as MOFs and porous polymers. This research is driven by the need to understand carbon capture processes from various carbon dioxide sources and sinks. The second is about designing polymers for systemic circularity, such as polydiketoenamines, which requires an examination of reaction and diffusion processes at molecular, nano-, and meso-scales. In both these cases, we use magnetic resonance spectroscopy and imaging methods. As the author, I consider it my responsibility to ensure such studies are framed within the context of systems and processes capable of delivering meaningful technological solutions.

9:00 AM *BI01.02.02
Electrified Ammonia Synthesis at Ambient Conditions KarthishManthiram; California Institute of Technology, United States

Chemical synthesis is responsible for significant emissions of carbon dioxide worldwide. These emissions arise not only due to the energy requirements of chemical synthesis, but since hydrocarbon feedstocks can be overoxidized or used as hydrogen sources. Using renewable electricity to drive chemical synthesis may provide a route to overcoming these challenges, enabling synthetic routes which operate at benign conditions and utilize sustainable inputs. We are developing an electrosynthetic toolkit in which distributed feedstocks, including carbon dioxide, dinitrogen, water, and renewable electricity, can be converted into diverse fuels, chemicals, and materials.

In this presentation, we will share recent advances made in our laboratory on nitrogen fixation to synthesize ammonia at ambient conditions. Specifically, our lab has investigated a continuous lithium-mediated approach to ammonia synthesis and understood the reaction network that controls selectivity. We have developed non-aqueous gas-diffusion electrodes which lead to high rates of ammonia synthesis at ambient conditions. The solid electrolyte interphase is found to be controlling of lithium-mediated nitrogen reduction rates and selectivities, as understood through cryogenic transmission electron microscopy.

9:30 AM BI01.02.03
The Energy Justice of Soft Materials for Photoelectrochemical Hydrogen Generation CaseyM. Davis[1], MichaelF. Toney[1] and AnnL. Greenaway[2]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States

Hydrogen generation has been gaining traction as a form of relatively cheap, safe, and flexible renewable energy as it becomes increasingly important to transition away from fossil fuels. However, the majority of hydrogen is generated using fossil fuels, hindering progress towards a sustainable energy future. To address this challenge, it will be necessary to use renewable energy with economic and non-toxic materials to generate hydrogen. Soft materials such as π-conjugated polymers have shown promise for photoelectrochemical (PEC) hydrogen generation. Although inorganic PEC systems are more developed, organic systems have advantages such as tunability, narrow bandgap, and cost-effective synthesis.
In addition to scientific viability, the implementation of PEC technology requires careful analysis of the relevant social and environmental landscapes. Therefore, this work illustrates the energy justice aspects associated with soft materials for PEC to maximize the technology's success and societal benefits. In the scientific process, end-product impacts are generally not considered during early stages. It is crucial to analyze soft PEC systems at an early technology readiness level to create equitable outcomes as well as develop materials and chemical processes with minimal negative impact. Producing a fossil-free technology does not guarantee positive social and environmental outcomes, and marginalized communities may still experience disproportionate burdens. While it may appear counterintuitive to long-term plan for a technology that is still in the developmental stage, the scientific community has historically been driven by advancing to the next step in the scientific process rather than thoroughly assessing societal needs.
Before the development of technology, it will be crucial to identify key sectors where hydrogen deployment can make a difference, whether that be grid supplementation, cement manufacturing, or shipping. To implement soft PEC systems in the selected sector three tenets of justice must be considered: distributional justice, recognition justice, and procedural justice. Distributional justice involves planning the PEC infrastructure in a way to benefit marginalized communities. Soft materials have an advantage due to the lower impact of resource extraction compared to inorganic systems. Recognition justice requires respecting and valuing all sections of society. Oil and gas workers could be retrained for PEC plants in communities that are economically reliant on fossil fuel generation. Lastly, procedural justice ensures equal consideration of all stakeholders without discrimination. Large-scale transparency and education on incoming infrastructure will address this issue. A series of metrics are applied to understand how soft PEC hydrogen generation will meet these three tenets of justice.
Hydrogen infrastructure is a controversial topic in the renewable energy community, partly because of the grey hydrogen dominating the market. Understanding and thoroughly assessing the implementation of green hydrogen will have significant benefits. Effectively implementing these equity considerations may delay time to full implementation of these technologies but is a necessary step. We argue that having a solid plan ensures that technology aligns with actual needs, promoting long-term social and environmental justice.

SESSION BI01.03: Batteries and Energy Justice
Session Chairs: Emma Kendrick and Nicholas Weadock
Wednesday Afternoon, November29, 2023
Hynes, Level 1, Room 111

1:30 PM BI01.03.01
Sustainability for Materials Research: A Quebec Strategy and Approach LauraCacot; University of Montreal, Canada

How can sustainability be integrated into the research culture?

In September 2015, UN member states adopted the Sustainable Development Program known as Agenda 2030. This program defines targets to be reached by 2030 to meet the challenges of the current and future environmental crisis.
The UN's Sustainable Development Goals (SDGs) provide a reference framework for operationalizing sustainable development, including adaptation to climate change, improving global health and reducing social and environmental inequalities. This framework proposes 17 SDGs divided into a number of targets which, taken together, will ensure a more viable future for generations to come.

Universities have a role to play in building a more sustainable future, through knowledge development, education and knowledge transfer on major societal issues. Furthermore, universities can contribute by adopting sustainable approaches throughout the entire research process, from conceptualization to execution.
Our work builds on these concepts by developing tools for more sustainable scientific research, both in terms of the research object and the way research is carried out in the laboratory. Additionally, our objective is to identify barriers and overlooked areas in research when adopting a sustainable development approach. This works aims to brings researchers together to explore and discuss innovative strategies and best practices for incorporating sustainability into research practices. By recognizing the intrinsic connection between research and sustainability, we can foster interdisciplinary collaboration, enhance knowledge transfer, and accelerate the adoption of sustainable principles across various academic disciplines.

1:45 PM *BI01.03.02
Implementing Societal Considerations and Energy Justice into FECM's Carbon Management R&D KelliRoemer[1] and LisaGrogan-McCulloch[2]; [1]Department of Energy, Office of Fossil

Energy and Carbon Management, United States; [2]U.S. Department of Energy, United States

To reach U.S. climate goals of net-zero emissions economy-wide by 2050, the United States will likely have to capture, transport, and permanently sequester significant quantities of carbon dioxide (Larson et al., 2020). In addition, there is growing scientific consensus that carbon capture, utilization, and sequestration (CCUS) and carbon dioxide removal (CDR) will likely play an important role in decarbonization efforts globally (IPCC, 2018). The Department of Energy's (DOE) Office of Fossil Energy and Carbon Management (FECM) envisions enabling the demonstration and ultimately deployment of technologies for carbon management and mitigating challenges of fossil fuel use in a just and sustainable way, with the goal of achieving net-zero greenhouse gas emissions by mid-century (FECM, 2022). Building the clean energy economy will create new infrastructure that holds the potential to drive new regional economic development, technological innovation, and high-wage employment for communities across the United States as we work to make progress on the nation's climate goals. At the same time, it is critical to understand and address the societal considerations and impacts of these projects at local, regional, and global levels. This presentation will share how FECM is implementing the principles of energy and environmental justice throughout the planning, processes, and outcomes of its work in alignment with Executive Orders 14008 and 13985 (Federal Register 2021a, 2021b); share lessons learned from early, two-way community and regional engagement efforts discussing carbon management; and discuss requirements for Community Benefit Plans necessary for FECM funded projects R&D.

Global PV Supply Chains: Costs and Energy Savings, GHG Emission Reductions JieLiu and XiaoShen; Bo-Zhi Digital Labs, China

In the battle against climate change, accelerating clean energy development is crucial. A global supply chain and cooperation in renewable energy technologies are vital for success. However, the increasing trend towards domestic protectionism in the clean energy sector may result in significant cost increases and hinder efforts to tackle climate change. Our study examined the cost savings, energy savings, and greenhouse gas emissions reduction achieved through a globalised solar PV module supply chain compared to a hypothetical scenario where domestic manufacturers supplied an increasing proportion of installed capacities over ten years from 2004 to 2021. We focused on five representative countries: China, the United States, Germany, Japan, and India. Our analysis revealed substantial cumulative savings in these countries, with cost savings totalling US$181 billion (165-179 billion), energy savings reaching 2.26 EJ-eq (1.99-2.56 EJ-eq), and greenhouse gas emissions avoidance amounting to 105 Mt CO_2-eq (73-145 Mt CO_2-eq). Future projections from 2022 to 2050 under two IEA scenarios indicate continued savings. This analysis highlights a globalised supply chain's significant cost, energy, and emissions benefits. Coordinated policy reforms are needed to facilitate clean energy trade and technology transfer to achieve global environmental goals.

3:30 PM *BI01.03.04
Sustainability in New Battery Technology Developments EmmaKendrick; University of Birmingham, United Kingdom

The definition of sustainability is such that it can mean many things to different people. In this work we discuss the aspects of sustainability which relate to new battery technologies and developments. We examine the impact of materials, energy, and the environment in achieving a comprehensive circular supply chain for battery materials. This includes considering the importance and scarcity of materials, the manufacturing process for both materials and batteries, their lifespan, and the potential for recycling and reusing materials at the end of their life cycle.

Circular Materials choices and supply are influenced mainly currently by cost, however with different minerals and materials being on different global critical materials lists, alternatives may be needed. lithium, graphite, phosphate, silicon and cobalt are all on the EU and the UK critical materials lists, indicating that there is a supply chain risk and that the materials are of high economic importance. Using the 4 R's of sustainability, reduce, reuse, recover and recycling we can start to reduce our reliance on these materials. In this way sodium-ion batteries are being considered as an alternative, where substitution for lithium, cobalt and graphite for sodium, iron and hard carbon can be achieved. This leads to significantly lower cost materials, however when initial LCA's are performed on these batteries (per kWh) the embedded carbon is significantly higher. Other factors of sustainability must be taken into consideration; recyclability and time in use.
In this work we discuss some of the design for disassembly aspects for sodium-ion and lithium-ion batteries. Recycling routes are discussed and the materials recovery and the reuse cases for these materials. Often the recovery rates are influenced by the design of the cells and the electrodes, and we propose routes for electrode manufacturing, compositions and design considerations to maximise the performance and the recovery rates of those materials.

4:00 PM *BI01.03.05
This Isn't a Simulation: A View from the Common Tangent of Social Justice and Computational Materials Science GeraldJ. Wang; Carnegie Mellon University, United States

The fields of *computational materials science* and *social justice* are not -- to use a term more popular in the latter -- heavily intersectional. Nevertheless, in this talk, we will argue that there are numerous opportunities for -- to use a term more popular in the former -- common-tangent constructions between the two. Faced with accelerating global crises that both partially stem from and can be partially solved though materials science, it is clear today that the scientists and engineers of tomorrow must have fluency with both technical and social considerations, including their interrelationships. We highlight two opportunities to engineer a virtuous cycle that simultaneously elevates technical rigor and social-justice awareness, specifically in the context of computational materials science education: (1) identifying physical and mathematical concepts that are value-neutral in the abstract yet have significant justice-related implications in practice (especially in the context of thermodynamics, entropy, and optimization); and (2) deeply integrating the history of science and mathematics to highlight technical contributions from diverse individuals (especially in the context of the history of condensed-matter simulation). We emphasize throughout that technical rigor is a *sine qua non* for social justice, and that both are mutually enriching for the other.

4:30 PM *BI01.03.06
Lithium-Ion Batteries for Electric Vehicles—Impacts Across the Entire Life Cycle Linda L.Gaines; Argonne National Laboratory, United States

Materials for lithium-ion batteries (LIBs) come from across the globe to the United States, leaving a variety of impacts along the way, both positive and negative, ranging from opportunities for economic growth to possible habitat destruction to disruption of sacred ground to emissions that must be mitigated. This presentation will track the batteries through their entire lifecycle from materials in the ground through transportation, manufacture, and use, via possible repurposing, all the way to recycling to characterize energy use and emissions, and to identify the inequities that unavoidably arise in any supply chain.

5:00 PM BI01.03.07
Metal Hydride Reclamation from Ni-MH batteries for Small-Scale Power Generation NicholasJ. Weadock; University of Colorado at Boulder, United States

Electrification of rural communities and technologically- or economically-developing countries can be limited by the pace of infrastructure installation. Point-of-use power generation from hydrogen fuel cells offers a scalable solution provided the design is low-cost, safe, and robust. A major source of cost and reliability issues is the hydrogen storage technology itself, with the current state-of-the-art being high-pressure gas storage in composite tanks [1,2]. The balance-of-plant components for compression, filling, temperature and pressure regulation, and safety only add to the cost and complexity. Hydrogen storage in intermetallic metal hydrides (MH), a class of materials which store hydrogen interstitially in a metal alloy, circumvents the issues related to high pressures by targeting a hydrogen release pressure equivalent to fuel-cell operational requirements. MH storage for fuel cell generation has been explored and initial reports suggest a reduction in cost and safety is possible with the correct selection of the MH alloy [1–3]. Leading candidates for MH storage are $LaNi_5$-based AB_5 alloys which have favorable kinetics, cycle life, and hydrogen release pressures [4,5]. However, the monetary and environmental costs of rare-earth mining, and competition for other applications of rare-earth metals were not considered in previous analyses.
Here, I present an alternative source for AB_5 MH alloys – discarded hybrid electric vehicle (HEV) batteries. HEV like the Toyota Prius utilize the Ni-MH battery chemistry with AB_5 alloys in a cathode-limited design. Prius batteries alone contain up to 8 million kg of AB_5 MH, representing 3850 MWh of power generation from fuel cells [6]. I will demonstrated that AB_5 MH recovered from end-of-life Toyota Prius battery modules readily absorb and desorb hydrogen and retain the AB_5 crystal structure with limited $La(OH)_3$ corrosion product. Furthermore, I will present structural, spectroscopic, and hydrogen capacity and release characterization of these AB_5 MHs and assess the feasibility for re-use as gas-phase hydrogen storage materials. Finally, I will contextualize the approach proposed here within the established field of rare-earth recovery from e-waste.

8:00 PM BI01.04.01
Approaches of Centering Indigenous Concerns in The Context of Material Science and The Environment GregorKos[1], ColeDelisle[2], WassimNijaoui[1], YanLiu[1], JulieDelisle[2], PatrickRagaz[2], IngoSalzmann[1] and TanjaTajmel[1]; [1]Concordia University, Canada; [2]Kahnawà:ke Environment Protection Office (KEPO), Canada

Indigenous communities are often disproportionately affected by environmental pollution, either because of nearby resource extraction in remote areas or due to industrial and transport emissions in urban areas, amongst other reasons. The latter is the case for the Mohawk community of Kahnawà:ke, located on the South Shore of Tiohtiá:ke/Montreal, where major sources of air pollution such as car/ship/train traffic arteries converge towards a bridge across the St. Lawrence River and the St. Lawrence Seaway passes very close to the centre of daily activities. Furthermore, major industrial installations are located just across the limits of the community with little information about local emissions. While the community has long identified these sources of pollution and potential impact on health, little data has been collected so far due to a lack of suitable monitoring systems. Together with community members, we as scholars working in fields as different as Material Science, First Peoples Studies, Science Education, Decolonizing Curriculum and Pedagogy, Environmental Science, and Science and Technology Studies, came together to explore how these issues which the community of Kahnawà:ke is experiencing, can be addressed and how science and technologies can be employed to support the community's concerns.
The establishment of a Community Science Low-Cost Air Quality Monitoring Network (AQMN Kahnawà:ke) - (together with a small number of commercial sensors -) addresses several goals formulated by the Kahnawà:ke Environmental Protection Office (KEPO) and Concordia University in the framework of the "Decolonizing Light" project. Funded by the New Frontiers in Research Fund (NFRF) of the Government of Canada, the Decolonizing Light project explores different ways to contribute to anti-colonial scientific practices and to center Indigenous issues and concerns. The theme of the project exemplarily focuses on light (rather than optics) because light is ubiquitous in every society, language, and culture. In everyday life, light is a key element that defines familiar aspects like color and warmth. In physics, light is exploited as the primary carrier of information about nature (e.g., in astronomy), used as the primary probe for the fundamental properties of matter (e.g., in spectroscopy). Therefore, "decolonizing light" can be seen as a metaphor for anti-colonial science and technological development that reflects on the broader social impact as well as on the politics of science and technology.
The goals of AQMN Kahnawà:ke include (i) making the monitoring of hyper-local pollutant concentrations available to the community, (ii) installing a representation of regional air quality due to a dense network of stations (much denser than government or municipality operated networks) to represent regional air quality, (iii) studying the potential to study the impact of specific installations and infrastructure, and, (iv) democratizing scientific expertise by raising awareness and scientific knowledge about air quality and its measurement within the community at large, rather than among experts alone.
To date, fourteen air quality monitors have been built by community members during workshops held in Kahnawà:ke in 2022 and 2023. Locations are chosen across the community following local knowledge available across the community. This project provides tools for data management, processing, and visualisation to make concentrations and pollution maps available for the benefit of all community members and the particular air quality studies conducted by KEPO. Preliminary results, lessons learned, and conclusions for the broader material science community will be presented.

Multimodal Probes Nanoscale Structure-Function Relationships—From Halide Perovskite Photovoltaics to Organic Neuromorphic Materials DavidS. Ginger; University of Washington, United States

Establishing structure-function relationships is a key challenge for new semiconductor materials ranging from the halide perovskites being commercialized for thin film photovoltaics to organic semiconductors being explored for applications ranging from energy storage to neuromorphic compusting. For example, in both families of materials, mixed ionic/electronic conduction takes place. This mixed conduction is often desirable in organic semiconductor films in the case of bioelectronics or neuromorphic computing. However, ionic motion is often deleterious to the performance and stability of materials like halide perovskite semiconductors. We describe applications of multimodal microscopy -- with a particular emphasis on combining scanning probes with optical and electron microscopy -- to understand the correlations between local microstructure, defect densities, conductivity, and ionic motion in these materials. The results point the way to reduced halide vacancy concentrations and improved the stability of halide perovskites, while suggesting new ways for increasing the performance of organic mixed ionic/electronic conductors such as redox active conjugated polymers.

11:00 AM *CH01.01.02
Time-Resolved KPFM in UHV BenjaminGrevin; CNRS, France

Kelvin Probe Microscopy (KPFM) is a well-known variant of AFM that allows probing the electrostatic landscape on the surface of a sample at the nanoscale by measuring the contact potential difference. Since the early 1990s, various approaches have been implemented to improve the performance of KPFM in terms of spatial, potentiometric and temporal resolution. Several research teams continue to work in this direction, and KPFM is still an evolving technique in many respects. In particular, the development of KPFM-based approaches specifically designed to study photogeneration mechanisms and nanoscale charge dynamics in photovoltaic and optoelectronic materials is a very active research area.
Over the past decade, several powerful approaches for time-resolved surface photovoltage measurements have been developed, thanks to the efforts of an ever-growing community of researchers working with AFM setups operated under ambient (or neutral gas) conditions. In contrast, time-resolved KPFM implementations on UHV non-contact AFMs remain confidential. In this communication we will show that the "nc-AFM under UHV community" can learn a lot from the experiences of the "ambient AFM community". First, we will show how a data-cube spectroscopic variant of the pump-probe KPFM (pp-KPFM) scheme originally proposed by Murawski et al. [1] can be implemented on an nc-AFM. This implementation allows mapping 2D - truly quantitative - time-resolved images of the SPV. An interesting alternative for time-resolved SPV measurements is the analysis of the intermodulation products between the mechanical oscillation of the cantilever and the photogenerated surface potential [2]. The translation of this promising technique from ambient conditions, where it has been well established, to ultra-high vacuum poses significant challenges due to the enhanced quality factors [3]. We will show how this issue can be overcome and that time-resolved SPV images - consistent with the output of pp-KPFM data - can be obtained by intermodulation spectroscopy with an nc-AFM. Pros and cons of both approaches are discussed through a series of examples on organic, inorganic and hybrid photoactive materials. In particular, it will be shown that beyond the ability to probe the SPV dynamics, these new approaches allow revealing phenomena that would remain hidden to conventional SPV imaging. Finally, we will also show how these developments offer real prospects for ultimate resolution photo-potential imaging.

11:30 AM CH01.01.03
Probing The Interfacial Energetics in Organic Semiconductor Blends for Photovoltaics AnirudhSharma[1], JulesBertrandie[1], JianhuaHan[2], JulienGorenflot[1], FredericLaquai[1] and DeryaBaran[1]; [1]King Abdullah University of Science & Technology, Saudi Arabia; [2]University of Wuerzburg, Saudi Arabia

The energetics of materials play a critical role in charge transfer at the donor (*D)* - acceptor *(A)* interface in organic photovoltaics (OPVs),[1] yet a clear correlation between material energetics and key device parameters is missing. This is primarily because of a lack of criteria for choosing the most suitable method to determine the ionization energy (*IE*) and electron affinity (*EA*) of solar cell materials that could precisely predict the energy level alignment at the *D/A* interfaces. Consequently, the development of new high-performing donor and non-fullerene acceptor materials has led to contradictory claims about the role of energetic offsets at the *D-A* interface. This makes it difficult to establish design rules for the development of future materials.
In this work, we systematically investigate the frontier molecular orbital energies of a library of organic semiconductors and their molecularly mixed blends via different methods; in particular, low-energy inverse photoelectron spectroscopy (*LE-IPES),* which is a relatively novel and non-destructive technique that enables the direct determination of EA of organic semiconductors with high precision. By characterizing and fabricating thin films and devices based on over 12 different D/A blends, we demonstrate the significant differences which have been an ongoing debate in the field for energetic losses and device performances.[2]
We show that the *IE* and *EA* values measured using ultraviolet photoelectron spectroscopy (*UPS)* and *LE-IPES* are the most relevant in understanding the charge generation mechanism in solar cells. We further demonstrate how the energy levels of organic semiconductors evolve when blended with energetically dissimilar materials,[3] and the impact of morphology and phase segregation on the resultant energetics. Probing a range of small molecule - small molecule and polymer: small molecule D/A blends, we show that the photovoltaic gap E_{pv} (IE_{donor}-$EA_{acceptor}$)

measured from neat materials can be insufficient in some cases, for establishing material-property relationships in solar cells. By controlling the D/A ratio in molecular blend films, we probe the changes induced in E_{pv} of D/A blends as a result of intermixing, intermolecular and electrostatic interactions between the D/A materials. We rationalize these findings to the resultant photovoltaic parameters and voltage losses in OPVs.
Lastly, from OPVs based on six different *D-A* blends having systematically varying *IE*-offsets (ΔIE), we convincingly demonstrate that ΔIE plays a crucial role in charge generation. In contrast to earlier works, we show that a vanishing ΔIE is detrimental to device performance.
Overall, these findings establish a solid base for reliably evaluating material energetics and interpreting property-performance relationships in solution-processed organic solar cells.

11:45 AM CH01.01.04
Cascading Exciton Management for Efficient Organic Photovoltaic Cells YuanLi, ZhaoyunJin and GuodanWei; Tsinghua-Berkeley Shenzhen Institute, China

Compared with non-fullerene acceptor (NFA), which has the advantages of high crystallinity and exciton diffusion coefficient, the polymer donors are limited by large Stokes shift and energy disorder, showing a lower exciton diffusion distance and higher non-radiative energy loss which limit their application in organic solar cells (OSCs). Herein, we reported a simple reverse-sensitization strategy and an organic small molecule thermally activated delayed fluorescence (TADF) material (BPhA-QAO) was designed and synthesized, which as solid additives was introduced into the widely studied PM6:BTP-4F based OSCs to enable a significant efficiency increase from 16.3% to 18.2%. Ultrafast optic and spectroscopic studies reveal that BPhA-QAO can transfer its long-lifetime singlet excitons to the polymer donor through energy transfer to ensure adequate exciton lifetime to expand its diffusion distance, and achieve better exciton dissociation efficiency. Morphological studies show that BPhA-QAO promotes the formation of more J-type aggregation for PM6, while inhibiting the stacking behavior of BPT-4F, regulating the degree of phase separation, and forming smaller domain sizes. Conductive AFM (C-AFM) shows that more thorough mixing of donor/acceptor improves the efficiency of exciton dissociation and charge transfer. This work demonstrates that the introduction of small molecule TADF materials based on the reverse-sensitization strategy is an effective method to achieve highly efficient organic solar cells.

Interfacial Water and Ionic Liquids on Electrode Surfaces with Angstrom Resolution DianaMendez Arvelo and RicardoGarcia; ICMM-CSIC, Spain

Solid-liquid interfaces play a key role in several disciplines and applications, including electrochemical conversion and storage. The understanding at the molecular scale of the electrical double layer is critical in many applications[1]. Three dimensional AFM (3D AFM) is an advanced Atomic Force Microscopy technique that allows imaging in the angstrom range the structuring of liquids next to a solid surface[2-3]. Here, 3D AFM was applied to study the interaction of liquid water and some ionic liquids on graphite surfaces. We have imaged in real-time the evolution of graphite-water interfaces. We show a transition from hydration layers separated by 0.3 nm (similar to van der Waals diameter of a water molecule) to hydrocarbon layers characterized by distances of 0.45 nm. A molecular dynamics simulations model explains the process[3]. The 3D AFM was also applied to study the structure of the electrical double layer of ionic liquids on graphite when applying an external voltage to the surface, which changes the organization of the liquid molecules.

Electrochemical Performance of Mo Doped $LiNiO_2$ Cathodes for Next Generation LIBs MisbahMumtaz, Narayan SimritKaur and SerenaCussen; The University of Sheffield, United Kingdom

At present the choice for cathodes in electric vehicles (EVs) due to high power and energy density are $LiNi_xCo_yAl_{1-x-y}O_2$ (NCA, x > 0.8) and $LiNi_xMn_yCo_{(1-x-y)}O_2$(NMC, x ≥ 0.5). Cobalt poses problems to these cathode chemistries with regards to its high price, environmental damage during its mining, and ethical concerns during its acquisition. To overcome this, research has led to nickel–rich cathodes to maximise theoretical capacity while decreasing the reliance on cobalt. However, Ni-rich cathode have problems practically achieving this increased capacity of (200–220)[1] mAh g^{-1} due to the occurrence of degradation mechanisms that hinder cycling stability, for example the formation and propagation of microcracks in the secondary particles during galvanostatic cycling. One method of combatting the electrochemical cycling instability in the cathodes is doping, which tailors the elemental composition of the transition metal material to stabilise the layered structure. Molybdenum is reported to effectively enhance the cycling stability of the lithium nickel oxide ($LiNiO_2$, LNO) structure. A solid-state approach was used to synthesise Mo–doped $LiNiO_2$ compositions by milling lithium hydroxide monohydrate, nickel hydroxide and molybdenum oxide and calcining the material in an oxygen–rich atmosphere. The $Ni(OH)_2$ precursor was synthesized using CSTR via co–precipitation method. The X-ray diffraction pattern collected between (10° to 90°) revealed that all powders are well crystalised and single phase with no additional peaks. All the powders belong to R3m space group. At 003 hkl, peak broadening phenomenon is observed, which shows increased Mo content causes broadening. This feature can be correlated to the presence of micro strain due to Li/Ni cation mixing. The X-Ray analysis of the powders revealed a degree of off stoichiometry due to variation of ($I_{(003)}/I_{(104)}$ peak intensity. As a result of doping the lattice parameters underwent changes (expansion/contraction) as depicted by XRD and confirmed by Topas refinement. Scanning electron microscopic (SEM) images depicted that growth of the primary particles is affected by the Mo doping. As there is a massive difference is particles size of LNO and Mo-1% doped LNO. Mo cause increased anisotropy by modifying the surface energy leading to a superior growth direction. The SEM images verify the doping process and show a change in microstructure by forming smaller primary particles. SEM images revealed the formation of pore free particles with central equiaxed in shape particles where quasi-spherical secondary construction is maintained. The electrochemical performance of the LNO and Mo doped LNO (1 and 2)% was characterized at (3.0 - 4.3) V using a 2032 coin-type half-cell with a Li metal anode. The electrochemical data revealed 251.7 mAh g^{-1} first charge capacity compared to 207.6 mAh g^{-1} for LNO. Mo doped cathodes revealed 90% better retention capacity after the first 50 cycles. Mo-doped cathodes have cycled noticeably better than LNO. The kinetic hindrance peak below 3.6 V is an additional redox couple that is only present in LNO. This variation in the lattice due to doping is beneficial for the electrochemical performance helping stabilise the lattice. It is observed that Mo doped compositions exhibited less polarization as compared to LNO in dQ/dV vs. Voltage plots. This feature assisted in smooth transition of H2 to H3 phase during the electrochemical cycling process. The proposed Mo (1 and 2)% doped compositions have delivered superior energy density and stable cycling ability unlike conventional cathodes. The long cycling of Mo doped 1% for 500 cycles shows improved performance against microcracks in the cathode.

Structure-Performance Relationships in Energy Conversion Applications: Multi-Stage Data Quantification Method for Comprehensive Surface Analysis of Large-Scale Anode Electrodes VineethaVinayakumar[1,2], AdarshJain[1] and DorisSegets[1,2]; [1]Institute for Energy and Materials Processes–Particle Science and Technology (EMPI–PST), University of Duisburg–Essen (UDE), Germany; [2]Center for Nanointegration Duisburg–Essen (CENIDE), University of Duisburg–Essen (UDE), Germany

Efficient operation of energy conversion applications relies on the optimization of anode electrodes. Improving anode performance and efficiency involves optimizing their fabrication process (1). The surface microstructure of anodes plays a crucial role in their functionality, necessitating precise characterization (2). Atomic force microscopy (AFM) has proven to be a powerful technique for examining the nanoscale microstructure of anodes. However, AFM has limitations when investigating large electrode areas, posing challenges in evaluating the surface microstructure of large-scale electrodes.

In this study, we developed a multi-stage data quantification method to overcome AFM's limitations and measure large electrode areas. We validated our approach by testing anodes fabricated under various spray coating process conditions. Our method effectively provides valuable information on homogeneity, surface smoothness, and the presence of cracks or defects, enabling an overall assessment of electrode quality. Additionally, the combination of statistical analysis and matrix-based analysis in our approach demonstrates its potential to benefit material scientists and extend its application to analyze the micro/nanostructure of other materials in various applications, providing new insights for optimization. Integrating surface analysis measurements with electrochemical analysis is a crucial step in determining overall anode quality. The findings obtained through our multi-stage data quantification method using AFM can be directly correlated with electrochemical analysis to gain a comprehensive understanding of the anode's performance and establish structure-performance relationships. By combining these techniques, we can understand the relationship between surface morphology and the anode's electrochemical properties, activity, and cycling stability. This connection between surface analysis and electrochemical analysis yields crucial insights into anode performance and ultimately advances the development of energy conversion technologies.

Revealing the Bonding Nature and Electronic Structure of Early Transition Metal Dihydrides AnnaRegoutz[1], CurranKalha[1], LauraRatcliff[2], GorgioColombi[3], ChristophSchlueter[4], BernardDam[3], AndreiGloskovskii[4], Tien-LinLee[5], PardeepThakur[5], PrajnaBhatt[1], YujiangZhu[1], JuergOsterwalder[6], FrancescoOffi[7] and GiancarloPanaccione[8]; [1]University College London, United Kingdom; [2]University of Bristol, United Kingdom; [3]Delft University of Technology, Netherlands; [4]DESY, Germany; [5]Diamond Light Source, United Kingdom; [6]Universitaet Zuerich, Switzerland; [7]Universita di Roma, Italy; [8]IOM-CNR, Italy

Hydrogen as a fuel plays a crucial role in driving the transition to net zero greenhouse gas emissions. To realize its potential, obtaining a means of efficient storage is paramount. One solution is using metal hydrides, owing to their good thermodynamical absorption properties and effective hydrogen storage. Although metal hydrides appear simple compared to many other energy materials, understanding the electronic structure and chemical environment of hydrogen within them remains a key challenge.

This work presents a new analytical pathway to explore these aspects in technologically relevant systems using Hard X-ray Photoelectron Spectroscopy (HAXPES) on thin films of two prototypical metal dihydrides: $YH_{2-\delta}$ and $TiH_{2-\delta}$. By taking advantage of the tunability of synchrotron radiation, a non-destructive depth profile of the chemical states is obtained using core level spectra. Combining experimental valence band spectra collected at varying photon energies with theoretical insights from density functional theory (DFT) calculations, a description of the bonding nature and the role of d versus sp contributions to states near the Fermi energy are provided. Moreover, a reliable determination of the enthalpy of formation is proposed by using experimental values of the energy position of metal s band features close to the Fermi energy in the HAXPES valence band spectra.

3:00 PM CH01.02.05

Troubleshooting CNT Bundling using the Electrospray Method to Achieve Thick Electrodes IlgyuKim and Ji-WonJung; University of Ulsan, Korea (the Republic of)

CNT, a nanomaterial with a 1D structure providing efficient electron transport, is well known as an excellent electron-conducting material and a key element for realizing thick electrodes. However, due to its high aspect ratio, there is significant Van der Waals force present; therefore, when used at a certain level or higher, it aggregates, which causes performance degradation, limiting its use.
In this work, we solve the bundling problem by applying a feasible electrospray method. This approach achieves a $LiFePO_4$/CNT composite with uniform morphology, even with high CNT content, and is confirmed with Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM) analysis. In addition, we found out that it shows enhanced capacity retention and longer battery life compared to the conventional mixing-only method.

3:30 PM *CH01.03.01

Improved Sensitivity of Printed Piezoelectric Sensor Arrays for Large Area Ballistocardiography PeterZalar, MariekeBurghoorn, JoostFijn, LarsRikken, PeterRensing, Jeroenvan den Brand, Dagode Leeuw and EdsgerSmits; Holst Centre / TNO, Netherlands

Holst Centre is an applied research institute specializing in the development of flexible and thin electronics through industrially relevant fabrication methods. Our mission over the past two decades has been to drive technological advancements that enable the industrialization of printed electronics systems, transforming future concepts into tangible realities.

Ballistocardiography (BCG) is a non-invasive technique that examines the heart's activity by measuring the ballistic forces generated during each heartbeat, eliminating the need for on-skin sensors, unlike electrocardiography (ECG). This unique characteristic makes it an unobtrusive measurement method.

To achieve sensors with optimal sensitivity, we have successfully demonstrated a universal method for enhancing effective transverse charge constants. Our methodology has been validated using a printable piezoelectric polymer called poly(vinylidene fluoride-co-trifluoroethylene) (P(VDF-TrFE)). Through our research, we have shown that discrete sensors can accurately detect displacements of less than 1 µm, dynamic forces of approximately mN, and accelerations of around 1 mm/s^2, precisely meeting the requirements for high-quality BCG measurements.

By employing printable sensors, we have scaled up our demonstration to a "human-sized" prototype measuring 60 x 90 cm, equipped with 255 piezoelectric sensors. This enabled us to measure spatially resolved BCG measurements of an individual with exceptional quality. The heart rate obtained from our measurements has been corroborated optically using photoplethysmography (PPG). The universality of our approach allows for the creation of increasingly sensitive piezoelectric sensor architectures, crucial not only in healthcare but also in various sensing and actuating applications.

Diffuse Scattering as a Probe of Static and Dynamic Local Structure MichaelF. Toney; University of Colorado Boulder, United States

Local atomic structure often differs from the global average structure as measured with diffraction and yet the local structure has a profound impact on properties. This structure-function relationship applies in many materials classes, ranging from organics to Li-ion battery cathodes to perovskites. Accurately characterizing this local structure has proven challenging but recent advances in diffuse scattering (“between” Bragg peaks) has enabled local structure determination.

In this talk, I will discuss the importance of local structure and how this can be quantified and will demonstrate this for organic-inorganic hybrid halide perovskites [1,2]. These materials are a recently re-invigorated class of semiconductor that have demonstrated very high efficiencies for solar cells after just over a decade of research. While the importance of lattice dynamics and dynamical (dis)order has been recognized in these materials, their nature is only poorly known and understood. We used X-ray and neutron diffuse scattering coupled with molecular dynamics to quantify the nature, size, and time scale associated with dynamical local order in $CH_3NH_3PbI_3$ and $CH_3NH_3PbBr_3$ perovskites. We observe that the nominally cubic perovskite consists of dynamical, two-dimensional sheets of lower symmetry tetragonal regions of about 3 nm diameter with several picosecond lifetimes. The implications on halide perovskite properties will be discussed.

Energy Harvesting at Solid/Solid and Solid/Liquid Interfaces: Decoupling Charge RonaldLeon[1], ShuaijiaChen[1], PeterC. Sherrell[2,1], JosephJ. Berry[1] and AmandaEllis[1]; [1]The University of

Melbourne, Australia; [2]RMIT University, Australia

Smart wearable energy harvesting devices can convert friction or mechanical energy (i.e., applied stress) into electric energy and are hence, highly sought after for a variety of applications such as: smart watches, smart gloves, smart shoes, and other electronic devices. However, reported piezoelectric outputs in literature are often convoluted with friction induced contact electrification. In this talk we use a simple signal processing method to analyse different contact and motion induced voltage signals, probing the origin of charge from piezoelectric fluoropolymers and various triboelectric polymers. We have developed a method to identify the source of generated charge by taking time domain data, traditionally used by researchers in the field of contact electrification and processed this data for the first time into the frequency domain (via a Fast Fourier Transform (FFT). The bandwidth (Hz) of the signal varies based on the motion of charge within solid | solid interfaces. The differences in bandwidth of the FFT signal is intrinsically linked to the type of charge being measured. This type of detail cannot be observed in the time domain data, and we have used this to decouple piezoelectric responses from contact electrification and electrostatic charge induction. We propose simple steps to analyze piezoelectric measurements by placing more emphasis on data extraction and data analysis with a clear set of parameters, that will promote sustainable electrical characterization practices of future piezoelectric and hybrid triboelectric energy harvesters.

We also apply this method to liquid | solid interfaces to determine the mechanisms of charge generation at liquid and solid interfaces and apply this knowledge to control and precisely utilize charge. Data collection was performed using a combination of dynamic contact angle measurements with correlated voltage and charge measurements. Correlated electrical measurements to contact angle enabled effects such as contact-line pinning on charge and voltage outputs to be elucidated.

High-Efficiency a Transpiration-Driven Electrokinetic Power Generator based on Two-Faced Hydrophilic/Hydrophobic Carbon Nanofibers Utilizing Water Transpiration Ho-JinLee[1], Tae GwangYun[2] and Ji-WonJung[1]; [1]University of Ulsan, Korea (the Republic of); [2]Ajou University, Korea (the Republic of)

Hydro-electric technology, which uses minimal amounts of water to generate electricity, is receiving substantial attention due to its simplicity and environmental friendliness. However, the low energy density of such technology constrains its practical applications. In this study, we present the application of a transpiration-driven electrokinetic power generator (TEPG) based on nitric acid-treated carbon nanofibers (N-CNFs). These N-CNFs possess both hydrophilic and hydrophobic properties, which enables high energy efficiency. A polyacrylonitrile (PAN) solution was electrospun and underwent a carbonization process to create carbon nanofibers (CNFs). Half of the hydrophobic CNFs were then treated with nitric acid to convert them into hydrophilic, while the other half retained their hydrophobic properties. The TEPG system, equipped with these dual-featured CNFs, utilizes the capillary action of water on the hydrophilic carbon surfaces. This interaction facilitates the absorption of water, and the resulting electrical double layer at the solid (CNF)/liquid (water) interface provokes the accumulation of protons (H^+). The existence of these two distinct regions – the proton-driven electrical double layer and hydrophobic CNFs – creates a potential difference between the wet and dry regions, thereby producing the driving force for energy generation. Consequently, the N-CNF-TEPG is a self-sufficient energy generator that does not require continuous work input due to its inherent transpiration action.

Atto-Ampere Nanoelectrochemistry GeorgGramse; Johannes Kepler University, Austria

We recently introduced a new technique for versatile nano-electrochemical measurements at the atto-Ampere level (3 orders of magnitude below the previous state of the art) based on an up-conversion of the electrochemical current to GHz frequencies.[1] For example, this allowed us to image the electrochemical current of non-moving redox molecules at the nanoscale for the first time.
We also showed that the potential of this approach is even more prosperous, since it can be employed for quantitative mapping of the nanoscale impedance spectra as a function electrochemical potential (CV) and frequency (EIS). We developed a closed framework that allows for a rigorous analysis and quantification of the measured complex impedance signal covering a wide frequency domain (DC to GHz) [2]. A global understanding of the nano-electrochemistry at the nanoscale on these systems is now possible, including the diffusive double layer effects.
Interestingly, we stress that an important feature is that DC and GHz excitations have a different impact on the ions at the solid electrolyte interface (SEI), which provides additional degrees of freedom to understand the nano electrochemical processes. Our work was demonstrated on a model system (ferrocene undecane thiol) that has greatly interested electrochemists and molecular electronics communities [1,2]. Finally we will show exciting new applications on more complex 2-dimensional material systems for energy applications.

***In Situ* Raman-Electrochemistry for Routinely Characterizing Electronic Properties of Dopped SWCNTs**NaimishSardesai; Metrohm, United States

Electrical conductivity of single wall nanotubes (SWCNTs) plays a critical role in high-performance flexible batteries. Doping SWCNT is a well-known technique to modify their electronic properties and improve electrical conductivity. In this presentation, we demonstrate *in situ* Raman-electrochemistry as a unique technique for both predicting electronic properties and understanding the charging mechanism of SWCNTs. We demonstrate this by electrochemically doping SWCNT with both chloride and tetraethylammonium tetrafluoroborate to study simultaneous changes in Raman intensity and/or shifts with respect to applied potential. Our study shows hysteresis of the cyclic voltammogram and Raman spectra during doping cycles. We demonstrate the impact of doping on D, G, 2D and RBM bands of the nanotubes at different voltage states.

Investigation of the Mechanism of Polydiacetylene Mechanochromism in the Aqueous Solution JianluZheng and KaoriSugihara; The University of Tokyo, Japan

1. Introduction
Polydiacetylene (PDA) is a special kind of pi-conjugated material widely used in sensing applications[1] due to its facile polymerization and dual signals (blue-to-red color change and turn-on fluorescence) upon exposure to external stimuli. The chromatic transition has been explained as a shortening in effective conjugation caused by the torsion of polydiacetylene backbone[2]. Despite pH-dependent or ion strength-dependent thermochromism having been extensively studied before, the related mechanochromism at the nanoscale is left unstudied. In 2021, Sugihara Group[3] demonstrated the first quantitative and anisotropic force-fluorescence correlation of polydiacetylene in air by friction force microscopy (FFM) combined with fluorescence microscopy. In this work, we expanded this technique towards a biological buffer solution to study the mechano-responses fluorescence of PDA.
2. Method
10, 12-Tricosadiynoic acid was assembled onto an oxygen-plasma-activated glass coverslip by the Langmuir-Blodgett (LB) method, followed by UV exposure to fabricate the PDA multilayer films. FFM combined with fluorescence microscopy was an appropriate technique to investigate the quantitative relationship between the applied force and the readout signal, fluorescence.
3. Result and discussion
As the standard atomic force microscopy (AFM) could only apply vertical force which is perpendicular to the substrate at the nanoscale, it usually fails to activate the PDA due to its anisotropic properties. FFM being one mode of AFM can detect the lateral force (friction force)[4]. FFM combined with fluorescence microscopy was an appropriate technique to investigate the quantitative relationship between the applied force and the readout signal, fluorescence. PDA film was scanned by FFM at different setpoints under HEPES buffer solution (pH 7.4, NaCl 150 mM). At the same time, the responses of PDA against the nano-forces were recorded by fluorescence microscopy. The force-fluorescence correlation in buffer solution is different from that in the air due to the water molecule may break the hydrogen bonding between the headgroup. After then we varied the pH and the ionic strength to modulate the hydrogen bonding, and the electrostatic interaction, and investigated how they affect the force sensitivity. Consequently, PDA film became more force-sensitive in the basic environment due to the deprotonation at the carboxyl headgroups. In addition, the force sensitivity slightly rose as the NaCl concentration became higher which can be explained by the reduction of the interfacial pKa.
4. Conclusion
We proved the quantitative mechanochromism of PDA under an aqueous environment by integrating FFM and fluorescence microscopy. pH change or NaCl was used to pre-treat the PDAs, whereas lateral forces were subsequently applied to measure the force sensitivity. In other words, non-mechanical stimuli can be used to pre-stimulate PDAs to improve their force sensitivity.

Both pH change and the addition of NaCl elevated the blue state energy, which made it easier for the system to go over the potential wall when the force was applied, enhancing the force sensitivity. This strategy to pre-stimulate by pH or NaCl is convenient for improving the force sensitivity of PDA, which will open a new pathway for developing easy-to-use (naked-eye detection) point-of-care diagnostic tools.

Operando X-Ray Absorption Spectroscopy of Solid Electrolyte Interphase Formation on Silicon Anodes JackSwallow and RobertWeatherup; University of Oxford, United Kingdom

The development of improved lithium-ion batteries (LiBs) is critical to societies transition towards net-zero. However, more widespread deployment requires improvements in energy density, economic cost and cycle-lifetime. Various cathode and anode materials are under consideration for next-generation LIBs, and the interfacial stability of these materials in contact with the electrolyte is a critical consideration. The formation of a stable solid electrolyte interphase (SEI) is critical to long term LiB performance, however a detailed mechanistic understanding of SEI formation remains elusive, in-part due to the complex electrolyte decomposition reactions that occur. Whilst X-ray spectroscopy, and in particular X-ray absorption spectroscopy, has become a staple characterisation technique to obtain electronic structure and chemical information from battery materials interfaces, it is nearly always performed post-mortem (with cells disassembled in a glovebox, washed, and transferred into the measurement chamber) which can result in unwanted side reactions and removal of labile SEI species.

Here, we demonstrate a novel operando methodology to explore the formation and evolution of the SEI on amorphous silicon (a-Si) anodes during the formation cycle. a-Si is of particular interest in the Li-ion battery community as a result of its extremely high specific capacity[1]. A specially designed cell that incorporates a silicon nitride membrane as an X-ray transmissive window allows the electrode surface to be probed in real time whilst performing electrochemical cycling[1,2,3]. This synchrotron-based approach uses a modulating beam chopper and lock-in amplifier, to perform total electron yield mode X-ray absorption spectroscopy, providing unique nm-scale sensitivity to buried-interfaces. The methodology allows spectroscopic tracking of the onset potentials for the formation of different SEI species, and for identification of O- and F-containing species in the SEI. Cross-referencing to cycling data, complementary bulk sensitive fluoresecent yield (FY) XAS measurements, and density function theory (DFT) calculated core-hole spectra enables identification of the electrolyte and SEI species, and the dominant mechanisms of SEI formation. Without FEC present, LiF formation is detected at 0.6 V vs. Li/Li^+ prior to significant lithiation of the a-Si, whilst at lower potentials the SEI grows in thickness with an increased contribution from organic components containing -C(=O)O- species. The observed sequential formation of inorganic and organic components is implicated in layering of the SEI. With FEC as an additive we see the onset of SEI formation at much higher potentials (1.0 V vs. Li/Li^+), and attribute the improved cycle life seen with this additive to the rapid healing of SEI defects formed during delithiation. This work demonstrates a new X-ray measurement approach that can provide surface sensitive chemical information of buried electrode interfaces, which has the potential to allow us to better understand the complex degradation and formation processes occurring at battery electrode interfaces during cycling. This work was performed in collaboration with two internationally-leading user facilities (Diamond Light Source, UK and ALBA, Spain) and involved collaboration between researchers at the Universities of Oxford and Cambridge.

9:15 AM CH01.04.05
High Speed Mapping of Surface Charge Dynamics via Sparse Scanning Kelvin Probe Force Microscopy MartiCheca, AddisS. Fuhr, RamaK. Vasudevan, MaximZiatdinov, IliaIvanov, KyleP. Kelley, NeusDomingo Marimon, StephenJesse and LiamCollins; Oak Ridge National Laboratory, United States

Unraveling local dynamic charge processes is vital for progress in diverse fields, from microelectronics to energy storage. This relies on the ability to map charge carrier motion across multiple length- and timescales and understanding how these processes interact with the inherent material heterogeneities. Towards addressing this challenge, we introduce high-speed Sparse Scanning Kelvin Probe Force Microscopy (SS-KPFM), which combines sparse spiral scanning and image reconstruction via Gaussian process optimization. SS-KPFM enables sub-second imaging rates (3.3 fps) of nanoscale charge dynamics, representing several orders of magnitude improvement over traditional KPFM methods. Bridging this improved spatiotemporal resolution with macroscale device measurements, we demonstrate the applicability of this approach by visualizing electrochemically mediated diffusion of mobile surface ions on a $LaAlO_3/SrTiO_3$ planar device, processes which are known to impact band-alignment and charge-transfer dynamics at such heterointerfaces. Additionally, we track oxygen vacancy diffusion generated under a biased tip, at the single grain level in polycrystalline TiO_2. Temperature-dependent measurements reveal a charge diffusion activation energy of 0.18 eV, in good agreement with previously reported values and backed up here by further modelling. Together, these findings highlight the effectiveness and versatility of our method in understanding ionic charge carrier motion in microelectronics or nanoscale material systems.

Ginsberg[1]; [1]University of California, Berkeley, United States; [2]Arizona State University, United States; [3]The University of Chicago, United States; [4]Stony Brook University, The State University of New York, United States; [5]SLAC National Accelerator Laboratory, United States; [6]Brookhaven National Laboratory, United States

Design advances for the bottom-up assembly of highly ordered functional nanomaterials have generated a wide range of fundamental questions that must be answered to continue to advance material properties, recently including strong electronic and mechanical coupling. We focus on colloidal nanocrystal advances that incorporate electrostatics to promote the formation of ordered superlattice structures from nanocrystals with high dielectric constants. Through a multiscale suite of hard X-ray scattering experiments ranging from small- to wide-angle, incoherent to coherent, and storage ring to free electron laser over a wide dynamic range of time scales, we characterize the phases, their fluctuations, and the dynamic interconversion between phases of this enigmatic system, non-invasively and in real-time, identifying the helpful role of a liquid-like intermediate phase that admits an unusually high degree of control over product yield, size, and order. We find that controlled, ordered assembly requires a balance of nanocrystal screening and surface charge that is facilitated by moderate to high dielectric ratios between the nanocrystals and their surroundings. We also find that laser absorption reversibly alters the surface charge and growth of the ordered superlattice phase and intend to leverage these finding to infer strategies to self-assemble more common low-dielectric nanocrystals into ordered structures by driving them far from equilibrium with optical excitation.

Surface Studies to Understand Formation and Lithiation of New Silicon-Based Anodes via Neutron Depth Profiling RalphGilles[1], LukasGrossmann[1], JiriVacik[2], AntoninoCannavo[2] and GiovanniCeccio[2]; [1]TU München, Germany; [2]Nuclear Physics Institute, Czechia

Analytical methods for characterizing surfaces that have been under electrochemical influence are in great demand, as many electrochemical processes originate here and are therefore important for cell performance. Electrode surfaces are a good example of how neutron techniques contribute to the understanding of lithiation processes [1,2]. Currently, attempts are being made to replace graphite anodes with silicon-based anodes with a significantly higher specific capacity. Since pure silicon anodes have a short lifetime due to the large volume expansion,

microscale silicon particles with partial lithiation are investigated [3]. This type of anode combines high capacity, rate stability, and low cost. Besides an overview of how neutrons with their unique properties solve specific electrochemical problems on different length and time scales, this contribution shows how neutron depth profiling determines the Li distribution across the whole depth of the electrode coating in the pristine state, after the formation cycles and after 15%, 25% and 30% of the lithiation process. Taking into account SEI formation, electrode swelling and phase transformation from crystalline to amorphous Si, conclusions are drawn on how the surface lithiation process occurs under electrochemical changes.

Tracking Charge of Disordered Carbon Electrodes with Raman Spectroscopy - Mapping Insights from Electron Doped Activated, Hard and Black Carbons. HectorJ. Lancaster, ThomasS. Miller and ChristopherA. Howard; University College London, United Kingdom

Disordered carbon is an essential ingredient in batteries, fuel cells, supercapacitors and electrolysers. The types typically used are chars (commonly referred to as hard carbons), carbon blacks and activated carbons. For a given application, these often-overlooked materials provide several key functions, such as tuning conductivity, porosity or surface area. They are all cheap, widespread and integral to their parent devices.

Raman spectroscopy is a powerful, non-destructive, inexpensive and relatively facile surface-sensitive technique. That being said, in the electrochemical literature the vast majority of Raman characterization on carbon materials is limited to often tenuous claims, derived from poor statistical inferences, about an electrode's defectiveness. These are based on an oversimplified understanding of the ratios of D (disordered) and G (graphitic) Raman peaks. Promisingly, recent studies have begun to explore the potential power of using operando Raman spectroscopy as an effective tool for determining things such as the sodiation mechanism in hard carbon electrodes. [1] The relative power of Raman analysis in electrochemical systems is highlighted by comparison with a contemporary study, which employed far more complex and expensive techniques to reach similar findings. [2]

In this presentation, I will share new and fundamental insights into the Raman effects of heavy electron doping disordered carbons, revealed by controllably tuning the concentration of electrons in an isolated system. The work serves as an analogue for surface and interfacial charge transfer phenomena present in electrochemical devices. I will discuss how D peak trends can be used as a sensitive and simple fingerprint of electrode charge and explain why conventional D:G ratio rules may not apply to these systems. Ultimately, this technique can be widely implemented to measure and optimise the next generation of disordered carbon containing electrodes.

Modulating the Voltage Decay and Cationic Redox Kinetics of Li-Rich Cathodes via Controlling the Local Electronic Structure Heng-LiangWu and Hung-LingYu; National Taiwan University, Taiwan

Li-rich layered oxide cathodes with conventional transition metal cation and unique oxygen anion redox reactions deliver high capacities in Li-ion batteries. However, the oxygen redox process causes the oxygen release, voltage fading/hysteresis, and sluggish electrochemical kinetics, which undermine the performance of these materials[1-4]. In this talk, the effect of the local electronic structure is elucidated on the reaction mechanism and electrochemical kinetics of Li-rich cathodes by using operando quick-scanning X-ray absorption spectroscopy with online gas chromatography[5]. The local electronic structure of Li-rich cathodes varies with the excess Li (i.e., Li_2MnO_3 phase) and Ni contents. Compared to the Li-rich cathodes with higher amounts of Li_2MnO_3 phase (high excess lithium content (HLC) cathode), those with lower Li_2MnO_3 contents (low excess lithium content (LLC) cathode) exhibit reversible anion redox reactions and suppressed voltage hysteresis. Interestingly, the kinetics of the TM redox process in the LLC cathode is slower than that in the HLC cathode. Thus, the amount of Li_2MnO_3 phase affects both the reaction mechanism and kinetics of Li-rich cathodes. The evolution of the dynamic structure needs to be taken into account when addressing the cation and anion redox chemistry in Li-rich cathode. Our findings provide new insights into the reaction mechanism and kinetics of the TM redox reactions, showing that the electrochemical stability and kinetics of TM redox can be tuned by modifying the Li_2MnO_3 phase content.

11:15 AM CH01.05.04
Temperature-Dependent Dynamic Spin Disproportionation in the Battery Cathode $LiNiO_2$. AndreyPoletayev[1], JackSwallow[1], RobertGreen[2], RobHouse[1], BenjaminJ. Morgan[3], RobertWeatherup[1] and M. SaifulIslam[1,3]; [1]University of Oxford, United Kingdom; [2]University of Saskatchewan, Canada; [3]University of Bath, United Kingdom

Layered lithium nickel oxide $LiNiO_2$ represents the end-member of industry-leading lithium-ion battery cathodes, $Li(NiMnCo)O_2$. The properties of $LiNiO_2$ (LNO) are responsible for much of the degradation of such cathodes, especially during high-voltage operation above 4.2 V, presenting an opportunity to improve their energy density by extending the operating voltage window. Here we focus on the computational and experimental understanding of LNO and its presumed delithiated state, layered NiO_2. LNO possesses several unusual properties: (1) gradual lattice distortions rather than abrupt phase transitions upon cooling, (2) gradual changes to vibrational spectra upon cooling, (3) heat-activated electronic conductivity with a variable activation energy, (4) temperature-dependent NiO_6 distortions, and (5) ubiquitous antisite defects.

We reconcile all of these observations with a dynamic spin disproportionation model where nickels exist in three interconverting spin states (S = 1, ½, and 0), reminiscent of formal charges +2, +3, and +4. This model explains the gradual variation of the physical properties of LNO across temperatures [1]. Since small variations in the level of theory lead to substantial changes in the predicted behavior and its temperature dependence, we verify computational predictions experimentally. Resonant inelastic x-ray scattering (RIXS), temperature-resolved bulk-sensitive x-ray absorption spectra, and x-ray magnetic circular dichroism (XMCD), all at the nickel L-edge, confirm first-principles predictions.

11:30 AM CH01.05.05
Covalent-Assisted Seeding Silicon Nanoparticles into Sn/SiOC Dual Active Matrix as a High-Performance Anode Material for Lithium-Ion Batteries KwanghyunDo, ChangyongPark, JeongukHwang, SucheolKim, YejuJung and HeejoonAhn; Hanyang University, Korea (the Republic of)

Research for high-capacity electrode materials is being actively conducted to realize high-energy-density batteries for electric vehicles. This direction of research necessarily requires silicon-based anodes. Si shows the highest theoretical capacity among anode materials and low working voltage but has a critical drawback of mechanical instability from which all electrode degradation begins. Various materials have been introduced to accommodate the volume expansion of silicon and protect the surface of pulverized silicon from penetration of electrolyte. Among them, silicon oxycarbide (SiOC) is an attractive active matrix for silicon. SiOC active matrix has a higher specific capacity than graphite and a very low theoretical volume change (~ 22%). In addition to capacity and volume change, the tetrahedral C-doped silica network and free carbon domain of SiOC give higher connectivity of glass network than SiO_2 and act as a chemical and/or physical barrier to alkaline or HF solution, resulting in superior electro-chemo-mechanical stability.

Several approaches, such as pyrolysis with silicone oil or crosslinking with polysiloxanes, have been tried to combine Si nanoparticles (Si NPs) and SiOC matrix. However, the particle size cannot be controlled, forming a bulky SiOC monolith, which causes sluggish Li^+ diffusion. In addition, there is a problem in that the surface of Si NPs is exposed during lithiation/delithiation

because the previous methods simply engage Si NPs without chemical bonding or interaction. Therefore, a method of controlling the size of SiOC and inducing chemical bonds between Si NPs and SiOC is desired.

In this study, the silicon alkoxide-based sol-gel method was introduced to design Si NPs-seeded preceramic SiOC based on covalent bonds. Additionally, to further enhance several electrochemical performances of the Si@SiOC composite, we incorporated Sn nanocrystals into the SiOC matrix via carbothermal reduction. We expected that the formation of SnO(OH), a precursor of metallic Sn, would change the morphology of composite particles into secondary particles by hindering the growth of spherical SiOC particles and creating nanovoids between the primary particles. This morphological change can be anticipated to improve cyclability by providing voids that can additionally accommodate the volume change of the entire particles. Moreover, the Sn/SiOC dual active matrix can enhance the (de)lithiation kinetics of the Si@Sn/SiOC electrode due to improved electrical and ionic conductivity. Firstly, we confirmed that the composite was successfully synthesized through various material analyses. We successfully controlled the size of particles by setting the reaction time and unveiled the mechanism of Si@Sn/SiOC complexation. Secondly, the coin cell-type battery test was performed to figure out the effect of covalent-assisted seeding (CAS) of Si NPs on the electrochemical behavior of Si@SiOC electrode and the effect of Sn/SiOC dual active matrix on the electrochemical behavior of Si@Sn/SiOC electrode. After cycling, we conducted ex-situ cross-sectional SEM analysis and electrochemical impedance spectroscopy of the electrodes and demonstrated the beneficial effects of Sn/SiOC dual active matrix in which the propagation of charge transfer resistance and mechanical fracture were much suppressed than that of Si@SiOC. We also revealed that incorporating Sn nanocrystals improved the specific capacity of the electrode by reducing the polarization of the electrode and increasing the lithiation kinetics of Si. Finally, through this study, we proposed an approach that takes advantages while complementing the disadvantages of each Si and SiOC and clarified the role of each Si, Sn, and SiOC component in the Si@Sn/SiOC electrode during (de)lithiation.

11:45 AM CH01.05.06
$NaCuO_2$ as Cathode Materials Studied Through Resonant Inelastic Soft X-Ray Spectroscopy (RIXS) ZengqingZhuo, WanliYang and JinghuaGuo; Lawrence Berkeley National Laboratory, United States

Anionic redox reactions have been proposed for a decade to provide higher capacity and higher power compared with conventional transition metal redox. However, the fundamental mechanism remains elusive and highly debated. Here, we are working on a model electrode system, $NaCuO_2$, to reveal the both cation and anion evolution upon the electrochemical cycling through high efficiency mapping of resonant inelastic X-ray scattering (mRIXS). Through the characterization of the oxygen state and copper state, we finally provide a comprehensive understanding of the electrochemical cycling mechanism of the $NaCuO_2$. We clarify that lattice oxygen redox dominates the reversible bulk redox, while the surface reactions with carbonation decomposition and Cu reaction also contribute the cycling capacity. This work suggests the important role of transition metals and their coupling and hybridization effect to oxygen for maintaining reversible oxygen redox activities.

SESSION CH01.06: Photovoltaics II
Session Chairs: Ilka Hermes and Philippe Leclere
Tuesday Afternoon, November28, 2023
Sheraton, Third Floor, Commonwealth

1:30 PM *CH01.06.01
The Nanoscale Photovoltaics Laboratory on a Tip StefanA. Weber[1,2], YenalYalcinkaya[1], PascalN. Rohrbeck[1], KonstantinosBidinakis[1], RüdigerBerger[1] and IlkaHermes[3]; [1]Max Planck Institute for Polymer Research, Germany; [2]University of Stuttgart, Germany; [3]Leibnitz Institute for Polymer Research, Germany

Solar cells based on metal halide perovskite (MHP) materials will enable cheaper and more energy-efficient photovoltaic and optoelectronic devices compared to current silicon-based technologies. To advance MHP technology further, however, will require a better understanding of the fundamental processes leading to energy losses, unstable operation conditions and premature aging. The macroscopically observed properties of optoelectronic MHP materials and devices are the result of the complicated interplay between nanoscale structure and function. Thus, the key to understanding MHP materials is the micro- and nanoscale characterization of the many nano- and microscale structures; from sub-granular twin domains, over grain boundaries and interfaces to lateral variations in crystal grains orientations and facets. For such nanoscale photovoltaic measurements, scanning force microscopy methods are ideal, as they allow correlated measurements of structure and function.
In this presentation, I will present some of our recent activities in the development of specialized scanning probe microscopy methods to study hybrid perovskite materials. Based on static and time-resolved Kelvin probe force microscopy (KPFM), we have developed unique techniques for mapping the surface potential and photovoltage. Using cross sectional measurements, we map and record the potential distribution across different layers of solar cell devices under operating conditions [1–4]. Here, the key to a reliable cross-sectional KPFM measurement is the connection of a high-resolution quantitative KPFM operation mode [5] and the preparation of a smooth surface through the solar cell. We use a combination of mechanical fracturing of the cells with a complex polishing process using ion beams. Using a pointwise spectroscopy technique, we can record and map the surface photovoltage (SPV) dynamics with 10-20 nm lateral resolution. With this Nano-SPV technique, we revealed local SPV overshoots in the vicinity of grain boundaries following an illumination pulse. The overall aim of our research is to address some of the key challenges of MHP research, such as phase segregation, degradation and interface heterogeneity, to enable a deeper understanding of the different loss mechanisms and intrinsic instabilities that currently limit the application of MHP solar cells.

2:00 PM CH01.06.02
TEM and XPS Investigations of Multi-Layer Solar Selective Absorber: Thermal Stability FlorianChabanais[1], MireilleRichard-Plouet[1], JonathanHamon[1], NicolasGautier[1], AissatouDiop[2], BabacarDiallo[3], BéatricePlujat[2], ThierrySauvage[3], ÉricTomasella[4], LaurentThomas[2], AudreySoum-Glaude[2] and AntoineGoullet[1]; [1]Nantes Université, CNRS, Institut des Matériaux de Nantes Jean Rouxel, IMN, France; [2]Université de Perpignan Via Domitia - PROMES-CNRS UPR 8521, France; [3]CEMHTI-CNRS UPR 3079 (Conditions Extrêmes et Matériaux : Haute Température et Irradiation), Université d'Orleans, France; [4]Université Clermont Auvergne, CNRS, SIGMA Clermont, ICCF, France

The solar energy resource is still relatively under-exploited although it could cover most of our energy needs. Beyond the development of photovoltaics, there is a worldwide challenge to deploy large-scale concentrated solar thermal power plants. To address this issue, materials with high absorption in the visible range, low emissivity and good temperature resistance are required. To this end, multi-layered optical thin films produced by plasma processes are developed in the NANOPLAST project (nanoplast-project.cnrs.fr, ANR-19-CE08-0019).

This study is focussed on the investigation of the absorbing active layer with or without air annealing at 500°C.
First, composite monolayers W-SiC:H are obtained by reactive magnetron sputtering from a W target combined with tetramethylsilane (TMS-$Si(CH_3)_4$) diluted in Ar plasma.
TEM and XPS characterisations were carried out to get insight into the nature of the absorber and the anti-reflective top films. Depending on the TMS fraction in the discharge, the quantity of Si introduced in the W-SiC:H material can be tuned.

In dedicated conditions (5 and 8% TMS), W nano-crystallites could be identified by coupling STEM-HAADF (Scanning Transmission Electron Microscopy - High-Angle Annular Dark Field) images, EDS mapping and High Resolution imaging. In other conditions (20 and 28% TMS), amorphous layers are observed. In XPS, we were able to analyse the different surface chemical environments of the samples. Under low TMS content, we observed a significant occurrence of W-C bonding whereas no Si is incorporated in the layer. By decomposing the obtained survey spectra and identifying the related components, we were able to achieve quantification of the species as a function of the TMS concentration.

Second, multi-layers of SiC:H/metallic W/SiC:H were also prepared. Upon annealing at 500°C in air for duration up to 48h, XPS profiles indicate that excepting a diffusion of oxygen from

the surface in the upper SiC:H layer, the W interlayer acts as a blocking layer for oxidation. However after annealing for 96h, the triple layer is severely modified with segregation of the different species involved.
TEM images confirmed these major modifications.

2:15 PM CH01.06.03
Direct Measurements of Donor HOMO – Acceptor LUMO Offset at The Interface of C60/Pentacene Model Organic Solar Cells using Photoemission and Inverse Photoemission Spectroscopy GyuhyeonLee, Min-JaeMaeng, Kyu-MyungLee, Jong-AmHong and YongsupPark; Kyung Hee University, Korea (the Republic of)

In organic light-emitting diodes (OLEDs) and heterojunction organic solar cells (OSCs), the energy offset between HOMO and LUMO, also called the transport gap (E_{tr}) is substantially different from optical gaps due to the relatively large exciton binding energies. However, the difficulty to independently measure the LUMO levels makes it hard to elucidate important things like electron injection barrier at the cathode in OLEDs and the voltage loss mechanisms in Voc of OSCs.
We have recently developed highly sensitive inverse photoemission spectroscopy (IPES) instrument specifically for the LUMO level measurement of organic semiconductors. In combination with the existing ultraviolet photoemission spectroscopy (UPS) we could determine all the relevant transport energy levels (HOMO, LUMO, Fermi level and vacuum level) in any organic semiconductor surface and interface. In addition, combination of the electron source for IPES and the electron energy analyzer for UPS allowed us to utilize reflection electron energy loss spectroscopy (REELS) to determine optical gaps. We first demonstrate that all these measurements can be performed for an identical sample as a function of thickness. We also determine the energy levels at C60/pentacene interface so that the factors affecting the voltage losses that led to observed Voc value of this model planar heterojunction organic solar cells can be evaluated.

Multimodal Operando Microscopy Reveals that Nanoscale Performance Disorder Dictates Efficiency and Stability of Perovskite Solar Cells KyleFrohna[1], CullenChosy[1], AmranAl-Ashouri[2], Yu-HsienChiang[1], MilosDubajic[1], JuliaE. Parker[3], JessicaM. Walker[3], BartRoose[1], SteveAlbrecht[2], MiguelAnaya[1] and SamuelD. Stranks[1]; [1]University of Cambridge, United Kingdom; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [3]Diamond Light Source, United Kingdom

The optoelectronic properties of next generation semiconductors such as halide perovskites are dominated by nanoscale variations in structure[1,2], composition[3,4] and photophysics[5,6]. While microscopy provides a proxy for ultimate device function, past works have typically focused on neat films fabricated on insulating substrates – therefore missing additional recombination losses from transport layers and charge extraction losses entirely[7–9].
In this presentation, I will discuss a multimodal, *operando*, microscopy toolkit designed to measure nanoscale current-voltage curves, recombination losses and chemical composition in a wide array of state-of-the-art perovskite solar cells before and after extended operational stress. By imaging the same scan areas before and after operation, we determine point by point changes in recombination and transport losses on length scales from entire device down to sub-micron.
We apply this toolkit to reveal that perovskite solar cells with the highest performance and stability have the lowest initial performance spatial heterogeneity. We show that perovskite solar cells can tolerate considerable chemical and photophysical heterogeneity in the absorber itself, but cannot tolerate heterogeneous charge extraction, a finding missed by conventional microscopy. If the interfaces are not stabilised appropriately, the contacts dominate degradation pathways, introducing spatially varying transport, recombination, and hysteresis losses. With well-tuned contact layers, perovskite absorbers dominate degradation and minor modulations of the composition can induce or prevent extreme halide segregation and precipitate formation which are both detrimental to performance. These *operando* measurements uniquely unveil the underpinnings of perovskite solar cell performance and stability. The microscopy toolbox can be readily tuned for alternative device structures and semiconductors.

Uncovering the Individual JV Curves of Fully Evaporated Perovskite-Silicon Tandem Solar Cells FedericoVentosinos[1,2], SofiaChozas Barrientos[1] and HenkJ. Bolink[1]; [1]University of Valencia, Spain; [2]IFIS Litoral, Argentina

Tandem devices combining perovskite and silicon solar cells are promising candidates to achieve high power conversion efficiencies at low cost, with already proven devices exceeding 33%. Despite the ever-increasing performance and the improved stability of perovskite solar cells, there is need for characterization techniques for these complex structures to fully understand and optimize them. This becomes a challenge in 2 terminal (2T) tandem devices given the nature of the series connection between them. Due to this junction, the density current in the JV curve corresponds to the minimum of both subcells, while the total voltage is the sum of each subcell. This implies that knowing the short circuit current density (J_{sc}), the open circuit voltage (V_{oc}) and the fill factor (FF) of the full device does not translate into knowing the individual behavior of each subcell. In the case of J_{sc}, quantum efficiency measurements with light and voltage biasing can be used to reveal the behavior of each subcell. Suns-Voc with selective illumination can also give approximate values of individual V_{oc} in the case of very good selectivity. However, it is difficult to obtain information about the FF for each subcell. In this communication we show how a technique developed for studying tandem devices based on thin film silicon materials can be applied to our fully evaporated perovskite on textured silicon 2T tandem devices. To accomplish this, an extra source of illumination (a laser for each subcell in our case) is used to to keep one of the subcells at its V_{oc} while changing the working point at 1 sun illumination of the full stack, hence, revealing the behavior of the other subcell. This allows us to re-construct each subcell individual JV curve of each subcell at 1 sun illumination, giving direct access to all the relevant parameters.
We will explaine how the technique works and what are the underlying assumptions and limitations. Particularly, I will discuss the relevance of having good selectivity (meaning, generating voltage in only one of the subcells) and how to solve this issue in the case of poor selectivity. Secondly, we will point out how an extra procedure is needed, since perovskite based solar cells suffer from known issues, such as ion migration and scan rate dependency, from which silicon based tandem devices did not suffer. To overcome these problems, we will propose a methodology that ensures the reliability of the constructed individual JV curves.
Finally, we show this method for our vacumm deposited perovskite tandem solar cells, highlighting the evolution of the main parameters (V_{oc}, J_{sc} and FF) as a function of light soaking time.

The Critical Morphological Structures for Solvents Insensitive Processed Organic Solar Cells RuiZhang and FengGao; Linköping University, Sweden

The power conversion efficiencies (PCEs) of lab-sized organic solar cells (OSCs), usually processed from low-boiling-point and toxic solvents, have reached high values over 19%. However, the key limiting factor for green-processed OSCs is imperfect micro-morphology, which dominating a significant drop of the efficiency. Importantly, the final device parameters are always super sensitive to the solvents selected during solution-processed procedures. Herein, we obtain uniform PCEs over 18% in OSCs processed from a series of different solvents involving chloroform, chlorobenzene, toluene, (p-, o-, m-) Xylene by carefully designing of the OEG sides chains in non-fullerene small molecules. The specific intermolecular interactions formed in solution states dominate those uniform device parameters. Our inspiring strategy provides a broaden land view to develop large-area and high-efficiency OSCs from green solvents, figuring out the way towards industrial development of OSCs.

SESSION CH01.07: Novel Characterization Techniques I

EXAFS Analysis of Mn-Alloyed TiO_2 Coatings Grown by Atomic Layer Deposition: Probing the Crystallization Behavior DevanSolanki[1,2], DeyuLu[3] and ShuHu[1,2]; [1]Yale University, United States; [2]Energy Sciences Institute, United States; [3]Brookhaven National Laboratory, United States

Introduction

TiO_2 is a nontoxic, wide bandgap semiconductor with many excellent physical properties such as high chemical stability in acids and bases and good optical transparency to visible light, making it an excellent candidate for photoelectrocatalysis. Atomic Layer Deposition (ALD) enables synthesis of conformal coatings on various substrates by its layer-by-layer, surface-growth mechanism. However, controlling the crystal structure, which can modulate properties such as the band gap and band edge positions, remains a challenge as TiO_2 is often amorphous as deposited but can be annealed into multiple polymorphs such as anatase, rutile, and brookite. Despite progress in understanding the reaction mechanisms and intermediates associated with the deposition of binary materials via ALD, there are still many questions surrounding the structure-processing relationship of ternary materials. For example, the role that dopants or alloying agents play in determining key properties such as oxidation state and crystal structure remain open questions.

Methods:

The X-Ray Absorption Spectroscopy (XAS) and X-ray Absorption Near Edge Structure (XANES) measurements were conducted at the Inner Shell Spectroscopy beamline of the National Synchrotron Light Source II (NSLS-II) at Brookhaven National Lab. The data was collected at room temperature with the energy calibrated using a Ti foil. The Athena software package was used to calibrate the energy and normalize the data using the recommended parameters. XAS was collected in fluorescence mode with $\mu(E) = I_f/I_0$ where I_f is the fluorescence intensity and I_0 the incident intensity. Each spectrum is flattened so that the overall spectrum has an asymptotic behavior approaching 1.

Results:

The primary pre-edge feature in the TiO_2 sample, centered at 4968 eV is due to the oxygen vacancies and resultant undercoordinated Ti. The absorption maximum of that pre-edge feature is unchanged after the incorporation of Mn. However, there is a narrowing of the peak in $TiMnO_x$ samples relative to the TiO_2 and an enhancement of the shoulder peak that appears at 4972 eV. The separation between the apex of the first and second pre-edge feature corresponds to the crystal field splitting energy of the Ti 3d states. This indicates that the incorporation of Mn, while not having an effect in the oxidation state of the Ti, does perturb the local steric coordination environment. Quantitative analysis of this feature was not possible due to the background variation between the different samples and the low absolute intensity of the peak.

Analysis of the Mn K-edge reveals that the oxidation state of Mn in the as-grown TiMnOx is independent of Mn concentration. One explanation for this fractional oxidation state could be the incorporation of Mn into multiple different sites. The pre-edge feature is comparable to experimental and computational Mn_3O_4 spectra. The position of the white line can be explained either by the electrostatic model or as continuum resonances. In the electrostatic model, as the oxidation state increases, the electrons are more tightly bound to the nucleus, requiring higher energy to be excited. The continuum model considers both the excited atom and the surrounding ones, and as the absorber-scatter distance gets shorter, the energy of the continuum state increases with $1/r^2$. As higher oxidation states result in shorter bond lengths, the energy increases as oxidation state increases. In addition, the intensity of the white line intensity is proportional to the filling of 3d orbitals. As the 3d orbitals gets more occupied, the intensity of the white line goes down due to the reduction in possible population states. As the position of the white line remains constant between the as grown TiMnOx samples, the increase in sharpness of the K-edge in the 16:1 sample relative to the 2:1 sample could be explained by the combination of a slightly increased oxidation state and longer Mn-O bond.

Microwave Resonator-Based Characterization of Surface-Adsorbate Interactions and Carrier Dynamics in the Photocatalytic Production of Solar Fuels KarthikShankar, NavneetKumar, AminMoradkhani, JohnGarcia, Md MasudRana and MasoudBaghelani; University of Alberta, Canada

Solar fuels such as hydrogen (generated through water-splitting) and short chain hydrocarbons - methanol, methane & formate (generated through the photoreduction of CO_2) capture the energy of photons in the chemical bonds of portable gaseous and/or liquid fuels. Solar fuels solve the intermittency and energy storage density problems associated with photovoltaic and solid-state battery technologies respectively. Furthermore, solar fuels are highly compatible with the existing energy production and distribution infrastructure and therefore constitute an economically feasible method to make the transition to more renewable energy sources. However, such positive outcomes first require a several fold increase in the photoconversion efficiency (PCE) of photocatalytic solar fuel production processes from values of 2-5% to at least 10-15%. The principal bottlenecks limiting higher PCEs in photocatalytic water-splitting and CO_2 photoreduction relate to large electron-hole recombination losses and inefficient charge transfer processes involving adsorbed reactants and/or reaction intermediates. Conventional methods used to measure carrier dynamics in photocatalytic systems such as femtosecond transient absorption spectroscopy, DC photoconductivity, DLTS, EPR, etc only provide information on either free or trapped carriers but not both simultaneously and are frequently difficult to use for *operando* characterization. Microwave resonators integrated with photoreactors offer a novel characterization methodology to obtain deeper insights into the underlying chemical & electronic processes and also perform *operando* monitoring of the reaction. A key advantage of this methodology is that both mobile and trapped photogenerated carriers interact strongly with microwaves through the photodielectric effect and photoconductive effect respectively. Thus microwave resonators are able to provide information on the number of free and trapped carriers and the time-scales of trapping & recombination processes through monitoring the real and imaginary portions of the complex permittivity of photocatalysts placed in the coupling gap of high-Q microwave resonators. In addition, the high frequency spectra also provide information on the nature of the adsorbates and their interaction with the surface of the photocatalyst. Microwave characterization has enabled us to measure & monitor the interactions of a single monolayer of organic adsorbate with free and trapped carriers generated using light illumination in a TiO2 photocatalyst. We recently extended the microwave resonator-based characterization to other semiconductor systems of interest for energy applications. Regenerative feedback techniques are used to achieve very high quality factors since the sensitivity of the complex permittivity detection is directly related to the value of Q. The selectivity of this characterization methodology has been expanded by monitoring multiple resonance frequencies in the GHz range on a single microwave resonator. This work will discuss the design, fabrication and testing of high-Q microwave resonators consisting of photocatalysts in their active region.

4:15 PM CH01.07.03

Thermal Characterization of an Epitaxial Gallium Nitride Film via Spatial-Temporal-Resolved X-Ray Diffraction ThanhNguyen[1], TyraEspedal[1], BuxuanLi[1], ZhantaoChen[2], HaidanWen[3] and MingdaLi[1]; [1]Massachusetts Institute of Technology, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Argonne National Laboratory, United States

The characterization of the thermal properties of thin films, in simultaneous cross-plane and in-plane measurements, remains nontrivial and challenging despite the development of advanced techniques. Non-contact methods such as time-domain and frequency-domain thermoreflectance are typically the measurement of choice for different films, but tends to suffer from a relatively large error and a lack of sensitivity to the in-plane thermal transport; thus, new novel approaches continue to be investigated especially in the context of thermal management in prospective electronic devices. In this work, we report preliminary measurements of thermal properties of an epitaxial thin film of gallium nitride (GaN) transfered onto a silicon wafer using synchrotron-based pump-probe x-ray diffraction. We observe a decaying signal of the (002) Bragg peak position of GaN as a function of delay time as well as by the spatial distance set between the pump laser and x-ray probe. These measurements provide simultaneous time- and spatial-resolved information about the phonon thermal transport in the system allowing us to characterize both cross-plane and in-plane thermal properties of the film. In addition, we support the analysis with frequency-domain thermoreflectance and Raman measurements. The measurements provided by this novel x-ray based approach enables detailed characterization of the thermal properties of an epitaxial gallium nitride film -- with important implications for epitaxial thin film characterizations and enhancing thermal management in power electronics.

4:30 PM CH01.07.05

Direct Measurement of Solid-Liquid Interfacial Energy Using a Meniscus IshratZarin[1], JingchengMa[1,2] and NenadMiljkovic[1,3,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]The University of Chicago, United States; [3]Kyushu University, Japan

Solid-liquid interactions are central to diverse processes. Human wellness benefits from understanding cellular behavior in complex biofluids. The soil and crops in our environment respond to the absorption of rain and agricultural sprays. In energy systems, the affinity of a solid to the working fluid determines the efficiency of boiling and condensation. Within fuel cells and batteries, the electric double layer, made up of water molecules near a metal electrode, plays a key role in electrochemistry. To quantitatively describe these solid-liquid interfaces and interactions, the solid-liquid interfacial free energy is used. This free energy arises from the imbalanced force on the liquid surface molecules that are attracted by the solid atoms on one side, and by the bulk liquid on the other side. Although vital to many processes, the direct and accurate measurements of solid-liquid interfacial energy remain a challenge. The most widely used approach to determine solid-liquid interfacial energy is the liquid droplet contact angle technique, which was first introduced in the 1960s. When a liquid droplet is in contact with a chemically homogenous and smooth solid surface, it shows partial wetting and forms a spherical liquid cap, enabling the estimation of solid-liquid interfacial energy from the measured droplet contact angle. Although this method works well for soft and low-surface-energy materials such as polymers, it is not applicable for high-energy surfaces like metals, ceramics, or semiconductors, because the droplet spreads and eliminates the ability to measure a finite contact angle. Here, in contrast with the classical approach of probing a droplet, we instead probe a liquid meniscus to directly measure the solid-liquid interfacial energy of a solid surface. We develop the solid-liquid interface by using the following steps: we first let a vertically suspended plate touch a liquid surface and allow a liquid meniscus to form. We then attach a thin and smooth solid film on this liquid meniscus, thus creating a solid-liquid interface that replaces the original liquid-air interface. The curvature of the solid-liquid-meniscus changes when compared to a free water meniscus, which is caused by the solid-liquid interfacial interaction, and which enables the measurement of solid-liquid interfacial energy from analysis of the meniscus profile.

8:00 PM CH01.08.01
First-Principles ELNES Simulation of P-O Based Materials KosukeKawabata and TomoyukiTamura; Nagoya Institute of Technology, Japan

Phosphate materials have been attracted attention for as energy materials and used for cathode materials in rechargeable batteries. In particular, the phosphate materials are expected to be used as storage electrodes storing sodium because they have many voids [1]. The physical properties of phosphate materials are greatly affected by the Q^n value (the number of bridging oxygens coordinated to phosphorus). We found that the difference in P-Q^n values greatly affects the diffusion of Na^+ ions and protons in phosphate glasses using first-principles molecular dynamic simulations [2]. This suggests that ionic conductivity can be designed by controlling the P-Q^n distribution of phosphate materials. In the experiment, Q^n values are usually measured using magic angle spinning nuclear magnetic resonance (MAS-NMR) techniques. But they are average information, and spatial information cannot be obtained. In recent years, electron energy-loss spectroscopy (EELS) in transmission electron microscopy (TEM) has become increasingly important for the structural characterization of materials in high spatial resolution. In particular, the near-edge structure (ELNES) can provide detail and local information on chemical bonding, valence states, and coordination. In this study, the spatial distribution of P-Q^n value in phosphate materials will be observed in the combination of TEM-EELS observation and first-principles calculations.
We performed a series of first-principles PAW calculations of P *L*-edge ELNES spectra with QMAS code [3] for phosphate crystal models with different P-Q^n values. These crystal models were taken from Materials project [4]. In the calculated spectra, the first peak shifted to the lower energy side as the P-Q^n value decreased. This trend agrees with experimental results . This suggests that the P-Q^n value can be determined using first peaks of ELNES spectra.To investigate the origin of each peak, we compared the partial density of states (PDOS) to the ELNES spectra. It was found that peak positions of ELNES spectra clearly coincided with the PDOS peak. This suggests that the first peak p1 originates from excitation from the core 2p state to the 4s state, while the second peak originates from excitation from the core 2p state to the 3d state.
In conclusion, TEM-EELS will play an important role in the practical application of high-performance phosphate-based materials.

Ion Insertion and Transport in Between the MXene Layers: Control the Charging Mechanism YuanZhang, DanzhenZhang and YuryGogotsi; A.J. Drexel Nanomaterials Institute, United States

Owing to an expanding economy and growing population, there is increasing consumer demand for freshwater. Electrochemical water desalination technologies such as capacitive deionization (CDI) can achieve energy-efficient water desalination. MXene is a cation-selective material that can intrinsically suppress the ion-swapping effect in the desalination process. However, to explore MXene application in electrochemical water treatment, a deeper understanding of the charge transfer mechanism is required. In this work, the ion transport in between MXene layers under in-situ-UV-vis spectroscopy has been monitored. Compared with unconstrained spray-coated $Ti_3C_2T_x$ MXene films, physically confined MXene with fixed interlayer spacing has shown an unextraordinary ability to suppress redox reactions.

8:00 PM CH01.08.03
Dynamic Glycol Additive Adsorption for Durable Aquoues Zn-Ion Batteries and Rationalized the Performance Through Machine Learning YuanShang and DipanKundu; University of New South Wales, Australia

The benefits of aqueous zinc battery (AZB) chemistry are primarily derived from the energy-rich zinc metal anode and mild aqueous electrolytes. However, the incompatibility between these two, evident in zinc's corrosion and consequent dendrite problem, presents a significant challenge in enhancing the battery's cycle life under practical conditions. Although electrolyte additives are an effective solution, finding additives that operate at low volume concentrations remains challenging. In this study, we screened alkanol and alkanediol chemistries and discovered highly efficient additives that function at a feasible concentration of 1 volume%, thereby preserving the electrolyte's aqueous nature. These additives generate a dynamic solid-electrolyte interphase through electrode interfacial filming, successfully mitigating zinc corrosion and dendrite formation, and enhancing cyclability under strenuous conditions in both half-cell and full-cell configurations. We also offer a machine learning-based analysis of the additive's performance, emphasizing the relative significance of key physicochemical descriptors. This analysis provides a logical approach to future additive discoveries.

8:00 PM CH01.08.04
High-Performance Oxide Thin-Film Transistors based on Indium with Nano-Iaminate Structure using Plasma-Enhanced Atomic Layer Deposition CheolHeeChoi[1] and TaikyuKim[2]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Since the discovery of amorphous indium-gallium-zinc oxide (a-IGZO) by the Hosono group in 2004, oxide semiconductors have been intensively studied. a-IGZO, with desirable electrical characteristics such as moderate mobility (~10 cm^2/Vs), very low leakage current (<10^{-12} A), and reasonable bias stability, gained significant attention in the display industry as a backplane technology due to its low processing temperature (~400°C) and relatively low manufacturing cost. Consequently, a-IGZO became the standard backplane technology for active-matrix organic light-emitting diode (AMOLED) television displays. However, a-IGZO faced challenges in high-end mobile AMOLED displays requiring short switching times due to the high pixel density (ppi). As a result, low-temperature polysilicon (LTPS), which offers high mobility (>80 cm^2/Vs) and excellent bias stability, has been predominantly used as the backplane technology for mobile AMOLED displays. Currently, high-end mobile AMOLED displays employ LTPS and oxide (LTPO) technologies for the backplane, consisting of LTPS and IGZO TFTs for driving and switching transistors, respectively. The hybrid concept of LTPO technology can provide high resolution, fast frame rates, and low power consumption simultaneously. However, the challenging manufacturing process of LTPO technology remains a drawback, resulting in high manufacturing costs and low yield rates. Developing oxide TFTs with high mobility and reliability to compete with LTPS TFTs is a demanding engineering task.
In this study, a single diode with a 2 nm confinement layer (CL) thickness of either indium-gallium-oxide ($In_{0.84}Ga_{0.16}O$) or indium-zinc-oxide ($In_{0.75}Zn_{0.25}O$) and a barrier layer (BL) of gallium oxide (Ga_2O_3) was designed to achieve excellent electrical performance in thin-film transistors (TFTs). The formation of multiple channels within the oxide nano-laminate (NL) structure was proven to occur near the CL/BL hetero-interface in the form of a quasi-2D electron gas (q2DEG), where free charge carriers accumulate, leading to superior carrier mobility. The q2DEG near the oxide interface, designed for Fermi level (EF) engineering, was utilized to implement the NL structure in oxide semiconductors by adopting different oxide materials. The engineered q2DEG structure ensures excellent stability by reducing the trap density of the oxide NL compared to single-layer oxide TFTs. The optimized device with $In_{0.75}Zn_{0.25}O/Ga_2O_3$ NL TFT exhibited remarkable electrical performance: a mobility (μFE) of 77.1 ± 0.67 cm^2/Vs, a threshold voltage (V_{TH}) of 0.70 ± 0.25 V, a steep subthreshold swing (SS) of 100 ± 10 mV/decade, an $I_{ON/OFF}$ ratio of 8.9×10^9, a low operating voltage range of ≤ 2 V, and excellent stability (ΔV_{TH} of +0.27, -0.55, and +0.04 V for positive bias temperature stress, negative bias illumination stress, and constant current stress, respectively). The improved electrical performance, based on in-depth analysis, is attributed to the existence of q2DEG formed near the carefully designed CL/BL hetero-interface. TCAD simulations were performed theoretically to validate the formation of multiple channels in the oxide NL structure, with the formation of q2DEG near the CL/BL hetero-interface. These results clearly demonstrate that introducing heterojunction or NL structure concepts into this ALD-induced oxide semiconductor system is a highly effective strategy to enhance carrier transport characteristics and improve the bias stability in TFTs.

Nanographenes with Fully-Substituted Group 7A Elements: The Chemistry in Lithium-ion Battery Anodes Hui QiWong[1,2], FebriBaskoro[1] and Hung-JuYen[1]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Graphene has received intensive scientific attentions as an electrode material for lithium-ion batteries because of its extraordinary physical and electrical properties. However, the lacking of structural control and restacking issues have hindered its application as carbon-based anode materials for next generation lithium-ion batteries. To tackle these problems and improve its performance, several modification approaches such as edge-functionalization and electron-donating/withdrawing substitution have been considered as promising strategies. In addition, group 7A elements have been known as critical elements due to their electronegativity and electron withdrawing character, which can regulate the electronic and structural properties of materials. Herein we elucidated the chemistry of nanographenes with fully-substituted group 7A elements as lithium-ion battery anodes. The nanographenes have been synthesized via bottom-up organic synthesis to ensure the structural control. Our study reveals that the present of halogen atoms on the edge not only tuned their structural and electronic properties, but also impacted material stability and reactivity as well as Li^+ storage capability. Further systematically spectroscopic study indicates that the charge polarization caused by halogen atoms could also regulate the

Li^+ transport, charge transfer energy, and charge storage behavior of nanographenes. This study provides a deep understanding on the molecular design of nanographene anodes for next-generation lithium-ion batteries.

0.01 to 0.5 Sun is a Realistic and Alternative Irradiance Window to Analyze Urban Outdoor Photovoltaic Cells Ka LaiWong, ChujunZhang, ZhuoqiongZhang, MingweiHao, YuanyuanZhou and Shu KongSo; Hong Kong Baptist University, Hong Kong

Solar cells have penetrated many cities as Building Integrated Photovoltaic (BIPV) or the energy source for standalone Internet of Things (IoT) devices. Traditionally, photovoltaic (PV) cells are evaluated using 1 sun irradiance. However, in a city, factors such as air pollution, cloudiness and cell installation orientation may attenuate the receivable solar energy. Also, the power conversion efficiency (PCE) of a PV cell is highly irradiance-dependent. Evaluating urban outdoor PV cells using 1 sun irradiance could lead to inaccurate prediction of PCE and overestimated output power in actual usage. Herein, we analyzed daytime irradiances of 11 cities located across the globe. Our results show that realistic irradiances (RI) in most cities are between 0.01 and 0.5 sun, reflecting the irradiance under a cloudy to mostly sunny sky. Under such an RI window, the PCEs of 9 different PV technologies were compared. 7 PV technologies have compromised performance. 2 PV technologies, organic and perovskite PVs, show enhanced PCE under the RI window and are favorable for urban outdoor applications. The tested perovskite PV reached 21% PCE while the non-fullerene-based organic solar cell has improved to 18% PCE under a cloudy sky. The potential of powering IoT devices with these PV technologies under sub-optimal irradiance conditions in cities is also highlighted.

Functional Separator Enabling Improved Cycling Performance of Lithium Metal Batteries DaheeSong[1], JunHyeokSeo[1], MinjaeKim[1], Kuk YoungCho[2] and JuyeonIm[1]; [1]Hanyang University, Korea (the Republic of); [2]Hanyang University(ERICA campus), Korea (the Republic of)

Battery research worldwide is focused on developing next-generation batteries, and the lithium metal battery has emerged as a promising candidate. This advanced battery design replaces the conventional graphite anode with a lightweight lithium metal anode, offering high capacity and a low oxidation-reduction potential. A high-nickel cathode with increased nickel content and a lithium metal anode are required to achieve high-energy-density lithium batteries.
However, rapid capacity degradation caused by dendrite formation due to the deposition of transition metals from the cathode onto the lithium metal and the formation of an unstable solid electrolyte interface (SEI) layer during battery operation is challenging. A well-designed functional separator approach can effectively mitigate these issues and improves the performance of the lithium metal battery by minimizing the byproducts of side reactions. This study demonstrates the crucial importance of restricting the movement of transition metal ions to the lithium metal anode, contributing to enhanced operational performance and stability of the lithium metal battery.

8:00 PM CH01.08.08
Understanding the Relationship between Separator Parameters and Characteristics of Practical Lithium Metal Batteries JunHyeokSeo, MinjaeKim, DaheeSong and Kuk YoungCho; Hanyang University(ERICA campus), Korea (the Republic of)

The demand for low-cost, high-energy-density lithium-ion batteries (LIBs) has risen due to the entry of grid-level energy storage systems (ESSs) and electric vehicles (EVs) into the market. Lithium metal batteries (LMBs) promise improved energy density, but safety issues related to Li dendrite growth and reactivity persist. The separator, which prevents short circuits, plays a vital role in the performance and safety of LIBs.
Selecting an appropriate separator thickness is crucial because reducing the separator thickness significantly enhances the volumetric energy density and electrochemical performance of LMBs. In addition, the results of the study identify pore closure within the separator as a critical issue affecting cell failure. Effective prevention of pore closure involves maintaining robust mechanical properties, achieving the appropriate solid electrolyte interface composition, and suppressing lithium dendrite growth during cycling. Balancing mechanical strength and low resistance in the separator, along with developing materials to inhibit pore closure, advances the commercialization of high-energy-density LMBs with improved performance and longevity. This study investigates the relationship between separator parameters and practical lithium metal batteries (LMBs) characteristics to achieve stable and long-term cycling performance for successful commercialization.

8:00 PM CH01.08.09
On the Electro-Mechanical Property Characterization of Piezoelectric Inorganic and Hybrid Materials for Energy Harvesting Systems PierreNickmilder[1], EmelineSchmidt[1,2], MartinLefebvre[1], Marie-HélèneChambrier[2], AntonioDa Costa[2], AnthonyFerri[2], RachelDesfeux[2] and PhilippeE. Leclere[1]; [1]University of Mons, Belgium; [2]Universite d'Artois, France

The energy crisis presents one of the most significant challenges of our century, necessitating the urgent exploration of new methods for electricity generation. A promising approach involves the development of systems made of materials with piezoelectric properties for charge generation and transport. While certain materials such as PZT exhibit excellent piezoelectric properties, the presence of toxic lead hinders their applicability. Consequently, alternative materials such as innovative lanthanide-based tungsten oxide (Ln2WO6), which demonstrate piezoelectric behavior, need to be explored in detail [1-3]. Furthermore, organic materials such as poly(vinyl difluoro ethylene) (PVDF) – based materials possess inherent piezoelectric properties, albeit with weaker coefficients than their inorganic counterparts. However, the addition of piezoelectric nanoparticles like BiFeO3 (BFO) nanoparticles can enhance their piezoelectric response. This study aims to characterize two distinct types of materials, the inorganic Gd2WO6 oxide in thin film and the hybrid system made of PVDF-b-trifluoro ethylene (PVDF-trFE) block copolymer containing BFO nanoparticles, and subsequently develop a hybrid material that combines the flexibility of the organic component with the structural resistance of the inorganic counterpart, while ensuring piezoelectric sensitivity. To achieve this, we utilized Piezoresponse Force Microscopy (PFM), an Atomic Force Microscopy (AFM) mode based on the inverse piezoelectric effect. Even though the PFM is still universally used to quantify piezo and ferroelectric properties, recent studies have revealed that a significant contribution of the electromechanical response captured by PFM is unfortunately due to artifacts, mostly by electrostatic interactions between the surface and the tip being the most dominant of them [4].
In addition to conventional PFM, another mode has been developed, such as switching spectroscopy PFM (ssPFM). This mode uses a script where the electromechanical response is continuously monitored while alternating between the polarization step and the non-polarization step. The contribution of electrostatic interaction can be minimized by identifying the electrostatic blind spot (ESBS) [5], the laser position on the cantilever that minimizes the electrostatic contribution. This limitation of long-distance electrostatic interaction can be verified through an “almond nut” test. [6] From those data, the ferroelectric hysteresis from the studied material can be extracted.
Through our research, we aim to contribute to the development of piezoelectric hybrid materials with enhanced electromechanical properties. These materials hold significant potential for addressing the energy crisis and driving advancements in electricity generation and utilization.

8:00 PM CH01.08.10
Understanding the Role of Lithium Borate as the Surface Coating on High Voltage Single Crystal $LiNi_{0.5}Mn_{1.5}O_4$Na RiPark[1], WeikangLi[1] and Y. ShirleyMeng[2]; [1]University of California, San Diego, United States; [2]The University of Chicago, United States

Researchers investigated the potential of using lithium borate (LBO) to enhance the performance of high-voltage spinel lithium nickel manganese oxide (LNMO) cathode material in lithium-ion batteries (LIBs). LNMO/graphite (LNMO/Gr) full cells commonly suffer from capacity fading, limiting their practical applications. To address this issue, a dry mixing method was employed to apply an LBO coating on the LNMO surface. The LBO-coated LNMO exhibited improved cycling stability compared to uncoated LNMO in full cells, achieving a practical 3 mAh/cm^2 areal capacity. Various characterizations were conducted to understand the coating's effect on the cathode, electrolyte, and anode. The LBO-coated LNMO demonstrated a 5 nm cathode electrolyte interphase (CEI) with reduced phase change after long-term cycling, while the uncoated LNMO showed negligible CEI with noticeable phase change. Surprisingly, no boron was detected on the surface of the coated sample. Electrolyte and anode analyses revealed that the coating acted as a reservoir, gradually dissolving into the electrolyte and generating BF_4^- species. Consequently, the coating mitigated the dissolution of nickel and manganese from LNMO, as well as the extensive formation of a solid electrolyte interphase (SEI) on the anode side, leading to significant improvements in the cycling stability of the full cells. The insights gained from this study may serve as a guide for surface modification techniques applied to other high-voltage cathode materials with related electrolyte additive designs.

8:00 PM CH01.08.11
Structural-Plasmonic Relationship of Crystalline Copper Oxide Microcubes Decorated with Plasmonic Gold Nanoparticles EsterV. De Almeida[1,2], Diericd. Abreu[3], Douglasd. Lopes[1,2], BrunoG. Fonseca[2], EduardoR. Nascimento[2], MichelleL. de Souza[2], LuisH. de Lima[4], PaolaCorio[1] and AlexandreBrolo[2]; [1]University of Sao Paulo, Brazil; [2]University of Victoria, Canada; [3]Universidade Federal do Ceara, Brazil; [4]Universiade Federal do ABC, Brazil

Copper oxide semiconductors are the most prominent catalyst for CO_2 electrochemical reduction. In recent years, a myriad of properties has been arising from new combinations between distinct nanomaterials. The superficial decoration of copper oxide with noble metal nanoparticles presents plasmonic synergistic effects resulting from local crystalline structure perturbation. In this way, different characterization methods of materials can be used to elucidate the structural, electronic, and optic properties of nanomaterials. In this work, we combined these three approaches to understand the role of the addition of plasmonic gold nanostructures to semiconductive copper oxide microcubes. The green synthesis of nanomaterials is an important factor. This way, we used a $CuCl_2$ salt in basic medium and later a soft reductant addition. To add the Au nanoparticles, we added a Au^{3+} solution and due to the reduction potential of Cu_2O being lower than gold, nanoparticles are naturally formed. On our SEM images of synthesized nanoparticles, we observed that Cu_2O nanoparticles have a well-defined cubic shape and flat surface and mean size of 536.40 nm ± 179.41 nm. Also, the gold addition to the Cu_2O nanoparticles does not change its shape but creates a rugous surface with size distribution of rough structures of about 35.47 nm ± 9.38 nm. EDS analysis of Au-Cu_2O confirms that this roughness can be attributed to gold nanostructures. A XPS analysis shows that on Cu_2O the surface is composed of Cu^0 (931.1 eV), CuO (934.2 eV) and Cu_2O (932.5 eV) while Au-Cu_2O surface is composed by CuO (932.0 eV) and Cu_2O (932.4 eV) due to copper oxidation on gold presence. To understand about the crystalline structure of our materials, we used a XRD analysis which shows very sharp peaks for both materials, indicating a monocrystal behavior. The peaks present in Cu_2O sample can be attributed to Cu_2O cubic (ICSD: 98-062-8621) with the main facet (111). The addition of gold to the Cu_2O does not change the crystallinity but we observed the arising of peaks attribute to gold structures (ICSD: 98-016-3723). These results are consistent with the SEM images and show the success of the proposal synthesis. Cyclic voltammetry was performed to understand the electrochemical behavior of materials and shows a reduction event occurring at -0.40 V on Cu_2O sample, which can be associated with the reduction of Cu^+ to Cu^0 (-0.36 V). On Au-Cu_2O, the voltammogram does not show the -0.40 V event, but a new event is observed at - 0.90 V. The presence of gold on the surface could protect the Cu^+ on the surface by the spillover effect. When oxygen atoms are adsorbed on the catalyst surface, the gold structure act as an electron source reducing O_2 to active species. Electronic properties were analyzed by UV-vis-NIR showing two bands of Cu_2O in 506 and 651 nm and 624 nm for Au-Cu_2O, there were no observed gold plasmonic bands for Au-Cu_2O but a broad shoulder on the infrared region. Dark field microscopy data shows the optical properties. Two bands with a maximum at 488 and 583 nm are attributed to Mie resonance of copper oxide. When gold is added to the Cu_2O bands positions change to 476 and 623 nm, respectively. According to the literature, gold nanoparticles around 40 nm have a $\lambda_{scattering}$ at 500 nm. Applying potential from 0.00 V to -0.80 V (vs. Ag/AgCl), we observed that Cu_2O sample does not present changes in the spectral pattern, however on Au-Cu_2O, as more cathodic the applied potential, the higher the intensity of 476 nm band. To apply a negative potential to a metallic structure means to inject electrons on its Fermi level, dislocating it to a different energy. Combining these results with Raman spectroscopy in different potentials, we observed changes in position and intensity for Cu_2O bands. Thus, our hypothesis is that gold nanoparticles cause distortion on Cu_2O crystalline lattice, favoring electronic density on gold nanostructures rather than a distribution over the surface.

Imaging of Photoinduced Electrochemiluminescence at Hematite (α-Fe_2O_3) Photoanodes TaeyoonKim, JoohoonKim, SungeunHan and MisolHwang; Department of Chemistry, Kyung Hee University, Korea (the Republic of)

We study intuitive observation of electrochemical reactions through images obtained from photoinduced electrochemiluminescence (PECL), which combines light-addressable electrochemistry (LAE) and electrochemiluminescence (ECL). LAE provides information about electrochemical reactions through photogenerated carriers. In this study, we used stable hematite (α-Fe2O3) as a photoanode in an aqueous solution. Hematite has the advantage of obtaining a high spatial resolution due to the short diffusion distance of the minority carrier. By comparing the images of ECL and PECL, it was confirmed that the onset potential in PECL was lower. Using this method, we were able to observe that photogenerated carrier induces additional ECL reactions. Additionally, we used a digital mirror device (DMD) that allows for the flexible controllability of the light illumination shape of and confirmed the matching of the illuminated area and the ECL emission area. Furthermore, we propose the potential application of PECL imaging for characterizing the properties of single nanorods.

Operando Diffraction Technique to Investigate the Electrochemically Deposited Mg Interface ShengqiFan[1] and NiyaSa[2,1,3]; [1]Indiana University Bloomington, United States; [2]Argonne National Laboratory, United States; [3]University of Massachusetts Boston, United States

Shengqi Fan[1], Niya Sa[1]
University of Massachusetts Boston[1]
Magnesium (Mg) has gained significant attention as a potential candidate for high-performance energy storage systems due to its high volumetric capacity and abundance. However, the practical implementation of Mg-based batteries faces challenges stemming from a limited fundamental understanding of the Mg electrodeposition/dissolution process. The complex crystallographic structure evolution at the deposited Mg interface during electrochemical cycling plays a crucial role in the performance and durability of Mg batteries. In this study, we present an in-situ X-ray diffraction technique that enables real-time monitoring and characterization of the electrochemically deposited Mg interface. By analyzing the diffraction patterns obtained under various applied voltages, we have obtained valuable insights into the dynamic changes in peak positions and the lattice parameters at the electrode surface during Mg deposition and dissolution. Our findings could potentially contribute to the development of optimized electrolyte formulations and improved electrochemical cell designs for Mg-based batteries.

8:00 PM CH01.08.14

Importance of Interface Engineering Between the Hole Transport Layer and the Indium-Tin-Oxide Electrode for Highly Efficient Polymer Solar Cells SujungPark[1], FebrianT. Wibowo[2], NarraV. Krishna[2], JihoRyu[1], HeunjeongLee[1], JinheeLee[3], Yung JinYoon[2], Jin YoungKim[2], Jung HwaSeo[3], Seung-HwanOh[4], Sung-YeonJang[2] and ShinukCho[1]; [1]University of Ulsan, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]University of Seoul, Korea (the Republic of); [4]Korea Atomic Energy Research Institute, Korea (the Republic of)

In early studies on organic solar cells with high conductivity PEDOT:PSS, the contact between ITO and PEDOT:PSS was considered ohmic. However, because low-conductivity PEDOT:PSS (such as AI4083) is mainly utilized in contemporary solar cells, the contact between ITO and PEDOT:PSS is not ohmic anymore. Despite the high possibility that there are serious interface problems, little attention has been paid to the interface between PEDOT:PSS and ITO. Most of the previous studies of interfaces in organic solar cells have focused on the interface between the active and charge transport layers. In this work, we have employed a conjugated polyelectrolyte that uses potassium poly[9,9-bis(3′-sulfonatopropyl)fluorene-alt-(9-(2,7-diethylheptyl)-carboazole)] (WPFSCz-) between ITO and low-conductivity PEDOT:PSS to overcome complicated organic-inorganic interfacial problems. The insertion of the WPFSCz- layer provides substantial advantages in the operation of polymer solar cells. First, the inserted WPFSCz- layer modifies the work-function of ITO, thereby forming an effective cascading energy alignment, which is favorable for good hole transport. Second, the introduction of the WPFSCz- layer eliminates interfacial trap sites. The reduction in traps reduces recombination losses at the interface, resulting in an improvement in the fill factor. These effects result in a significant increase in the efficiency of non-fullerene solar cells based on PM6 and Y6, from 15.86 to 17.34%. In addition, we have found that the problem of the interface in contact with ITO occurs not only in PEDOT:PSS, but also in oxide-based charge transport layers. We have confirmed that the insertion of the WPFSCz- layer between ITO and a MoO_3 (or ZnO) charge transport layer shows the same positive results.

8:00 PM CH01.08.15

Impact of Morphology Change on Hole Transfer Dynamic During Charge Separation Process DongchanLee[1,1], JihoRyu[1], SebinKim[1], Chang-MokOh[2], In-WookHwang[2] and ShinukCho[1,1]; [1]University of Ulsan, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)

Although it was clearly elucidated that the change in the overall bulk-heterojunction (BHJ) morphology of PM6:Y6 induced by the difference in solvents results in a performance variation in the entire solar cell. The charge dynamics during the charge separation process induced by morphological changes have not yet been deeply studied. Based on mobility and photocurrent related studies, it was inferred that holes were deeply involved in these charge generation and separation processes. The decrease in exciton dissociation probability observed in the PM6:Y6 solar cell fabricated using CB (PM6:Y6-CB) was found to be due to the change in hole transfer state caused by morphological changes. For the PM6:Y6 solar cell fabricated using CF (PM6:Y6-CF), it was determined that the density of state (DOS) of effective hole transfer state ($^hE_{CT}$) was small, as $^hE_{CT}$ and Y6 HOMO were almost degenerate, and the lower $^hE_{CT}$, which can interfere with hole transfer, was also formed minimally. However, for PM6:Y6-CB, the overlapping region of $^hE_{CT}$ and highest occupied molecular orbital (HOMO) of Y6 shifted towards the lower energy side (upper $^hE_{CT}$) and a lower effective $^hE_{CT}$ that can act as a defect was significantly formed. These facts obtained by EL deconvolution were clearly confirmed in time-resolved photoinduced absorption spectroscopy. As a result, it is concluded that the decrease in fill factor (FF) and current density (J_{SC}) in PM6:Y6-CB is due to the degradation of hole transfer from Y6 HOMO to PM6 HOMO, which is analyzed as the morphological changes in non-fullerene acceptor (NFA) solar cells affect the formation of hole transfer levels, which in turn affects the charge separation efficiency.

8:00 PM CH01.08.16

Characterization of Ag_3BiI_6 Rudorffite Absorber for Ambient-Air-Stable, Lead-Free and Efficiency Solar Cells Through Scanning Kelvin Probe Analyzer Ming-ChungWu[1,2], Kai-ChiHsiao[1], Yin-HsuanChang[1], Jia-MaoChang[1] and Ting-HanLin[1]; [1]Chang Gung University, Taiwan; [2]Chang Gung Memorial Hospital at Linkou, Taiwan

Perovskite solar cells, renowned for their exceptional power conversion efficiency (PCE), hold promise as a sustainable and renewable energy solution. However, the utilization of lead-based absorbers in these cells raises significant concerns due to the toxic nature of lead. Their stability in ambient conditions is also a challenge should be overcome for their further development. To

address these issues, we investigated the feasibility of adopting a novel lead-free material, Ag_3BiI_6 rudorffite absorber, as an alternative active layerto replace the conventional lead-based perovskite absorber.**[1,2]** Ag_3BiI_6 rudorffite absorber layer is prepared by using a large scalable thermal-assisted doctor blade coating methodAs a novel light absorber layer, realizing the localized work function of Ag_3BiI_6 helps to optimize the energy level in its device. In this study, we employed a scanning Kelvin probe analyzer (KP Technology, SKP 5050), equipped with red, green, and blue LED light sources with a total power of 300 mW, to measure the constant potential difference (CPD) and investigate the local work function of the Ag_3BiI_6 rudorffite absorber. The scanning Kelvin probe analyzer, a highly sensitive and non-contact scanning probe technique, allows us to assess the light response of the absorber layer by measuring the light-induced CPD under different wavelengths. The CPD of the absorber layer serves as an indicator of the light response of Ag_3BiI_6 rudorffite, providing insights into its performance when exposed to various incident light. With assistance of Kelvin probe analyzer, we optimized the energy level alignment between the carrier transporting layers and the Ag_3BiI_6 rudorffite absorber layer, resulting in an improved PCE of doctor-bladed devices from 2.06% to 2.77%. Taking advantages of band alignment, these devices retain 90% of their initial PCE over 3,000 hours in ambient without any unencapsulation. Moreover, the scalability of our approach is also demonstrated and the device with an active area of 1.00 cm^2 achieves a PCE of 2.03%.**[3]** In summary, our study highlights the potential of Ag_3BiI_6 rudorffite as a viable substitute for lead-based perovskite absorbers in solar cells. Its superior environmental safety, stability, and scalability make it an attractive candidate for the development of sustainable energy technologies.

Tracing Electrochemical Charge-Carrier Insertion into Vanadium Oxide Cathode in Aqueous Zinc-Ion Batteries ChangminLee, DonghoKim, YoungjaeHong, YounghwanLim and Sung-YoonChung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

With growing concerns regarding the safety and cost issues of Li-ion batteries, extensive research is focusing on suitable alternatives. Among the candidates, aqueous electrolyte-based batteries have recently gained significant attention due to their non-flammable nature compared to organic electrolytes. As a water-based solution is utilized as the electrolyte, the role of protons, in addition to the primary redox charge carriers inserted in cathode materials, has become a crucial scientific issue in the field of aqueous battery research. Especially, under low-pH conditions, i.e., highly acidic electrolyte, the presence of protons becomes significant, potentially affecting the overall capacity and redox potential. Despite numerous studies investigating proton insertion into oxide cathodes, there is a lack of clear interpretations regarding the intercalation behavior. Therefore, to comprehensively understand the ambiguous role of protons in cathode materials within aqueous rechargeable batteries, it is essential to conduct systematic investigations covering a wide range of proton concentrations.
Herein, we investigate the behavior of inserted charge carriers in V_2O_5 cathode oxide in two different cell types. In the presence of sufficient proton supply, such as beaker-cell configuration, the pH of the electrolyte influences the insertion process. Under low-pH conditions, we found that protons are inserted into the cathode before Zn ions. Otherwise, under high-pH conditions, Zn-ion serves as a major charge carrier, while the impact of protons on discharge voltage or capacity becomes less significant. To validate the generality of our hypothesis, we also demonstrate similar pH-dependent behavior in Na-, Mg- and Al-ion electrolytes. We established this mechanism through the integration of various analytical techniques. X-ray photoemission spectroscopy (XPS) spectra reveal valence state change of cathode materials and energy dispersive X-ray spectroscopy (EDS) elemental mapping directly visualizes and quantifies the Zn-ion and proton insertion. By employing a combination of X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) spectra, we gain insights into the overall oxidation state changes and bonding length alternations as a result of carrier-ion insertion. Furthermore, we examined the influence of electrolyte volume by adopting a coin-cell configuration. In this type of cell with a relatively small volume of acidic electrolyte, a substantial influence of protons observed in the low-pH beaker-cell test was not identified. Based on the aforementioned results, we conclude the proton contribution to discharge capacity is only significant when a sufficient amount of highly acidic electrolyte is utilized.

8:00 PM CH01.08.18

Zinc-Bridged Lithium on Carbon Nanofibers for Enhancing Anode-Free Li-Metal Battery Performance IlgyuKim[1], HoJinLee[1], SuhyeonLee[2], SangjoonKim[2] and Ji-WonJung[1]; [1]University of Ulsan, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

With the introduction of the "Anode-Free" concept in Li-metal batteries, various studies have been conducted to address the chronic issue of irreversible cycle performance caused by Li dendrite growth. To this end, here we synthesized a Zn-deposited carbon nanofiber (Zn-CNF) composite using thermal shock synthesis to employ as the Li-Metal battery anode. By incorporating Zn as an electrodeposition catalyst, we achieved a remarkably low Li nucleation overpotential, promoting homogeneous Li growth on the CNF substrate and limiting Li dendrite formation. This was confirmed through half-cell and symmetric cell plating-stripping tests and full-cell galvanostatic tests. Furthermore, morphological and chemical analyses, including Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM), were conducted to elucidate the structural and compositional properties of the synthesized materials

Non-Destructive Steady-State and Time-Resolved Photoluminescence (TRPL) Characterization of Photovoltaic Devices ChristianOelsner, VolkerBuschmann, EugenyErmilov, BitaRezania, FelixKoberling and RainerErdmann; PicoQuant GmbH, Germany

Over years, (time-resolved) photoluminescence spectroscopy (TR)PL has been established as one of the fundamental methods for analyzing the photophysical properties of a wide variety of samples, ranging from organic molecules to semiconductor materials and photovoltaic (PV) devices. The combination of luminescence spectral and lifetime information provides a better understanding of photophysical processes and their dynamics in PV materials. This understanding can be further enhanced by including spatial information.

Herein, we will demonstrate that the combination of time-resolved laser scanning microscopy and PL spectroscopy provides a powerful characterization tool. This combination allows mapping of a broad range of phenomena including TRPL, carrier diffusion, SHG/2PE, wavelength and power dependent emission with high spatial resolution, for various sample geometries e.g., thin films. Therefore, one can infer structural-to-photophysical relationships in new classes of PV materials which ultimately leads to the optimization of the PV device performance.

Time-Resolved Concentration Profiling of $LiPF_6$ in EC:EMC Electrolytes in Lithium Ion Batteries ConorPhelan, GregoryJ. Rees and RobertWeatherup; Department of Materials, University of Oxford, United Kingdom

Liquid phase electrolyte lithium-ion batteries (LIBs) typically consist of a lithium salt dissolved in a mixture of cyclic and linear alkyl carbonates. Continuum models typically treat the electrolyte co-solvents as a single variable, dubbed the "single-solvent approximation" . However, recent work in the area has called the validity of this asumption into question [1]. Herein, we develop a new continuum model to describe the dynamics of multicomponent electrolyte solutions and directly compare model predictions with experimentally measured concentration profiles which can be obtained using potentiometric magnetic resonance imaging (MRI) [2] and Raman spectroscopy [3] to investigate the validity of this significant assumption. The developed model is applied to a 1M LP57 type electrolyte (1 M LiPF6 in EC:EMC v%:v% 3:7) to better understand the salt and solvent dynamics in commercial LIB electrolytes. This demonstrates that EC and EMC show distinct concentration gradients, challenging the validity of the "single-solvent approximation" which has been widely used to this point in LIB modelling. The developed model was parameterized solely using classical MD simulations for a 1M LP57 type electrolyte. The effects of electrolyte solvation structures are manifested on the continuum scale. Most notably effects arising from Li^+ ion solvation by EC and EMC molecules are observed. A dragging effect is observed on solvent molecules due to the motion of the Li^+ ions they solvate, which influences the concentration gradient of the solvent molecules under an applied current. The concentration gradients of both the solvent molecules and salt ions influence the composition of the solid-electrolyte interphases that form in LIBs, making the understanding of how these gradients change under applied currents of crucial importance. These results have provided fundamental insight into how the solvation structure of commercial LP57 electrolytes affects the transport properties and concentration gradients of the electrolyte components, which will inform the development of improved electrolytes for LIB applications.

Enhancing Next-Gen Photovoltaic Cells: Unveiling Optoelectronic Properties through Hyperspectral Imaging Laura-IsabelleDion-Bertrand[1], FelixThouin[1], ChristofSchultz[2], BertStegemann[2] and César OmarRamirez Quiroz[3]; [1]Photon etc., Canada; [2]University of Applied Sciences – HTW Berlin, Germany; [3]FOM Technologies, Denmark

In recent years, the photovoltaics scene has undergone significant transformations, resulting in an unprecedented diversity of solar materials. Despite recent advancements, the widespread commercialization of most emerging technologies remains challenging. This can be partly attributed to material inhomogeneities and the difficulties associated with up-scaling. One specific aspect that requires attention to bridge the cell-to-module gap while maintaining high efficiencies in both CIGS and perovskite-based solar cells, is the laser patterning process for series interconnections of cells. It is crucial to establish control over the underlying process of P1, P2, and P3 laser ablation lines and identify any associated power losses.

The optimization of a solar cell fabrication process, including the laser ablation process, requires high-performance and specialized measurement systems. To address this demand, Photon etc, in collaboration with IRDEP (Institute of Research and Development on Photovoltaic Energy), has developed a global hyperspectral imaging platform (IMA™) for solar cell analysis. This platform provides rapid acquisition of photoluminescence (PL), electroluminescence (EL), and absorbance maps. Most luminescence imaging characterization techniques provide data in arbitrary units, which limits their interpretation because of the lack of information. With this challenge in mind, researchers at IRDEP have designed a method for spectral and photometric calibration [1]. This technique has been implemented in Photon etc.'s platform and allows obtaining the absolute number of photons emitted at a specific energy from every point on the sample's surface. By performing this calibration, researchers can further investigate Planck's law to access the quasi-fermi level splitting (QFLS) [2].

In this framework, we combined global hyperspectral imaging with absolute calibrated photoluminescence to extract spatial distribution of several optoelectronic of triple cation perovskite ($Cs_{0.05}(FA_{0.79}MA_{0.16})_{0.95}PbI_{2.49}Br_{0.0,51}$), CIGS ($Cu(In_x,Ga_{1x})Se_2$) [3] and CIGS/perovskite tandem solar cells patterned with ns and ps laser pulses. Maps of the PL quantum yield (PLQY), effective QFLS, open circuit voltage (V_{oc}), Urbach energy (E_u), optical diode factor (ODF), and shunt resistance (R_{sh}) were obtained. These mappings provide insights that help determine the optimum process window for patterning. Moreover, this hyperspectral imaging system enables selective excitation and characterization of the bottom cell (CIGS) and the top cell (perovskite). This capability allows a spatially resolved detection and analysis of the laser-induced defects at each individual patterning step, thereby enabling conclusions to be drawn regarding the specific effects on each sub-cell.

Fabrication of ZnV_2O_4 Nanoparticles Embedded in Carbon Nanofibers as a Cathode Material for High-Performance Aqueous Zn-Ion Batteries Jeong-HoPark, IlgyuKim, Na yeongKim, SubinLee and Ji-WonJung; University of Ulsan, Korea (the Republic of)

Recently, lithium-ion batteries have led the related market. However, the price of Li is expected to increase continuously, leading to unbalance of demand and supply for LIBs used for electric vehicles (EVs) and energy storage systems (ESS). For replacing LIBs, electrically rechargeable aqueous zinc-ion batteries (ZIBs) have been spotlighted due to Zn's attractive properties, such as being environmentally friendly, low price, and high stability. Nevertheless, the low capacity of ZIBs is attributed to low-capacity cathode material, restricting their practical utilization. To increase the capacity of ZIBs, ZnV_2O_4 containing the Zn element has recently been considered. However, the ZnV_2O_4 cathode developed so far shows various problems of low electronic conductivity and low surface area limiting reactionsites. Here, we suggest ZnV_2O_4 nanoparticles embedded in carbon nanofibers (ZVO@CNFs) as a promising cathode material for ZIBs. The ZVO@CNFs were synthesized using the electrospinning process and heat treatments, including stabilization and carbonization. The fabricated ZVO@CNFs were investigated by SEM, TEM, XRD and XPS to confirm how can the ZVO nanoparticles form inside. In addition, Raman analysis was conducted to know the composition of ZVO@CNFs and crystal lattice information and EA analysis was carried out to obtain wt% of ZVO in the CNFs. The ZIB cell with the ZVO@CNFs was evaluated for its feasibility. Charge and discharge tests and rate tests were conducted and CV(Cyclic Voltammetry) test was conducted to determine the voltage window, reversibility, and impurities in the system where the redox reaction occurs.

X-Ray Elemental and Crystalline Phase Distribution Analysis of the Process to Produce Hydrogen and Ammonia from Iron and Carbonated Water HiromiEba[1], YagiHayao[1], TianLiu[1], NorikaNakazawa[1], KeiichiFukami[1] and KenjiSakurai[2]; [1]Tokyo City University, Japan; [2]Imaging Physics Laboratory, Japan

Currently, hydrogen energy is attracting much attention as a clean and sustainable energy alternative to fossil fuels, and the demand for hydrogen fuel used in fuel cell vehicles is expected to increase. We focused on the hydrogen (H_2) production through the reaction of Fe metal obtained from scrap iron with carbonate water (CO_2 and H_2O) [1]. Ammonia (NH_3) is also an important raw material for nitrogen fertilizers used in agriculture, and it has been identified as a potential hydrogen carrier in recent years. However, NH_3 is mainly synthesized by the Haber–Bosch process, which requires high temperature and pressure. To lower the environmental burden, it is necessary to achieve NH_3 synthesis under milder conditions. Therefore, we investigated the production of NH_3 ammonia from iron nitride (Fe_4N) and carbonated water at ambient temperature and pressure [2].

The reaction mechanism was understood to be a redox reaction of hydrogen (H) derived from water molecules carried by carbonic acid (H_2CO_3 and HCO_3^-) with Fe to ionize Fe and produce H_2. When iron nitride was used as the raw material, NH_3 was formed by reaction with N. CO_2 promoted the reactions, allowing them to proceed at lower temperatures, and was absorbed and immobilized as iron carbonate ($FeCO_3$). Since the reaction involved solid, liquid, and vapor phases, analysis of each phase was conducted. In particular, we analyzed the distribution of elements and crystal structures, considering that it is important to observe the electrochemical reaction on the solid phase surface, i.e., the corrosion phenomenon of iron material.

We have developed a non-scanning X-ray fluorescence (XRF) imaging setup that enables rapid observation of elemental distribution using a projection-type configuration and a two-dimensional detector [3]. 2D spatial XRF image is acquired in a single shot, and temporal changes in the distribution can be obtained by repeating the imaging step.

For the analysis of specific mini-regions, a confocal X-ray setup was constructed [4]. The first polycapillary focusing optic was used as the X-ray incident channel and the second polycapillary focusing optic was used as the X-ray detection channel. The focal points of both overlap, and the X-ray signal from the confocal can be observed. Using this confocal X-ray optics, the measurement was repeated while scanning the sample on the XYZ stage. A 3D scan of the sample through the confocal provides a spatial distribution of the components that make up the sample. Both the projection and confocal setups are not limited to the XRF analysis, but can be applied to other X-ray analyses as well: by detecting X-ray diffraction (XRD) signals, distribution images of crystalline phases can be obtained. In the presentation, we will report the results of the observation of the reaction processes as changes in XRF and XRD distributions using these setups.

Polarization-Induced Inversion of Singlet and Triplet Excited States: Towards New Photocatalytic and Optoelectronic Materials JaeyuneRyu[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Harvard University, United States

The phenomenon of inversion between singlet and triplet excited states (INVEST), which runs counter to Hund's rule, holds great potential for revolutionizing the mechanisms underlying photocatalysis and optoelectronics. Despite the recent theoretical advancements in understanding this phenomenon, there is a dearth of experimentally feasible approaches for implementing INVEST, which impedes its systematic integration in future applications. This work presents a compelling instance of INVEST that is prompted by environmental polarization effects. By utilizing a simple heptazine molecule as a model chromophore, we demonstrate the switching of the delayed fluorescence mechanism from the conventional thermal activation to one that involves INVEST upon phase transition of solvents. The freezing medium alters the local electrostatics surrounding the chromophore, as evidenced by the observed luminescence rigidochromic shift, which leads to the reversal of the relative spin energetics as measured by temperature-dependent time-resolved PL kinetics. Our preliminary computation suggests that there may exist a differential polarization effects on singlet and triplet excited states as they possess disparate polarity. Ultimately, this work lays a new mechanistic foundation for utilizing local polarization to achieve INVESTThe phenomenon of singlet-triplet inversion, which defies Hund's rule, holds tremendous potential for revolutionizing the mechanisms underlying photocatalysis and optoelectronics.

Characterization and Identification of Precipitates Formed on the Cathode Surface in Static Zn-Br Battery DongrunJu and DanSteingart; Columbia University, United States

Static zinc-bromine batteries (ZBBs) are a promising and low-cost grid electrochemical energy storage device for energy generation shifting to the use of renewable energy. The sacrifice of an externally forced flow source and membranes in the cell design lowers the battery manufacturing cost but leads to long-term cycling fading. Specifically, an unknown precipitation reaction at the cathode surface during charging forms a thin solid film raising the charge transfer resistance and lowering cycling efficiency and capacity. For the first time, the precipitate was characterized and identified as an insoluble polycrystalline zinc hydroxide bromide hydrate (ZHB) with a layered structure. By investigating the influence of different compositions and concentrations of electrolytes and charging conditions, we proposed that pH variation of electrolytes caused by electrolyte concentration polarization during charging are the immediate factors contributing to ZHB precipitates. In addition, in the long-term cycling, hydrogen and bromine loss also indirectly contributes to irreversible precipitation. In turn, optimization cycling protocols and control of pH are key to suppressing the formation of the precipitate. Overall, understanding and addressing long-term cycling fading is crucial for the advancement of rechargeable battery technologies, allowing for improved performance, extended cycle life, and enhanced reliability in grid energy storage systems.

T-SEM EDS and TKD Combined for Elemental and Crystallographic Analysis. MeikenFalke, PurveshSoni and RobertBrandom; Bruker, Germany

To understand the behavior of any nanostructure, analysis of the chemical composition and its arrangement on the nanoscale is vital. We demonstrate the combination of energy-dispersive X-ray spectroscopy (EDS) and transmission Kikuchi diffraction (TKD) in SEM for studying the elemental composition and crystallographic properties of solar cell materials prepared as FIB lamellae. We show that achieving useful results at nanometer scale in a suitable amount of time in SEM, not STEM, is possible by combining on-axis TKD [1] with an annular EDS detector [2] and specimen preparation by FIB. The results are quantitative element maps and line profiles combined with crystal phase and orientation distribution in the absorber and buffer layers of CIGS solar cells investigated in SEM.
The annular EDS detector is placed horizontally between the specimen and the pole piece achieving a solid angle for X-ray collection of about 1 steradian enabling high count rates also in case of low X-ray yield, for example from thin lamellae, light elements and during fast scanning of beam sensitive and/or large specimens. The annular arrangement of the active SDD quadrants parallel to the specimen surface around a central aperture to pass the electron beam enables a high take-off angle as well, minimizes absorption effects and allows the analysis of rough topography or bent specimens. This geometry is easily combined with diffraction pattern acquisition using a detector directly underneath the specimen.
Quantitative EDS of electron transparent lamellae can deliver element distribution and even the specimen thickness, the latter if applying the EDS Zeta-factor method [3]. Crystallographic grain phase, size and orientation are accessible via TKD. The combination of crystallographic and chemical information on the nanoscale via TKD and EDS is particularly promising for correct quantitative analysis. Small grains can lie in front of each other and produce mixed diffraction patterns. Therefore, to interpret grain size and orientation from TKD correctly, the lamella thickness must be known. Lamella thickness can be determined using sample tilt in the FIB which also enables calibrating the Zeta-factors for successful quantitative chemical analysis.

Testing Microscopic Theories of Electric Field Fluctuations Over Metal Films VirginiaE. McGhee, ChristopherPetroff, KonradHedderick, LaraA. Estroff, RogerF. Loring and JohnA. Marohn; Cornell University, United States

Stochastic electric and magnetic fields are present near metal surfaces. These fluctuations can have a number of experimental consequences. They can lead to extraneous friction and frequency noise in scanning probe experiments, limiting the achievable force sensitivity. They can furthermore result in decoherence in nitrogen vacancy center and ion trap quantum computing experiments. The theoretical description of these fluctuations is a topic of active research.[1–3] To test these theories we are carrying out measurements of electric field fluctuations over thin metal films at room temperature in high vacuum. In these experiments we infer the height dependence of stochastic electric fields and electric field gradients, from measurements of non-contact friction and frequency noise, respectively. This data can be used to decide among competing theories – are the stochastic electric fields caused by dielectric fluctuations of surface adsorbates or thermal fluctuations of electrons in the underlying metal? The study of electric field fluctuations could be a powerful tool for probing the electronic structure of quantum materials.

Methodology for Measuring 1/f Noise in Thin Film Piezoelectric Devices for Energy Harvesting and Sensor Applications KevinKam, ChristineMcGinn, OliverA. Durnan, QingyuanZeng and IoannisKymissis; Columbia University, United States

Polyvinylidene difluoride-trifluoroethylene (PVDF–TrFE) thin films have been utilized as a flexible sensing and energy harvesting material due to their piezoelectric capabilities [1]. A common use of PVDF-TrFE is in the development of acoustic sensors. Previous literature has reported applications as a microphone for cochlear implants [2] and as piezoelectric energy harvesters [3]. For these applications, it is important to understand the electrical noise generated by the device to accurately determine its noise floor, as it is the primary factor in determining critical sensor metrics like limit of detection and signal to noise ratio (SNR).
The primary challenge in measuring noise in an acoustic MEMS system is the normalization of the noise floor. PVDF thin films are constantly vibrating, even without external input, due to its flexible and deformable nature. Small fluctuations in the acoustic and electronic environment can then make drastic changes in the noise floor, impacting the accuracy of the overall sensor or system.
In this work, we are interested in characterizing the noise current generated by the sensor due to the underlying properties of the material in the absence of external interference. This measurement is useful in providing a more accurate noise budget and electrical model to aid in the design of interfacing circuitry. Proper characterization of noise allows for the rigorous quantification of SNR and minimum detectable signal amplitude which are important metrics for any sensor.
The metrology system has three main components, 1) an insulated, anechoic chamber made with thick metal walls to reduce acoustic and electromagnetic interference 2) an SRS low-noise pre-amplifier to amplify the generated noise current 3) a spectrum analyzer, to measure the noise spectral density of signals in the range 40 Hz to 25 kHz. Together, these components provide a low-noise measurement environment suitable to study intrinsic noise generation.
To test the efficacy of the system described above, a printed PVDF-TrFE device described in [4] was measured. Before any noise measurements were taken, the test device's capacitance was measured. Likewise, its output voltage over time when exposed to acoustic stimulation was recorded using an ADMET Universal Testing System with readout electronics designed in [4]. These measurements affirm that the device acts as a capacitive piezoelectric acoustic sensor. Finally, once the devices were characterized, they were placed in the chamber and the current noise measurements were taken in the 40 Hz - 25 kHz band.

8:00 PM CH01.08.29
$CaFe_2O_4$-Type Post-Spinel Host Compounds as Mg Battery Cathodes PatrickP. Ding[1], JohnT. Vaughey[2], G.J. Snyder[1] and KennethR. Poeppelmeier[1]; [1]Northwestern University, United

States; [2]Argonne National Laboratory, United States

The development of an Mg battery promises a high energy density at a low material cost. A primary roadblock for Mg batteries is the identification of a cathode material with sufficient kinetics and stability. Previous first-principles calculations have suggested a low migration barrier for Mg^{2+} in host compounds with the $CaFe_2O_4$ (CF) structure. In this work we experimentally investigate the electrochemical properties against Mg metal of several lithium post-spinel compounds with the CF structure including $LiVTiO_4$, $LiCrTiO_4$, $LiMnSnO_4$, and $LiFe_{0.5}Ti_{1.5}O_4$. To open the tunnels for Mg intercalation, the lithium post-spinels are chemically delithiated with Br_2/acetonitrile prior to electrochemical characterization. Structural characterization of the delithiated cathode materials is carried out including powder x-ray diffraction, scanning electron microscopy, and solid-state nuclear magnetic resonance spectroscopy. The capacity, potential, and stability of the cathode materials are detailed along with a consideration of the interactions of the Mg anode/cathode with the $Mg(TFSI)_2$-based electrolyte. From these results and a comparison of the Mg cathode performance with the performance of the lithium post-spinels as lithium battery cathodes, we further our understanding of the CF structure as a monovalent and multivalent intercalation host.

8:00 PM CH01.08.31
SNDM Study on Cubic and Hexagonal Epitaxially Stacked SiC MOS Interfaces YasuoCho[1], HiroyukiNagasawa[2], MasaoSakuraba[1] and ShigeoSato[1]; [1]Tohoku University, Japan; [2]CUSIC Inc., Japan

The layer structure of 3C-SiC(111) stacked on 4H-SiC(0001) is expected to be effective in reducing the specific on-resistance (R_{on}) of power MOSFETs operating at high voltages. This is because the channel is formed in the 3C-SiC layer, which shows low interface density of sate (D_{it}) at interface with SiO_2, and the depletion region extends toward the 4H-SiC layer with high breakdown electric field.
Recently, the simultaneous lateral epitaxy (SLE) method, in which 3C-SiC and 4H-SiC are grown transversely at the same time, has been proposed as a technique for fabricating this structure and has attracted much attention[1].
However, there was no specific study that experimentally evaluated D_{it} at the MOS (SiO_2 /SiC) interface on the SiC layer grown by SLE and verified the effect of 3C-SiC (111)/4H-SiC (0001) structure with simultaneously formed SiO_2 oxide film on the MOSFET performance.
On the other hand, we have studied the evaluation of the SiO_2/SiC interface using scanning nonlinear dielectric constant microscopy (SNDM) and reported that the relative standard deviation (RSD), which is the signal fluctuation (standard deviation) in the SNDM image (d*C*/d*V* image) normalized by its mean value, can be used to evaluate D_{it} [2] and that the local deep level transient spectroscopy (DLTS) method using the time-resolved SNDM (tr-SNDM) method can quantitatively evaluate the two-dimensional distribution of D_{it} itself [3].
In this paper, by using these two techniques, we characterize MOS interfaces on epitaxially stacked 3C-SiC(111)/4H-SiC(0001) grown by SLE.

Nanoscale Fluctuation Analysis on Capacitance-Voltage Profiles of Semiconductors by Time-Resolved Scanning Nonlinear Dielectric Microscopy KoheiYamasue and YasuoCho; Tohoku University, Japan

Wide-bandgap semiconductors such as SiC, GaN, and diamond are promising materials for next-generation power devices. However, the performance of MOS devices using wide-bandgap semiconductors has not yet reached the level expected from their excellent material properties. For example, the on-resistance of 2-3 kV-class SiC MOSFETs is limited by low MOS channel mobility. Channel mobility is dominated by the quality of the dielectric-semiconductor interface such as SiO_2/SiC. To investigate the cause of low channel mobility from a microscopic perspective, we have proposed the application of scanning nonlinear dielectric microscopy (SNDM) to study dielectric-semiconductor interfaces. SNDM is a near-field microwave scanning probe microscopy method that is exceptionally sensitive to the change in capacitance between the conductive tip and the sample [1]. SNDM can detect the change in microscopic MOS capacitance when measuring a semiconductor wafer with gate dielectric top layer. In particular, time-resolved SNDM (tr-SNDM), an extension method of SNDM, has recently permitted the detection of rapid changes in local capacitance more accurately than conventional SNDM [2]. Tr-SNDM has therefore enabled local DLTS (deep level transient spectroscopy) and local CV (capacitance-voltage) profiling, which give nanoscale spatial resolution to DLTS and CV profiling [3].
Here we present a local CV profiling method based on tr-SNDM and application to the SiO_2/SiC interface [3]. We show how microscopic CV profiles are obtained by tr-SNDM and their nanoscale spatial fluctuations are analyzed in a real-space. Spatial fluctuations of local CV profiles reflect the potential fluctuations at the interface, or surface potential fluctuations. We apply our method to a SiO_2/SiC interface treated by NO-POA (post-oxidation-annealing). We extract feature values from the local CV profiles and their derivative (d*C*/d*V*-*V*) profiles to quantitively investigate the fluctuations of local CV profiles. By extracting the voltages at the infection points of local CV and d*C*/d*V*-*V* profiles, we can characterize the fluctuations of local CV profiles in depletion, accumulation, and intermediate regions. We found that the spatial fluctuations of local CV profiles are reduced by NO-POA (post-oxidation-annealing) treatment, as expected, but still larger than the thermal energy at room temperature (~26 meV) even in deep depletion region. This indicates the density fluctuations of fixed charges including the carriers trapped at the deep levels are high enough to create significant potential fluctuations at the interface. In addition, we found that fluctuations become higher as the interface are accumulated by the dominant carriers. This suggests that dominant carriers trapped to acceptor-type interface defects further increase the spatial non-uniformity of the interface. It is known that surface potential fluctuations are strongly related to the carrier transport properties of the channel. Therefore, our results suggest that high surface potential fluctuations may be the cause of low channel mobility in SiC MOSFETs. Our method can also be applied to other dielectric-semiconductor interfaces such as Al_2O_3/diamond and Al_2O_3/GaN and will give microscopic insights on these interfaces.

The New Strategy of the Gas Sensor Platform through Triboelectric Nanogenerator YujangCho, JaehyunKo and Il-DooKim; KAIST, Korea (the Republic of)

In the age of the Internet of Things (IoT), the significance of sensor devices that can operate independently through self-power sources has taken center stage. In this regard, the triboelectric nanogenerator (TENG), which is gaining attention as a renewable energy source, has been applied as a self-powered gas sensor by coupling it with a gas sensor. However, the existing TENG only serves as a power supplier for the gas sensor's minimal power requirements, making it challenging to apply it as a practical gas sensor while ensuring its continuity. Herein, we report on a self-powered multifunctional hydrogen gas sensor (SPMH-gas sensor) that utilizes a palladium-deposited polytetrafluoroethylene (PTFE) nanofiber-based membrane as the TENG friction surface, enabling sensing of hydrogen gas. The SPMH-gas sensor detects changes in voltage resulting from the movement of electrons during the conversion of mechanical energy into electrical energy, enabling effective sensing. The highly durable PTFE nanofiber substrate ensures stable sensor detection performance even under mechanical deformation. Moreover, it operates at room temperature and provides feedback on gas leakage through the spontaneously generated electrical energy. The change in output performance of the TENG according to the electron movement variation in the presence of gas exposure brings about expandability to various gases.

8:00 PM CH01.08.34
Explaining Concepts and Applications of Second-Order X-Ray Diffuse Scattering in Materials Characterization MauricioB. Estradiote, RafaelaF. Penacchio and SergioL. Morelhao; University of Sao Paulo, Brazil

X-ray diffuse scattering (DS) generally arises from any departure that structures have from a perfectly regular atomic lattice. In crystals, thermal DS is caused by scattering from lattice vibrations and provides valuable information about the lattice dynamics of materials. Historically, DS was the first tool to determine phonon dispersion relations experimentally [1]. With the advent of synchrotron radiation technology, it has reemerged as a feasible method for studying phonons in contrast with inelastic X-ray and neutron scattering that require complex experimental equipment, long acquisition times, and, in the case of neutron scattering, large single crystals [2]. However, high-flux synchrotron X-rays, approaching 10^{15} ph/s/mm^2, in addition to zero noise area detectors, have also revealed a relatively unknown 2nd-order DS process, first called diffuse multiple scattering (DMS) [3], which appears as a kind of Kikuchi lines [4] for monochromatic X-rays. In recent years, accidental observation of DMS lines has become increasingly frequent for high-flux synchrotron beamline users working with monocrystalline materials such as epitaxy-based nanostructured devices. Although DMS lines carry intrinsic 3D information on structural and vibrational properties of the crystal lattice, their predictability and

practical applications have been open to investigation for about a decade. In this work, we introduce the concept of bright and dark Bragg cones required to understand and describe DMS lines. The intensity distribution along DMS lines depends on the actual primary source of DS in the material, as demonstrated for isotropic DS plus truncation rod of a perfect semiconductor surface and a particular case of thermal DS in skutterudites [5,6] as obtained by first principle calculation. A survey is given on computer codes for 3D reciprocal space maps [7], thermal DS simulation, and prediction of the most visible and susceptible DMS lines.

Quantifying the Interface Delamination between Polymer Binder and Active Materials for High Energy Density Electrode Materials AkshayPakhare, MartinaBorges, AbdulrahmanAlfadhli, IgorBezsonov, AmitChanda and SivaNadimpalli; Michigan State University, United States

High capacity and durable Li-ion batteries is important for the advancement of electric vehicle and renewable energy technologies. Group IV elements such as Si, Ge, and Sn are promising alternatives as anodes in lithium ion batteries compared to the conventional graphite and these elements offer significantly higher theoretical capacities as compared to traditional graphite anode. However, these high capacity materials suffer from poor cyclic performance due to volume expansion (e.g. Si expands ≈ 300%) induced stresses and the associated electrode fracture. In a commercial composite electrode, such volume expansion also induces significant stresses at the interface between active (e.g. Si) particle and polymer binder; the binder holds the active particles together and enables successful operation of battery. The volume expansion of particles during cycling causes interface failure, leading to electrical isolation of active particle. This mechanism results in significant capacity fade in composite electrode batteries during cycling. In spite of the importance, no systematic study on the interface failure behavior exists at present. In this talk, we will focus on quantifying the interface fracture between the PVdF (a polymer binder) and Si. We have also measured the effect of thermal oxide (SiO_2) on the interface failure and quantified the interface degradation due to electrochemical cycling.

Hysteresis and Transient Behaviour in Current Voltage Measurements of Antimony Selenide Solar Cells Punchirala ArachchigeUdari Imalka Wijesinghe and OliverHutter; Northumbria University, United Kingdom

Antimony selenide (Sb_2Se_3) is an attractive light-absorber used in low-cost, non-toxic, earth-abundant thin-film solar cells with rapidly rising efficiency values. Currently, many n-type metal oxides have been investigated as buffer layers in Sb_2Se_3 solar cell architectures. Among them, titanium oxide (TiO_2) is commonly used as the buffer layer because of its significant optoelectrical properties. The current density−voltage measurement of Sb_2Se_3 solar cells in FTO/TiO_2/Sb_2Se_3/P3HT/Au configuration shows a hysteresis-like distortion that depends on the voltage scan direction, scan rate, scan range, and voltage bias conditions prior to measurement. The presence of hysteresis can significantly influence the photovoltaic properties of devices, which can overestimate or underestimate the accurate power conversion efficiency of solar cells. The fabricated solar cells showed a normal hysteresis where the forward scan result exhibits lower performance than the reverse scan under certain circumstances. We identify this phenomenon is caused due to charge carrier accumulation which may be because the capacitive charge is quickly discharged through charge separation. In addition, the accumulation of oxygen vacancies at the TiO_2/Sb_2Se_3 interface can reduce charge extraction, and at the same time, significantly accelerate the charge recombination at the interface, which also leads to unfavorable hysteresis. However, the hysteretic effects are not observed in devices utilizing alternative buffer layers like ZnO and SnO_2, suggesting that the buffer absorber interfaces have a significant effect on transients in Sb_2Se_3 absorber devices. Therefore, further improvements of Sb_2Se_3 solar cells are essential through careful surface engineering of existing TiO_2 or through a judicious choice of alternative interfacial layers.

Minimizing the Perturbation of the Applied Magnetic Field by Optimizing Solid-State NMR Probe Structures JasminSchoenzart[1,2], JohnStringer[2] and ThomasGennett[1]; [1]Colorado School of Mines, United States; [2]PhoenixNMR, LLC, United States

The NMR probe is likely the most specialized part of the NMR spectrometer with respect to the sample and is often the only component that needs to be exchanged when switching between different NMR samples (*e.g.* liquid, solids, gels) and experiments (*e.g.* static, spinning). It is essential that the probe locates the sample in the most homogeneous part of the magnetic field within the magnet, to allow for the best recorded spectra possible. In an ideal case, the probe itself would not perturb the applied magnetic field, yet effects of perturbation can be observed, which is why shimming of the probe is essential before every NMR experiment. In this work we want to present ways to minimize the perturbation of the applied magnetic field by optimizing solid-state NMR probe structures. This is achieved by a combination of simulations and experiments, which take susceptibilities of all parts in the NMR probe into account to then study the net effect upon the sample. Based on those results, modifications to NMR probes can be made, to minimize unwanted contributions. The smaller the perturbation of the applied magnetic field, the narrower the observed possible linewidth and the higher the resolution of the experiment.

Characterization of Beam Sensitive Samples Through Dose Fractionated Spectrum Imaging AndrewThron[1], LiamSpillane[1], RayD. Twesten[1] and RobertColby[2]; [1]Gatan Inc., United States; [2]ExxonMobil Technology and Engineering Company, United States

Acquisition of EELS spectrum images (SI) from dose-sensitive samples has proved technically challenging due to the relatively low critical dose thresholds above which Radiolysis occurs. Multipass SI continuously sums multiple, rapidly acquired passes together until the desired accumulated dwell time is achieved, rather than acquiring a single pass with a long pixel dwell time. This fractionates the dose over several passes, gives rapid feedback on sample integrity, and the ability to correct sample drift between frames. If passes continue to be summed above a critical dose, spectra analysis will be compromised. Due to read noise, optically coupled CCD and CMOS cameras require longer dwell times to achieve a sufficient signal-to-noise ratio. This requires the dose to spread over a larger sample area, limiting the measurement's spatial resolution [1].
Here we show how multi-pass, *in-situ* SI enables the application of EELS to dose-sensitive samples. Multi-pass *in-situ* SI saves each pass individually while fractioning the dose over multiple passes. If the acquisition of a SI continues above the critical dose, compromised spectra are removed post-acquisition, and only the pristine passes are summed together. This is particularly advantageous since the critical dose for a sample may be unknown. Combining the sensitivity of a direct electron counting detector with multi-pass *in-situ* SI decreases the pixel dwell time. This fractionates the dose over more passes and enables the SI to be acquired at a higher spatial resolution.
Calcium carbonate ($CaCO_3$) was used as a model system since the critical dose thresholds for reduction and mass loss are well characterized [2]. We observe mass loss through the reduction of O and C concentrations. The formations of voids are observed to occur heterogeneously, likely at defects. Due to the increased sensitivity of direct detection, we can track the evolution of the Ca $L_{2,3}$ near-edge fine structure (ELNES) to pinpoint when the onset of radiolysis starts. Furthermore, by monitoring the ELNES, we confirm that reducing the dose rate increases the critical dose at which voids form, from $4.4x10^4$ $e^-/Å^2$ to greater than $1.3x10^5$ $e^-/Å^2$.
We then apply EELS Multi-pass *in-situ* spectrum imaging to a more challenging blended polymer film of polycarbonate (PC) and poly(styrene-acrylonitrile) (SAN). The PC/SAN film has a significantly lower dose threshold of 10 $e^-/Å^2$, compared with the calcium carbonate films. By fractionating the dose over several passes, we can map the distribution of the PC and SAN phases using references from the C K-edge ELNES. Due to the direct electron detector sensitivity, we acquired phases maps with a spatial resolution of 20-30nm, which was previously impossible with optically coupled cameras [1].

Recent Progress in Cryogenic Electron Microscopy and Spectroscopy for Energy MaterialsY. ShirleyMeng[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

The applications of cooling holders into energy materials started from the very beginning of the commercialization of side entry holders. Its primary applications were focused on minimizing electron beam induced damage in beam sensitive materials. These materials include for example reactive materials for energy storage and conversion (lithium, sodium metal anodes, lithiated graphite and silicon, etc.), soft materials for membrane technologies, interphase materials after wet-electrochemical cycling, catalysts that are extremely small (<3-5nm), or those containing ligands and molecules. A more profound application of Cryo-EM perhaps is the enabling of tomographic S/TEM imaging, which requires an extended acquisition time, of beam sensitive materials. The biggest challenge in cryo-EM experiments, particular for high resolution imaging and chemical analysis, lies in the limited stability, which is affected by multiple factors, such as the temperature variation on the specimen tip, the mechanical instability induced by the heavy liquid dewar, the bubbling and the constant evaporation of liquid nitrogen/helium. In this talk, I will discuss a few recent endevours to overcome these barriers, using the energy storage materials studies as the example.

Exploring Surface Properties: A Multi-Frequency AFM Approach LamiaaS. Elsherbiny[1], SergioSantos[2], MatteoChiesa[1] and AmalAlGhaferi[1]; [1]Khalifa University, United Arab Emirates; [2]UiT-The Arctic University of Norway, Norway

In the field of atomic force microscopy (AFM), a comprehensive understanding of surfaces is of the utmost importance, particularly in the energy industry. The quest for cost-effective and sustainable GaAs production is addressed in this study through the novel use of graphene as a key component. This approach hinges on the understanding of the van der Waals interactions between graphene and semiconductors, with the goal of reducing production costs for GaAs-based devices, primarily solar cells. To decipher the complex dynamics governing tip-surface interactions, a thorough investigation was conducted by combining multimodal AFM techniques with advanced machine learning algorithms, thereby facilitating a systematic and data-driven investigation. The significance of surface comprehension within the AFM field formed the basis of this study. The surface forces are analyzed through Atomic Force Microscopy (AFM), providing high-resolution topographical data and valuable insights into the surface energy of materials. By using a combination of bimodal and trimodal AFM techniques, they were able to increase sensitivity and resolution, allowing for the collection of multiple datasets that accurately reflected the complex interaction of forces. Having established the critical role surfaces play, it is essential to dive into a complex examination of tip-surface interactions. Through meticulous analysis, we were able to identify specific analytical properties that provided valuable insights into the essence underlying these interactions. These properties were crucial in deciphering the governing power law, thereby shedding light on the optimal parameters that define the system. Machine learning was used to correlate the different parameters with the governing power law. Through extensive training on diverse datasets containing known power laws, the model acquired the remarkable ability to classify and identify the power corresponding to the given properties. This development sped up the analysis process, improving efficiency and guaranteeing precision. Beyond the domain of GaAs substrates, the refined capabilities of the machine learning model represented a significant step forward. Automatic identification and classification of the power law became possible, resulting in enhanced accuracy and a streamlined process for determining optimal parameters. This methodology has repercussions outside of the energy industry, enabling insights into diversified tip-surface interactions in a variety of applications. The developed method can accelerate the understanding of surfaces for the purpose of photoelectric devices. By digging deep into the vast domain of van der Waals forces, analytical properties, and machine learning techniques, we can gain unmatched understanding of the interactions within GaAs substrates. Thus, enhancing the fabrication process of thin film solar cells.

Local Capacitance-Voltage Profiling of Al_2O_3/OH-Diamond (111) by Scanning Nonlinear Dielectric Microscopy KoheiYamasue[1], YuOgata[1], TsubasaMatsumoto[2], NorioTokuda[2] and YasuoCho[1]; [1]Tohoku University, Japan; [2]Kanazawa University, Japan

Diamond is one of a wide bandgap semiconductor materials and receiving considerable attention because of its high potential to power device applications. It has recently been shown that inversion type p-channel metal-oxide-semiconductor field-effect transistors (MOSFETs) with normally-off operation have been fabricated using a P-doped and OH-terminated diamond body on a diamond (111) substrate with an atomic layer deposited Al_2O_3 gate dielectric [1]. However, there still remains an issue of lower channel mobility towards the practical applications of diamond based power MOSFETs [2].

To give a microscopic insight on the physical origins of the low channel mobility, here we investigate an Al_2O_3/OH-diamond (111) interface by time-resolved scanning nonlinear dielectric microscopy (tr-SNDM). Tr-SNDM is a near-field microwave based scanning probe microscopy that has high sensitivity to the variation of microscopic MOS capacitance formed by the metallic tip, insulating gate dielectric layer in contact with it, and underlying semiconductor layer [3]. By using tr-SNDM, here we performed local (microscopic) capacitance-voltage (CV) profiling of Al_2O_3/OH-diamond (111). Unlike typical macroscopic CV profiling, we can obtain local CV profiles at different measurement points and visualize their nanoscale spatial fluctuations in a real-space. Spatial fluctuations of the local CV profiles reflect potential fluctuations at the interface, or surface potential fluctuations, that should be suppressed to increase the channel mobility of MOSFETs.

The sample was fabricated from a highly B-doped p^+ CVD diamond layer (200 nm) grown on a high-temperature high-pressure synthesized p-doped (111) substrate (300 μm) for ohmic contact formation with an underlying gold electrode layer. The sample had atomically flat surfaces by etching the bare surfaces by anisotropic diamond etching process based on carbon solid solution reaction into Ni. Subsequently, hydrogen plasma etching treatment was applied to form (111)-oriented terrace and step structures on the p-type diamond surfaces. The sample was further treated by the OH-termination process of the diamond surface. A 50 nm thick Al_2O_3 top dielectric layer was formed by atomic layer deposition. For comparison, we also measured a hydrogen-annealed thermally oxidized Si (H-annealed SiO_2/Si) wafer with very high interface quality.

By using our local CV profiling method, we were able to visualize spatial fluctuations of the local CV profiles on the Al_2O_3/OH-diamond (111) sample. In addition, we found that the Al_2O_3/OH-diamond (111) has much higher spatial fluctuations than hydrogen-annealed SiO_2/Si. The standard deviation of the observed fluctuations was as high as 0.9 V, while that of hydrogen-annealed SiO_2/Si was 0.08 V. Basically, the high fluctuations are attributable to the high density and non-uniform spatial distributions of interface charges such as interface defects and fixed charges. A more detailed analysis suggests that the high fluctuations at the Al_2O_3/OH-diamond(111) interface are dominated by voltage-independent charge states such as fixed charges and interface defects with deep energy levels. An additional measurement called local DLTS using tr-SNDM also indicates that interface defects at shallower energy levels also contribute to the fluctuations. These results suggest that the reduction of interface defects, fixed charges, and their density fluctuations is necessary to improve the quality of the Al_2O_3/OH-diamond(111) interface.

Automated Band Gap Characterization Matches the Rate of High-Throughput Materials Synthesis AlexanderE. Siemenn[1], BasitaDas[1], HamideKavak[1,2], EuniceAissi[1], FangSheng[1] and TonioBuonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]Cukurova University, Turkey

Significant progress has been made in recent years to accelerate the rate of materials synthesis using high-throughput methods. For example, we use combinatorial solution-based synthesis methods to produce and anneal 100 unique $FA_xMA_{1-x}PbI_3$ perovskite samples in only 20 minutes. However, traditional characterization techniques are not designed to match this accelerated rate of synthesis. Depending on the number of samples processed, the characterization of materials often requires hours or days for a domain expert to complete using conventional techniques, in turn, bottlenecking the process of high-throughput experimentation. We record that it takes a domain expert approximately 4.3 hours to characterize the band gaps of 100 unique $FA_xMA_{1-x}PbI_3$ perovskite samples. To accelerate the rate of characterization, we design an automated method to measure and extract the direct band gap of perovskite materials using computer vision segmentation of spatially resolved hyperspectral reflectance data. This vision-driven band gap extractor uses the Tauc-transformed reflectance data of each sample to recursively segment and iteratively minimize the RMSE of regression fit lines to those curves, enabling the autonomous computation of band gap across arbitrarily many samples captured and segmented in a single hyperspectral image. We demonstrate the processing throughput of the band gap extractor to be 100 samples in 180 seconds (and the potential for further acceleration using more powerful computational resources), with the spatial hyperspectral measurement only taking 10 seconds. Hence, our proposed method of automated band gap characterization is approximately 6x faster than our high-throughput sample synthesis and annealing process, circumventing a characterization bottleneck during the high-throughput experimentation of materials. We validate the proposed method on over 1,200 unique $FA_xMA_{1-x}PbI_3$ perovskite samples and demonstrate an accuracy of over 90% relative to ground truth acquired by a domain expert while achieving a throughput 85x faster than the domain expert.

Implications of Dispersivity and Crystallinity on X-Ray Scattering of Nanoparticles AdrianaValerio[1], RafaelaF. Penacchio[1], FabianeTrindade[2], MauricioB. Estradiote[1], AndreSantarosa

Ferlauto[2], StefanW. Kycia[3] and SergioL. Morelhao[1]; [1]University of Sao Paulo, Brazil; [2]Universidade Federal do ABC, Brazil; [3]University of Guelph, Canada

Control of shape and size dispersivity and crystallinity of nanoparticles (NPs) has been a challenge in identifying these parameters' role in the physical and chemical properties of NPs. There are many examples, such as improved catalytic performance of CeO_2 NPs by adjusting size, morphology, and lattice perfection [1,2], tuned nonlinear optical response in $BiFeO_3$ nanocrystals for biomedical imaging applications by narrowing phase and size dispersivity [3,4], and self-stabilized catalysts based on NPs with crystalline core and amorphous shell [5]. The need for reliable quantitative tools for analyzing the dispersivity and crystallinity of NPs is a considerable problem in optimizing scalable synthesis routes capable of controlling NP properties. The most common tools are electron microscopy and X-ray scattering techniques. However, each technique has different susceptibility to these parameters, implying that more than one technique is necessary to characterize NP systems with minimum reliability. Wide-angle X-ray scattering (WAXS) is mandatory to access information on crystallinity. In contrast, electron microscopy (EM) or small-angle X-ray scattering (SAXS) is required to access information on the whole NP sizes. EM provides average values on relatively small ensembles compared to bulk values accessed by X-ray techniques. Besides the fact of SAXS and WAXS weight size distribution differently [6], SAXS is easily affected by NP-NP interaction distances. Because of all the variables involved, there have yet to be proposed methodologies for cross-analyzing data from two techniques that can provide reliable quantitative results of dispersivity and crystallinity. In this work, we propose a SAXS/WAXS-based methodology for simultaneously quantifying size distribution and degree of crystallinity of NPs. We demonstrate the most reliable and easy-to-access size result for each technique, how to compare them, and how to identify NP-NP interaction effects underneath the SAXS intensity curve. Experimental results are show for cubic-like CeO_2 NPs. WAXS size results from two analytical procedures are compared, line profile fitting of individual diffraction peaks in opposition to Rietveld analysis via GSAS software. The impact of shape dispersivity is also evaluated for both techniques. A possible extension of the proposed methodology for cross-analyzing EM and WAXS data is suggested.

Analysis of Dynamics of Sodium Electrolyte with Aluminum Additives with Nuclear Magnetic Resonance Spectroscopy AllenZheng[1], StevenG. Greenbaum[1] and MicheleVittadello[2]; [1]Hunter College, United States; [2]Medgar Evers College, United States

As part of the development of beyond-lithium batteries, research on sodium electrolyte chemistries have shown many promising systems. Though more challenging, there is also great interest in developing electrolytes for aluminum-based batteries. Mixed Na/Al-catenated ionic liquid electrolytes were developed utilizing an atomically disordered form of sodium chloride salt, denoted as δ-NaCl, of various concentrations which was mixed with 1-ethyl-3-methylimidazolium chloride and aluminum chloride $(EmImCl/AlCl_3)_{1.5}$/$(\delta\text{-NaCl})_x$. Pulsed-field-gradient nuclear magnetic resonance spectroscopy was utilized to determine transport mechanics of ions at various concentrations. The results reveal improved aluminum transport mobility with higher sodium salt concentration despite increased viscosity, indicating significant changes in the Al coordination shell with increasing δ-NaCl concentration.

10:15 AM CH01.09.08
Quantitative Analysis of Tomographic Images for Understanding Discharge Phenomena in Alkaline Zn-MnO_2 Batteries DominickGuida, AlyssaStavola and JoshuaW. Gallaway; Northeastern University, United States

In situ synchrotron CT was used to obtain volumetric reconstructions of sealed commercial Zn-MnO_2 batteries. The voxel resolution was 2.93 μm/voxel with sufficient field of view (FOV) that a volume of approximately 200 mm^3 encompassing the entire battery diameter could be probed in a reasonable time frame. The reconstructions show the internals of partially discharged anodes, which visualizes the morphology and distribution of the active phases. A novel segmentation algorithm converted the tomographic images to the discrete phases present, allowing quantitative analyses to be performed. In particular, one dimensional (1D) radial profiles of ZnO and undischarged Zn were calculated, for direct comparison to the output of a computational battery model. Within these batteries, the Zn anode includes a current collecting pin that is frequently off centered. A pseudo-cylindrical coordinate system was designed to characterize the competing ionic and electronic effects in these batteries. This allows cylindrical symmetry to be maintained, despite the off centered current collecting pin. This is an imperative step in directly comparing quantitative experimental results to 1D model predictions.

The discharge of an alkaline Zn-MnO_2 battery involves a dissolution-precipitation mechanism at the Zn anode, where Zn dissolves into the electrolyte and precipitates out as ZnO. The zincate ion is highly mobile in alkaline media, leading to active material redistribution and complex morphologies of ZnO discharge products. Throughout the discharge, a Zn particle must be connected to the electronically conducting Zn network, while also maintaining contact with the electrolyte to sustain further discharge.[1] Localized precipitation of ZnO will impede hydroxide transport through that region and degrade cell performance.[2] Modeling has been used to simulate the performance of these commercial batteries, though model predictions do not match experimental results under numerous discharge conditions that are typical in real-world use cases.[3] By characterizing commercial Zn-MnO_2 batteries under various discharge conditions, this work seeks to improve modeling capabilities through a better understanding of the discharge behavior of Zn anodes.[4]

These quantitative analyses showed Zn and ZnO distribution was highly dependent on the discharge protocol. A pulsed discharge allows more microporous and spatially distributed ZnO to form off of the active Zn surface, reducing the passivating effects of ZnO formation.[4,5] Furthermore, the rate at which the cell is discharged dictates where the bulk of the reaction occurs in the anode. At high rates, a conventional reaction zone near the separator can be seen and is verified by model predictions. However, at lower rates this reaction zone inverts and has the majority of Zn dissolution and ZnO precipitation near the current collecting pin, which is not predicted by current models.[3] By analyzing the discharge of Zn anodes using segmented tomography in pseudo-cylindrical coordinates, the factors that dictate ZnO distribution and morphology can be more thoroughly understood and used to guide the development of battery models.

The Influence of Ammonia Concentration on the Precipitation of Ni(OH)2 Precursor in the Synthesis of LiNiO2 Cathode Materials for Lithium-Ion Batteries Narayan SimritKaur[1,2], SerenaCussen[1,2] and BethanyI. Johnston[1,2]; [1]University of Sheffield, United Kingdom; [2]Faraday Institution, United Kingdom

Lithium-ion batteries have been implemented in the energy storage market for many decades, used as rechargeable batteries in portable devices, electric vehicles and a wide range of other applications. Ni-rich layered oxides as cathode materials in Li-ion batteries are of great interest due to the high energy density and theoretical capacity of 274 mAh/g of LiNiO2. [1] To improve fast lithium-ion diffusion in lithium-ion battery cathodes, enhance the limited capacity due to oxygen release and phase changes, reduce cost and toxicity and most importantly, inhibit unethical mining of cobalt, alternative compounds to replace cobalt in LiCoO2 are investigated by substituting different transition metals, such as Ni, Mn, or Al on the Co site in the structure. The increase of the Ni content and decrease of the Co content increases the capacity and lowers the costs in $/kWh, as Ni provides higher performance and a high energy-density. To cope with the higher demand of volume constrained applications, the volumetric energy-density is to be considered and is achieved by a high tap density of the active material, which is related to particle size, particle size distribution and morphology. [2] However, for high-nickel content cathodes, degradation processes like Li/Ni mixing [3], surface layer deconstruction [4], particle cracking[5], decomposition reactions with the electrolyte [6] and slow Li+ diffusion kinetics [7] occur, leading to lower capacity retention, a loss of capacity in the first cycle and thus an overall insufficient cycling stability.
There are many research publications about optimising the calcination process of the Ni(OH)2 precursor and LiOH*H2O, [8][9][10], but currently, very little focus on the precursor material itself, its particle size and morphology, which affects the structural and electrochemical behaviour. The accumulation of mechanical strain due to repeated c-axis contraction and relaxation during charge/discharge processes lead to particle cracking, electrolyte infiltration, structural decay and results in a reduced electrochemical performance. To counter this, a large study regarding the morphology, particle size, and electrochemical behaviour of Ni(OH)2 precursor material produced in a highly controlled environment (*batch stirred tank reactor* BSTR) has been undertaken and the first results are presented here. A higher transition metal to ammonia ratio during synthesis leads to larger and more spherical secondary particles, a narrow particle size distribution, a higher tap density and also improved electrochemical cycling. We are able to tune the particle size and morphology by adjusting the ammonia ratio, leading to initial discharge capacities up to 254 mAh/g (3-4.3V, C/2) while the 1st cycle capacity loss increases with increasing Ni:ammonia ratio.

Rapid *In-Situ* Electrochemical Formation of Partially Disordered Spinel from Mn-Rich Disordered Rocksalt CathodesTuckerM. Holstun[1,2], TaraMishra[2], LiliangHuang[2], XiaochenYang[1,2] and GerbrandCeder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

We present the development of an electrochemical formation method that enables rapid and *in-situ* formation of a partially disordered spinel phase from an initially disordered rocksalt (DRX) cathode. Recent studies on Mn-rich DRX materials have demonstrated the emergence of a spinel-like phase during cycling, resulting in improved capacity retention, energy density, and rate capability compared to materials which do not transform[1,2]. However, this transformation process typically requires weeks of cycling at relatively low rates, posing significant challenges for the commercialization of such materials.
To gain a deeper understanding of this transformation process, we carry-out a systematic study to determine whether the formation process of these spinel-like materials can be accelerated through a precycling formation process. By employing a novel electrochemical approach to purposefully stimulate the transformation, we successfully reduce the time required from several weeks to as little as one day for Mn-rich DRX. Extended cycling and synchrotron X-ray diffraction confirm that these materials exhibit both equivalent performance and resulting structure to those obtained through conventional cycling over a much longer duration. Further characterization of this material using HAADF and 4-D STEM reveals the complex local structure of the spinel-like partial ordering. It is hoped that such a practical electrochemical formation method will allow for an acceleration of research on these earth-abundant and energy-dense materials.

Thin-Film SiO_x Coated Carbon Nanofibers as Stable Anodes for Lithium-Ion Batteries Na yeongKim and Ji-WonJung; University of Ulsan, Korea (the Republic of)

With the increase in the capacity of cathode materials in lithium-ion batteries(LIBs), the demand for novel anode materials with high theoretical energy density is following. Up to now, many candidates have been reported; silicon-based composites are considered a prospective alternative due to their abundant reserves and high energy density. However, The primary disadvantage of Si, electrochemical irreversibility during the charge/discharge process, hinder widespread use.
In this study, we adapted SiO_x-coated carbon nanofibers (SiOx-CNFs) composite to the binder-free anode current collector for lithium-ion batteries. The composite has a structure where a thin amorphous SiO_x (thickness ~100nm) is coated on the CNFs surface and is successfully synthesized by electrospinning and sputtering. This structure, surface SiO_x-coated porous CNF, breaks through the significant drawback of Si-based composites, pulverization of Si element during the charge/discharge cycle. In addition to this, due to the structure of porous CNF, we achieved the curtail of electrode weight.
Scanning Electron Microscopy (SEM) and X-ray diffraction (XRD) analyses are carried out to confirm the morphology and crystallinity. Furthermore, with cyclic voltammetry analysis, fast reaction kinetics and excellent electrochemical reversibility are verified. The cycle test is also conducted to prove excellent capacity and cyclic stability.

11:30 AM CH01.10.04

Realization of Highly Stable O-Redox Cathodes via Real-Time Analysis on the Solid-State Synthesis for High-Energy-Density Batteries SeungminLee, Sang HyukGong and Hyung-SeokKim; Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Layered sodium manganese oxides (NMO) have been proposed as promising cathode materials for large-scale batteries owing to their cost-effectiveness [1]. However, their low capacities have hindered the increase in energy density, necessitating the development of high-capacity NMO cathodes. One approach to increasing the theoretical capacities of NMO cathodes is by utilizing the oxygen (O)-redox reaction, which is enabled by the electrochemically-active lattice oxygens through the introduction of substitutes or vacancies in the transition metal (TM) layer [1]. The stability of the O-redox reaction depends on the in-plane distribution of substitutes or vacancies in the TM layer, influencing the distance between the participating O atoms and the energy barrier for TM migration [1-2]. However, the realization of in-plane structure during synthesis and its correlation with the O-redox stability, has not been studied.
In this context, we aim to explore the structural changes of NMO during solid-state synthesis and assess the effect of synthetic parameters on its in-plane structure and O-redox stability. To monitor the changing structure during synthesis, we employ time-resolved X-ray diffraction (TR-XRD) analysis throughout the synthesis process. In addition, electrochemical tests are conducted to evaluate the O-redox stability. By analyzing these results and conducting further structural characterization (e.g., high-resolution electron microscopy (HR-TEM) and X-ray absorption spectroscopy (XAS)), the correlation between synthetic parameter and O-redox stability is suggested.

11:45 AM CH01.10.05

Cryo-TEM for Atomic Imaging of Solid Electrolytes in Li-Ion Batteries HongkuiZheng and KaiHe; University of California, Irvine, United States

Transmission electron microscopy (TEM) is an indispensable method to characterize materials structure and composition at the atomic scale, which is particularly important for battery research to investigate crystal lattices, defects, as well as microstructural and chemical heterogeneities within materials used in battery electrodes, electrolytes, and other components. Despite the rapid advancement of in situ TEM that has enabled the real-time observation of various dynamical phenomena and chemical processes during battery cycling and phase transformations, there are still pressing challenges that need to be addressed in order to obtain accurate and reliable findings relevant to real-world applications. For example, the radiation damage by the high-energy electron beam, as well as the side reactions between lithium compounds and moisture and oxygen in the air, are required to be avoided or mitigated. Therefore, it is desired to develop reliable electron microscopy and microanalysis strategies for the characterization, analysis, and diagnosis of real-world battery materials, for which cryo-TEM is of unique powerfulness.

Here, we report the technical development of effective methodologies and instrumentation to tackle the critical issues described above. Specifically, we developed a seamless workflow to integrate the cryo-TEM techniques with low-kV and low-dose settings to minimize the impact of electron beam radiation and sustain the original material structures from radiolysis and knock-on damage. We also built a dedicated air-free transfer system to present unwanted by-products of sensitive Li-containing species caused by side reactions with oxygen and moisture during sample preparation and transfer. With careful control of imaging conditions through a series of control experiments, we provided benchmarks for damage-free atomic-scale microscopy and microanalysis using cryo-TEM. These results were demonstrated in the atomic imaging of garnet-type solid electrolyte $Li_7La_3Zr_2O_{12}$ (LLZO), a promising superionic conductor for next-generation solid-state Li-ion batteries. It is expected that this approach can be generalizable to implement in the reliable characterization of a large variety of sensitive materials for energy storage relevant to real-world technologies.

The Barocaloric and Structural Properties of Choline-Based Plastic Crystals JoshuaLevinsky[1], PhillippaPartridge[1], DominikDaisenberger[2] and ClaireHobday[1]; [1]University of Edinburgh, United Kingdom; [2]Diamond Light Source, United Kingdom

The currently ubiquitous vapor-compression method of refrigeration has a significant downside, namely its reliance on volatile refrigerants with large global warming potentials. In order to overcome this challenge, alternative solid-state refrigerants which exhibit similarly large entropy and temperature changes by the application of external stimuli have to be identified. A promising approach to this problem is found in the utilization of the hydrostatic pressure-induced entropy and temperature change, the so-called barocaloric effect, which accompanies structural phase transitions. This approach avoids the need for volatile refrigerants with large global warming potentials and promises a higher thermodynamic efficiency [1].
Thus far only the class of molecular plastic crystals, compounds which exhibit solid phases characterized by large degrees of orientational disorder and plastic-like mechanical properties, have been shown to exhibit colossal barocaloric effects on par with commercial hydrofluorocarbon refrigerants [2]. The exceptionally large barocaloric response found in plastic crystals originates from structural phase transitions from an ordered state to an orientationally disordered state, characterised by a large isothermal entropy change, dS, and large barocaloric coefficient dT/dP. Plastic phases can also be obtained in ionic systems built from weakly interacting highly symmetric globular ions. Additionally, the introduction of transition-metals into this type of system provides an avenue towards designing multifunctional or multicaloric materials [3].
In this work, we explore the expansive chemical parameter space of hybrid ionic plastic crystals and study the effect of anion substitution on the structural phase transitions and barocaloric properties of plastic crystals based on the choline cation. By employing pressure- and temperature-dependent single crystal/powder diffraction and differential scanning calorimetry experiments, this structure-property relationship is studied in detail. Demonstrating the ability to tune the transition temperature, dS and dT/dP via chemical exchange, the results of this work can then be used to inform the design of future solid-state refrigerants .

Measuring Chemical Composition, Optical and Thermal Properties at the Nanoscale with AFM Probes—Applications to Energy Materials. AndreaCentrone; National Institute of Standards and Technology, United States

Measuring and controlling chemical composition and optical properties (i.e., stoichiometry, defects, bandgap) at the nanoscale is critical for engineering materials in photovoltaics and other optoelectronics applications. Measuring nanoscale thermal properties such as thermal conductivity (η) and interfacial thermal conductance (G) is crucial for engineering thermoelectric devices. While conventional Fourier-transform IR (FTIR) spectroscopy and time-domain thermoreflectance (TDTR) reliably measure, chemical composition and thermal properties, respectively; unluckily they have insufficient spatial resolutions (few µm). Furthermore, TDTR typically requires long measurement times (≈120 s/pixel) and suffers from high uncertainties (i.e., ΔG>35%) when measuring materials with low η.

Photothermal induced resonance (PTIR) [1,2,3] is a scanning probe technique that employs an AFM tip as a local detector to transduce proportionally the photothermal expansion of the sample induced by light absorption into AFM cantilever oscillation amplitudes. By leveraging lasers tunable from 400 nm to 16000 nm the PTIR set up in my lab yields absorption spectra (electronic or vibrational) and maps with a wavelength-independent resolution as high as 5 nm. This way, PTIR can map the sample composition, molecular conformation, and bandgap at the nanoscale.
After introducing the PTIR working principle, I will discuss its application in measuring ion migration,[4] bandgap,[5] and ferroelastic domains[6] in trihalide perovskites that are of great interest in photovoltaics as they combine high efficiency with ease of fabrication and low materials cost.

While PTIR has found broad applications in measuring materials compositions, conventional AFM probes lack the sensitivity and bandwidth required to measure the fast, time-domain, sample thermalization which is linked to the local thermal properties (η and G) of the sample. In contrast, the PTIR setup developed at NIST leverages new optomechanical AFM probes[7,8,9] that achieve low detection-noise (≈1 fm/$Hz^{1/2}$) over a wide (>100 MHz) bandwidth. This way, the entire, time-domain, thermal expansion of the sample is measured at once with high spatial (≈10 nm) and temporal (≈ 4 ns) resolutions, yielding composition (IR absorption), η and G maps, concurrently. Compared to conventional TDTR, these measurements achieve ≈6000x higher throughput (20 ms/pixel), >140x higher spatial resolution and record-low uncertainty (ΔG≈2%). Compared to conventional PTIR (ringdown, AFM-IR), they achieve higher sensitivity (≈700x) and throughput (≈500000). Furthermore, the high resonance frequency of these custom probes (10 MHz) is ideal to achieve high spatial resolution.[10] We believe that this novel setup will be critical for measuring thermal properties at the nanoscale and for improving the performance of thermoelectric devices.

Characterizing Thermal Diffusivity of Semiconducting Polymers by Scanning Photothermal Deflection (SPD) Technique Ka LaiWong, Ka LokChiu, ChujunZhang and Shu KongSo; Hong Kong Baptist University, Hong Kong

Owing to their relatively low thermal conductivity, heat is trapped in most organic semiconducting devices resulting in operational instability and shortened device lifetime. To overcome these issues, it is important to understand and enhance device heat-dissipation. However, related studies on organic semiconductors are rare. Here, we present a self-developed scanning photothermal deflection (SPD) technique to study the thermal transport of common organic photovoltaic (OPV) polymers and bulk-heterojunctions (BHJs). In SPD, heat diffusion in an organic film is probed by photothermal deflection method utilizing the mirage effect. In general, the thermal diffusivities for conjugated polymers increase in the order of amorphous < 1D < 2D polymers in the range of 0.1 to 2 $mm^2 s^{-1}$ (Nano Select, 2(4), 768-778). High-performance 2D polymers such as PM6 has high thermal diffusivity values comparable to stainless steel. In contrast, fullerene- and ITIC-based BHJs have significantly lower thermal diffusivities, as the heterogeneous blend may disrupt the polycrystalline structure of the polymer and slow down the intramolecular phonon transport. On the other hand, reduction due to heterogeneous blend is less noticeable in all-polymer BHJs, indicating that a polymer-rich topology benefits dominated intramolecular phonon transport. Also, SPD technique can be applied to study Y acceptors and their BHJs (Advanced Functional Materials, 31(32), 2101627).

3:30 PM CH01.11.04
Entropy-Engineered Thermoelectrics: The Role of Symmetry-Driven Structure and Transport Property Evolution YukunLiu, HongyaoXie, ZhiLi, ChristopherWolverton, MercouriG. Kanatzidis and VinayakDravid; Northwestern University, United States

High-entropy thermoelectrics are garnering considerable attention owing to their exceptional energy conversion efficiency, improved stability, and expanded composition space. Nevertheless, understanding the impact of entropy engineering on thermoelectrics remains a challenge. The presence of diverse atomic species can give rise to a variety of mixing reactions, potentially leading to structural and chemical inhomogeneity at multiple length scales. This heterogeneity can profoundly affect transport properties, whereas a comprehensive exploration of these effects is lacking.

IV–VI group semiconductors, including PbQ, SnQ (Q = S, Se, Te), and GeTe, are among the most promising thermoelectric materials. In light of their potential, we choose $PbGeSnTe_3$ as the model system for further research. Through alloying CdTe to $PbGeSnTe_3$, we progressively increase the configurational entropy and study the resulting evolution in structure and transport properties in $PbGeSnCd_xTe_{3+x}$. Our findings reveal that $PbGeSnTe_3$ adopts a rhombohedral structure (*R*3*m*) at room temperature and undergoes a phase transformation to a cubic structure (*Fm*-3*m*) above 373 K. Through transmission electron microscopy (TEM) analysis, we observe densely distributed polar domains mediated by inversion and twin boundaries, leading to structural inhomogeneity. *In situ* heating TEM results reveal the disappearance of domains during phase transformation at high temperatures, followed by reversible formation upon cooling. These observations indicate that the loss of inversion symmetry induces the formation of domains with different polarities. The polarity switching between each domain results in significant strain fluctuations that suppress phonon propagation. Variable temperature 4D-STEM (scanning transmission electron microscopy) analysis demonstrates the strain distribution evolves upon heating due to domain evolution, contributing to an abnormal temperature-dependent thermal conductivity in the low-temperature range.

We further demonstrate the effectiveness of entropy engineering in tailoring the microstructure and transport properties through controlling crystal symmetry. By alloying CdTe, the increase in configurational entropy of $PbGeSnCd_xTe_{3+x}$ results in a progressive reduction of the phase transition temperature and stabilizes $PbGeSnCd_{0.2}Te_{3.2}$ in a cubic structure (*Fm*-3*m*) at room temperature. The increase in crystal symmetry eliminates the symmetry-breaking process during synthesis, preventing the formation of domains and consequently eliminating abnormal thermal conductivity behavior. Additionally, the Seebeck coefficient exhibits significant improvement, attributed to an increased density-of-states effective mass from 1.36 m_0 (free electron mass) to 2.63 m_0. This enhancement compensates for the degradation in charge carrier mobility, resulting in an improved thermoelectric performance with a maximum figure-of-merit (*ZT*) of 1.63 achieved at 875 K.

This study reveals the presence of structural inhomogeneity in high-entropy thermoelectrics, emphasizing the need for a comprehensive investigation at nanoscale to establish a robust structure-property relationship. Furthermore, we demonstrate that entropy engineering offers a promising avenue for tailoring microstructures and transport properties by modifying crystal structures. This finding opens new possibilities for the development of next-generation thermoelectric materials.

3:45 PM CH01.11.05
Barocaloric Cooling: A Combined Experimental and Computational Study. PhillippaPartridge[1], JennyPringle[2], CharlesJ. McMonagle[3], AnthonyE. Phillips[4], RichardJ. Dixey[4], JoshuaLevinsky[1] and ClaireHobday[1]; [1]University of Edinburgh, United Kingdom; [2]Deakin University, Australia; [3]SNBL at ESRF, France; [4]Queen Mary University of London, United Kingdom

Refrigeration accounts for 17% of the global electricity usage. The current vapour-compression technology releases greenhouse gases which has led to the demand for solid-state replacements.[1] Refrigerant effects can be induced in materials named barocaloric solids through the application of hydrostatic pressure which causes a change in isothermal entropy and adiabatic temperature of the system.
Organic ionic plastic crystals (OIPCs) are a class of materials which exhibit at least one solid-solid phase transition upon varying the temperature of the system. Upon cooling these structures, the mobility of the ions becomes limited, increasing the order within the structures. It is thought that OIPCs have the ability to undergo disorder-order phase transitions which would result in large entropy changes.[2] In this work we investigate the phase behaviour of the OIPC (cyanomethyl)trimethylammonium hexafluorophosphate, via experiment and simulation. Variable temperature and high-pressure crystallography and thermoanalytical methods were performed to understand if it has the desired characteristics of a barocaloric material. At room temperature, (cyanomethyl)trimethylammonium hexafluorophosphate is in a high symmetry, disordered, trigonal phase, upon cooling to 253 K the structure transitions to an ordered, monoclinic phase. The isothermal entropy change associated with this solid-solid phase transition has been experimentally determined to be 138 $J K^{-1} kg^{-1}$ and molecular dynamic simulations will be used in order to understand the configurational, rotational and vibrational contributions towards this value.

4:00 PM CH01.11.06
Heat Transfer across Van der Waals Atomic Interaction at Solid Interface SeunghoeKoo[1], JaeheePark[1], JunkiJung[1], Hyo JaeYoon[2], SeunghaShin[3], MinsubHan[1] and KyeongtaeKim[1]; [1]Incheon National University, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]The University of Tennessee, Knoxville, United States

Thermal energy transfer at the interface by the atomic interactions is the most fundamental energy transport mechanism for transferring thermal energy between materials. Recent advances in nano and atomic technology have made the size of device structures reach from several nanometers to several angstroms. As a result, heat transfer through the interface is more important than heat transfer within the material. Because of this importance, various studies on heat transfer through the interface have been conducted, but since the development of a device that can precisely control atomic interaction and measure heat transfer is very challenging, accurate verification of interfacial heat transfer through atomic interaction has not been achieved. Here, we developed and utilized scanning thermal probes to measure interfacial heat transfer while controlling van der Waals(vdW) energy at nanometer contacts. In particular, the atomic-milling method was used to fabricate the tip of the probe with an atomically flat surface and the relationship between vdW interaction and interfacial heat transfer was investigated proceeding the milling. Based on the experimental results obtained from the four samples, it was confirmed that high-frequency phonons modes were suppressed according to the binding energy inside each material and the vdW interaction energy. We also use the lattice-dynamical calculation and Molecular Dynamics(MD) simulation to validate the approach of suppression effects due to vdW interactions. Finally, we present the advanced approach that applies the vdW interaction energy of the interface to the DMM. This study provides insight into the theory of heat transfer through interface made of vdW interactions, and presents a milestone for considering interactions between materials for the development of various devices such as 2D materials and self-assembled monolayers.

Soft PhotoElectroChemical Systems for Solar Fuels ErinL. Ratcliff; University of Arizona, United States

Highly scalable, durable π-conjugated polymer materials provide control over local environments afforded through synthesis, long-lived charge carrier lifetimes, and flexible, low-cost, and scalable thin film formats which circumvent the shortcomings of inorganic materials (surface states, grain boundaries, challenges in processing, and mechanically unstable platforms). The Center for Soft PhotoElectroChemical Systems (SPECS) is an Energy Frontier Research Center focused on the basic science questions that underpin the development of low-cost, robust energy conversion and energy storage technologies based on new organic polymer (plastic) electronic materials. These materials are predicted to fill a critical position in the U.S. energy portfolio, providing for next-generation fuel-forming platforms (energy conversion) and batteries (energy storage) that cannot currently be achieved with conventional (hard) inorganic materials.

The realization of all-organic semiconductor systems that capture light energy and convert it into chemical energy requires a detailed understanding of structure-property relationships governing the interconnected dynamics of photo-generation, transport, and electron transfer across multiple interfaces. Dark electrochemical processes must be understood before increasing the complexity via light-matter interactions. This talk will focus on increasing complex, multiple interface platforms, towards the goal of photons-to-electrons-to-molecules energy conversion processes. A number of emerging *in situ/operando* spectroelectrochemical and scanning electrochemical cell microscopy approaches will be discussed for this exciting new area of energy conversion. Examples of operando x-ray photoelectron spectroscopy will also be discussed for chemically-resolved electrochemical measurements (CREM).

4:45 PM CH01.12.02
Ultra-High Resolution Electrocapillarity Correlates Interfacial Structure and Battery Performance JianweiS. Lai and FeifeiShi; The Pennsylvania State University, United States

The electrode-electrolyte interface governs the kinetics and reversibility of all electrochemical processes. However, its structure and key properties often remain in theoretical models and simulations, due to the long-standing absence of direct experimental techniques. Electrocapillarity is a classical technique that directly probes the interfacial structure via interfacial tension measurement. In this work, we modernized this technique with ultra-high resolution and sampling rate. Its application on Zn-battery electrolytes reveals a unique local Zn^{2+} concentration distribution and interfacial structure constructed by Cl^- specific adsorption, which favors fast Zn deposition/stripping kinetics. The renaissance of electrocapillarity allows us to directly correlate the electron transfer kinetics and zinc battery performance with interfacial structure, which will serve as a universal tool to guide the design of better electrolytes.

8:00 PM CH01.13.01
***In Situ* Formed Inorganic Conductive Network Enables High Stability and Rate Capability of Single-Crystalline Nickel-Rich Cathodes**XiChen; City University of Hong Kong, Hong Kong

Single-crystalline Ni-rich cathodes are promising for the next generation of high-energy-density Li-ion batteries due to their better capacity retention than their polycrystalline counterparts. However, there is still much room for improving the electrochemical performances when considering their surface degradation and severe kinetic hindrance during cycling. Herein, we report a strategy to construct an *in situ* formed robust Li-conductive Li_3PO_4 layer on the surface of the single crystalline $LiNi_{0.83}Co_{0.12}Mn_{0.05}O_2$ cathode particles. This Li-conductive layer significantly increases the Li-ion diffusion coefficients and suppresses detrimental surface phase transformation. *In situ* XRD reveals that the improved kinetics alleviate the local stress at high voltage. The as-prepared single-crystalline $LiNi_{0.83}Co_{0.12}Mn_{0.05}O_2$ delivers good durability (96.8 % after 100 cycles at 1 C) and excellent rate capability (177.08 mAh g^{-1} at 5 C). This work provides a facile and efficient strategy to improve the cyclic performance and boost the rate capability of single-crystalline Ni-rich cathodes.

8:00 PM CH01.13.02
Platinum Selenide Nanoparticles Synthesis and Their Reaction with Butyllithium Breaking the Long-Range Ordering Structure VictorS. Lemos, Danielde Moraes, IaraPataca, OlavoF. Verruma, CarolinaTorres, Naga VishnuMogili, AngelaAlbuquerque, FlavioL. Souza, EdsonR. Leite, IngridGutiérrez, DaniloB. Janes and JoãoB. Souza Junior; National Center for Research in Energy and Materials, Brazil

$PtSe_2$ is a Transition Metal Dichalcogenide (TMDC) material with potential applications in fields such as sensors, electronics, and catalysis[1]. Despite significant progress in the production of 2D monolayers of $PtSe_2$, the synthesis of controlled $PtSe_2$ nanoparticles (NPs) remains unexplored[2]. Here, we present a novel procedure for selenizing previously synthesized Pt NPs, resulting in high-quality crystalline $PtSe_2$ NPs. Pt NPs were initially synthesized using platinum acetylacetonate (II) as precursor and oleic acid and oleylamine as ligands. The reaction was performed using standard colloidal wet chemical synthesis ir air-free system. These Pt NPs were then combined with excess of selenium and sealed in a custom stainless-steel reactor with an interior composed of high-purity alumina (Al_2O_3) ceramic TGA pan, under an inert N_2 atmosphere inside a glovebox. Then, the reactor was heated at 400°C for two hours. After cooling, excess selenium was solubilized with trioctylphosphine (TOP) and separated via centrifugation under inert conditions. The material was further purified by adding acetone, followed by centrifugation and supernatant removal. $PtSe_2$ reaction with n-butyllithium was also studied. The mixture was stirred at room temperature in an ultrasonic bath. Afterward, the mixture was washed sequentially with hexane, acetone, and deionized water to eliminate the LiOH byproduct. This reaction with butyllithium led to cleavage of the covalent bond along the ab-plane of the 2D material (intralayer) and disrupted the $PtSe_2$ long-range structure. The result was a $PtSe_x$ nanomaterial with a minor deselenization process, retaining short-range ordering while altering the local structure, as confirmed by Raman and ePDF analyses. XPS analysis also revealed a decrase in the concentration of selenium a the surface compared to $PtSe_2$. Both types of nanoparticles exhibited improved performance in the hydrogen evolution reaction (HER) compared to bulk $PtSe_2$. TEM analyses indicated that $PtSe_x$ kept the morphology of previouly $PtSe_2$ samples, however the crystallite volume are much smaller. Unusual crystallographic facets could apper in the $PtSe_x$ sample potentially serving as additional active sites for hydrogen adsorption, in contrast to the standard catalytic performance on the basal plane (001) and its defects reported in the literature. The disruption of Long-Range Ordering (LRO) in $PtSe_x$, compared to $PtSe_2$ NPs, appears to enhance charge carrier mobility, further contributing to the improved catalytic performance as studied by electrochemical impedance spectroscopy (EIS). Consequently, the results presented here suggest that $PtSe_2$ NPs can be produced using a rapid and straightforward method compared to the conventional selenization process, making them valuable as catalysts[3]. Future advancements in $PtSe_2$ NPs, including doping, defect control, and nano-heterojunction studies, have the potential to enhance their performance.

Effect of Pore Size on Surface Properties of Porous Solids: Determining the Hydrophilicity of Carbon Supports using the Hansen Solubility Parameters and Dielectric Spectroscopy AbdullahAlShuaibi[1,2] and EmmanuelP. Giannelis[1]; [1]Cornell University, United States; [2]King Faisal University, Saudi Arabia

Hydrophilicity is a crucial property in determining the performance and applications of porous materials. In this study, we investigate the correlation between the hydrophilicity and pore size of porous carbons, focusing on microporous carbon (Vulcan XC72) and mesoporous Hierarchical Porous Carbons (HPCs). We evaluate the stability of the suspension and relate it to the Hansen Solubility or Affinity Parameters (HSP). In addition to the above, we correlate the properties of the solids with dielectric spectroscopy in order to provide insights into the surface characteristics of the materials.

Using the HSP method, we calculate affinity parameters for different porous carbon samples. The method provides a quantitative way to evaluate their affinity behavior and compatibility in various solvents. The results show a correlation between pore size and hydrophilicity. Microporous carbon exhibits higher hydrophilicity due to enhanced water interaction with the surface within smaller pores. In contrast, mesoporous carbons show relatively lower hydrophilicity. These findings agree with the observed trends in dielectric response, reflecting smaller water clusters for microporous carbon and larger clusters for mesoporous carbon as calculated from their anomalous low-frequency dispersion (ALFD) behavior. The work provides further insights into the surface behavior of porous carbons (and porous solids in general) and be used to design materials for specific applications such as water treatment and energy storage enabling opportunities for efficient and sustainable technologies in the future.

Insights on The Disordered Nature in Amorphous-Based Anode Materials from Electron Pair Distribution Function AnujPokle[1], MarteSkare[2], ShihuiFeng[3], CheukW. Tai[3], AsbjørnUlvestad[2], XiaodongZou[3] and ØysteinPrytz[1]; [1]University of Oslo, Norway; [2]Institute for Energy Technology, Norway; [3]Stockholm University, Sweden

In material science, the ability of structural determination at high spatial resolution is critical for understanding their properties. Over the years, traditional X-ray and electron diffraction techniques have successfully determined crystalline structures. Nevertheless, new techniques are necessary as conventional methods cannot provide detailed structural information to probe the disordered structures, such as nanostructured and amorphous materials.

The pair distribution function (PDF) method based on X-ray and neutron diffraction is widely employed for providing quantitative information in amorphous materials [1]. Nonetheless, understanding medium-range structural order in amorphous materials is non-trivial, where the position of atoms cannot be assigned by any equation based on translation vectors. Electron Diffraction (ED) related PDF (ePDF) in Transmission Electron Microscope has the advantage of investigating ordering locally. However, ePDF-based analyses may be affected by dynamical effects, altering the scattering intensities.

This work aims to expand the developed methodology to battery materials, by employing electron diffraction data to obtain PDF coupled with electron energy loss spectroscopy [2]. This will enable us to investigate the role of volume expansion during lithiation in silicon-carbon-based anode materials which is crucial for the functioning of the electrode.

Thickness Dependence and *In Situ* Studies of Nanomechanical Properties of Polymer Thin Films Upon Gas-Polymer Interaction using Amplitude Modulation Frequency Modulation (AMFM) Atomic Force Microscopy (AFM)SuwarnaDatar, BishakhaRay and PramodBankar; Defence Institute of Advanced Technology (DIAT), India

Polymer thin films are used for several applications and their thickness reduction is most important in future generation storage devices when they are used as dielectrics. Thickness reduction inevitably affects the quality of the polymer films. Furthermore, for environment safety these polymers are also used for the adsorption of the Volatile organic compounds (VOCs). Understanding the nanomechanical properties of thin polymer films and the effect of their interactions with VOCs on these properties is important in several applications like environment monitoring systems in closed spaces, sensors, electronics and packaging systems. In the present work we try to study the effect of thickness on the nanomechanical properties of polymer thin films in two different forms; deposited on the substrate and free standing films using Amplitude Modulation Frequency Modulation (AMFM) Atomic Force Microrscopy (AFM). The study has been done for polymer films of polystyrene and polymethacrylate deposited on the substrate and as free standing films. Changes in the measurement of Young's modulus of the polymer when it is free standing and deposited on the substrates were observed with respect to the thickness of the film. It has been observed that as the thickness of the film is reduced the young's modulus measured for the two forms of the films do not match. The causes of changes have been discussed based on the interaction of tip with the free-standing and substrate deposited films. Furthermore, it is observed that the interaction of VOCs is quite different in both cases which is analyzed based on the changes observed in young's modulus by AMFM measurement. AMFM is a unique technique to study nanoscale viscoelastic properties of polymers. It can map the elastic properties of materials with unprecedented spatial resolution. In AMFM, conventional amplitude modulation and frequency modulation modes are combined to measure viscoelastic properties of materials with sub-10 nm resolution. The results have been discussed highlighting the importance and uniqueness of AMFM techniques in such measurements.

Cathode Electrolyte Interphase on the Surface of High-Nickel Cathode Materials based on Different Residual Lithium Species SangbeomKim[1], InhyeKim[1], Hyun-seungKim[2] and YoungjinKim[1]; [1]Kangwon National University, Korea (the Republic of); [2]Korea Electronics Technology Institute, Korea (the Republic of)

The development of residual lithium compounds (LiOH and Li_2CO_3) on the surface of high-Ni cathodes pose severe practical challenges that are extremely important to battery performance, despite the fact that such high Ni content in layered oxide cathodes might deliver desired energy density enhancement [1]. Residual lithium compounds may undergo spontaneous formation on cathode materials with high nickel content when subjected to H_2O and CO_2 in the surrounding atmosphere during storage. The presence of residual lithium on the surface enables the electrochemical oxidation of Li_2CO_3, leading to the evolution of gases such as O_2 and CO_2 at a high voltage. The release of gas during the cycling process leads to the expansion of the battery, hence substantially elevating the likelihood of cell rupture while in operation. In addition, the highly alkaline hydroxide ion derived from remaining lithium content induces the gelation and flocculation phenomena during the slurry coating procedure, mostly through the defluorination process of the polyvinylidene fluoride (PVdF) binder present in the slurry. The occurrence of gelation and flocculation during the slurry casting process gives rise to the formation of uneven surfaces, which represents a significant challenge in the commercial mass manufacturing of high-nickel layered oxide cathodes. This suggests that the practical application of the high-nickel layered oxide, which exhibits superior performance, is challenging unless there is meticulous control over the remaining lithium content. Extensive research has been performed in recent times to address the challenges associated with the dry coating process of high-Ni multilayer oxides. The careful management of residual lithium contents in high-nickel cathodes is imperative due to the safety and slurry gelation problems associated with their impact. However, research on cathode electrolyte interphase (CEI) components and electrolyte decomposition according to residual lithium components (LiOH and Li_2CO_3) is insufficient to date because experimental design and advanced analysis are challenging.

In this study, we present for the first time a comprehensive analysis of the formation of CEI with regard to residual lithium components from $LiNi_{0.9}Co_{0.05}Mn_{0.05}O_2$ (NCM90) with little difference in bulk structure. The NCM90 was obtained with different lithium hydroxide sources to form different residual lithium compounds and their content. It was shown that an increase in Li_2CO_3 content in NCM90 results in the significant formation of CEI as well as the presence of distinct CEI species. This finding was obtained by advanced analytical techniques such as Time-of-Flight secondary ion mass spectrometry (TOF-SIMS) and X-ray photoelectron spectroscopy (XPS). Furthermore, the LiOH concentration present on the surface of NCM90 electrode materials was analyzed using the titration method, wherein methanol was utilized as the solvent for the preparation of the analyte [2]. It is anticipated that this study will make a valuable contribution to the comprehension of methods for lowering residual lithium as well as developing new electrolyte additives in high-nickel layered oxide cathodes, benefiting both the academic and industrial sectors.

Subnanometer-Scale Mobile Structures Localized at an Interface Between One-Dimensionally Aligned Sulfonate Groups and Water Investigated by Three-Dimensional Scanning AFM MasayukiMorimoto and HitoshiAsakawa; Kanazawa University, Japan

The sulfonate groups play critical roles in various interfacial phenomena, such as proton conduction and ion exchange. In proton-conductive materials such as Nafion, control of the network structure formed by the coexistence of hydrophobic chains and sulfonate groups leads to efficient proton conduction. Understanding the spatial distribution of water molecules and ions around sulfonate groups at the single functional group scale is required to elucidate the proton conduction mechanism. For this purpose, a technique for directly measuring the interface between sulfonate groups and water at the nanoscale is required. Although direct measurements of local interfacial waters and ions are difficult even with well-established methods, a three-dimensional scanning atomic force microscope (3D-AFM) can visualize the local interfacial structures at subnanometer resolution by combining frequency modulation AFM (FM-AFM).
In this study, we directly measured the interfacial structure formed on one-dimensionally arranged sulfonate groups in a self-assembled monolayer (SAM) with the coexistence of hydrophobic alkyl chains by 3D-AFM. Prepared sulfonate-terminated alkanethiols SAMs (SO_3-SAM) showed stripe-like structures. Owing to the lying-down orientations of sulfonate-terminated alkanethiol molecules in the stripe-like structures, one-dimensionally aligned structures of the sulfonate groups were formed. As a result, the 1D-aligned sulfonate groups were surrounded by hydrophobic alkyl chains. The lying-down SO_3-SAM structures can be considered a structural model for a controlled nano-environment where hydrophobic groups and sulfonate groups coexist. Our results suggested that the growth and collapse of mobile interfacial structures exist at the SO_3-SAM surfaces based on analysis of the successive AFM images. In addition, the mobile interfacial structures were localized in the hydrophilic region with the 1D-aligned sulfonate groups. The 3D-AFM measurements were performed to understand the spatial distribution of the mobile interfacial structures. By analyzing the 3D-AFM images obtained at the interfacial nanospace, the mobile interfacial structures were visualized as localized regions with higher repulsive forces than the surrounding areas. In the presentation, we will discuss the detailed analysis of FM-AFM and 3D-AFM images and the origin of mobile interfacial structures.

Ferroelectric $SrTiO_3$ Induced by Energetic Ion Irradiation FuxiangZhang; Songshan Lake Materials Laboratory, China

$SrTiO_3$(STO) is a very important electric material and bulk STO has a centrosymmetric cubic structure at room temperature, and there is a cubic to tetragonal structural transition at 105 K [1].

The dielectric constant of SrTiO3 deviates from the classical Curie–Weiss law at low temperature, and it increases rapidly (up to 1.8×10^4 at 1.4 K) as the temperature is reduced [2]. The low temperature electric behavior of STO approaches a ferroelectric phase transition; however, bulk STO is still paraelectric to the lowest temperature as a result of quantum fluctuations [3]. The 'quantum paraelectrics' or 'incipient ferroelectronics' of STO and other perovskite oxides have been a topic of considerable interest during the past few decades [3]. The ferroelectric transition of STO at low temperature can be induced by strains from lattice mismatch for thin films, chemical or isotopic substitution, electric field, pressure and controlled grain size. Due to important applications in electronic devices, the coupling between strain and ferroelectricity in STO has been intensively studied, and the relevant work is well illustrated in a recent review article [4]. By controlling the in-plane lattice strain, the critical temperature *Tc* of ferroelectric transition in thin film SrTiO3 or superlattice can be profoundly enhanced [5,7,8], even to room temperature [6]. However, the biaxial strains in thin films depend on the choice of substrate and film thickness, which turns out to be challenging for the synthesis of uniformly strained films because of the undesirable relaxation that occur when the thickness of a sample exceeds the critical values.
In this work [9,10], with energetic ion irradiation, bulk STO turnes form paraelectric to ferroelectric at room temperature due to the irradiation-induced strain. The strain profile in bulk STO is determined by symmetric X-ray diffraction and simulation. The irradiation induced atomic-level defects are characterized with high resolution TEM. The ferroelectric properties of the damaged zone is measured directly with microelectronic techniques. All the results suggest that the out-of-plane strains induced by ion bombardment make a local phase transformation of bulk STO from cubic to tetragonal and result in ferroelectricity at room temperature.

Resistive Switching Behaviors of TiO_2 Protection Layers via Electrochemical Forming Process for Robust Photoelectrochemcial Water Splitting Dong SuKim, Hak HyeonLee, Kun WoongLee and Hyung KounCho; Sungkyunkwan University, Korea (the Republic of)

In typical photoelectrochemical (PEC) cells using cuprous oxide (Cu_2O), semiconductor photoabsorbers have passivated by protection layers, such as TiO_2, where the trade-off between high photocurrent and durable stability is inevitably involved with their thickness in the typical energy band transport along the conduction band. Herein, as a strategically advanced charge transport mechanism, an outstanding conducting filament transport mechanism for vigorous and robust PEC operation is innovatively suggested, which is motivated from the concept of nano-filaments showing non-volatile metallic-like current flow characteristics in resistance-change memory devices. The breakdown-like electrochemical forming behavior effectively occurs with rapid current increase in voltage sweep over ~ 2 V vs. RHE and the fundamental properties of filaments, such as diameter, density, and conductivity, have been controlled by varying artificially compliance currents. Especially, it should be noticed that this process requires i) no top electrodes obstructing the light harvesting and the injection of photo-charges into electrolytes and ii) no individual forming process sweeping point-by-point bias, and provides iii) electrochemical forming sites with homogeneous and dense distribution. Additionally, some photocorrosive sites inducing photocurrent degradation are perfectly passivated by preferential photoelectrodeposition of co-catalysts. In consequence, from the electrochemical filament forming process and selective Pt-photoelectrodeposition on filaments, the $Cu_2O/AZO/TiO_2$ photocathodes exhibit unprecedented photocurrent density of about 11.9 mA/cm^2 and open circuit potential of 0.73 V and produces vigorous hydrogen and oxygen evolutions for over 100 h, even though the TiO_2 passivation film has exceeding 100 nm thickness.

Revealing of Photocatalytic Performance Variations of $ZnIn_2S_4$ Nanoparticles using *In-Situ* XPSHangilLee; Sookmyung Women's University, Korea (the Republic of)

$ZnIn_2S_4$ nanoparticle (NP) photocatalysts were successfully synthesized to investigate the wavelength-dependent photocatalytic activity owing to the concentration of Zn vacancies at the surface of the $ZnIn_2S_4$ NPs. in situ X-ray photoelectron spectroscopy were performed to investigate the effect of Zn vacancies on the photocatalytic activity of the $ZnIn_2S_4$ NPs. Furthermore, the wavelength-dependent photocatalytic degradation (PCD) activity of the $ZnIn_2S_4$ NPs using 2,5-hydroxymethylfurfural (HMF) was investigated over a wide range. The selective oxidation of HMF using $ZnIn_2S_4$ NPs resulted in the formation of 2,5-furandicarboxylic acid via 2,5-diformylfuran with an efficiency of over 40% over a wide wavelength range. Thus, the irradiation wavelength for PCD depended on the number of defect structures introduced into the $ZnIn_2S_4$ NPs by the sulfur source.

Highly Reversible Zinc Metal Anode Enabled by Zinc Fluoroborate Salt-Based Hydrous Organic Electrolyte ShuyunWang; City University of Hong Kong, Hong Kong

Although $Zn(BF_4)_2$ contains favorable ingredients of fluorine for the formation ofZnF_2 rich- Zn^{2+} ion conducting SEI, the aqueous electrolyte based on inorganic Zn salt of $Zn(BF_4)_2$ xH_2O shows high Hammett acidity with pH value <1, which gives rise to severe corrosion of metallic Zn electrode and thermodynamically spontaneous HER. Here, we employ a hydrophilic organic solvent of VC and $Zn(BF_4)_2$ $4H_2O$ for a hydrous organic electrolyte, denoted as ZnBF-VC. With the ZnBF-VC electrolyte used, the VC molecules preferably adsorb on the Zn surface to block H_2O molecules and Zn metals, which formed the structure of $Zn(VC)_{2.89}(H2O)_{1.28}(BF4)_{1.83}$. The distinct SEI enables favorable Zn^{2+} ion transport and can protect metallic Zn electrode from corrosion, side reactions and dendrite formation. Consequently, the Zn-Zn cells cycled over 2200 h and the Zn-Cu asymmetric cells maintained a CE of ~99.7% over 550 cycles at 1 mA cm^{-2}. Whereas, the Zn-Zn cells broke after only 74 cycles in aqueous electrolyte. Additionally, the Zn-MnHCF full cell with ZnBF-VC demonstrates excellent cycling stability, achieving a high specific capacity of 146.2 mAh g^{-1}, and a high retention rate of 85.3% over 1300 cycles at 0.4 A g^{-1}, while the cell using the referred ZnBF- H_2O electrolyte survived only ~6 cycles.

8:00 PM CH01.13.12
Characterization and Testing of Porous Boron Nitride Towards Application in Adsorption-Based Processes AnoukL'Hermitte[1,2], DanielM. Dawson[3], PilarFerrer[4], KanakRoy[5], GeorgHeld[4], MarcusH. Yio[2], TakuyaHirosawa[6], ToshihiroIsobe[6], SharonAshbrook[3] and CamillePetit[2]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom; [3]University of St Andrews, United Kingdom; [4]Diamond Light Source, United Kingdom; [5]Banaras Hindu University, India; [6]Tokyo Institute of Technology, Japan

Industrial separation processes account for 10-15% of the global energy consumption.[1] The energy cost of large-scale gas and liquid separations like distillation can be significantly reduced by moving towards adsorption processes. An example of an inorganic adsorbent is porous boron nitride (BN): this material exhibits high surface area and porosity, and benefits from greater oxidative and thermal stability than common carbonaceous adsorbents.[2] Our group previously developed a new method to produce porous BN with enhanced surface area, tunable porosity[3] and promising liquid and gas separations performance. In more recent work, we explored the potential of porous BN as an efficient and moisture-resistant adsorbent for molecular separations at industrial scale. To do so and foster scaling-up, two questions have been addressed: 1) "How does porous BN form and what are the controlling synthesis parameters?" and 2) "How can one enhance the water stability of this adsorbent?".
To address point 1, we investigated the formation mechanism of porous BN using a range of analytical and spectroscopic techniques including, among others, solid-state NMR and synchrotron-based X-ray absorption spectroscopy.[4] This in-depth characterization exercise of porous BN and its intermediates obtained at different temperatures allowed us to propose a detailed formation mechanism that involves carbon nitride as intermediate. We showed how the porosity develops in the material, what synthesis factors can influence it and what gases are responsible for its generation. Overall, our study allowed to support with more certainty the hypotheses formulated in previous reports in the field.
To address point 2, we developed two functionalization routes to modify the surface of porous BN and enhance its hydrophobicity and resistance to moisture.[5] The first route involved direct silylation of porous BN powder followed by pelletization, whereas the second route used chemical vapor deposition on porous BN pellets. In parallel, we developed a method relying on saturated salt solutions[6] to mimic two different levels of humidity exposure relevant to storage and sorption testing conditions. Using FTIR, XRD, XPS, μXRF, TGA, N_2 sorption and mercury intrusion porosimetry, we analyzed the samples before and after functionalization, as well as before and after exposure to humidity. Our results pointed to the efficiency of the functionalization approach to produce moisture-resistant BN-based adsorbents. Therefore, thanks to the extensive use of characterization techniques, this research paved the way for scaling up the synthesis of porous BN towards lower carbon emissions in industrial applications.[7]

Correlating Electrical, Catalytic Properties with Pair Distribution Functions of Nano-Cu-Ceria Siu-WaiChan, YanheLi, Syed SaamRassol, HaotianChen and HaolanSun; Columbia University, United States

This study delves into the influence of copper doping on the electrical conductivity of cerium oxide nanoparticles. We employ a combination of Pair Distribution Function (PDF) analysis and Impedance Spectroscopy (EIS) to investigate the structural and electrical characteristics of Cu-doped CeO2 nanoparticles synthesized via a coprecipitation method. Previously, such prepared nano-Cu-ceria has shown exceptional catalytic activity better than other nano Cu-ceria's.

To conduct our investigation, we pressed and sintered nanoparticles of 2-8%Cu-doped CeO2 into bulk pellets, enabling AC impedance measurements. Synchrotron PDF results reveal correlations between doping concentration, particle size, and the equilibrium lattice parameter, providing insights into the structural modifications induced by Cu incorporation. Additionally, we find Cu doping to have a significant impact on the electrical properties of CeO2 nanoparticles, seeing a correlation between doping concentration, conductivity, and charge carrier density, which also correlate catalytic activities.

In summary, this research advances our understanding of the structural changes induced by Cu doping in cerium oxide nanoparticles and underscores the direct influence of doping concentration on electrical characteristics as well as catalytic properties. These findings hold promise for tailoring materials with enhanced electrical and catalytic performance for a wide range of applications and reactions.

8:00 PM CH01.13.14
Generating Electrical Power from Low-Grade Waste Heat through Thermoelectrochemical Cells Utilizing Titanium Carbide Electrodes Byung-JoLee, Sang-MunJung and Yong-TaeKim; POSTECH, Korea (the Republic of)

In response to growing environmental concerns and the limitations of traditional carbon-based fuels, there has been significant research into sustainable energy resources, particularly those that harness ambient energy sources such as thermal, wind, kinetic, and solar energy. However, efficiently harvesting low-grade waste heat, produced by sources like power plants and environmental body heat, has remained a challenge due to the cost and inefficiency of large-scale thermal energy conversion devices. Thermoelectrochemical cells (TECs) are highly effective devices for converting low-grade waste heat into electricity. However, TECs that rely on hexacyanoferrate (Fe(CN)64–/Fe(CN)63–, HCF) electrodes often use expensive metals like platinum (Pt), which hinders their practical use. In this study, we propose an alternative to Pt electrodes for TECs in the form of titanium carbide (TiC) electrodes, synthesized through the thermal decomposition of CH4. While titanium itself is challenging to use in TECs, TiC emerges as a promising non-noble metal electrode due to its exceptional stability and reaction kinetics, suitable for various electrochemical systems. Our experiments revealed that TiC-based TECs achieved a power output of 397.20 mW m–2, nearly matching that of Pt electrodes. Additionally, TiC demonstrated long-term stability in the electrolyte during operation, suggesting its potential to replace Pt electrodes and facilitate the commercialization of TECs.

8:00 PM CH01.13.15
Bias-Free Copper-Nickel Alloy/Graphene/Si Heterojunction as Catalytic Photocathode for Photovoltaic-Assisted Ammonia Production Hsing-WenWu[1], LuYang-Sheng[1], LiShao-Sian[1] and ChenChun-Wei[2]; [1]National Taipei University of Technology, Taiwan; [2]National Taiwan University, Taiwan

With the rise of world's population, the demand of energy is also getting higher, which further accelerates the consumption of fossil fuels and the destruction of natural ecosystems. Solar energy is an alternative to fossil fuels because it has the highest energy content. However, the development of solar energy is limited by its intermittency and volatility, therefore storing solar energy becomes an important issue. Since ammonia is a suitable compound for storing solar energy, and it is a carbon-free chemical with high energy density, the production of ammonia becomes an important goal in our research.
The mainstream production of ammonia in the industry relies on the Haber-Bosch process, which requires harsh operating conditions at high temperatures and pressure. An alternative technique based on the green synthesis route of ammonia by catalytic reactions has recently attracted tremendous interest.
With efficient catalyst materials, ammonia is produced from nitrogen or nitrate by sequential reactions at ambient conditions. However, nitrogen is an inert molecule and has strong triple bond, causing a lower faradaic efficiency under nitrogen (N_2) reduction reaction (NRR). Furthermore, the potential barrier to triggering ammonia reduction is still high; thus, external energy, such as electric potential, is always required to drive the reaction. The potential barrier to triggering ammonia reduction is still high; thus, external energy, such as electric potential, is always required to drive the reaction. Here we report an improved ammonia reduction system of Cu-Ni coated graphene/HJT photocathode promoted by the photovoltaic effect. A commercial Si solar cell was attached with a monolayer of graphene where Cu-Ni catalyst was then directly grown on it by electrochemical deposition.
We attempted to electrochemically electrodeposition Cu-Ni nanostructures on graphene/HJT as an electrocatalyst for NtRR. Cu and Ni have the same crystal structure (FCC), similar valence, close values of atomic radii, and electronegativity, allowing the formation of homogeneous solutions over the entire composition range. Next, we test the catalytic performance of Cu-Ni /Gr/HJT in the electrochemical nitrate reduction reaction. Our results show that graphene is an excellent supporting material for Cu-Ni catalysts and an efficient medium for transferring photogenerated electrons from Si solar cell to Cu-Ni nanostructure.
As a result, the additional solar energy boosted the reaction kinetic of Cu-Ni catalysts for ammonia reduction. Under AM 1.5G solar simulator illumination, the overpotential required for ammonia reduction is suppressed at least by 100mV, leading to improved Faraday efficiency from 80% to over 90% and yield rate from 525 $\mu g\ h^{-1}cm^{-2}$ to 750 $\mu g\ h^{-1}cm^{-2}$.
To achieve bias-free reaction, we intend to replace batteries with solar cell. Additionally, we replace Pt (anode material) with Ni-Fe LDH since it possesses better performance for oxygen evolution reaction (OER).

8:00 PM CH01.13.16
Micro Four-Point Probe for Anisotropic Thermal Diffusivity Mapping NeetuLamba[1], Braulio BeltránPitarch[1,2], MuhamedDawod[3], AlexBerner[3], BennyGuralnik[2], YaronAmouyal[3], OleHansen[1], NiniPryds[1] and Dirch HjorthPetersen[1]; [1]Technical University of Denmark, Denmark; [2]KLA, Denmark; [3]Technion–Israel Institute of Technology, Israel

High-resolution microscale thermal diffusivity characterization is vital for a deeper understanding of materials used in thermoelectric energy harvesters, nano/microelectronic, and thermal management. Analyzing the thermal properties of individual grains can advance the development of these materials, however, only a few techniques currently exist for microscale characterization of the thermal properties.
Micro four-point probe (M4PP) has been widely used by the semiconductor industry to characterize thin films for sheet resistance, carrier mobility, and magnetoresistance. Currently, we are exploring the use of M4PP for estimating the thermal properties of materials including the Seebeck coefficient, thermal diffusivity, and the temperature coefficient of resistance.
Here, I will present a novel method for measuring the thermal diffusivity of individual grains with varying orientations using the M4PP. The local thermal diffusivity measurements were performed on a prototypical bulk thermoelectric Bi_2Te_3 sample at room temperature. The thermal diffusivity was then correlated with the orientation of the grains measured with electron-backscattered diffraction (EBSD). The method for measuring thermal diffusivity proposed in this study provides rapid and accurate thermal characterization, thereby opening up opportunities for a detailed understanding of microstructures.

Ester Side Chain Functionalization Enhances Mechanical Properties of Poly(3-hexylthiophene) while Maintaining High Hole Mobility LexiR. Knight[1], QuynhTran[1], GuanchunRui[1], GageMason[2], PiumiKulatunga[2], AlexanderBushnell[1], SoniaHou[1], LeiZhu[1], SimonRondeau-Gagne[2] and GenevieveSauve[1]; [1]Case Western Reserve University, United States; [2]University of Windsor, Canada

Poly(3-alkylthiophene)s represent a class of polymers known for their easy synthesis and tendency to crystallize which makes them promising candidates for facilitating charge transport in organic electronics. Organic electronics, including organic photovoltaics (OPVs) and organic thin-film transistors (OTFTs), have several advantages including their lightweight nature, cost-effectiveness, ease of fabrication, and flexibility. For a polymer to be a good candidate in organic electronics, it must have high charge transport and high flexibility, two properties that are often mutually exclusive. To increase both electrical and mechanical properties, we introduced ester groups in the side chains into poly(3-alkylthiophene). Esters are known for their plasticizing effect. Here, we synthesized and characterized two sets of random copolymers: poly(3-alkylthiophene-2,5-diyl)-ran-(3-(6-pentanoatehexyl)thiophene-2,5-diyl) in which the alkyl side chain is either hexyl (P3HT series) or dodecyl (P3DDT series) with varying ester content. The optical, thermal, structural, mechanical, and electrical properties of the copolymer series were investigated. Both electrical and mechanical properties were optimized at 10% ester content in the P3HT series: high fracture strain of 29%, high tensile strength at 3.9 MPa, and large toughness of 90 J/m^3 all while maintaining the same charge carrier mobility as P3HT at 0.12 $cm^2V^{-1}s^{-1}$. The mechanical and electrical properties of the P3DDT series did not fluctuate much with varying ester content between 0-25%, potentially due to the crystallization of the longer side chains altering the microphase separation. Differential Scanning Calorimetry (DSC) and Grazing Incidence Wide-Angle X-ray Diffraction (GIWAXD) suggest microphase separation between the dodecyl side chain and main chain of the P3DDT series which was not observed in

the P3HT series. Therefore, the ester functionalization did not plasticize the P3DDT series as well as in the P3HT series. These results show that a small ester functionalization can significantly increase the flexibility of the polymer while maintaining high charge transport.

Thin Films of Fluorescent Pigments acting as a Wavelength-Shifter to Improve The Efficiency of Solar Cells OtávioJ. de Oliveira[1], Natáliad. Coutinho[1], ThaisCrestani[2], Gabriel ThomasD. de Freitas[1], Ana Paulad. Modesto[1], WesleyC. Muscelli[1], MarceloG. Villalva[1] and FranciscoC. Marques[1]; [1]State University of Campinas, Brazil; [2]BYD, Brazil

Although silicon and perovskite solar cells have achieved efficiency as high as 26% [1], their efficiency is still limited by several factors, such as reduced efficiency in the ultraviolet region of the solar spectrum [2]. One of the proposed mechanisms to overcome this problem is to use wavelength-shifting materials. Here we investigate the properties of low-cost photoluminescent pigment thin films currently used in coatings, graphic arts, cosmetics, and adhesives. The objective was to evaluate the ability to shift ultraviolet light to the wavelength where silicon solar cells are most efficient (around 600 nm). Precursor solutions were prepared by dissolving the pigment in ethanol. The deposition of the thin film was carried out using the spin-coating technique. After each deposition, the substrates were placed on a heating plate (100°C) for 10 minutes to evaporate the solvent. The pigments (powder and thin films) were characterized by X-ray diffraction, AFM, UV-Vis transmittance, and photoluminescence. The XRD diffractogram is compatible with the expected structure of organic pigments, presenting an amorphous characteristic. Photoluminescence measurements show that PL emission covers a range of 500 – 650 nm, which is in the region of highest efficiency of silicon solar cells. Thin films deposited by spin-coating have good uniformity. Absorption occurs in the wavelength range of 300 to 700 nm, being more intense in the UV range. PL emission, on the other hand, is shifted to the range 550 to 700 nm. The optical and structural properties of the films demonstrated the potential use of low-cost fluorescent pigments as wavelength shifters for application in solar cells. Further investigations are needed to evaluate the effect of these films on solar cells.

Temperature-Dependent Transport Properties of High-Performance Metal Halide Perovskites ChaeyounKim[1], OkiGunawan[2], MinjinKim[3], Dong SukKim[4] and ByunghaShin[1]; [1]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]IBM T. J. Watson Research Center, United States; [3]Korea Institute of Energy Research (KIER), Korea (the Republic of); [4]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of)

We have recently developed a “temperature-dependent carrier-resolved photo-Hall” technique that enables measurements of various transport properties in temperature ranges from 20K to 340K. In the field of optoelectronics applications, the transport characteristics of minority carriers as well as majority carriers are crucial. However, Hall measurement, which is one of the fundamental characterization methods in the semiconductor field, has a limitation in that only information on the majority carrier can be obtained. We have previously developed a “carrier-resolved photo-Hall” technique that enables the extraction of critical parameters for both majority and minority carriers in electronic materials, such as carrier density, mobility, recombination lifetime, and diffusion length. This technology is enabled by a new photo-Hall equation and a highly sensitive AC Hall system based on parallel dipole line magnets. Furthermore, since the temperature can significantly affect the carrier transport and recombination processes in solar cells, understanding the temperature-dependent behavior of charge carrier transport is important for comprehending solar cell performance and operation. Here we report our recent advancements in the “carrier-resolved photo-Hall” technique that allows photo-Hall measurements in the temperature range of 20-340K. A temperature-dependent photo-Hall analysis was successfully performed on a reference single crystalline p-type silicon and on a metal halide perovskite exhibiting a solar cell efficiency of 25.7%. We investigated important information such as temperature-dependent photoconductivity, mobility scattering mechanisms, and dopant energy levels. In the high-performance perovskite thin film samples, the mobility of electrons and holes increased with temperature up to room temperature and then decreased with the further increase of temperature, indicating impurity scattering and phonon scattering are dominant below and above room temperature, respectively. Also, we investigated the influence of temperature and light intensity on transport characteristics, such as carrier density of photo-generated charges, lifetime, and diffusion length. The lifetime and carrier density of photo-generated charges increased with temperature, and this increase can be advantageous in situations where solar cells heat up during operation. This advance in transport characterization technologies will provide a more detailed understanding of carrier transport properties of electronic materials and contribute to the further development in many applications including solar cells.

Title: Structural, Magnetic, and Magnetocaloric Properties of Erbium and Aluminum Co-Doped $HoCrO_3$ Compound JolaikhaSultana; The University of Memphis, United States

This study describes the synthesis and magnetocaloric properties of rare-earth chromite’s, viz., $HoCrO_3$, $Ho_{0.67}Er_{0.33}CrO_3$ and $Ho_{0.67}Er_{0.33}Cr_{0.5}Al_{0.5}O_3$ orthochromites These materials are considered functional materials with interesting magnetic and magnetocaloric properties, making them suitable for potential applications in magnetic refrigeration. The samples were synthesized using facile sol-gel auto combustion method, As confirmed by X-ray diffraction analysis, the resulting compounds have a pure orthorhombic crystal structure with the space group Pbnm,. The lattice parameters and volume of the samples were observed to decrease with the substitution of Al^{3+} ions. This decrease can be attributed to the smaller ionic radius of Al^{3+} compared to Cr^3. The bond angle and bond-length of Cr-O-Cr of studied compounds were observed to vary with the substitution, which observed to have influence on their magnetic and magnetocaloric properties. The magnetic measurements were performed using PPMS in the temperature range 5K -300K and field up to 5T. The temperature dependent magnetization curve shows magnetic transition at 141 K for $HoCrO_3$, 135 K for $Ho_{0.67}Er_{0.33}CrO_3$, and 35 K for $Ho_{0.67}Er_{0.33}Cr_{0.5}Al_{0.5}O_3$, respectively. The magnetization and magnetic entropy change (ΔSm), determined from magnetic isotherms, were found to increase with the introduction of Er and Al doping. The maximum magnetic entropy change observed was 6.46 $Jkg^{-1}K^{-1}$ for $HoCrO_3$, 8.04 $Jkg^{-1}K^{-1}$ for $Ho_{0.67}Er_{0.33}CrO_3$, and further increased to 9.70 $Jkg^{-1}K^{-1}$ for $Ho_{0.67}Er_{0.33}Cr_{0.5}Al_{0.5}O_3$ under an applied field of up to 5T. This enhancement in magnetization and magnetic entropy change is attributed to the Al^{3+} substitution, which affects the Cr^{3+} -Cr^{3+} exchange coupling due to changes in the Cr1-O1-Cr1 bond angle and Cr1-O1 bond lengths.
The study concludes that the co-doped chromite’s, particularly Er^{3+} and Al^{3+} co-doped $HoCrO_3$, have not been previously reported in the literature. The observed magnetocaloric properties, especially in the Al^{3+} doped samples, suggest their potential for low-temperature magnetic refrigeration applications.

Aluminum Doped $GdCr_{0.5}Al_{0.5}O_3$ and $TbCr_{0.5}Al_{0.5}O_3$ Chromate Compounds: A Comparative Magnetocaloric Effect Study JolaikhaSultana[1], AsrafSawon[2], GraceBrzykcy[2], ArjunPathak[2] and SanjayMishra[1]; [1]The University of Memphis, United States; [2]University at Buffalo, The State University of New York, United States

Magnetocaloric materials are substances that exhibit a change in temperature in response to an applied magnetic field. They have the potential to be more efficient and environmentally friendly than conventional refrigeration systems that rely on vapor compression. Lanthanides orthochromites are materials that include both lanthanides and transition metals, making them suitable candidates for magnetocaloric research because of their unique magnetic properties. Earlier studies showed that doping with Lanthanide ion (A-site) or, transition metal ion (B- site) or both sites can bring about desirable structural and electronic changes in the material, enhancing its magnetic properties. This study examines the effect of substituting Al^{3+} ions at the B-site of $GdCrO_3$ and $TbCrO_3$ orthochromites on their structural, magnetic, and magnetocaloric properties.

The samples were synthesized using the sol-gel auto combustion method. X-ray diffraction study confirms the presence of a pure orthorhombic phase with the *Pbnm* space group. The lattice parameters and volume of the samples decreased with Al^{3+} substitution due to the smaller ionic radius of Al^{3+}(0.535 Å) compared to Cr^{3+}(0.615 Å). Magnetic measurements were conducted between 5K and 300K under magnetic fields up to 0.2 T. The magnetization measurements revealed the antiferromagnetic ordering of Cr^{3+} spins with a Neel temperature (T_N) of approximately 169K for $GdCrO_3$ and 157K for $TbCrO_3$. The substitution of Al^{3+} at the Cr^{3+} site led to a decrease in Neel temperature, T_N , indicating a modification of the magnetic behavior in the doped samples. The temperature dependence of the magnetic entropy change (-ΔSm) for different applied magnetic fields (ΔH) demonstrated that the values of -ΔSm decreased with increasing Al^{3+} substitution. The maximum values of -ΔSm were found to be 27.30$Jkg^{-1}K^{-1}$ at 7K with a 5T applied field for $GdCrO_3$ and 16.60$Jkg^{-1}K^{-1}$ at 7K with a 5T applied field for $GdCr_{0.5}Al_{0.5}O_3$. Similarly, for $TbCrO_3$, the maximum value was 11.53$Jkg^{-1}K^{-1}$ at 7K with a 5T applied field, while for $TbCr_{0.5}Al_{0.5}O_3$, it was 4.20$Jkg^{-1}K^{-1}$ at 11K with a 5T applied field. The observed variation in maximum entropy changes is attributed to the Al^{3+} substitution in the studied chromite’s, which influences the Cr^{3+}- O^{2-}-Cr^{3+} exchange coupling by altering the Cr1-O1-Cr1 bond angle and Cr1-O1 bond lengths. It is noted that Al^{3+} doped $GdCrO_3$ and $ErCrO_3$ have not been previously reported in the literature. The magnetic entropy values obtained are comparable to those of other studied chromite’s, suggesting that these compounds hold promise for low-temperature magnetic refrigeration applications.

Leveraging Image and Data Processing Techniques to Investigate Ionomer Distribution within Catalyst Layers of PEMFCs and PEMWEs MariahBatool[1], MaryamAhmadi[1], CarlosBaez-Cotto[2], LindaNey[3], JeronimoHorstmann[3], JaysonFoster[4], NadaZamel[3], ScottMauger[2], SvitlanaPylypenko[4] and JasnaJankovic[1]; [1]University of Connecticut, United States; [2]National

Renewable Energy Laboratory, United States; [3]Fraunhofer Institute for Solar Energy Systems ISE, Germany; [4]Colorado School of Mines, United States

Advanced materials characterization tools such as scanning transmission electron microscopy and energy dispersive spectroscopy (STEM/EDS) offer a surfeit of information, only a fraction of which is comprehensible and evident to the human eye. This is especially true for complex, multi-component electrochemical systems such as polymer electrolyte membrane fuel cells (PEMFC) and water electrolyzers (PEMWE) where understanding component interactions within membrane electrode assembly (MEA) is a challenging task [1]. This understanding is crucial to optimize the electrodes in MEAs and achieve a high performance and durability of these devices. Therefore, to aid deeper analysis ranging from better visualization to quantification of such microstructural features, the utilization of advanced data science algorithms and image processing tools and techniques, in conjunction with advanced imaging and spectroscopy techniques, become categorically essential [2].

In this study, an in-house developed framework built on Python is utilized to study ionomer distribution and its interaction with the catalyst within the catalyst layer for PEMFCs and PEMWEs synthesized/fabricated via different manufacturing processes. Ionomer-catalyst interaction affects the protonic conduction, mass transport, and catalyst utilization but is often difficult to visualize and quantify without optimized imaging and specialized data processing which is made possible via the developed framework [3]. Sensitivity analysis was carried out to optimize the framework's performance to accurately reflect the changes in microstructure due to variations in synthesis/fabrication parameters. Not only did the framework help explore ionomer connectivity but also measured the degree of ionomer-catalyst coverage through rapid analysis requiring minimal user interaction. Furthermore, the applicability and implications of using the developed framework to form structure-performance correlations were evaluated yielding valuable insights about ionomer behavior in inks and electrodes. The introduced framework exhibits great potential which allows it to extend its utility to other clean energy applications with minimal adjustments.

Non-Destructive Performance Comparison of Li-Ion 2032 Coin Cells for Non-Ambient Temperature Applications ShintaroInaba[1], SimonJi[2] and HillarySmith[1]; [1]Swarthmore College, United States; [2]Princeton University, United States

Coin cell batteries have long found diverse applications in small consumer products. Rechargeable lithium-based coin cells are now commercially available offering an eco-friendly alternative, but their use is not as widespread. Performance of these batteries under non-ambient temperature conditions is important for many applications, but note widely investigated. We report on a non-destructive, temperature-dependent performance comparison of three different commercially available, rechargeable 2032 coin cell models. Batteries were cycled galvanostatically over at least 100 cycles at three different temperatures: 60°C, 24°C, and 0°C. In-situ data collection was performed using temperature-controlled test chambers. We observed highest initial capacity in higher temperature cycling, but faster capacity fade. During room temperature cycling we also observe an increase in initial capacity over the first ~40 cycles that may be consistent with a similar phenomenon observed in Li-ion pouch cells with graphite anodes. Differential capacity analysis was performed to determine the mechanism of cell deterioration and investigate the rise in capacity. Detailed results from temperature-dependent electrochemical cycling, along with X-ray diffraction and scanning electron microscopy analysis, will be presented to explain differences in cell performance across battery models and temperatures.

Laser-Based Measurements Meet or Exceed Electron Microscopy in The Detection of Surface Damage ThomasW. Pfeifer[1], EricR. Hoglund[2,1] and PatrickE. Hopkins[1]; [1]University of Virginia, United States; [2]Oak Ridge National Laboratory, United States

The detection of surface or near-surface abnormalities, whether in the form of contamination, oxide growth or crystalline defects, is of interest across a wide variety of research areas. Similarly, common tools for sample preparation may create surface defects without the user realizing. For example, we found that Focused Ion Beam (FIB) milling, used for Transmission Electron Microscopy (TEM) sample preparation or for the generation of fiducial markers, may create a large ion-affected region surrounding the milled hole.

To investigate the detectability and spatial extent of these defects, we mill a series of holes in a silicon wafer (Using a Helios UC G4 FIB-SEM with gallium ions. holes are 10μm square, created under a variety of beam current / energy / exposure time conditions). We then use two pump-probe laser metrology tools (Time Domain (TDTR) and Steady State Thermoreflectance (SSTR)) with samples mounted on motorized stages to explore detection of the spatial extent of damage. We also use atomic-resolution Scanning Transmission Electron Microscopy (STEM) and Energy-dispersive X-ray spectroscopy (EDX) (using a Thermo Fisher Scientific Themis system at 200 kV) on samples prepared at varying distances from the FIB hole.

As the pump-probe experiments typically require a metal film to be deposited on all samples, we first use TDTR and SSTR to measure the thermal boundary resistance (TBR) between a metal film (80 nm aluminum, e-beam evaporated) and silicon, observing changes measurable up to 300 μm from the edge of the hole in the most severe case. Comparing this to the STEM results, an unusually high gallium concentration can be found between the aluminum and silicon at 200 μm away (more than seen in a reference TEM sample prepared in an identical manner). Similarly, a slightly disordered region is seen within the first ~ 10 nm of silicon, suggesting low-energy errant gallium ions may be responsible.

When the aluminum capping layer is excluded however, SSTR was capable of measuring a difference out to > 600 μm. This signal is less easily interpreted as a change in thermal properties, but a notable change is visible nonetheless. By comparison, the only visible changes to the sample occur no more than 50 μm beyond the edge of the hole. Two more TEM samples were made at 500 μm and 1 mm away from the hole, and no substantial differences were found.

These findings suggests that laser-based pump-probe experiments are equally if not more capable at detecting surface damage as compared to EDX or atomic-resolution STEM. These laser based experiments are also substantially cheaper and faster to operate, not requiring the use of electron microscopy or extensive sample preparation. Furthermore, this is the first observation of extreme spatial effects due to FIB milling to our knowledge, and the precise nature of this damage warrants further study.

8:00 PM CH01.13.25

Investigating The Effect of Manufacturing Processes on The Lonomer Network in PEMWE and PEMFC Catalyst Layers using Microscopy and Python-Based Data Processing MaryamAhmadi[1], MariahBatool[1], CarlosBaez-Cotto[2], LindaNey[3], JeronimoHorstmann[3], JaysonFoster[4], NadaZamel[3], ScottMauger[2], SvitlanaPylypenko[4] and JasnaJankovic[1]; [1]University of Connecticut, United States; [2]National Renewable Energy Laboratory, United States; [3]Fraunhofer Institute for Solar Energy Systems ISE, Germany; [4]Colorado School of Mines, United States

With the increasing demand for hydrogen production as a source of clean energy, proton exchange membrane water Eelectrolyzers (PEMWEs) and proton exchange membrane fuel cells (PEMFCs) are crucial components of the clean energy field, offering sustainable alternatives for energy conversion and storage. With the need to significantly increase the production of these devices, scale up manufacturing of their catalyst layers using different methods, such as slot die, gravure, screen printing or rod coating, is becoming a focus of industry and researchers. The aim is to speed up the fabrication, but also enhance the efficiency, durability, and cost-effectiveness of these systems [2].
Quality assessment in terms of electrochemical performance, but also in terms of visualization and quantification of the catalyst layer parameters are essential. Advanced characterization techniques, including microscopy and spectroscopy, are powerful tools to elucidate microstructure, morphology and spatial distribution of elements in these layers [3]. Of special interest is the ionomer network within the catalyst layers, influencing proton conductivity and electrochemical reactions, and playing a vital role in the efficiency and performance of both PEMWEs and PEMFCs [1]. Elucidating and quantifying its distribution is a challenging task.
This work presents our recently developed framework to visualize and quantify ionomer distribution, together with other structural and compositional parameters, for the catalyst layers fabricated using different manufacturing processes. The framework utilizes advanced image processing algorithms to process acquired STEM EDS maps from inks and electrodes [4]. It aims to automatically identify phases, particles, and elemental distributions within the microstructure, to see the ionomer connectivity in inks and their corresponding electrodes via different manufacturing processes such as slot die with different flow rates and gravure with different rod sizes, as well as different mixing times in ink preparations [5]. Moreover, in order to establish correlations between inks and electrodes for different materials systems and microstructural arrangements, the developed data processing protocols are applied in both fuel cells and electrolyzers.

Study of Growth and Structural Phase Transition in CrN/MgO(001) Thin Films Studied by Variable Temperature X-Ray Diffraction KhanAlam[1,1], RodrigoPonce-Perez[2,3], KaiSun[4], AndrewFoley[2], NoboruTakeuchi[2,3] and ArthurR. Smith[2]; [1]King Fahd University of Petroleum and Minerals, Saudi Arabia; [2]Ohio University, United States; [3]Universidad Nacional Autonoma de Mexico, Mexico; [4]University of Michigan–Ann Arbor, United States

Abstract
Interest in studying CrN thin films has been increasing due to their interesting structural[1,2], electronic[3], and magnetic[4] properties. We have investigated the structural phase transition in high-quality CrN thin films grown on MgO(001) substrates using molecular beam epitaxy. Our analysis, which combines cross-sectional transmission electron microscopy and X-ray diffraction, has revealed that the CrN film exhibits an epitaxial relationship with the MgO substrate along three orientations: $[100]_{CrN}/[100]_{MgO}$, $[110]_{CrN}/[110]_{MgO}$, and $[001]_{CrN}/[001]_{MgO}$. These films display tensile strain or compression at the CrN/MgO(001) interface, which gradually relaxes during film growth. Furthermore, our temperature-dependent X-ray diffraction measurements have provided evidence of a first-order structural phase transition. Complementing our experimental findings, we conducted first-principles theoretical calculations to identify a stable model for the CrN/MgO interface. These calculations yielded two possible models for the interface, both of which feature a monolayer of chromium oxide positioned between the CrN and MgO layers.

All-Electronic and Flow-Through Differentiation of Microparticles based on Permittivity UzayTefek[1], BurakSari[2], HashimAlhmoud[1] and SelimHanay[1]; [1]Bilkent University, Turkey; [2]Sabanci University, Turkey

There is an increasing need for the identification of microparticles in environmental and material science applications. Microplastic pollution in water resources has especially attracted the attention of the scientific community in recent years. Currently, Raman Spectroscopy and Fourier Transform Infrared Spectroscopy are used for the identification of microplastics: however, these techniques are expensive, non-portable, and extremely time-consuming. On the other hand, portable microplastic analysis systems can increase the localization accuracy while decreasing the cost and response time of pollution in water resources.

For microparticle analysis, impedance cytometry may serve as an ideal platform. Indeed, the differentiation of microplastics (e.g. polystyrene microparticles) *versus* cells has been demonstrated long time ago and repeatedly reported in different applications. However, these demonstrations are facilitated by the fact that cells have a large water content which induces a sharp contrast in impedance signal compared to non-biological particles. In other words, the high permittivity of water found in biological particles (such as cells and seeds) render them readily distinguishable from any other non-biological particle with no water content. Therefore, the real challenge in environmental screening is the differentiation of **non-biological microparticles amongst themselves** (*e.g.*, plastics *versus* glass particles) since the impedance difference they generate is very similar due to the shielding effect of water. This capability can also be applied to the screening of engineered microparticles.

Here we demonstrate an all-electronic way to differentiate two important class of non-biological microparticles based on their permittivity differences: polystyrene (a typical microplastic) and soda lime glass (the most common household glass). To do so, we integrated a low frequency impedance cytometry sensor with a high frequency microwave sensor on the same microfluidic channel . The low frequency sensor detects the geometrical volume of the particle, whereas the microwave sensor yields a value proportional to the multiplication of the geometrical volume and the Clausius-Mossotti factor of the particle, a factor which depends on particle permittivity.

The analysis results indicate that with high classification accuracy (>94%), microparticles of these two material class can be differentiated from each other. In this case the experimentally extracted values of the Clausius-Mossotti factors of the two species closely follow the theoretically expected value. We further demonstrate the capability to monitor the changes in the permittivity values of single cell as they are fixed with glutaraldehyde.

The classification capability for microparticles of different composition at high throughputs opens the way for important applications in environmental, materials and biological sciences.

8:00 PM CH01.13.28

Nanomechanical Testing of Printed Nanolayers for Application on Flexible Organic Electronics Devices SpyridonKassavetis[1], TheodoraKalampaliki[1], ArgirisLaskarakis[1], ChristosKapnopoulos[1], VolhaHeben[1], VasiliosKyriazopoulos[2], EvangelosMekeridis[2] and StergiosLogothetidis[1]; [1]Aristotle University of Thessaloniki, Greece; [2]Organic Electronic Technologies P.C. (OET), Greece

Flexible organic printed electronics devices (FOPEs) such as Organic Photovoltaics (OPVs) and Organic Light Emitting Diodes are paving the way to new advanced low-cost and large area products for solar energy harvesting and lighting, respectively. FOPE devices are comprised by sequential functional nanolayers with a thickness ranging from 30 nm to 500 nm, which are printed the one on top of the other using different solution, printing and curing conditions. The mechanical properties of the individual layers, the adhesion among these nanolayers and their interfaces play critical role to the FOPEs performance and service life.
In this work, we focus on the OPVs devices and we extensively test the mechanical properties of the OPV nanolayers such as the Transparent Conductive Oxide (TCO), the Electron transport layer (ETL), and the active nanolayer with the target to enable understanding on the nanomechanical testing of soft and flexible materials and hybrid (inorganic / organic) interfaces a, and contribute to the performance and durability optimization of new next generation FOPEs. Therefore, we have developed a protocol for the nanomechanical testing of the OPVs' nanolayers based on the nanoindentation (NI) to probe the mechanical properties of the individual layers as well as the OPV device as a whole and to provides quantitative results at the nanoscale level. The Continuous Stiffness Measurements NI set-up was used to study the mechanical behavior of the nanolayers and their interfaces in the OPV stack in relation to the thickness and the surface roughness of the nanolayers, with the aim of accurately extracting the Elastic Modulus (E) and the Hardness (H) of the nanolayers. Atomic Force Microscopy and Spectroscopic Ellipsometry (SE) was also used to gain information about the surface and the optical properties, respectively, while SE was also used measure the thickness of the printed nanolayers layers. Two different TCOs were tested, ITO and IMI, grown on top of flexible PET substrate. Both samples showed elastic / plastic deformation. For ITO/PET the E and H values were calculated to 26 GPa and 4.5 GPa, while for the IMI/PET the E=15 GPa and H=3.2 GPa. In both cases, the E and H values were affected by the compliant PET substrate. Both TCO did not de-adhere from the substrate after NI testing. Tin Oxide (SnO) nanolayer was used as the ETL functional nanolayer and it was printed be slot die coating on top of TCO. The NI testing showed that the printed SnO nanolayers did not de-adhere from the flexible TCO/PET substrate, while their E and H values were 9.2 GPa and 0.58 GPa, respectively.

8:00 PM CH01.13.29
Advanced Fluorescence Microscope and Smart Cloud Algorithm in Real-Time Quantitative Processing and Analysis of Electroconvection DuhanZhang; Massachusetts Institute of Technology, United States

In an electrochemical cell at high current densities, electroconvection plays a critical role in determining the morphology of electrodeposited metals. The resultant dendrite formation leads to risky battery performance failure. Over the past decades, though intensive theoretical analysis and experimental effort have been done, the detailed structure and dynamics of electroconvection remain unknown, because experimental observations lacked the resolution to expose the fundamental, hierarchical spatial structure of these flows, while the data processing algorithms were not fully established for large sample size. To address this shortcoming, we built an advanced optical electrochemical cell that fits in situ imaging with a superresolution fluorescence microscope. By observing and recording real-time motions of electrolytes, electroconvection flows have been interrogated at unprecedented, high temporal and spatial resolution. As a complement to the visualization studies, a cloud computing
analysis algorithm was developed by combining a higher resolution Particle Image Velocimetry algorithm and a machine learning model to enable velocity distribution data over the entire optical field of view at nanoscale or microscale spatial resolution. Consequently, detailed velocity maps are obtained across the optical electrochemical cell, allowing us to quantitatively measure and analyze the initiation and evolution of
the hierarchical microstructures inside the electroconvection in a unidirectional electric field. With these powerful tools, we further studied the effect of polymer viscoelasticity on electroconvection and electrodeposition. The addition of an ultrahigh molar mass polyethylene oxide to the electrolytes transforms the materials to a viscoelastic fluid state that changes the electroconvection dependence on time and voltage and induces a smooth electrodeposition on the metal anode by unique polymer rheological properties. Especially, the relaxation of long polymer chains in the electrolyte provides a promising manner to prevent dendrite growth. We further analyzed these observations using
direct numerical simulations for Newtonian and viscoelastic fluid models, and the quantitative analysis of experimental results indicates good consistency with simulation predictions.

8:00 PM CH01.13.30
Advanced Hydrovoltaic Energy Generation using a Hierarchical NiFe LDH-Decorated CuO Nanowire Mesh Device Ji YoungPark, Jun YoungKim, Gwang-MyeongGo and Yong-HoChoa; Hanyang University, Korea (the Republic of)

The contemporary energy landscape is undergoing a transformative shift, driven by the dual imperatives of environmental sustainability and technological advancement. As traditional energy sources deplete and global concerns over carbon emissions and environmental degradation mount, there's a pronounced urgency to find viable renewable energy solutions. Central to this quest is the principle of energy harvesting—capturing ambient energy from the environment and converting it into usable electrical power. Traditional methods such as solar and wind, while revolutionary, come with their own sets of challenges including intermittency and geographical limitations. In such a scenario, the prospect of harvesting energy from more omnipresent and less variable sources has gained significant scientific attention. Hydrovoltaic energy, which leverages the potential energy in water, presents one such avenue. The structural foundation of this advanced hydrovoltaic device is a meticulous assembly of nickel-iron layered double hydroxides (NiFe LDHs) deposited on copper oxide nanowires (CuO NWs). These NWs are firmly anchored to Cu meshes, creating a stable yet intricately detailed hierarchical nanostructure. Such a configuration has been optimized for the rapid diffusion of ion-rich water infiltration. Central to this capability is the LDH layer, which acts as a mediator, enhancing the device's inherent hydrophilic attributes and subsequent energy-harvesting efficiency. When subjected to a 3.3 M $CaCl_2$ solution droplet of 200 µL, the device consistently registers a power output in the vicinity of 250 nW/cm^3. Remarkably, the energy generation capability of this configuration remains robust over prolonged durations, with a life cycle exceeding one month without noticeable degradation. The underlying mechanisms propelling this efficiency were thoroughly investigated. We identified that the NiFe LDH layer plays a pivotal role in augmenting the potential difference across the device, resulting in enhanced electricity generation. The electricity stemming from ionic infiltration and diffusion was elucidated, and strategies for device renewability were explored. Anticipating industrial applications, we also evaluated the device's scalability. Emphasis was placed on serial allocation strategies, demonstrating the potential for modular expansion and integration into larger systems. Collectively, this research signifies a substantial stride in hydrovoltaic energy generation, utilizing sophisticated nanostructures to effectively capitalize on readily available hygroscopic salts and seawater, paving the way for future green energy applications.

SESSION CH01.14: Batteries II
Session Chairs: Liam Collins and Michael Toney

***In Situ* Monitoring Redox Processes in Energy Storage Materials using UV-Vis Spectroscopy**DanzhenZhang[1], Ruocun (John)Wang[1], XuehangWang[2] and YuryGogotsi[1]; [1]Drexel University, United States; [2]Delft University of Technology, Netherlands

Understanding energy storage mechanisms in electrochemical energy storage devices lays the foundations for improving their energy and power density. Herein, we introduce a simple and easily accessible *in situ* ultraviolet-visible (UV-Vis) spectroscopy method to distinguish battery-type, pseudocapacitive, and electrical double-layer charge storage processes. $Ti_3C_2T_x$ MXene in aqueous acidic and neutral electrolytes, and lithium titanium oxide (LTO) in an organic electrolyte will be used to demonstrate the technique. We found a correlation between the evolution of UV-Vis spectra and the charge storage mechanism. The electron transfer number for $Ti_3C_2T_x$ in an acidic electrolyte was calculated using quantitative analysis, which was close to previous measurements using X-ray absorption spectroscopy. Further, we tested the methodology to distinguish the non-Faradaic process in $Ti_3C_2T_x$ MXene in a water-in-salt electrolyte, despite well-defined peaks in cyclic voltammograms. *In situ* UV–Vis spectroscopy is a fast and cost-effective technique that effectively supplements electrochemical characterization to track changes in oxidation state and materials chemistry and determine the charge storage mechanism.

8:15 AM CH01.14.02
In-Situ TEM Probing of Charge Transport Behavior Across Solid Electrolyte Interphase in Rechargeable Batteries ChongminN. Wang; Pacific Northwest National Laboratory, United States

Solid electrolyte interphase (SEI), a thin layer that forms between active electrode and electrolyte, critically governs the performance of rechargeable batteries. An ideal SEI is expected to be electrically insulative to prevent a persistently parasitic reaction between the electrode and the electrolyte, while ionically conductive to facilitate Faradaic reactions of the electrode. However, the true nature of these two characteristics of SEI layer remains hitherto unclear due to the lack of a direct characterization method, leaving a range of behaviors of rechargeable batteries unelucidated. Here, we use in-situ bias transmission electron microscopy to directly measure the electrical properties of SEIs formed on Cu and Li. We discover that the current-voltage characteristics of SEIs resemble certain electrical conductance, rather than electrical insulation as conventionally assumed. The SEI with a higher electrical conductance tends to exhibit a greater thickness and more complex topographic features, consequently leading to an inferior electrochemical performance. The work solves the long-standing mystery as how SEI function electrically during electrochemical operation, providing unprecedented insight towards achieving better battery performance by rationally designing SEI properties.

8:30 AM CH01.14.03
Treatment of Polyethene Trephthalate Glycol Sheet using Liquid-Liquid Treated PEDOT:PSS using Ethylene Glycol and Dimethyl Sulphide for Supercapacitor Application MelkieG. Tadesse[1,2] and Jörn FelixLübben[1]; [1]Albstadt-Sigmaringen University, Germany; [2]EiTEX-Bahir Dar University, Ethiopia

Flexible electronics are the growing demand for wearable electronics. Intrinsically conductive polymers such as poly(3,4-ethylene dioxythiophene) polystyrene sulfonate (PEDOT: PSS) is the most widely studied polymers with two mixtures of monomers. Many breakthroughs have been made in enhancing the conductivity of PEDOT: PSS using various ionic liquids treatments. However, getting high conductivity remains the challenge for these types of treatment. Herein, the production of highly conductive PEDOT: PSS polymer is obtained through a density-based liquid-liquid contact method which realizes the separation of highly conducive PEDOT with the hydrophilic PSS. This was confirmed by measuring the conductivity and observing through FTIR and Ramana spectroscopy. Polyethene terephthalate glycol (PETG) sheet was surface modified using oxygen-plasma and the liquid-liquid was treated using ethylene glycol and dimethyl sulfoxide PEDOT: PSS was drop cast on the PETG and dried for several hours. The treated PETG was surface analysed using SEM and the potential application of the sample for supercapacitor was confirmed using cyclic voltammetry and impedance measurements. Both confirmed the use of these films for supercapacitor fabrication was possible.

8:45 AM CH01.14.04
Non-Depletable Electrolyte Design for High Energy Li-S Batteries. XiaoweiWang[1], SaurabhParab[1] and Y. ShirleyMeng[2]; [1]University of California, San Diego, United States; [2]The University of Chicago, United States

The cycling stability of high-energy lithium-sulfur batteries is severely hampered by the consumption of electrolytes and lithium metal. The bottleneck urges the development of new electrolyte systems. Herein, we developed a toolbox of characterization to identify the limiting factors in Li-S batteries under practical lean Li and electrolyte conditions like Cryo-FIB 3D reconstruction, Cryo-TEM, and Plasma FIB EBSD. As guided by the root reasons specified, we strategically synthesized a stable aromatic lithium salt as a $LiNO_3$ alternative that is mostly used in current Li-S batteries. This lithium salt has a similar redox mediation property to $LiNO_3$ that inhibits the overcharging issue causing polysulfide shuttle. Uniquely, the newly developed aromatic lithium salt forms stable intramolecular bonding that avoids decomposition like $LiNO_3$. Besides, the salt can coordinate with polysulfide to alleviate the reaction with lithium. The non-depletable electrolyte design is evaluated by the conventional C-S cathode with a high loading under lean electrolyte and lithium conditions. The Li-S cells using the new electrolyte deliver over 370 cycles with 75% retention in sharp contrast to 75 cycles of the cells in baseline electrolyte (1 M LiTFSI, DOL/DME=1:1). This works sheds light on the pivotal role of Li-S electrolytes and paves the way for extending the cycle life of practical high energy Li-S batteries.

9:00 AM CH01.14.05
Understanding Formation Processes in Anode-Free Lithium Metal Batteries GunnarThorsteinsson[1], WesChang[2], ZoeHerman[1] and DanSteingart[1]; [1]Columbia University, United States; [2]Drexel University, United States

Cell formation is a critical step in the manufacturing of secondary batteries. The mechanisms governing formation in next-generation lithium metal batteries, where lithium is plated a copper substrate, differ from conventional lithium ion batteries, where lithium intercalates into graphite. Understanding how rate of formation relates to subsequent cell cycling performance is critical to unlock the potential of high energy-density anode-free cells. However, the effect of formation rate in anode-free lithium metal batteries on capacity retention is not well understood. Here we show that a faster C/3 formation protocol results in markedly altered chemomechanical signature as compared to a standard C/10 formation step. Operando acoustic transmission is used to measure physical changes during the first formation cycle and its effects on long-term cycling of anode-free lithium metal pouch cells. Variations in amplitude and time-of-flight across different electrolytes tested are attributed to differences in gas formation, cell swelling and lithium deposition morphology. NMC532 cathodes paired with a high concentration ether electrolyte is shown to be particularly prone to gas formation, which is mitigated by the use of a localized high concentration ether electrolyte and single-crystal NMC532. The results highlight differences in formation behavior between anode-free lithium metal cells and lithium-ion cells.

9:15 AM CH01.14.06
Low Melting Alkali-Based Molten Salt Electrolytes for Lithium Metal Batteries CanhM. Vu and ChibuezeAmanchukwu; The University of Chicago, United States

Liquid electrolytes for lithium metal batteries (LMBs) raise safety concerns because the highly volatile and flammable organic solvents hinder their practical deployment. In contrast, solid-state electrolytes promise improved safety but suffer from poor electrode/electrolyte interfaces. In this work, we develop nonvolatile and nonflammable low melting alkali-based molten salts as electrolytes for LMBs. A ternary mixture of bis(fluorosulfonyl)imide salts shows a eutectic temperature at 45 ^oC and exhibits higher current densities and improved cycling compared to nonvolatile ionic liquids, polymer composites, and inorganic solid-state conductors. The molten salt electrolyte exhibits excellent compatibility with both Li metal anodes (Coulombic efficiency ~99.8% and fast activation within five cycles) and high-voltage cathodes (~6 V stability). Li||NMC batteries retain 80% capacity after 100 cycles with an average Coulombic efficiency of 99.98%. Our low-melting molten salts provide a new class of electrolytes for the development of high-energy, long-cycling Li metal batteries.

9:30 AM CH01.14.07
Surface Analysis of Engineered Particles for Improved Battery Performance and Stability SarahZaccarine[1], IsaiahOladeji[2], KoukouSuu[2], JenniferMann[1] and KaterynaArtyushkova[1]; [1]Physical Electronics (PHI USA), United States; [2]ULVAC Technologies, United States

Next-generation battery materials are needed to achieve high energy density, fast charging times, and long device lifetimes while remaining reliable and low-cost. Lithium metal batteries are a promising alternative to lithium-ion batteries but face stability concerns such as unstable solid-electrolyte interphase (SEI) growth and Li dendrite formation. Similarly, high-energy-density cathode materials like nickel manganese cobalt (NMC) and nickel manganese oxide (LNMO) have stable performance at high potentials but are susceptible to cathode dissolution in the electrolyte as well as unstable SEIs. Engineered particles (Ep) can stabilize electrode interactions, improving battery safety, SEI formation, and performance. However, batteries are multi-layered, complex systems with many components and interfaces that are difficult to handle and characterize. Understanding the chemical composition, distribution, and morphology of Ep-treated anodes/cathodes is necessary to prepare uniform, well-dispersed, high-capacity electrodes for optimized performance.

Developments in X-ray photoelectron spectrometers open up new capabilities to address these challenges. X-ray photoelectron spectroscopy (XPS) is ideal for analyzing thin layers and interfaces of battery materials due to its surface (~10nm) and chemical state sensitivity. Multi-technique XPS instruments offer additional operating modes and analytical options to enable the thorough characterization of battery materials. In this talk, a fully automated, multi-technique scanning XPS/HAXPES microprobe was used to address many challenges of analyzing battery materials, including an inert environment transfer vessel for air-free handling; microprobe X-ray source with <5µm spatial resolution for 100% certainty of area selection for small-area spectroscopic analysis and chemical mapping; and the hard X-ray source and cluster ion gun source for analyzing buried interfaces without damaging the chemistry. Combined, these powerful capabilities enable thorough characterization of macro- and microscopic battery materials for a direct link between the chemistry and performance of Ep-treated battery electrodes.

SESSION CH01.15: Novel Characterization Techniques IV
Session Chairs: Philippe Leclere and Stefan Weber
Thursday Morning, November30, 2023
Sheraton, Third Floor, Commonwealth

10:15 AM +CH01.15.01
Resolving the Impact of Structural Defects on the Charge Carrier Transport in (Opto)electronics IlkaHermes[1], StefanA. Weber[2], YenalYalcinkaya[2] and LiamCollins[3]; [1]Leibniz Institute for Polymer Research Dresden e.V., Germany; [2]Max Planck Institute for Polymer Research, Germany; [3]Oak Ridge National Laboratory, United States

Extended structural defects, like grain or domain boundaries in polycrystalline semiconductors, can introduce mid-bandgap trap states, host dopants or lead to electrostatic barriers. The implications of these local defects for charge carriers in materials used for (opto)electronic applications can be manifold: They can act as non-radiative recombination centers, delay or restrict the charge transport or, in some cases, improve the transport properties though a change in doping.
Here, we will discuss how electrical and electromechanical atomic force microscopy (AFM) in combination with complimentary techniques can not only resolve extended defects, but also capture their electronic or (electro)mechanical properties and relate these defects to local changes in charge carrier transport. For instance, using electromechanical AFM, we visualized subcrystalline twin domains present in hybrid organic inorganic perovskites that are applied in photovoltaic devices. With the data analysis exacerbated by the mixed ionic and electronic conductivity of hybrid perovskites, we conducted advanced electromechanical AFM to decouple mechanical and electrostatic crosstalk, which finally revealed the ferroelastic nature of the domains. Correlating to spatial- and time-resolved photoluminescence suggest that the domain walls as extended structural defects delay the charge carrier diffusion by acting as electrostatic barriers. However, the possibility to tailor the arrangement and density of these ferroelastic domains allows engineering a directional charge transport and improved device performance.

10:45 AM CH01.15.02
Oxygen Redox Activity Characterization of Li-Stoichiometric Layered Oxides Through the Resonant Inelastic X-Ray Scattering (RIXS) Gi-HyeokLee and WanliYang; Lawrence Berkeley National Lab, Korea (the Republic of)

As the development of analytical technology has helped to identify ambiguous phenomena, applying the state-of-art resonant inelastic X-ray scattering (RIXS) technique to cathode materials closely identifies various phenomena in batteries. One of the most important discoveries through RIXS is oxygen redox, which can experimentally show the redox activity of oxygen, which was impossible to analyze with classical X-ray absorption or emission spectra. In highly charged electrodes, the discovery of features distinguishable from those of TM hybridized O further elucidates the redox mechanism oversimplified with the concept of the formal charge. The redox mechanism of Li-rich anode materials, which cannot be solely explained by TM oxidation, has been explained with a focus on their characteristic oxygen redox feature.
However, the discovery of oxygen redox features is not limited to cathode materials with Li-rich chemical composition. Oxygen redox features through RIXS were found in commercial anode materials such as $LiCoO_2$ and $LiNi_xCo_yMn_{1-x-y}O_2$ as well as trendy cathode materials such as $LiNi_{0.85}Co_{0.10}Al_{0.05}O_2$ and $LiNiO_2$. This means that the understanding of oxygen in the existing

redox process was inaccurate and suggests a lot about the strategy for coping with material degradation in the high state of charge established based on the incorrect understanding. Here, we look back at the generation of oxygen redox in “non-Li-rich” commercial cathode materials and revisit their redox mechanism. In addition, we intend to interpret based on a new redox mechanism along with the observed results of material degradation at high SOC, such as X-ray diffraction and differential electrochemical mass spectroscopy.

11:00 AM CH01.15.03
Three-Dimensional Imaging of Surface and Interface of Catalyst Nanoparticles by Electron Ptychography ZixiaoShi[1], Yu-TsunShao[1,2], HarikrishnanK. P.[1], DasolYoon[1], HectorD. Abruna[1] and DavidA. Muller[1]; [1]Cornell Univerisity, United States; [2]University of South Carolina, United States

Atomic-level understanding of nanoparticle structure is a central goal of modern heterogeneous catalysis. Many nanoparticles transform their surface structure during catalytic processes and generate a different phase on the surface to form a heterostructure, also known as “core-shell” structure. The influence of the core structure can result in modification of surface termination, strain effect, and polarization of shell catalyst, which will have a huge impact on catalyst performance. However, the shell structure can be discontinuous and relax its strain at the surface as it grows thicker. These details would be hidden by projection artifacts and the limited spatial resolution via conventional STEM imaging, and thus resolving these details requires a method that can reveal the 3D information with high spatial resolution.

Here we investigate MnN nanoparticles that serve as cathode electrode catalysts for anion-exchange membrane fuel cells (AEMFCs). We use multi-slice electron ptychography to characterize the catalyst surface layers in 3D, imaging with both heavy (Mn) and light elements (N, O) at lateral resolution which is limited by the thermal vibration of atoms themselves.[1] For 3D information, a single ptychographic reconstruction shows details of different MnN/Mn_3O_4 surfaces and interfaces at different depths of view. We separate the structural information from two different spinel nanoislands at different depths of view even when overlapped with sufficient details to allow us to study lattice displacements and strain separately from each grain. At the MnN/Mn_3O_4 interface, the Mn_3O_4 monolayer shows up to 3.0 % in-plane strain compared to Mn_3O_4, and leads to superior catalytic activity than Mn_3O_4 nanoparticles. This tensile strain of Mn_3O_4 shell decreases monolayer by monolayer when the Mn_3O_4 shell is growing thicker and starts to form nanoislands, and will relax to 1.2 % at the surface. This strain relaxation from the interface to surface of Mn_3O_4 provides quantitative insights into the relationship between the catalytic activity and in-plane tensile strain of Mn_3O_4 on MnN core.

11:15 AM CH01.15.04
Measuring Lithium Loss during Synthesis and Densification of $Li_7La_3Zr_2O_{12}$ by Synchrotron Diffraction and Tomography TimFister[1], TiffanyKinnibrugh[1], JessicaD. Macholz[1], AlbertLipson[1], AlexandraMoy[2], JeffSakamoto[2], JoanneStubbs[3], PeterEng[3], YanbinWang[3] and TonyYu[3]; [1]Argonne National Laboratory, United States; [2]University of Michigan, United States; [3]The University of Chicago, United States

The conductivity and, especially, the voltage stability of cubic $Li_7La_3Zr_2O_{12}$ (LLZO) make it one of the most attractive solid electrolytes for solid state batteries. However, the high temperatures required to synthesize and densify the ceramic electrolyte can lengthen its calcination and eventually lead to lithium loss. Here, we explore the interplay between cubic and tetragonal LLZO with the $La_2Zr_2O_7$ pyrochlore phase at high temperature as a function of precursor composition and size. Using *operando* synchrotron powder diffraction we show that nanoscale hydroxide precursors dramatically lower the formation temperature of LLZO compared to traditional, micron-sized oxide precursors. However, the nanoscale LLZO is prone to rapid lithium loss at high T, which can complicate further sintering and densification. To better understand the lithium loss mechanisms at both high temperature *and* pressure, we also study the densification of calcined LLZO pellets using computed tomography at pressures ranging from 0-5 GPa and temperatures up to 1400C using a novel large-volume press developed at the Advanced Photon Source. Using this setup, we demonstrate the ability to directly image lithium loss using computed tomography and show that high pressure lowers the temperature onset for surface decomposition to $La_2Zr_2O_7$.

11:30 AM CH01.15.05
Correlative SEM / AFM Microscopy - Combining Two High-Performance Methods for Nanoscale Measurements HajoFrerichs, SebastianSeibert, LukasStuehn, MarionWolff, DarshitJangid and ChristianH. Schwalb; Quantum Design Microscopy GmbH, Germany

The combination of different analytical methods for the qualitative and quantitative evaluation of material properties has become an essential part of today's characterization methods. In this context, the field of correlative microscopy represents an important technique for the simultaneous acquisition of complementary information. In particular, the combination of two of the most powerful microscopy techniques – scanning electron microscopy (SEM) and atomic force microscopy (AFM) – provides completely new insights into the micro- and nano-world to investigate even the smallest features of a sample with the highest resolution.[1-2] However, combining these two methods is not easy and remains challenging in terms of the instrumentation required. In most cases, both methods are used separately, and the obtained results cannot be truly spatially correlated. In this work, we present a unique inspection device that seamlessly combines SEM and AFM for characterization and process control of micro- and nanostructures. Due to the self-sensing piezoresistive cantilever technology used for the AFM scanner, the cantilever deflection signal can be measured completely electrically,[3] and a joint coordinate system between SEM and AFM allows the simultaneous acquisition of data directly at the region of interest. We will present a series of novel case studies to illustrate the advantages of this new tool for the interactive, correlative *in-situ* characterization of various materials and nanostructures at the nanoscale.

The first results focus on semiconducting ceramics based on $BaTiO_3$ with a positive temperature coefficient of resistance (PTCR). These materials, widely used in the field of self-regulating heating elements or temperature sensors, offer a wide range of applications in the energy sector. In this context, electrostatic force microscopy (EFM) combined with SEM shows that an accurate colocalized analysis of the grain boundary potential barriers of various $BaTiO_3$-based samples can be performed within nanometer resolution. The grain boundaries were localized using backscattered electron (BSE) detection and subsequently measured using the *in-situ* EFM technique demonstrating the influence of SiO_2 as a sintering agent on the barriers. Moreover, these results can be directly correlated with electron backscatter diffraction (EBSD) measurements to link the AFM and SEM data to the crystallographic microstructure of the samples.[4]

We will also present results for the *in-situ* characterization of nanowires, 2-D thin film materials, and multilayer samples to characterize their electrical, magnetic, topographic, and mechanical properties. The SEM allows the easy localization of single or multiple surface features, while the *in-situ* AFM allows the characterization of various "visible" and "hidden" surface and bulk properties. In this context, some aspects of advanced tip fabrication techniques such as focused electron beam induced deposition (FEBID) will also be briefly outlined to give an impression of how the fine-tuning of tip properties can be beneficial for correlated measurements.[5]

Due to the wide range of applications in inspection and process control of various materials and components, we expect this new inspection device to be one of the future key characterization tools for correlative SEM and AFM analysis.

11:45 AM CH01.15.06
Nanometer-Scale Viscoelastic Measurements of Polymers by Peak-Tracking Scanning Thermal Noise Microscopy KeiKobayashi; Kyoto University, Japan

We recently developed (classical) scanning thermal noise microscopy (STNM), where the thermal noise spectra of the cantilever were measured at every pixels during the raster scan, from which the resonance frequency (f_c) and Q images are reconstructed by the off-line analysis [1]. We demonstrated visualization of buried Au nanoparticles in a polymer matrix, since the surface viscoelastic property was modulated by the buried Au nanoparticles. STNM is a viscoelastic measurement technique based on the contact-mode AFM but without excitation of the sample stage or the cantilever unlike the conventional viscoelastic measurement techniques. However, collection of the thermal noise spectra typically requires more than 1 h, which has not been practical for wide applications.
In this presentation, we demonstrate the local viscoelastic property measurements of polymeric samples by peak-tracking (PT) STNM, which utilizes two lock-in amplifiers and a feedback loop to enable tracking of the resonance frequency peak in a real-time manner as well as frequency-modulation AFM, but based on the detection of the thermal noise of the cantilever. It allows us to simultaneously measure f_c and Q, which correspond to elasticity and viscosity in the frequency range of typically 100 kHz. The technique is compatible with force curve measurement, which is a low-frequency viscoelastic measurement technique. Therefore, we can obtain quantitative viscoelastic properties in different frequency ranges at the same time, which is useful to study viscoelastic properties of polymeric samples and their composites that are often frequency dependent.

1:30 PM *CH01.16.01
Observation of Structural Changes in Organometallic Perovskite Thin Film using Synchrotron X-Rays Sung HunLee, SeungyeonHong, In HwaCho and Hyo JungKim; Pusan National University, Korea (the Republic of)

Organometallic perovskite solar cells (PSCs) have been considered as one of the most attractive and promising next-generation solar cells due to their excellent photoelectric properties, including potential for low-cost fabrication based on solution processing. After Miyasaka's report of 3.9% power conversion efficiency (PCE) in 2009, PSCs have been developed rapidly, of which performance reached a highest PCE of 26.02% by Seok in 2023. The meticulous control of crystalline properties has played a pivotal role in significantly enhancing the PCE of PSCs. By manipulating and find-tuning the crystalline characteristics, such as identifying specific crystalline phases and clarifying the domain orientations within organometallic perovskite thin films, substantial advancements in PCE have been achieved. Especially, *in situ* observation of structural changes during the film formation gives insights how to effectively control the crystalline properties of the perovskite thin films. In this presentation, we would like to show the structural studies on perovskite thin films under various fabrication conditions such as post-annealing and spin-coating using synchrotron X-rays. We will present recent results of *in situ* Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) of samples to observe their crystalline properties during film formation, especially in the anti-solvent free system.

2:00 PM CH01.16.02
Charge Distribution in Perovskites Spatially Resolved by Scanning Microwave Impedance Microscopy VerenaWerf, JiashangZhao, JimKoning, JasmeenNespoli, JosThieme, MarcelBus and TomJ. Savenije; Delft University of Technology, Netherlands

Metal halide perovskites (MHPs) have demonstrated great potential for various electronic applications including solar cells, LEDs and X-Ray detectors. Most remarkably, high quality layers can be deposited by simple, wet chemical deposition techniques, yielding solar cells with a reported power conversion efficiency above 25%. Despite this simple and versatile processing method, the concentrations of trap states are very modest, which is attributed to the fact that most defects do not form a state within the optical band-gap. However, detailed analyses of photovoltaic devices based on these materials show that still the maximum attainable voltage is not yet reached. Part of the voltage deficit is often associated with loss mechanisms, which is a result of undesired non-radiative recombination of light induced charge carriers mediated by e.g. surface defect states. Hence to reduce the voltage deficit more information regarding these defects is necessary, e.g. what's the origin and how are these distributed over the MHP surface? It is important to realize that a locally high concentration of defect states leads to a locally smaller Fermi level splitting, reducing the PCE of the entire solar cell substantially.
Over the last few years a number of nanoscale techniques have been used to study the opto-electronic properties in MHP layers, including confocal photoluminescence measurements, Scanning Kelvin probe force microscopy and photoconductive atomic force microscopy. From these studies it was concluded that defect states are not homogeneously distributed over the surface. Despite these insights it is unclear to what extent excess charge carriers still get evenly spread over the MHP surface. To address this question, we use in this work scanning microwave impedance microscopy (sMIM) to reveal the local conductivity induced by optical illumination. sMIM is a rather new non-contact method able to locally probe the dielectric properties, i.e. the local permittivity and conductivity. This method has only been scarcely used to study MHPs and in particular effects of degradation on the local scale have been studied. Here we examined the charge concentration in two MHPs i.e. $Cs_{0.17}FA_{0.83}PbI_3$ (hereafter denoted as $CsFAPbI_3$) and $MAPbI_3$. We study these materials by comparing the MIM-Re and MIM-Im images recorded in the dark and under optical excitation using a green power LED. While in the dark the MIM-Re images show no contrast, with increasing the light intensities the contrast increases. By analyzing the images in detail we conclude that, in particular for $MAPbI_3$, the charge distribution is rather homogeneous. In contrast for the $CsFAPbI_3$ illumination leads to additional contrast even over a single grain, which we associate with the fact that $CsFAPbI_3$ shows a non-preferential orientation growth. Various facets with different surface termination will have an effect on the defect density and thus on the excess charge concentration. Hence for a $CsFAPbI_3$ layer featuring various planes, possibly even within a grain, a variation in excess charge concentration and hence more contrast over a single grain. This insight highlights the need for a homogeneous, preferential growth of the MHP absorber layer to generate a homogeneous charge distribution over the surface. For solar cells, a non-homogeneous distribution in carrier concentration leads to variation in the local Fermi level splitting, which should be suppressed to reduce the voltage deficit.

Structural Characterisation of $BaZrS_{(3-y)}Se_y$ Perovskite Thin Films via Scanning Transmission Electron Microscopy TigranSimonian[1,2], MichaelXu[2], IdaSadeghi[2], JackVan Sambeek[2], KevinYe[2], RafaelJaramillo[2], JamesM. LeBeau[2] and ValeriaNicolosi[1]; [1]Trinity College Dublin, Ireland; [2]Massachusetts Institute of Technology, United States

Chalcogenide perovskites show great potential for becoming solar cell materials due to their tuneable and direct bandgaps in the visible range, great physical properties compared to oxide perovskites, and use of nontoxic and abundant elements [1]. However, difficulties in growing thin films using chalcogen sources has hindered their progress until recently. Expanding on previous work on one-step synthesis of $BaZrS_3$ (BZS) thin films via molecular beam epitaxy [2], here we demonstrate the synthesis of a $BaZrS_{(3-y)}Se_y$ (BZSSe) alloy system using a BZS template layer on $LaAlO_3$ (LAO).
These BZSSe films are analysed via high resolution scanning transmission electron microscopy (STEM), energy dispersive X-ray spectroscopy (EDX) and electron energy loss spectroscopy (EELS). Both the template and the alloy are noted to be of a perovskite structure, with both growth modes as previously seen in pure BZS films, present. While the film is relaxed overall, there is a large concentration of out-of-plane antiphase boundaries (APBs) in the template region; conversely, there is a large concentration of in-plane APBs in the alloy region. EDX and EELS indicate the presence of diffused Se even down to the substrate interface, which correlates with the presence of APBs as a strain relaxation mode.

Microstructural Evolution of Perovskite Solar Cells during Thermal Annealing HolgerRoehm, AlexanderSchulz, TobiasLeonhard and AlexanderColsmann; Karlsruhe Institute of Technology, Germany

$MAPbI_3$ amongst other OMH perovskites is undergoing tetragonal-to-cubic phase transitions within the operational temperature range of solar cells. Many properties of these hybrid perovskite materials, such as piezoelectricity, pyroelectricity, ferroelectricity and ionic conductivity are directly linked to the crystal phase and temperature of the sample. Notably, polar domains that form in $MAPbI_3$ thin-films during the solar cell fabrication have been observed,[1,2,3] We have previously shown that poling of these domains can be achieved in an external E-field that is similar to built-in fields in solar cells during operation.[4]
In this work, we use Piezoresponse Force Microscopy to monitor an evolution of these domains that is triggered by common thermal treatment of perovskite solar cell at 100°C.[5] Our findings suggest that control over the domain structure in these light absorbing, semiconducting compounds may be essential in order to maximize performance and stability of hybrid perovskite solar cells. In particular, microstructural changes due to stress and strain when the thin-films undergo a tetragonal/cubic phase transition are an often overlooked factor responsible for degradation of perovskite solar cells. We show that local crystal defects can form and vanish both at ferroic domain walls and crystal grains and in turn modulate ionic conductivity and diffusion.
Finally, we extent our investigations towards triple-cation perovskites and investigate the dependence of the ferroelectric properties on the stoichiometric composition.[6]

Surface Structure of Lecithin-Capped Cesium Lead Chloride Nanocrystals using Solid-State and DNP NMR Spectroscopy DigantaSarkar[1], AbhoyKarmakar[1], AndriyStelmakh[2,3], MarcelAebli[2,3], FranziskaKrieg[2,3], AmitBhattacharya[1], ShanePawsey[4], MaksymV. Kovalenko[2,3] and VladimirMichaelis[1]; [1]University of Alberta, Canada; [2]ETH Zürich, Swaziland; [3]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [4]Bruker BioSpin Corporation, United States

Colloidal nanocrystals (NCs) of all-inorganic cesium lead halide perovskites ($CsPbX_3$; X = Cl, Br, I) have garnered significant attention due to their superior optoelectronic properties for LCD and LED displays, lasers, photovoltaic and photodetector applications compared to their bulk perovskite counterparts [1]. The choice of capping ligand, which controls the growth and dispersion of these nano-sized perovskites in organic solvents, can profoundly affect their surface structure by disrupting the atomic periodicity, consequently influencing their tailorable optical and electronic features [2]. Although there have been numerous theoretical and experimental investigations into $CsPbX_3$ NCs, only a limited number of studies provide a comprehensive, atomic-level description of the termination and ligand binding sites on the surface of $CsPbX_3$ NCs.
Solid-state nuclear magnetic resonance (NMR) spectroscopy is a powerful and robust spectroscopic method that offers an unprecedented understanding of atomic-scale structures of various classes of nanomaterials [3]. Here, we discuss a multinuclear (^{1}H, ^{13}C, ^{31}P, ^{133}Cs, and ^{207}Pb) solid-state and dynamic nuclear polarization (DNP) NMR spectroscopic approach to explore the structure of $CsPbCl_3$, ranging from bulk material to NCs capped with an inexpensive, natural, and mass-produced zwitterionic ligand, soy lecithin with trimethylammonium and phosphate head groups [4]; further complemented by diffraction-based techniques.
The solid-state ^{133}Cs and ^{207}Pb NMR experiments, employing both direct and indirect detection methods (such as cross-polarization, CP) on $CsPbCl_3$ NCs demonstrate high sensitivity towards the large differences in surface-to-core ratios between bulk and NCs as the crystal size decreases from microns to nanometres. We exploit the unique heteronuclear dipolar couplings between the lecithin ligand (^{1}H, ^{13}C, and ^{31}P) and the surface (^{133}Cs and ^{207}Pb) of the $CsPbCl_3$ NCs that allows us to directly determine the surface structure. For instance, the ^{1}H–^{133}Cs heteronuclear correlation (HETCOR) DNP NMR method investigates the proximity of the trimethylammonium group of lecithin to the surface ^{133}Cs atoms. Additionally, a combination of ^{1}H{^{133}Cs}, ^{1}H–^{31}P{^{133}Cs} CP, and ^{1}H–^{31}P{^{207}Pb} CP rotational-echo double-resonance (REDOR) NMR techniques provides a comprehensive understanding of how the phosphate group of lecithin binds to the surface of $CsPbCl_3$ NCs. These results were further substantiated by a series of classical molecular dynamics simulations to find the most thermodynamically stable binding mode of the lecithin ligand onto the $CsPbCl_3$ NCs surface. These findings have the potential to significantly advance the future spectroscopic investigation of ligand binding and surface structures in nanomaterials.

Tomographic AFM for Nanoscale Volumetric Mapping of Photovoltaics LuisA. Ortiz-Flores[1], YuanyuanZhou[2] and BryanD. Huey[1]; [1]University of Connecticut, United States; [2]Hong Kong Baptist University, Hong Kong

A range of characterization methods have been developed to investigate materials for energy systems, including their microstructure, chemical composition, and functionality—even in situ or in operando. However, the performance of many practical energy systems depends on, or succeeds despite, mesoscale features. Grain boundaries are unavoidable for most commercially viable devices, electrode interfaces are often critical, and property gradients naturally result from or indeed are engineered during fabrication. Truly nanoscale volumetric studies are therefore crucial, albeit challenging. Accordingly, we have advanced Tomographic Atomic Force Microscopy (TAFM) for studies of polycrystalline photovoltaics such as $MAPbI_3$ and related halide perovskites. Clear enhancements in photocurrents are observed for grain boundaries, which are investigated individually and networked. The effects of incorporating selective carrier transport layers such as SnO_2, NiO, and SPIRO are also discussed. Wider applications of this TAFM approach for piezoelectric energy harvesters, supercapacitors, fuel cells, batteries, and thermoelectrics will also be presented, all in the context of improving future device performance by better understanding 3-dimensionally heterogeneous structure-property correlations.

Electrical Scanning Probe Microscope Measurements Reveal Surprisingly High Dark Conductivity of Y6 and PM6:Y6 RachaelCohn, ChristopherPetroff, VirginiaE. McGhee and JohnA. Marohn; Cornell University, United States

Polymer:nonfullerene acceptor (NFA) solar cells have recently achieved record power conversion efficiency (PCE) of 19% [1], but the operation of NFA based solar cells is poorly understood and irreproducibility remains an issue. Charge injection from the substrate is proposed to lead to irreproducibility [2]. We use an electric force microscopy (EFM) technique, broadband local dielectric spectroscopy (BLDS) [3], to determine the film's conductivity. Here we report BLDS studies of the conductivity of PM6:Y6, PM6, and Y6 films in the dark and under illumination.

The Y6 conductivity is high and light-independent, dominated by background carriers even at 20 suns. The PM6:Y6 conductivity is linearly dependent on light intensity with an exponent of 0.58 ± 0.10, consistent with photoconductivity dominated by a single carrier (with the other carrier trapped). PM6 data indicate that the conductivity is out of range of our microscope's capability. This means that the conductivity is either lower or higher than we are able to detect. Based on the observed moderate conductivity of the PM6:Y6 blend, it is unphysical that the PM6 control would have higher conductivity than the blend.

It is generally assumed that a "good" solar cell material has a low dark conductivity, which gives a high V_{oc} [4]. Here we show that that is not necessarily the case, as we find PM6:Y6, a solar cell with high PCE, and Y6 to have a high dark conductivity. It is a challenge to understand how Y6 could have a high dark conductivity, yet form an excellent solar-cell junction with PM6. We adapt Gouy-Chapman theory from electrochemistry to estimate the charge injected from a metal into an intrinsic, updoped organic semiconductor. We conclude that the dark carriers are not being injected from the metallic substrate; they more likely come from impurities or chemical oxidation/reduction of the Y6.

BLDS is used to determine the film's charge response times. The charge response time is inversely proportional to conductivity; conductivity is calculated and plotted versus light intensity. We find that the ratio of the sample to tip capacitance, C_s/C_{tip}, is independent of light intensity. We know that C_{tip} is constant, so C_s/C_{tip} being independent of light intensity indicates that C_s is also constant; this means that the sample resistance, R_s, must be decreasing with increasing light intensity. From this we conclude that light changes R_s, not C_s, as is universally assumed in EFM experiments. We can thus resolve the change in conductivity and capacitance in a single measurement using BLDS.

Oxygen Incorporation in Close Space Sublimed ZnTe Thin Films for Photovoltaic Cells TamaraPotlog; Moldova State University, Moldova (the Republic of)

From 0.5% to 5% oxygen is incorporated into ZnTe through close space sublimated CdS/ZnTe thin film solar cells. The structural and optical properties of the oxygenated ZnTe thin films and CdS/ZnTe devices are investigated using field emission scanning electron microscopy, X-ray diffraction, optical spectroscopy and current-voltage characterization. The 5% oxygen content slightly increase the grain size while the crystallinity does not change. XRD analysis revealed a single-phase crystallinity of zincblende for all grown films. The bandgap of the as-deposited cells ZnTe thin films was bigger than the oxygenated ones. The values of the optical band gaps (E_g) vary in interval from 2.24 eV to 2.14 eV with increasing oxygen content from 0.5% to 5%. The values of the open circuit voltage (V_{OC}) and short circuit current density (J_{SC}) increase when the O_2 content increases in ZnTe. The current-voltage characteristics curve of the 5% oxygenated CdS/ZnTe solar cell at different illuminations show that decrease in illumination from 100 mW/cm^2 to 20 mW/cm^2 decreases the open circuit voltage from 0.76 V to 0.67 V. The fill factor and open circuit voltage are influenced by both the series and shunt resistances. The open circuit voltage V_{oc} and the efficiency increase logarithmically. Also, in this paper is discussed how illumination intensity affect the capacitance of the CdS/ZnTe solar cells.

Investigating Oxygen-Rich Alternative Calcination Approaches for NMC-811 Cathodes ThomasEntwistle, EnriqueSanchez-Perez and SerenaCussen; University of Sheffield, United Kingdom

The calcination of nickel-manganese-cobalt 8:1:1 hydroxide precursor to produce the $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ (NMC-811) is critical to maximise the practical capacity yielded from the cathode active material. This conventionally occurs in a high temperature furnace under a flow of oxygen gas for up to 15 hours at 750-850 °C, which promotes the formation of trivalent and tetravalent nickel ions which facilitate the electrochemical storage of energy in the desired α-$NaFeO_2$ layered $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ phase [1-3]. Here, we present an alternative calcination approach which utilises microwave heating to reduce the reaction time to 4 hours. Lithium peroxide (Li_2O_2) is also used as an alternative lithium precursor to act as an oxygen source during thermal decomposition. This removes the need for a separate oxygen gas source which, as well as being safer, could improve the processing conditions when moving to high-throughput syntheses.

This work investigates the impact of this microwave calcination procedure on the heat treatment of $Ni_{0.8}Mn_{0.1}Co_{0.1}(OH)_2$ with Li_2O_2 and a control lithium salt, lithium hydroxide (LiOH). The reaction conditions, and the material and electrochemical properties of the NMC-811 products are assessed to detail the difference between the conventional oxygen-fed calcination procedure and the alternative microwave calcination procedure. The microwave calcined approach using the Li_2O_2 salt yields initial discharge capacities of 160.5 mAh g^{-1}; whereas the conventional, oxygen-fed calcination approach with LiOH produces 204.4 mAh g^{-1}, when cycled between 3.0-4.3 V at C/20.

The cause of the disparity between the specific capacities was investigated, with high temperature in-situ X-ray diffractometry of $Ni_{0.8}Mn_{0.1}Co_{0.1}(OH)_2$ revealing the different mechanisms for the lithium integration and structural evolution during calcination with Li_2O_2 or LiOH. This, alongside morphological differences, provides insight into the challenges associated with the current microwave calcination procedures and highlights the requirements for further control over the particle morphology to minimise inter-granular resistance and capacity loss compared to conventionally heated furnaces.

8:15 AM CH01.17.02
Characterization of CeO_x-decorated Pd/C Catalysts Synthesized by Controlled Surface Reactions for Hydrogen Oxidation in Anion Exchange Membrane Fuel Cells Richard AndresOrtiz Godoy[1], Ramesh K.Singh[2], DarioDekel[2] and JasnaJankovic[1]; [1]University of Connecticut, United States; [2]Technion - Israel Institute of Technology, Israel

The high cost and difficult task of eliminating platinum (Pt) catalyst in a Proton Exchange Membrane Fuel Cells (PEM-FCs) are some of the main obstacles that thwart the wide adoption of fuel cells. For this reason, Anion Exchange Membrane Fuel Cell (AEM-FC) has been suggested as an alternative to the PEM-FC technology in which non-Pt metals may be employed. However, the common slow kinetics at the anode experienced during Hydrogen Oxidation Reaction (HOR) has been one of the challenges preventing the achievement of high-power density in the Pt-free AEM-FC. Here, our objective is to improve the efficiency of HOR catalysts by depositing various ratios of CeO_x/Pd catalysts onto carbon support using the Controlled Surface Reactions (CSR) process. It is expected that a homogenous distribution of CeO_x preferentially attached to Pd nanoparticles (NPs) can produce highly active CeO_x-Pd/C catalysts for HOR. In the present study, we offer a comprehensive characterization approach for the synthesized highly active catalyst and correlate the obtained structural/compositional parameters to its performance. The characterization of the catalysts was carried out using Inductively Coupled Plasma-Atomic Emission Spectroscopy (ICP-AES), X-ray Diffraction (XRD), High-Resolution Transmission Electron Microscopy (HR-TEM), Scanning Transmission Electron Microscopy (STEM) - Energy Dispersive Spectroscopy (EDS), Electron Energy Loss Spectroscopy (EELS), and X-ray Photoelectron Spectroscopy (XPS) to confirm the bulk composition, phases present, morphology, elemental mapping, local oxidation state and surface chemical states, respectively. The HRTEM micrographs indicated that Pd NPs were uniformly distributed on the carbon support with only some minor agglomeration. Additionally, the achieved high interfacial contact between CeO_x and Pd acquired on single Pd NPs was, for the first time, segmented and calculated using High-resolution STEM-EDS maps and Image J processing program by measuring the overlap intensities between Pd and Ce in the NPs. The intimate contact between CeO_x and Pd and the increase in their interfacial contact area with the addition of CeO_x in these NPs was observed. This interfacial contact area is higher than other previously reported Pd-CeO_x catalyst systems synthesized by other methods, suggesting that the CSR method can provide a more selective deposition of CeO_x on Pd. EELS was used to determine that the primary oxidation state of our oxide was in the form of CeO_2 and Ce^{4+} was predominantly present in CeO_x. However, the presence of Ce^{3+} cannot be ruled out, especially near the surface of the particles. The study also found that the already mentioned interfacial contact area was directly correlated to the electrochemical performance reflected on the HOR activity of the CeO_x-Pd/C catalysts. Additionally, to track the morphological, compositional, and structural changes at the nanoscale we used postmortem Identical location transmission electron microscopy (IL-TEM), to reveal the degradation mechanisms governing this new CeO_x-Pd/C catalyst material following Accelerated Stress Tests in a three-electrode electrochemical cell. The preliminary results have shown that CeO_x can act as a promising anchoring mechanism that prevents the mobility, agglomeration, and detachment of Pd at a considerably high degree when compared to samples without CeO_x.

Investigating Reversible Electrochemical Calcination in Tin (Sn) Alloy Anode for Calcium Ion Batteries SaidaCora[1], VincentBriselli[1], MingyuanGe[2] and NiyaSa[1]; [1]University of Massachusetts, United States; [2]Brookhaven National Laboratory, United States

Calcium (Ca) ion batteries have recently gained recognition as a viable, safe, and cost-effective solution to increase energy density capabilities of next-generation battery technology. However, their practical application has been hindered by the lack of suitable anode materials. Alloy anodes present an attractive avenue for the development of practical calcium-ion batteries, as they can overcome the surface passivation issues associated with Ca metal anodes. Recent studies have highlighted the electrochemical alloying capability of tin (Sn) anodes with calcium, making Sn a promising candidate for beyond lithium-ion battery technologies. In this study, we delve into the calcination and decalcination processes within Sn anodes for next-generation Ca-ion batteries. Utilizing Synchrotron X-ray nanotomography, we track the three-dimensional structural and chemical evolution of tin anodes in calcium electrolyte. Our investigation focuses on understanding the voltage-dependent distribution and homogeneity of Sn-Ca phases, as well as the morphological and structural changes of calcinated Sn. The findings from this study open up exciting possibilities for the design and optimization of calcium-ion batteries, bringing us closer to achieving high-performance energy storage solutions.

8:45 AM CH01.17.04
Revealing Charge Compensation Mechanisms in Battery Cathode Materials with X-ray Raman and Valence-to-Core X-Ray Emission Spectroscopy LijinAn; University of Oxford, United Kingdom

Ni-rich lithium nickel manganese cobalt oxides ($LiNi_xMn_yCo_zO_2$ (x+y+z=1), NMCs) materials are amongst the most promising cathodes to achieve higher energy density and lower cost batteries for electric vehicles. When reaching high charge states, an abrupt lattice contraction along the c-axis is observed giving rise to a large anisotropic volume change. This contraction has long been considered a consequence of oxygen participation in charge compensation arising from strong transition metal-oxygen (TM-O) covalency. Understanding how the structural change is related to electronic properties in the state of charge is essential to design NMCs with enhanced properties. However only limited information is available on the changes of cathode electronic structure upon cycling.

Although soft X-ray techniques such as X-ray photoemission spectroscopy (XPS) and soft X-ray absorption spectroscopy (sXAS) of O K-edge and metal L-edges can provide such information, the very short inelastic mean free paths of photoelectrons and short attenuation length of soft X-rays usually limit these techniques to vacuum condition. This changes the electrode working environment between operation and measurement, losing valuable information in the process. X-ray Raman spectroscopy (XRS) provides a viable alternative to sXAS where hard incident X-rays are used which become inelastically scattered by the sample. By selecting appropriate incident and analyser energies, light element K-edges (e.g. O K-edge) and TM L-edges become accessible without any modification to the battery set-up. Thus XRS combines the depth resolution of hard X-ray techniques with the electronic structure sensitivity of sXAS[1]. Furthermore, X-ray emission spectroscopy (XES) in the valence-to-core (VtC) region provides a more sensitive probe of bonding coordination and hybridisation for both metals and ligands[2]. This spectral region has proven to be particularly important in establishing a probe of metal-ligand interactions. It is uniquely suited to probe changes in TM-oxygen covalency in cathodes, that cannot be obtained through purely structural or other electronic structure measurements alone.

In this study, XRS and XES were employed to probe the electronic structures of conventional cathode materials ($LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ and $LiNiO_2$) at different state of charge. Using the benefits of XRS and VtC-XES discussed above, we can obtain unambiguous results that are not limited by the short penetration depths or unrealistic sample environments. We aim to answer long standing questions such as: how the oxidation state of the TM centres changes during (de)lithiation, and is excess capacity at high potentials mostly linked with the TM cationic redox or anionic (oxygen) redox. Whilst XRS and XES-VtC spectra can be complex to analyse, we have experience in computational calculation of K-edges using density functional theory, which will help elucidate their nature. Modelling the spectra will provide complementary information to interpret the charge compensation mechanism and structural phase changes that are still not well understood in cathode materials. The combination of experimental and theoretical approaches provides a new perspective for future studies toward the fundamental understanding of the mechanism governing the TM-O redox reactions in cathode materials. Such insight can inform future materials design, paving the way for the next-generation higher capacity batteries.

Microsized Hollow Silicon-Graphene Composite Anode for High-Performance Lithium-Ion Batteries SubinLee, Na yeongKim and Ji-WonJung; University of Ulsan, Korea (the Republic of)

The silicon-based anode has been studied as a potential replacement for the traditional graphite anode due to its abundance, low price, and high theoretical capacity (3,579 mAh/g@room temperature) for lithium storage, which is approximately ten times greater than that of graphite (372 mAh/g). Despite these advantages of silicon-based anodes, there are still several remaining vexing problems, such as structural instability induced by huge volume changes, low electrical conductivity, and an excessive, irregular formation of the solid electrolyte interphase (SEI) layers.
In this work, highly durable graphene-silicon composite materials were fabricated by using porogen to generate void space between graphene and silicon. We elaborately controlled the relative composition of active silicon and graphene. The composite properties were analyzed by scanning Electron Microscopy (SEM), transmission EM (TEM), X-ray photoelectron spectroscopy (XPS), and X-ray diffraction (XRD) analysis, which provide an insight into how the composite properties correlate with the lithium-ion battery performance.

9:15 AM CH01.17.06
Tracking the First-Cycle Evolution of Fe-Li, Mn-Rich (Fe:LMR) Cathode Material by Advanced Hard X-Ray Spectroscopic Methods Chun YuenKwok[1], SubhadipMallick[2], ChristopherPollock[3], ArturoGutierrez[2], MarmDixit[1], JasonCroy[2] and MahalingamBalasubramanian[1]; [1]Oak Ridge National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]Cornell High Energy Synchrotron Source, United States

As we strive for the decarbonization of our society, electrochemical energy storage technology emerges as a key player for enabling renewable energy sources. In this context, the development of battery cathode materials using earth abundant materials that can be ethically sourced is of utmost importance. However, our current understanding of the intricate causal relationships and correlations between redox mechanisms and structural changes in some of these materials remains severely limited. One of many of these examples is the Fe:LMR material.

A prominent challenge in designing functional Fe:LMR materials lies in the comprehension of the complex $Fe^{3+/4+}$ redox couple. Conventional X-ray absorption and Mössbauer spectroscopies have not been able to provide a definitive answer on the relationship between the state of charge/discharge of the battery and the status of the transitional metal species. In particular, the charge-compensation mechanism during and after the $LiMn_6$ activation process is a subject of ongoing debate, with conflicting results and theories proposed. These include reversible iron redox, iron oxidation followed by charge disproportionation, reductive coupling accompanied by metal migration, transient oxidized iron species followed by oxygen oxidation via ligand-to-metal charge transfer (LMCT), and peroxide formation, etc. This knowledge gap poses a significant challenge in developing the next-generation efficient and sustainable cathode materials.

To address the issue at hand, we exploit the important traits of hard x-ray spectroscopic methods to track the oxidation state and local structural environment of transition metals and correlate the structural evolution to the electrochemical profile. Through this work, we elucidate the intricate mechanisms occurring in these materials, which will contribute to the development of improved earth-abundant cathode materials and to develop Li-ion batteries that exhibit enhanced performance and longevity.

Development and Characterization of Novel Cation-Disordered Battery Electrode Materials DongchangChen, YouWang, BasiratRaji-Adefila and AlexandraOutka; University of New Mexico, United States

The emergence of cation-disordered battery electrode materials represents a major progress in solid-state materials for electrochemical energy storage applications. The disordered distribution of cations allows rich opportunities in designing diverse cation-disordered structures/compositions but also bring challenges in understanding their nature and energy storage mechanism. In this presentation, we will demonstrate our effort in developing all-new cation-disordered battery electrode materials and investigating their electrochemical properties. Moreover, we will present our approach in characterizing the unique structural features and working mechanisms of these novel electrode materials via a comprehensive array of spectroscopic techniques, ranging from X-ray absorption, solid-state UV-Vis absorption, vibrational spectroscopy, etc. Results of the work will bring transformative insights for various subfields of energy storage materials and investigation of hidden yet critical materials properties via in-depth spectroscopic characterizations.

10:15 AM CH01.17.08
Characterisation of Local Environments in Strongly Paramagnetic Battery Cathodes: A Combined Experimental and Theoretical Approach EuanBassey[1,2] and ClareP. Grey[2]; [1]Materials Science Laboratory, United States; [2]University of Cambridge, United Kingdom

Non-invasive techniques which probe the local environment around the paramagnetic redox-active transition metal (*TM*) centres in lithium- and sodium-ion battery (LIB and NIB, respectively) cathode materials are critical in developing a clear understanding of the phase transformations, redox processes and degradation mechanisms which take place at the cathode during operation of the battery.[1] Where NMR is increasingly used as a characterization technique for studying, for example, Li, Na and O local environments in paramagnetic battery materials, direct observation of the redox-active paramagnetic (*TM*) centres using NMR is not possible owing to rapid nuclear relaxation times.[2–4] EPR, however, enables investigation of these centres and is far less reported. Further, an understanding and assignment of these EPR spectra—made all the more challenging by strong electron-electron dipolar and magnetic exchange interactions—does not yet exist. In this work, we present a combined high-frequency EPR and density functional theory (DFT) study of the local paramagnetic environments in Li_2MnO_3, a model compound for the family of commercially successful, layered lithium-ion battery cathodes. By collecting EPR spectra at a range of frequencies (9 – 383 GHz) and temperatures (5 – 300 K) and comparing to DFT-calculated *g*-tensors, we clearly observe several unique local environments and assign these observed resonances to Mn^{4+} centres with different local environments [Figure 1]. We also examine the effect of magnetic exchange interactions on the spectra to explain the temperature evolution of these complex EPR spectra. The methodology presented in this work will be invaluable for studying paramagnetic centres in paramagnetic solids not only for LIBs and NIBs, but also in a range of *TM*-based materials for devices.

10:45 AM *CH01.18.01
A Spin on Redox Processes in Battery Electrodes RaphaëleClement; University of California, United States

Rechargeable batteries generate current through the transfer of electrons between paramagnetic and/or metallic electrodes. The interrelation between a material's magnetic and electronic properties, and its performance as a battery electrode, motivates the use of magnetometry and magnetic resonance tools to investigate redox processes during electrochemical cycling.[1] Moreover, interactions between magnetic moments or spins strongly depend on bond lengths and angles (orbital overlap), making such tools ideal probes of the local structure in crystalline, disordered, or even amorphous electrode materials.

In this talk, I will present our recent work combining *operando* magnetometry, high resolution *ex situ* solid-state NMR, and first principles calculations, to better understand the working principles and sources of irreversibility of magnetic and metallic conversion and intercalation electrodes. We show, for example, that the first cycle irreversibility of $LiNiO_2$ is partly caused by planar defects in the as-synthesized material, preventing Li intercalation at standard cycling rates.[2] NMR, magnetometry and ^{57}Fe Mössbauer spectroscopy allow us to identify and quantify conversion of the cryolite-like Na_3FeF_6 electrode,[3] and to monitor polymorphism and an electrochemically-induced phase transformation in the weberite $Na_2Fe_2F_7$intercalation cathode.[4]

A Novel Light Scattering Technique for the Study Of Li-Ion Dynamics and Characterisation of Battery Electrode Materials ChristophSchnedermann[1,2], AliceMerryweather[1,2], CathrynLangley[2], ClareP. Grey[1] and AkshayRao[1,2]; [1]University of Cambridge, United Kingdom; [2]Illumion Ltd., United Kingdom

We introduce a recently developed *operando* optical microscopy technique and provide examples of how it can be applied to mechanistic studies of lithium-ion battery electrodes and active material characterisation.Our technique probes state-of-charge changes in the active particles within the electrode during battery operation, based on the intensity variation of scattered light across each active particle. This enables detailed spatially-resolved data on an individual particle level to be built up for mechanistic studies but can also allow global statistics to be established at the electrode level.

The ability to quantify ion transport during battery operation within active particles and across the electrode helps to provide insights into how lithium-ion dynamics affect the (de)lithiation mechanisms and degradation mechanisms of battery electrodes, which is crucial to improving their electrochemical performance. Here, we present highlights demonstrating how our technique can be used to (1) track and quantify phase transitions in lithium cobalt oxide (LCO), (2) reveal kinetic phase separation in high-rate niobium tungsten oxide (NWO) anode materials, and (3) determine mechanistic origins of first-cycle capacity losses in Ni-rich nickel manganese cobalt oxides (NMC).

Finally, we showcase how the performance of the electrode can be quantified by monitoring the heterogeneous rate of (de)lithiation across hundreds of active particles in the electrode during normal battery operation. Using NMC and NWO as examples, we demonstrate how our technique can be used to determine both the proportions of active particles in the electrode exhibiting irregular, slower, faster and normal (de)lithiation rates, and the proportions of cracked and intact particles after successive cycles to monitor degradation and electrode cycling performance.

The generality of our technique means that it is agnostic to the underlying battery chemistry, and can be applied to study any battery electrode, such as Na-ion and multivalent-ion batteries.

11:30 AM CH01.18.03
Operando Study of Thermal and Chemical Events in Lithium Metal Batteries using Optical Fiber Bragg Grating Sensor CharlotteGervillie[1], WurigumulaBao[2] and Y. ShirleyMeng[2,1]; [1]University of California San Diego, United States; [2]The University of Chicago, United States

In the era of rapid energy transition, energy storage technologies offer a unique opportunity to facilitate a sustainable, low-carbon transition, thereby paving the way towards a cleaner and more resilient future. Lithium metal batteries have attracted significant research attention due to their groundbreaking high theoretical capacities, exceeding conventional graphite anodes in lithium-ion batteries by a factor of ten (3,860 milliampere hours per gram). However, the commercialization of lithium metal batteries is hindered by substantial challenges, including the growth of dendrites at the negative electrode as a result of uneven lithium plating and stripping. Additionally, the reactivity between lithium metal and the electrolyte leads to the formation of unstable solid-electrolyte interphase (SEI) layers, further compromising battery performance and cycle life.
To address these issues, researchers have extensively developed destructive characterization techniques to observe the lithium metal anode and quantify irreversible lithium metal formation. However, these studies lack real-time operando information, crucial for understanding the dynamic behavior of these systems. Recently, the emergence of optical fiber-based techniques has enabled the tracking of battery properties under realistic conditions, providing chemical, thermal, and mechanical data for lithium-ion and sodium-ion cells.
In this study, we demonstrate the utilization of optical fiber Bragg grating (FBG) sensors to monitor thermal and chemical events in anode-free commercial cells during real cycling conditions. By confirming the operando results with destructive characterization methods such as titration gas chromatography (TGC) and focused ion beam (FIB) imaging, we highlight the capability of this method to monitor the parasitic reactions (as solid electrolyte interface formation) happening in lithium metal cells under diverse conditions, including varying pressure, electrolyte formulation, and rate performances. Overall, the utilization of FBG sensors offers valuable insights into the reactivity, stability, and safety aspects of lithium metal batteries, thereby contributing to the ongoing development and optimization of these energy storage systems.

11:45 AM CH01.18.04
Freestanding LiPON: From Fundamental Study to Uniformly Dense Li Metal Deposition Under Zero External Pressure DiyiCheng, MinghaoZhang and Y. ShirleyMeng; University of California, San Diego, United States

Lithium phosphorus oxynitride (LiPON) is a well-known amorphous thin film solid electrolyte that has been extensively studied in the last three decades. Despite the promises to pair with various electrode materials, the presence of rigid substrate and LiPON's unique amorphous, air-sensitive nature set limitations to comprehensively understand its intrinsic properties for future development and applications. This work demonstrates a methodology to synthesize LiPON in a freestanding form that manifests remarkable flexibility and a Young's modulus of ~33 GPa. Solid-state nuclear magnetic resonance and differential scanning calorimetry results with high signal-to-noise ratio reveal the Li/LiPON interface bonding environments quantitatively and a well-defined glass transition temperature for LiPON. Combining interfacial stress and a seeding layer, FS-LiPON demonstrates a uniform and fully dense Li metal deposition without the aid of external pressure. Such a FS-LiPON film offers more opportunities for the fundamental study of LiPON material and associated interfaces, and provides perspectives for interface engineering in bulk solid-state battery.

SESSION CH01.19: Photovoltaics IV

1:30 PM *CH01.19.01
Scanning Probe IR Microscopy and Soft X-Ray Spectroscopy Reveal Local Composition and Molecular Orientation in Solution Processed Films for Organic Photovoltaics EllenMoons, LeticiaP. Christopholi, IshitaJalan, CleberMarchiori, LeifK. Ericsson, Stela AndreaMuntean and Janvan Stam; Karlstad University, Sweden

Solution-processed organic solar cells (OSC), a low-cost renewable energy technology, have shown record power conversion efficiencies approaching 20%. The recent leap in performance of OSC can be ascribed to the development of new electron acceptors, such as the Y-series of small molecules, that efficiently contribute to photogeneration of charges in the visible range. These molecules provide, however, new challenges for film processing due to their limited solubility and tendency to aggregate. The presentation will cover two examples where morphological analysis by means of advanced characterization techniques have provided in new insights in the molecular organization in spin-coated films. First, we present a study of the influence of the processing solvent on the orientation and packing of Y-series acceptor molecules in pure acceptor films by angle-resolved Near-Edge X-ray Absorption Fine Structure (NEXAFS) spectroscopy. Secondly, we demonstrate the use of AFM-IR spectromicroscopy to map the nano-scale composition of spin-coated donor-acceptor bulk heterojunction films. AFM-IR spectromicroscopy combines the high resolution of scanning probe microscopy with the precise chemical fingerprint of infrared spectroscopy. Using a pulsed, tuneable MIRcat laser, resonant enhanced tapping mode AFM-IR yields compositional maps of donor and acceptor molecules with low beam damage. This chemical mapping yields new insights in the nanostructure formation in molecular semiconductor films for emerging photovoltaic materials.

New Era of Material Characterisation: Resolving Electron and Hole Charge Carriers Properties by Constant Light Induced Magneto Transport ArtemMusiienko[1] and FengjiuYang[2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]National Renewable Energy Laboratory, United States

The development of novel and improvement of existing semiconductor and semi-insulating materials relies on the knowledge of free-charge transport properties. In particular, knowledge of minority and majority charge carrier diffusion lengths, lifetimes, mobilities, and concentrations allows tailoring the design of semiconductor devices and control effectiveness of solar cells, transistors, detectors, sensors, and LEDs. At the moment, the detection of minority and majority charge (electrons or holes) properties is challenging due to the natural limitation of the experimental methods. The broadly spread methods such as time-resolved photoluminescence (trPL), theraherz conductivity, and photoconductivity decay can detect lifetime for only a minority or only the majority of carriers, which control the fast decay component of the signal [1]. The additional drawback of the commonly used methods is that they probe charge carriers' properties in a transient regime which is not matched with device or material operation conditions in a steady state.

Recently, several studies used the Hall effect in a single carrier regime assuming an equal concentration of holes and electrons to assess the properties of photocarriers [2–5] In most cases, the concentrations, lifetimes, and diffusion length of electrons and holes are not equal in semiconductors due to the presence of traps. Thus, the equality of hole and electron concentrations leads to an incomplete or sometimes incorrect description of charge transport. This study introduces the Constant Light Induced Magneto Transport (CLIMAT) method [6], which combines light and magnetic fields to assess the transport properties of holes and electrons separately. CLIMAT provides access to fourteen material parameters compared to only two in the classical approach. We demonstrate that having direct knowledge of electron and hole properties enables us to determine quasi-Fermi level splitting and ideality factor, and predict the material's performance in a photovoltaic (PV) device configuration without constructing the full device.

We illustrate the implications of CLIMAT in two different systems: silicon and halide perovskite solar cells. For the first time, we differentiate electron and hole transport in these material systems using CLIMAT. We identify dominant recombination mechanisms in materials that hinder lifetime and diffusion length. Additionally, we reveal the differences in electron and hole lifetimes due to trap states. The experimental data are supported by charge transport drift-diffusion simulations.

The use of CLIMAT with AC magnetic fields can revolutionize the field by providing unique feedback on magnetic fields and light. This enables the study of carrier concentration, lifetime, diffusion length, and mobility as a function of light intensity. Furthermore, it allows for predicting the material's performance in a PV device configuration without constructing the full device. We anticipate that our approach will have applications in optoelectronic systems where device efficiency strongly depends on electron and hole transport. Specifically, CLIMAT can be utilized to characterize and optimize diffusion length and lifetimes in solar cells, sensors, LEDs, and transistors.

Quantifying Local Conductivity and Complex Dielectric Constant of Solar Cell Films Using Electrical Scanning Probe Microscope Measurements and Microscopic Theory JohnA. Marohn, ChristopherPetroff, VirginiaE. McGhee, RachaelCohn and RogerF. Loring; Cornell University, United States

Electrical scanning probe measurements, such as scanning Kelvin probe force microscopy (KPFM) and electric force microscopy (EFM), have been widely used to study inorganic, organic, and hybrid semiconductors. Frustratingly, the established theoretical description of electrical scanning probe measurements calculates cantilever forces and frequency shifts as a function of sample capacitance, essentially ignoring sample resistance. We have developed a new Lagrangian-mechanics theory of electrical scanning probe measurements that fixes this shortcoming [1]. In the new theory, the cantilever signal depends on sample resistance, sample capacitance, and tip capacitance.

A central feature of the new theory is a complex-valued transfer function, written in terms of tip capacitance and sample impedance, that relates the cantilever charge to the applied oscillating tip voltage. We show that cantilever frequency shift and dissipation (i.e., non-contact friction) depend, respectively, on the real and imaginary part of this transfer function evaluated at the cantilever frequency. The entire transfer function can be measured in a broadband local dielectric spectroscopy (BLDS) measurement [2] in which the mean cantilever force is observed as a function of the tip voltage's oscillation frequency [3]. BLDS measurements carried out on a wide range of organic and lead-halide perovskite semiconductors as a function of light intensity show that light primarily changes sample resistance, not capacitance (as assumed nearly universally in electrical scanning probe measurements).

From the measured sample resistance and capacitance, we wish to infer the sample's intrinsic resistivity and dielectric constant. The starting point for this task is the continuum electrostatic theory describing the forces, force gradients, and friction experienced by a charged cantilever over a semiconductor on a dielectric substrate developed by Lekkala, Marohn, and Loring [4]. Work is underway to apply this theory to a semiconductor on a metal substrate by taking the dielectric constant of the substrate to infinity in Lekkala's equations. The output of these computations will be semi-analytic theory for the cantilever frequency shift and dissipation versus voltage, and the BLDS signal versus frequency, written in terms of tip capacitance, sample thickness, sample resistivity, and sample dielectric constant.

Our theory covers both electronic and ionic conductivity. Having a quantitative scanning probe method to measure thin-film ionic and electronic properties is important because many new ionic/electronic materials for battery and solar-cell applications are, as synthesized, highly heterogeneous. Bulk measurements such as Hall effect, dielectric spectroscopy, and current-voltage measurements are dominated by the average behavior. Scanning probe measurements, in contrast, have high spatial resolution and can be used to demonstrate that some region of the heterogeneous material has favorable properties and is thus worth a further investment of capital to improve synthesis and/or processing.

2:30 PM CH01.19.04

Optimisation of a Polymerised Fullerene-Based Transport Layer for Organic Photovoltaics - Effect on Energetics, Active Layer Formation, and Device Performance NickyEvans[1], PhilippWeitkamp[2], OliviaGough[1], BenjaminPutland[1], RaghunathR. Dasari[3], SethR. Marder[4], KlausMeerholz[2], SelinaOlthof[2], MoritzRiede[1] and HenrySnaith[1]; [1]University of Oxford, United Kingdom; [2]University of Cologne, Germany; [3]Georgia Institute of Technology, United States; [4]University of Colorado Boulder, United States

Investigations into the charge transport layers used within organic photovoltaics (OPV) can help us in finding ways to improve device efficiency and stability. In particular, dedicated charge transport layers have the purpose of aiding in selective charge transport to the respective electrodes. Care has to be taken to ensure advantageous energy level alignment, resulting in minimised losses in solar cell device performance. Though the more commonly used electron transport layer materials in OPV, such as metal oxides, exhibit satisfactory optical and electronic properties, there is limited control over their energy-level matching within a device. Additionally, the stability of many of these materials, particularly under ultraviolet irradiation, is a limiting factor. This study investigates the use of an electronically and energetically tuneable, fullerene-derived electron transport layer for OPV, namely PCBCB. These films exhibit a reduction in solubility once they are treated by specific annealing conditions, which intriguingly allows for non-orthogonal-solvent based films to be processed on top of these layers. We investigated these films with respect to their conductivity as well as energetic properties and were able to tune these properties via the use of an electron-donating additive. It was observed that with an increased additive concentration, the conductivity increased while at the same time the physical film quality improved. Furthermore, the use of the additive led to a shift in the position of the Fermi level toward the lowest unoccupied molecular orbital, ultimately improving the energy level matching of the layer within the device stack.
Device stacks comprised of a PM6:Y6 donor-acceptor blend active layer were fabricated atop a series of such electron transport layers in an n-i-p architecture. Intriguingly, this resulted in variations in active layer morphology. The changes were explored using GIWAXS and significant differences in the crystalline stacking were found for the active layer deposited on top of doped fullerene-derivative ETL, in contrast to a metal-oxide transport layer. This is thought to be a product of different levels of phase segregration throughout the active layer, relating to differences in contact angle between the active layer and ETL when deposited. These morphological changes appear to result in significant differences in device performance characteristics, particularly in J_{SC} and consequently fill factor and power conversion efficiency. Thus, understanding the impact of prior layers on active layer formation could be integral to further understanding and optimising device performance characteristics.
Furthermore, a series of stability studies are currently being conducted to test the lifetime of OPV devices comprised of a fullerene-derivative ETL, in comparison to those using a typical zinc oxide (ZnO) electron transport layer. From intial results, we see that a highly ‘doped’ organic ETL and a bilayer of doped and nominally intrinsic transport layers, both lead to device performance that is close to competing with ZnO based devices, and an increased lifetime as compared to devices comprising of the metal oxide.

Determining the Depth Profile of the Active Ce^{3+} Species at Reduced Surfaces of Ceria PatrickM. Donahue[1], QingMa[1,2], PaulChery[1] and SossinaM. Haile[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Rapid and reversible surface reduction is central to the functionality of ceria (CeO_2 and doped derivatives) in catalysis and sustainable energy technologies, yet unanswered questions remain regarding its fundamental surface redox properties. This work supplies novel in-situ characterization of ceria surfaces, namely the termination dependence of surface reduction and the complete depth profile of the reduced Ce^{3+} species. This work is based on in-situ depth-resolved X-ray absorption near-edge spectroscopy (XANES) of CeO_2 thin films, for which we have developed a robust analysis method. As of the abstract submission date, the Ce^{3+} depth profile at the CeO_2 (111) termination has been determined at 800°C under an H_2/H_2O atmosphere ($pO_2 = 1.0\times10^{-19}$ atm); planned experiments in the coming months will characterize the CeO_2 (100) and (110) terminations and investigate an additional high-temperature reducing environment (~1000°C in medium vacuum). Previous studies suggest environment-dependent variations in both the form and magnitude of the Ce^{3+} profile [1], and surface reducibility is predicted to vary by termination [2]. This study directly addresses those areas of inquiry and considerably expands current knowledge of ceria surface properties under technologically relevant conditions. In turn, a deeper understanding of the exceptional redox properties of ceria can inform advanced design of catalysts and oxygen storage materials.

***In Situ* and Operando Characterization of Photocatalytically Active Faceted Semiconducting Nanoparticles**FriederMugele[1], IgorSiretanu[1], ShaoqiangSu[1], BastianMei[1,2] and GuidoMul[1]; [1]University of Twente, Netherlands; [2]Ruhr-Universität Bochum, Germany

Photo- and electrocatalytically active materials are expected to play an essential role in the transition towards sustainable processes for energy storage and chemical conversion. Performance and stability of the materials still need to be improved. Yet, the microscopic origin of their current limitations are often poorly understood. One key limitation is the lack of suitable techniques that allow for a detailed characterization of the structural and electrical properties of the interfaces on the nanometer scale. In this lecture, I describe our recent progress in establishing in situ and operando AFM spectroscopy for characterizing the surface charge and its response to illumination on photocatalytically active faceted nanoparticles of $SrTiO_3$ and $BiVO_4$ in ambient electrolytes of variable composition. Our measurements demonstrate the existence and pH-dependence of differences in surface potential between adjacent crystal facets, which are believed to drive the separation of photo-generated electron-hole pairs in photocatalysis. For visible light-driven $BiVO_4$, we monitor the variations of the local surface charge upon illumination, from which we extract the local surface photovoltage and thus the accumulation of charge carriers at the interfaces. The measurements suggest a strong influence of surface defects such as steps and disordered regions between adjacent facets for the accumulation of photo-excited charge carriers.
I will conclude the lecture with an outlook on upcoming challenges in AFM-based characterization of catalytic materials for the energy transition.

Structure, Thermodynamic and Thermomechanical Characteristics of Semiconducting Polymers: Nomenclature and Property Conundrums HaraldAde; North Carolina State University, United States

Organic semi-conducting polymer thin films are used in many organic electronic devices and have shown promising results in applications ranging from organic light emitting diodes to solar cells and biosensors. The molecular packing of the polymers controls a number of optical and electronic properties and the thermal and thermomechanical properties are critical for devices stability in blends, processing strategies, and mechanical failure modes. Due to the molecular design, semi-conducing polymers exhibit a continuing range of paracrystalline disorder, yet at the same time, they do not behave like classic paracrystalline materials. In fact, the classic structure and property paradigms and associated nomenclature don’t seem to apply. Classic material design labels such as random coil, rigid rod, hairy rod and bottlebrush seem to be delimiting structural characteristics, with semi-conducing polymers occupying the concept and parameter space in-between these limits, yet with characteristics that appear to be not just linear combination of the characteristics found in the classical limits. We review the current understanding and the various conundrums. For example, paracrystallites in a semi-conducting thin film are usually assumed to have a certain size and shape in three dimensions, which then can have a preferred edge-on or face-on orientation relative to the substrate with a random orientation in-plane. X-ray analysis indicates though that most materials exhibit only two-dimensional paracrystalline platelet ordering and might often resemble a layered glass. Thermomechanical characterization frequently indicate multiple relaxation transitions without the presence of a clear glass transition, yet a high temperature liquid-crystalline-like phase. Furthermore, the phase diagrams of semi-conducting polymers with ‘small molecule’ acceptors such as fullerenes or modern non-fullerene acceptors frequently exhibit reentrant phase boundaries that reflect upper and lower-critical solution temperature characteristics. The totality of information suggests that a new reference frame if not new paradigm and associated nomenclature is required to facilitate understanding and communication about the order, molecular packing, texture, thermomechanical properties, and structure-properties relations in semi-conducting polymers.

8:30 AM +CH01.21.01
Examining Indoor and Outdoor Stability of Non-Fullerene Acceptor Organic Solar Cells using a Bottom-Up and Top-Down Hybrid Approach Manjunatha ReddyG.N.; University of Lille, France

Efforts on molecular design, material processing and device engineering enabled new looms in the small molecule acceptor-based organic photovoltaics (OPVs) with power conversion efficiency (PCE) of over 19%, enticing further developments toward scalability and commercial viability. In doing so, it is paramount to resolve structure-stability-property interrelationships.[1-3] Here, we present a hybrid bottom-up and top-down NMR crystallography approach to correlate between morphology deterioration and performance degradation,[4] and provide an example of structure-stability-property relationship in PM6:Y6 bulk heterojunction (BHJ) solar cells.[5] The bottom-up strategy combines time-resolved magnetic resonance spectroscopy and crystallography modelling to disentangle the impact of the environment on the bulk and interfacial BHJ morphology, in order to gain insight into the molecular origins of photochemical, thermal and moisture-induced degradation reactions in PM6 and Y6 moieties.[5] A complementary top-down model examines macroscopic device properties including short circuit current density (J_{sc}), open-circuit voltage (V_{oc}), fill factor (*FF*), external quantum efficiency (EQE) and PCE values as a function of environmental parameters. The nanoscale PM6:Y6 BHJ morphology is resistant to an indoor operational condition at 22 °C, 700 lx and 45% relative humidity (RH) for over 4 years. In contrast to this, morphological degradation occurs upon photoirradiation (AM 1.5G), exposure to moisture at 85% RH and thermal annealing at 100-200 °C, leading to performance deterioration. The PM6:Y6 blend, PM6 and Y6 films exhibit different instability and degradation mechanisms, whereby the Y6 is more vulnerable to photoirradiation and (hydro)thermal treatment. Our results corroborate that PM6:Y6 morphology is acquiescent to indoor applications, calling for the design of environmentally stable molecular entities in order to formulate stable and efficient BHJ morphology for outdoor photovoltaics.

Charge Density in Nanorings from Scanning Force Microscopy MosheGordon, BenjaminGoykadosh, YonathanMagendzo and FredyR. Zypman; Yeshiva University, United States

Several systems of nanometer or sub–nanometer dimensions are electrically charged rings. For example, molecular pumps use electrically charged rings to link amino acids into growing peptides, the efficiency depending on charge magnitude and location. Knowledge of charge content is necessary to apply these pumps to assemble other architectures. More generally, charge plays a key role in the structure attained by large molecules when they self-assemble. Also, charged rings are current candidates as physical support of information storage for qubits for quantum computing. In addition, for applications in biosensing and nano-optoelectronics, micrometer and nanometer rings of charge have been synthesized from a variety of materials. For example, carbon nanorings with radii of a few have been obtained by self-assembly of carbonized pluronic P123. The most common gold nanoring has been synthesized by a variety of methods, while whole silver nanorings of diameter have been produced by solvothermal methods.
These examples underscore the relevance of understanding electrostatic measurements at the nanoscale with the **SFM** (scanning force microscope), and in particular, to understand those measurements on charged ring structures. While the **SFM** sensor mechanically responds to electrostatic inputs, it is not straightforward to connect this response to the electrostatic content of the sample under study. Specifically, **SFM** records a force trace which varies as the sensor explores different regions of the sample. In this study, we propose a method to convert this force curve into charge density content in the sample. We first solve the direct problem, whereby the SFM force is computed from the assumed know charge density. Afterward, we move to the realistic practical situation in microscopy and address the inverse problem. In the inverse problem, forces are measured in each voxel of a volume region above the sample and, using that information as input, the charge on the ring is produced.

Potassium Ions Pre-Intercalated Vanadium Oxide Cathodes for Aqueous Zn-Ion Batteries YinanLu; University College London, United Kingdom

Aqueous rechargeable zinc-ion batteries (ZIBs) have garnered considerable attention due to their safety, cost-effectiveness, and eco-friendliness. There is a growing interest in finding suitable cathode materials for ZIBs. Layered vanadium oxide has emerged as a promising candidate due to its high storage capacity for zinc ions. However, the development of high-performance zinc-ion batteries faces challenges such as irreversible phase transformation, sluggish diffusion of zinc ions caused by the high energy barrier between V_2O_5 layers, and hence low capacity than the theoretical value. In this study, we synthesized nanofibers of V_2O_5 intercalated with potassium ions (KVO) through a straightforward hydrothermal process. The introduction of potassium ions not only increased the interlayer distance ($d_{(001)}$ = 9.35 Å) but also reduced the V^{5+}/V^{4+} redox couple (from 7.18 to 1.01) thereby improving the electrochemical performance. The resulting KVO cathode exhibited a high specific discharge capacity (274.18 mAh g^{-1} at 0.1A g^{-1}, second cycle), enhanced cycling stability, and significantly reduced charge transfer resistance (8.92 **Ω**) compared to pristine V_2O_5 (98.67 mAh g^{-1} at 0.1A g^{-1} and 67.31 **Ω** charge transfer resistance). This study contributes to the understanding and advancement of KVO cathode materials, providing valuable insights for the design and optimization of cathode materials to enhance the electrochemical performance of ZIBs.

X-Ray Micro-Computed Tomography (XMCT) for Quantitative Morphometry of Topological Graphene-Based Aerogels and Carbon Foams SanjuGupta; Penn State University, United States

We report quantitative morphometry of freeze-dried graphene-based aerogels (GA, NGA, Gr-MWCNTs) and carbon foam (CF, CF-GA) monoliths, prepared by hydrothermal and organic sol-gel, respectively. X-ray micro-computed tomography (XMCT), in combination with SEM, allowed to visualize of internal microstructure in 3D space and the reconstructed volume renderings from 2D sliced images revealed hierarchical structures (interlaced thin sheets, honeycomb organization) and topological (interconnected pores background) domains. The influence of multi-walled carbon nanotubes (MWCNT) additions to graphene-like sheets and integration with carbon foam (CF) are assessed through volume-weighted pore size, wall thickness, and porosity levels, in compliance with physical properties. Composite porous solids elucidated crosslinking reinforced by a homogeneous distribution of CNTs into graphene aerogel (GA) and CF matrices. A consistent trend of NGA (and GA)>CF>Gr-MWCNT$_{2:1}$>CF-GA>Gr-MWCNT$_{3:1}$>Gr-MWCNT$_{5:1}$ was found from XMCT image processing and analyses significantly corroborate stability. These results provided insights and guide the design of porous carbonaceous materials for energy sciences and environmental engineering.

Commercializing Materials for Solution-Processable Near-Infrared and Short-Wave Infrared Photodiodes: Challenges and Solutions in Performance, Process and Production HidenoriNakayama, YasuoMiyata, KazuhiroMouri, KazuhiroNakabayashi and ShigeruNakane; Mitsubishi Chemical Corporation, Japan

Solution-processed near-infrared (NIR) and short-wave infrared (SWIR) organic photodiodes (OPDs) hold great promise as they can offer higher external quantum efficiency (EQE) for infrared light detection compared to silicon-based photodiodes, at a lower cost than InGaAs-based alternatives. However, commercialization of these OPDs faces hurdles in materials development and device engineering. In this presentation, we discuss the challenges encountered during our decade-long research as a chemical company, dedicated to providing reliable organic semiconductor materials to the market. These challenges can be classified into three categories: lab-scale device performance, fabrication process, and industrial-scale production.

To meet demands for higher sensing performance, particularly higher EQE with suppressed dark current, we have developed novel materials for the photo-active layer (PAL) and the hole transport layer (HTL) positioned beneath it. The PAL consists of a blend of donor polymers and non-fullerene acceptors (NFAs) which absorb lights in the NIR and SWIR regions. An OPD designed for sensing NIR exhibited an EQE of 80% at 940 nm with 5×10^{-6} mA/cm^{-2}, while another OPD designed for sensing SWIR exhibited an EQE of 45% at 1100 nm with a dark current of 4×10^{-5} mA/cm^{-2}. We will present updates on the device performances. The achieved low dark current in these devices can be partly attributed to the material design of the HTL. The HTL comprises a polymer with thermal-crosslinking moiety, enabling a wider range of solvent choice for PAL deposition, eliminating the need for “orthogonal” solvents. The HTL contains no additives or catalysts for cross-linking, which ensures minimal contamination in both the HTL and PAL, preserving the desired hole mobility. This HTL design is also successfully applied to our organic light emitting diodes and organic/perovskite photovoltaics technologies.

Addressing the process-related requirements in the electronics industry, we optimized the ink formulations for the PAL and HTL without the use of halogenated solvents. These inks maintain

consistent device performance for over three months. When fabricating OPDs on CMOS readout circuits on a silicon wafer, spin-coating emerges as the preferred choice due to its widespread utilization in the semiconductor industry's patterning process. We have achieved successful spin coating of our HTL on an 8-inch silicon wafer with a thickness variation of less than 3 nm across the entire layer. The PAL inks have been optimized to prevent dewetting on the HTL and ensure a smooth coating on top. To withstand subsequent reflow soldering and encapsulation processes, the OPD-CMOS stacks are heated to at least 200°C. We will present various technologies implemented to avoid thermal degradation and crystallization of NFAs during the heating process.

As for manufacturing, stringent quality control measures are imperative for reliable commercial production. The organic semiconductor community widely recognizes the batch-to-batch variations in semiconductor performance using commercially-available or laboratory-made organic semiconductors. We will discuss our approach to address this critical issue.

10:05 AM CH01.21.06
Effect of Polymer Coating on Magnetocaloric Properties of Garnet JolaikhaSultana[1], Santosh KarkiChhetri[2], JinHu[2] and SanjayMishra[1]; [1]The University of Memphis, United States; [2]University of Arkansas, United States

Magnetocaloric materials can be applicable in magnetic cooling technologies, thermomagnetic motors, or medical treatments. For any practical applications, magnetocaloric materials are formed into various geometries, e.g., cylinders, plates, spheres, etc. Oxide-based MCE materials can be formed using high-temperature sintering or via mixing with polymers to increase the material's formability. Further, coating these particles with polymers is a practical and effective method for inhibiting their agglomeration. However, the effect of polymer coating on MCE oxide material is not well explored. Given the above, this study focuses on understanding the influence of polyvinylpyrrolidone (PVP) on $Gd_3Fe_5O_{12}$ garnet's structural, magnetic, and magnetocaloric properties.

The garnet $Gd_3Fe_5O_{12}$ samples were synthesized using the sol-gel auto combustion method. PVP coating of powder proceeds by adding 5% PVP (M_w -31000-50000) to a solution of 150 mg of $Gd_3Fe_5O_{12}$ nanoparticles suspended in distilled water. The presence of PVP was recorded via FTIR and TGA. The XRD studies showed that the PVP coating did not affect the crystal structure of $Gd_3Fe_5O_{12}$. However, the XRD peaks became slightly broadened and decreased in intensity after coating. The BET-specific surface area of nanostructured uncoated and PVP-coated $Gd_3Fe_5O_{12}$ oxides was determined to be 54.41 (m^2/g) and 109.1 (m^2/g), respectively. A marked increase in BET surface area is observed for the PVP-$Gd_3Fe_5O_{12}$ sample.

Magnetic measurements revealed that both coated and uncoated particles exhibited superparamagnetic behavior at 300K and 5K, respectively. The PVP-coated particles showed lower magnetization than the uncoated particles, attributed to reduced effective mass and degradation of particle dipole-dipole interactions caused by the non-magnetic PVP coating. Further pinning of surface spins via bonding with PVP molecules may extend deeper into the particle, reducing the effective magnetization of the compound. Magnetic entropy (-ΔSm) and the samples' relative cooling power (RCP) were determined from the isothermal magnetization M vs. H data at different temperatures. The results showed a considerable increase in the peak temperature (57.5K) for PVP-coated $Gd_3Fe_5O_{12}$ compared to the uncoated sample. The peak temperature of 57.5K corresponds to a significant alteration in the material's magnetic properties. The maximum value of magnetic entropy change (-ΔSm) for uncoated $Gd_3Fe_5O_{12}$ was determined to be 3.80 $Jkg^{-1}K^{-1}$ at 37.5K with a 5T applied field, accompanied by a relative cooling power (RCP) of 380 Jkg^{-1}. On the other hand, for PVP-coated $Gd_3Fe_5O_{12}$, the maximum -ΔSm was found to be 3.38 $Jkg^{-1}K^{-1}$ at 47.5K with a 5T applied field, and the RCP was 308 Jkg^{-1}. Indeed, the observed maximum magnetic entropy changes at higher temperatures for the PVP-coated $Gd_3Fe_5O_{12}$ sample are noteworthy. Further, there is an unnoticeable change in -ΔSm value with PVP coating. This characteristic indicates that the PVP-coated garnet may have an advantage in terms of usability over a wider temperature range compared to the uncoated counterpart, which can potentially be a promising material for applications in cryogenic temperature magnetic refrigeration.

The Effect of Deposition Temperature and Oxygen Concentration on The Properties of NiO_x Films obtained by Sputtering: The Potential Use of NiO as Hole Transport Layers in Large-Area Perovskite Solar Cells WesleyC. Muscelli, Ana Paulad. Modesto, OtavioJ. de Oliveira, RafaelMerlo and FranciscoC. Marques; University of Campinas, Brazil

Perovskite solar cells are currently the most promising photovoltaic devices and have lately experienced extraordinary progress in efficiency and manufacturing technologies. The organic-inorganic perovskite with structure ABX_3 where A is typically methyl ammonium (MA), Formamidinium (FA) or Cesium (Cs); B is Pb or Sn; and X is Cl, Br or I, have recently emerged as an excellent class of semiconductors [1-3]. There are huge efforts to increase large-scale production of perovskite solar cells. One strategy is to develop the structure of the devices using physical techniques such as sputtering, thermal evaporation and atomic layer deposition. The sputtering technique has some advantages, as it is a well-known technique and already used to produce various materials in large areas. Among the materials used in the structure of perovskite solar cells, NiO has been proposed as a good option to replace Spire-OMeTAD as a p-type layer for hole transport [2,3]. Here, we study the effect of O_2 partial pressure and temperature on the preparation of NiO_x films by reactive sputtering. The films were deposited on glass and silicon substrates, with a polarization voltage of 200 V, base pressure of 6.5 x 10^{-6} torr and deposition pressure in an argon plus oxygen atmosphere of 5.0 x 10^{-3} torr, using nickel target. The films were characterized by XRD, FTIR and Raman in order to investigate the structure of the NiOx films. AFM and SEM were obtained to verify the morphology and surface roughness of the deposited films. The sheet resistance was obtained from the films deposited on glass substrate through the I x V curve using parallel coplanar contacts. EDS measurements were performed to estimate the composition of Ni and O atoms in the films. To evaluate the electrical properties, Hall Effect measurements were carried out on films. The sputtered NiOx layers exhibit amorphous structure, high transmittance and uniform surface at low deposition temperature. The Tauc s band gap estimated for the film with the highest oxygen concentration is in agreement with the value for NiO reported in the literature [2,3]. The results indicate sputtered-deposited NiO as a promising candidate for hole transport layer in the production of large-area perovskite solar cells.

Properties of AZO Films Grown by ALD as a TCO for Perovskite Solar Cells Ana Paulad. Modesto[1,2], DiegoG. Guzmán[1], RafaelMerlo[1], OtávioJ. de Oliveira[1], Thebano EmilioA. Santos[2] and FranciscoC. Marques[1]; [1]Institute of Physics Gleb Wataghin, Unicamp, Brazil; [2]Centro de Tecnologia da Informação CTI Renato Archer, Brazil

In recent years, aluminum-doped zinc oxide (AZO) has attracted much attention as a transparent conductive oxide (TCO) layer due to its high transmittance and low resistivity, which makes it an excellent candidate for various applications in optoelectronics, transparent photoelectric electronic devices, and in perovskite solar cells [1]. However, producing an AZO film with desirable electronic properties is still a challenge. Furthermore, the manufacture of perovskite solar cells in large areas still requires a lot of research, since all advances in the development of this type of cells have been obtained through the spin coating technique. As this technique does not allow the production of cells in large areas, it is necessary to develop cells with techniques compatible with production in large areas. Atomic Layer Deposition (ALD) is a relatively new technique that has been increasingly used in the study of perovskite solar cells, as it allows the production of films of high quality, homogeneity and conformal distribution on the substrate [2]. Therefore, in this work we studied the influence of aluminum concentration in zinc oxide on the optical and electronic properties of films deposited by ALD. Here, AZO thin film was deposited at 150°C employing trimethylaluminum (TMA), diethyl zinc (DEZ), and deionized water (DI) as precursors. DEZ and TMA were used as a source of metals (Zn and Al), while DI water was used as an oxidizing source to form AlZnO. The deposition consisted of 100 cycles, with each cycle having a pulse of the TMA precursor, a purge, a pulse of H_2O, a purge, following the same conditions as the DEZn precursor; and a purge. The films were characterized by UV-VIS to verify the optical properties of the films, profilometry to obtain the film thickness, and SEM to observe the morphology. From the optical data and film thickness, the refractive index (n) and band gap were calculated [3,4]. Electrical measurements were carried out using the Hall Effect measurement system, where resistivity, mobility and charge carriers' concentration were obtained. The ratio of Al:Zn pulses, which changes the aluminum concentration in zinc oxide, affected the measured optical and electrical properties. The results showed transmittance above 80%, optical gap between 3.3 to 3.8 eV, thickness of 153 to 196 nm. AZO films, deposited at relatively low temperature, have shown good electrical properties, making them promising TCOs in perovskite solar cells.

Constructing High-Performance Solar Cells and Photodetectors with A Doping-free Polythiophene Hole Transport Material JunjiangWu, JunweiLiu and LongYe; Tianjin University, China

Over the past decades, there has been a growing interest in solution-based solar cells and photodetectors. Hole transport materials (HTMs) have played a critical role in advancing these electronics. However, the development of low-cost and efficient HTMs has not been satisfactory. In this study, we propose the use of poly(3-pentylthiophene) (P3PT) as a dopant-free polymeric HTM for quantum dot (QD) and perovskite electronic devices. P3PT offers a simple, low-cost and versatile solution. Compared to the commonly used poly(3-hexylthiophene), P3PT exhibits reduced molecular aggregation and preferential face-on orientation. These properties greatly enhance hole transport in optoelectronic devices. As a result, the photovoltaic performance of QD/polythiophene solar cells improves from about 8.6% to 9.5%, while that of perovskite/polythiophene solar cells increases from about 16% to 18.8%. These values are the highest reported in their respective fields. In addition, the use of P3PT HTMs significantly improves the photodetection performance of QD and perovskite photodetectors by a factor of about 3. This indicates the great potential of P3PT in various emerging optoelectronic applications.

8:25 AM CH01/CH02.04
Achieving Record-High Stretchability and Mechanical Stability in Organic Photovoltaic Blends with A Dilute-Absorber Strategy SaimengLi and LongYe; Tianjin University, China

Organic solar cells (OSCs) offer a unique advantage over other photovoltaic technologies in terms of flexibility. To realize high-performance stretchable and wearable OSCs, apart from high power conversion efficiency (PCE), they must also have excellent tensile properties and mechanical stability, whereas the present metrics of photovoltaic films can hardly meet the application requirements. The stretchability and mechanical stability of active layer blend films are crucial for intrinsically stretchable devices that can work effectively under stress. Herein, we put forward a facile yet low-cost strategy to construct intrinsically stretchable OSC active layers by introducing a readily accessible polymer elastomer as a diluent to the organic photovoltaic blends. Remarkably, record-high stretchability with fracture strain up to 1000% and mechanical stability with elastic recovery>90% under cyclic tensile tests are realized in OSC active layers for the first time. Specifically, the tensile properties of best-performance all-polymer photovoltaic blends can be increased by up to 250 times after blending. Previously unattainable performance metrics (fracture strain >50%, PCE >10%) are simultaneously achieved in the resulting photovoltaic films. Furthermore, an overall evaluation parameter *y* is proposed for the efficiency-cost-stretchability balance of organic photovoltaic blend films. The *y* value of our dilute-absorber photovoltaic system is two orders of magnitude greater than the prior state-of-the-art. With the help of advanced neutron scattering and X-ray scattering techniques, the microstructure-mechanical performance/stability relationships of intrinsically stretchable OSCs are established.

8:40 AM CH01/CH02.05
Deuterated Solvents Yield Organic Solar Cells with Enhanced Efficiency and Thermal Stability KaiZhang; Tianjin University, China

The utilization of deuterium plays a crucial role in advancing the fundamental understanding of aggregate materials and their emerging functionalities. Specifically, resolving the solution structure of conjugated polymers becomes challenging in the absence of deuteration, particularly when employing solvents with high X-ray absorption coefficients such as chloroform. Nevertheless, there is a dearth of studies investigating the isotopic effects of casting solvents on the aggregated structures of photovoltaic polymers and their bulk-heterojunction blends. In this study, we presented a feasible and widely applicable approach of using deuterated organic solvents to establish the structure-performance relationships of organic solar cells (OSCs). We also unraveled the isotope effect of casting solvents on photovoltaic polymer systems from the aspects of thermal properties, molecular stacking, morphology, and device performance. This is the first-ever report to showcase the potential of deuterated solvent in OSCs. Our findings highlight the pronounced impact of relatively poor miscibility between deuterated solvents and photovoltaic polymers, which leads to an enhanced π-π stacking order. Furthermore, the utilization of deuterated solvents in film processing facilitates higher crystallinity and optimized morphology, resulting in improved device efficiency and notable enhancement in thermal stability. These results underscore the significance of solvent isotopic effects on the aggregated structure of conjugated polymer systems and unveil the potential of innovative approaches for fabricating high-efficiency solar cells with enhanced thermal stability.

Electron microscopy studies of dynamic processes in technological relevant gas environments have advanced considerably. Such *in situ* and *operando* observations can nowadays be obtained with atomic-scale resolution by confining the reactive environments between thin, electron-transparent membranes (1-2). While Si-based membranes are widely used, their several-nanometer-thicknesses impact the electron microscopy data and hamper quantitative image interpretations at the atomic-scale. To suppress this footprint of the membranes, it would be desirable to employ two-dimensional materials, such as graphene, that represent the thinnest imaginable membrane with nearly ideal molecular impermeability (3). In practise, however, graphene must be supported by solid substrates which establish graphene-substrate interfaces that compromise the impermeability of the graphene-seal (3-6).
Here, we provide a kinetic study of the gas leakage from SiO_2-based cavities sealed by few-layer-graphene (5-6). Specifically, we focus on electron energy loss spectroscopy (EELS) measurements to unambiguously probe the Ar content of sealed cavities as a function of time and temperature. The EELS data show that the gas content decreased exponentially with time and that the temporal decay constant followed an Arrhenius-like temperature dependency with an apparent activation energy on the order of 0.4 eV. Thus, these findings indicate that gas diffusion along the graphene-SiO_2 interface is a thermally activated process. Surprisingly, successive heating cycles of the cavities modified the Arrhenius dependency and reduced the Ar leakage at room temperature considerably, with up to six orders of magnitude as compared to leak-rates equivalent to those reported in literature. Thus, the thermal dynamics of the graphene-seals can be used to engineer the interface leakage and perfect two-dimensional materials as electron-transparent windows in miniaturized reactors for *in-situ* electron microscopy (6).

***In Situ* Ion Irradiation Study of Hollandite Ceramics Waste Forms**YuhanLi[1], LuminWang[1], TaoMa[1], KaiSun[1], KyleS. Brinkman[2] and JakeAmoroso[3]; [1]University of Michigan, United States; [2]Clemson University, United States; [3]Savannah River National Laboratory, United States

The ceramic materials with the structure of hollandite mineral have been proposed to serve as the nuclear waste form to host radionuclides (e.g., Cs) in the high-level nuclear waste (HLW) due to high waste loading capacity and excellent chemical durability. Radiation effects of a series of $Ba_{1.33-x}Cs_xFe_{2.66-x}Ti_{5.34+x}O_{16}$ hollandite (x = 0, 0.1, 0.667, and 1.33) were evaluated for their potential application as waste forms for both fission products (e.g., Cs) and transuranic elements (e.g., Pu and Am).

200-300 keV electrons were used to simulate the effects of ionizing radiation by beta- and gamma-decay of Cs, and 1.2 MeV Kr ions were used to simulate the effects of displacement damage caused by alpha-decay of the transuranic elements. Atomic resolution transmission electron microscopy (TEM) with elemental mapping was used to characterize the material before irradiation. *In situ* TEM was conducted during both electron and ion beam irradiations. *Ex situ* ion irradiation experiment with 8 MeV Fe^{3+} ion was conducted on bulk Ba- and Cs-hollandite samples and cross-section TEM images were captured with depth dependence.

The results are analyzed and evaluated comparing to the radiation tolerance of other potential ceramic waste forms, and to the doses that might be received in the required service times of waste forms with various level of loadings of different radionuclides.

***Operando* Electrochemical Liquid-Cell STEM at Energy Materials Interfaces**YaoYang[1], DavidA. Muller[2], HectorD. Abruna[2] and PeidongYang[1]; [1]UC Berkeley, United States; [2]Cornell University, United States

One of the outstanding grand challenges facing energy materials is to directly resolve the complex nature of active structures and capture real-time "*movies*" of reaction dynamics under operating conditions. The need for such fundamental understanding has stimulated the development of *operando*/*in situ* methods, which have greatly enhanced our ability to establish *operando* (operating) structure-property relationships of energy materials.
In this presentation, I will introduce our recent progress on developing *operando* electrochemical liquid-cell scanning transmission electron microscopy (EC-STEM), which simultaneously enables quantitative electrochemistry on microelectrodes and quantitative STEM based imaging, diffraction and spectroscopy. *Operando* electrochemical 4D-STEM in liquid has shown great potentials to interrogate complex structures of active sites of energy materials at solid-liquid interfaces. In particular, I will introduce two examples on dynamic Cu underpotential deposition at nanocrystal surfaces and counterintuitive cathodic (reductive) corrosion processes. I will present my latest work on multimodal *operando* studies of combining EC-STEM and correlative synchrotron based X-ray methods to elucidate the longstanding enigmatic nature of Cu active sites as Cu nanograins for selective CO_2 electroreduction.

Advanced Liquid Phase TEM for Nanoscale Investigation of Electrochemical Interfaces JungwonPark; Seoul National University, Korea (the Republic of)

Solid-solid and solid-liquid interfaces are key components for diverse systems of electrocatalytic chemical conversion and rechargeable battery. Critical electrochemical reactions at the diverse interfaces in those systems occur at the nanometer length scale. Despite the importance of the interfacial reactions, a lack of analytical tools that can characterize structural changes at the nanoscale level has hindered fundamental mechanistic understating of them. The recent development of liquid phase transmission electron microscopy (LPTEM) is gaining attention as a new tool to directly observe electrochemical reactions that occur in solid-solid and solid-liquid interfaces with high resolution. Here, we introduce a few examples where liquid phase TEM, in conjunction with other in situ characterization techniques, directly reveals important reactions at the interfaces of electrocatalysts and the electrolyte. Special efforts have been made to improve LPTEM as a reliable method for monitoring electrochemical process of supported metal catalysts in a condition of minimized electron beam perturbation. With this approach, LPTEM can successfully reveal how supported catalysts respond to electrochemical cycles in nanoscale spatial resolution. In situ observation based on LPTEM is also extended to investigation of important processes occurring at the electrode surfaces of diverse battery systems. Direct in situ TEM observation discloses the gradual growth of toroidal Li2O2 discharge product in the electrolyte with the redox mediator upon discharge in Li-air battery. The liquid phase TEM with electrochemical biasing capability is also applied to the studies of direct Li deposition on the metal electrode in Li metal battery system. Combined with cryo-TEM, it is found that the kinetics of Li deposition is determined by the mechanical and chemical properties of SEI, formed differently depending on the electrolyte.

***In Situ* TEM Characterization of Dislocation Dynamics in ZnS Under an Electric Field**YuZou; University of Toronto, Canada

Dislocation motion, an important mechanism underlying crystal plasticity, is critical for the hardening, processing, and application of a wide range of structural and functional materials. For decades, the movement of dislocations has been widely observed in crystalline solids under mechanical loading. However, the goal of manipulating dislocation motion via a non-mechanical

field alone remains elusive. Here we present real-time observations of dislocation motion controlled *solely* by using an external electric field in single-crystalline zinc sulfide (ZnS) – the dislocations can move back and forth depending on the direction of the electric field. We reveal the nonstoichiometric nature of dislocation cores and determine their charge characteristics. Both negatively and positively charged dislocations are directly resolved, and their glide barriers decrease under an electric field, explaining the experimental observations. This study provides direct evidence of dislocation dynamics controlled by a non-mechanical stimulus and opens up the possibility of modulating dislocation-related properties.

Electrochemical Liquid Phase TEM for CO_2 reduction: The Role of Liquid Flow Configuration Cecilia IreneGho[1,2], KatarzynaBejtka[1,2], MarcoFontana[1,2], StefanMerkens[3], AndreyChuvilin[3] and AngelicaM. Chiodoni[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Torino, Italy; [3]CIC nanoGUNE, Spain

Recently energy transition, together with climate change issue, is raising a lot of interest in research due to the need to reduce the fossil fuels dependence in favor of more clean technologies. In this context are involved particular chemical reactions, allowing to convert abundant and waste gases into valuable products, as fuels or chemicals. These are mainly thermochemical or electrochemical processes and take place in the presence of a catalyst, which is a material containing active sites that weakly bind the reactants to provide them into the correct orientation to form the desired products. Among these reactions, CO_2 electro-reduction reaction in acqueous electrolyte is of particular interest because it allows the exploitation of a pollutant gas using green solvents.
In order to study the catalytic activity, including the identification of active sites, the reaction intermediates and the chemical path of reactions, *in situ* approaches have been developed for different characterization techniques. *In-situ* liquid-phase TEM (LP-TEM) is gaining more and more attention, as it allows to observe the evolution of the morphology and crystalline structure of materials in liquid environment, under electrical or thermal stimulus[1].
In particular, the miniaturized electrochemical cell used to perform the LP-TEM has some drawbacks especially when the applied potential of the experiments is strongly negative. Unfortunately, the potentials required to perform the majority of the electrochemical reactions, in particular CO_2RR, requires potential lower than -0.8 V vs RHE. At these voltages, the platinum forming the electrodes catalyzes the water splitting reaction, causing the production of gaseous hydrogen and oxygen, which aggregates forming bubbles. As the cell is miniaturized, the formation of these bubbles tends to fill the cell and de-wet the electrodes, thus blocking the electrochemical activity. The flow of electrolyte inside the cell is supposed to bring away these side products but it is too weak to force bubbles away, due to the non-optimal geometry of the today available commercial chips.
In this paper we present a novel chip configuration, a prototype optimized to provide better liquid exchange inside the cell and expected to bring faster the gaseous products away. This chip has been validated first under the optical microscope observation with the aid of ad-hoc top glass chips, to confirm that the optimized microfluidic pattern can favor the gas bubbles removal from the electrode surface. With the validated configuration, LP-TEM measurements have been positively performed, also with increased flow rates, where a preferential path for bubbles has been assessed. This ensures that electrodes are continuously wetted by electrolyte during experiments, being able to perform electroreduction reactions for longer time, even when opening the potential window and going to more negative voltages. As a proof of concept, the electrodeposition of Zn has been performed, which was reported not being feasible with standard commercial chips[2]. This experiment confirms the good performance of the modified chips, with conditions similar to those used in literature[2], (e.g. 500 nA) and points out that the new geometry could be effective also for different electrochemical applications.

Study of Nanoparticle Reaction Dynamics Through Integration of Liquid-Phase EM with 4D-STEM and Electron Tomography QianChen; University of Illinois at Urbana-Champaign, United States

Nanoscale spatial heterogeneity (e.g., in composition, solution structure, temperature) and reaction kinetics are interdependent in various systems. For nanocrystals, on one hand, they are the prevalent functional materials for diverse applications in bioimaging, photoemission, catalysis, energy storage, and mechanical and optical metamaterials. On the other hand, the reactions related to the synthesis and functions of nanocrystals, such as growth, corrosion, and catalysis, can all be affected by nanostructural heterogeneity. In this talk, we will discuss our recent efforts on the study of nanoparticle reaction dynamics. While liquid-phase TEM provides direct imaging of solution phase nanoparticle reactions (growth or etching) in real-space and real time at nanometer resolution, four-dimensional scanning transmission electron microscopy (4D-STEM) discerns spatial heterogeneities in the phase, crystal orientation, and molecular species. Electron tomography, on the other hand, reveals the three-dimensional (3D) morphology of nanocrystals. Its coupling with liquid-phase TEM allows us to track the complete reaction coordinate instead of only two-dimensional projections of reaction trajectories. Our work new opportunities to study nanoscale solution-phase reactions where structural heterogeneity is a crucial integradient, such as the synthesis and application of heterostructured nanocrystals (e.g., Janus, core-shell), understanding nanocrystal reactivity which is empirically found to be related to nanostructure and strain, and mapping of orientational dynamics of nanocrystals in bioimaging and self-assembly.

Assembly and Phonon Vibrations of Nanoparticle-Based Maxwell Lattice ChangQian[1], EthanStanifer[2], ZhanMa[3], BinbinLuo[1], LehanYao[1], ChangLiu[1], WenxiaoPan[3], XiaomingMao[2] and QianChen[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Michigan–Ann Arbor, United States; [3]University of Wisconsin–Madison, United States

Maxwell lattice is idealized frames with marginally constrained degrees of freedom. The interesting properties such as isoenergetic structural degeneracy and topological soft modes are of growing research interest. However, both experimental materialization and theoretical modeling in the nanoscale remained unexplored. Here, we report the realization of Maxwell lattice in the nanoscale for the first time. A mass-spring model considering interaction beyond nearest neighbors is purposed to capture the relaxation modes in different experimental conditions. We expect this work to provide a guideline for the materialization of Maxwell lattice.

***In-Situ* Observation of Nucleation and Growth of Nanocrystals In and Out of Equilibrium**ZuochenWang, ChangLiu, ChangQian and QianChen; University of Illinois Urbana-Champaign, United States

Crystallization, the emergence of order from disorder, is a ubiquitous process underpinning different fields across the length scales over four orders of magnitude, with ramifications of epitaxial growth for metallurgy and semiconductor industry, mineralization, protein crystallization, geometric packing in colloidal physics. These fields investigate the formation kinetics and thermodynamics of crystal nucleation and growth with an emphasis on the length scale that the building blocks follow. However, the building blocks at different length scale may sample distinct energy landscape, owing to the increased importance of external fluctuations for smaller sized units. Here, using liquid-phase transmission electron microscope (TEM), we observe nucleation and growth process of both gold nanoparticle superlattices driven by electric fields and atomic crystals utilizing $CaCO_3$ as a model system. With the aid of machine learning, we realize single nanoparticle tracking, through which a series of dynamic processes are unveiled, including formation, annealing and reconfiguration of such assembly using gold nanospheres. Further scaling down to atomic level, we combine liquid-phase TEM imaging with four-dimensional scanning transmission electron microscopy (4D-STEM) to decipher and quantify the morphology change from real space and phase evolution from reciprocal space during crystallization process. We discuss the differences and similarities of nucleation and growth behaviors in nanoparticle superlattice and atomic crystals, providing opportunities and guidance to engineering of crystallization pathways and thus allowing quality control of crystalline materials for next-generation applications.

Unveiling Atomic Pathways of Nanomaterials Transformations Using Liquid Cell Electron Microscopy HaimeiZheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

With our development of advanced high-resolution liquid cell transmission electron microscopy (TEM), we study the transformation pathways of nanomaterials at the atomic level. Nanoscale materials growth and transformations are often directed by defects, thus the transformation pathways may deviate from the thermodynamic predictions. For example, we found ripening of Cd-CdCl2 core-shell nanoparticles is mediated by defects. Our observations revealed that the ripening was initiated by dissolution of the nanoparticle with an incomplete CdCl2 shell. And, the growth of a nanoparticle was achieved by generating dislocations followed by crack defects in the shell, and ion diffusion through the cracks. The formation and annihilation of crack defects in the CdCl2 shell, accompanied by disordering and ordering of the shell crystal lattice, allow for the core-shell nanoparticle ripening in the solution. In this talk, I present our most recent results on the unseen atomic pathways of nanomaterials transformations in liquid media.

Investigating the structural evolution and phase transformation of iron oxides is crucial for gaining a deeper understanding of geological changes on diverse planets and identifying oxide materials suitable for industrial applications. In this study, we employed in-situ heating techniques in conjunction with transmission electron microscopy (TEM) observations and ex-situ characterization to thoroughly analyze Akaganeite nanowires of varying sizes. Our findings offer compelling evidence for a size-dependent morphology evolution in Akaganeite nanowires, which can be attributed to the transformation from Akaganeite to Maghemite and subsequent crystal growth. Specifically, we observed that 50 nm Akaganeite nanorods transformed into hollow polycrystalline Maghemite nanorods, which demonstrated remarkable stability without arresting crystal growth under continuous heating. In contrast, smaller Akaganeite nanowires ranging from 20 to 8 nm displayed a propensity for forming single-crystal nanowires through phase transformation and densifying. Furthermore, we successfully captured the solid transformation of Maghemite to Hematite under vacuum heating conditions, suggesting a potential influence of orientation-dependent behavior on this transformation process. These significant findings provide new insights into the size-dependent structural evolution and phase transformation of iron oxides at the nanoscale, specifically in relation to diffusion-controlled crystal growth.

***In Situ* TEM Observation of Atomic Ordering in MnAl: Insights into Structural Transformation and Phase Evolution**ChaoyaHan[1], BrianLejeune[2], XiaoyuZhang[2], ChaoyingNi[1] and LauraH. Lewis[2,2]; [1]University of Delaware, United States; [2]Northeastern University, United States

Rare-earth-free magnets, MnAl in particular, have gained increasing interest due to concerns related to critical mineral supply chains. MnAl orders into the distinctive atomically ordered tetragonal $L1_0$ structure, referred to as the τ-phase, that exhibits high magnetocrystalline anisotropy and other desirable magnetic characteristics. In this work, the technique of *in situ* heating transmission electron microscopy (TEM) is employed to understand $L1_0$ ordering in MnAl and associated formation of lattice defects. Additionally, effects of applied magnetic field on ordering, as supplied by the built-in magnetic field of the objective lens of the TEM, are also investigated.

MnAl samples were synthesized by rapid solidification under an argon atmosphere, resulting in polycrystalline thin ribbons comprising the precursor disordered ε-phase that possesses a hexagonal close-packed structure. Specimens for TEM investigation were prepared using a focused ion beam (FIB). The lift-off samples were mounted on a heating chip with temperature control provided by an *in situ* heating specimen holder. The *in situ* heating experiment was performed with a Talos^{TM} F200C TEM operating at 200 kV, with additional post-heating observations conducted with TEM and with a spherical-aberration-corrected (S)TEM. To induce atomic order, the specimen was first heated from room temperature to 390 °C at 20 °C/min, held isothermally at 390 °C for 15 minutes, and then slowly cooled to room temperature.

Results indicate that atomic ordering initiates at grain boundaries at 365 °C and is completed in 8 minutes and 15 seconds after reaching at the isothermal treatment temperature of 390 °C in the magnetic field environment provided by the TEM pole-piece. The rate of ordering significantly decreases after the first 60 seconds since the start of the isothermal treatment at 390 °C. It is hypothesized that preexisting strain arising from the rapid solidification process promotes formation of the ordered phase from the disordered matrix phase. Atomic ordering is found to occur via a martensitic mechanism; strain introduced by this process may slow down the ε to τ phase transformation The effect of magnetic field provided by the TEM objective lens on the phase transformation is still under investigation.

This work was supported by the U.S. Department of Energy, Office of Basic Energy Sciences under Award Number DE SC0022168. Technical support from Dr. Yong Zhao and Dr. Yuying Zhang, and the instrument use at the W. M. Keck Center for Advanced Microscopy and Microanalysis of the University of Delaware are greatly appreciated.

SESSION CH02.03: Electro-thermal Processes
Session Chairs: Yujun Xie and Yao Yang
Tuesday Morning, November28, 2023
Sheraton, Third Floor, Berkeley

8:00 AM *CH02.03.01
Optimized Focused Ion Beam (FIB) Sample Preparation for High-Quality MEMS-Based *In-Situ* Electrical and Electro-Thermal (S)TEM ExperimentsVesnaSrot[1], RainerStraubinger[2], FelicitasPredel[1] and PeterA. Van Aken[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]Protochips Inc., United States

We present a novel and optimized FIB-based methodology for preparing samples on micro-electro-mechanical-system (MEMS) chips, enabling in-situ electrical and electro-thermal experiments within a scanning transmission electron microscope ((S)TEM). The fabrication of clean, contamination- and damage-free, electron-transparent lamellae is crucial for successful transmission electron microscopy (TEM) experiments. While FIB instruments are commonly used for preparing standard TEM samples, they often introduce damage and contamination, affecting the measured electrical properties.
Our newly developed FIB sample-preparation routine minimizes attachment/detachment steps and reduces the use of Pt fixation, enhancing the reliability of in-situ electrical and electro-thermal measurements. We extensively characterized the impact of different sample preparation parameters and lamella geometries on electrical measurements. Single-crystalline silicon (Si) wafers were utilized for our experiments. Our approach involves directly fixing the extracted lamella to the E-chip without intermediate attachment steps to the grid, resulting in superior sample quality. We demonstrate this through high-resolution STEM imaging and analytical methods [1].
We investigated the influence of various parameters on the current-voltage characteristics. Firstly, we studied the effect of Pt contact size and position on the electrical characteristics. Samples with Pt contacts deposited over the lamella surface exhibited superior stability and reproducibility. Secondly, different incident Ga-beam energies were employed for Pt contact deposition. Lamellae fixed with Pt contacts at 30 kV showed cleaner surfaces and sharper edges, leading to distinct differences in electrical responses compared to those fixed at 8 kV. Lastly, we examined the effect of lamella thickness on electrical characteristics, revealing distinct resistance variations attributed to different volume and area cross-sections.
Our optimized FIB sample-preparation methodology, based on an alternative geometry for the lift-out procedure, enables the production of high-quality and mechanically stable FIB samples on MEMS-based chips for in-situ electrical and electro-thermal (S)TEM experiments. This approach is applicable to various materials amenable to regular FIB preparation [2].

8:30 AM CH02.03.02
***In Situ* Heating and Biasing TEM Investigation of the Microstructural Evolution Occurring in Gold Nanogranular Films Showing Neuromorphic Behavior**AndreaFalqui[1], AlbertoCasu[1], YuriiIvanov[2], GiorgioDivitini[2], AngelicaM. Chiodoni[3] and PaoloMilani[1]; [1]University of Milan, Italy; [2]Italian Institute of Technology, Italy; [3]Italian Institute of Technology - CSFT@PoliTo, Italy

Nanogranular gold films prepared by supersonic cluster beam deposition, with thickness above the electrical percolation threshold, are well-known to show an overall neuromorphic behavior.

Indeed, they exhibit electrical features like those of biological neural networks, such as spiking and adaptation, and this makes them promising candidates for neuromorphic computing applications [1]. The current understanding for the phenomena underpinning such behavior is based on electrical measurements and speculative modelling. Thus, *in situ* heating and biasing transmission electron microscopy (TEM) imaging was performed, both in high resolution mode and at low magnification with high temporal resolution, to directly investigate what gives rise to the films' neuromorphic properties. Nanogranular gold films were deposited just above the percolation threshold, in order to ensure their electrical conductivity while keeping them sufficiently thin for TEM imaging. Upon overall *in situ* heating, the films de-percolated, i.e., they retracted their branched structure with no apparent mass loss. As a consequence, quite thick, well separated gold polycrystalline islands were formed over the whole heating substrate, a behavior resembling what previously reported for atom assembled films [2]. However, when subjected to sole *in situ* biasing in a two-electrode configuration, the thin, percolating films show electrical behavior quite similar to the thicker ones. Aiming at understanding what happened to the films morphology globally and locally, the whole area comprised between the biasing electrodes was imaged with high temporal resolution by a CMOS direct detection camera (Gatan K3) working with a limited dose rate, while the films were electrically stimulated first over a voltage ramp and then at constant voltage. Again, the main effect of the biasing is branches retraction, but in this case so spatially confined that the films undergo a very local de-percolation, thus with spatially limited rearrangement of their microstructure and concomitant formation of few, small and thick gold islands in the close, little areas involved. These results overall indicate a likely occurrence of extremely intense and local hot spots. Their temperature and extension are shown to increase with the applied voltage and can finally bring to local melting-dictated breaks of the amorphous silicon nitride constituting the deposition substrate of the films. Besides, further aspects still need to be investigated, such as, for instance, the possible determination of the temperature in the very local hot spots, and the chance of a not trivial concomitance of local heating by Joule effect and electromigration of gold atoms, which in previous studies have been indicated as possible physical mechanisms giving origin to the neuromorphic behavior of metal films. In any case, the *in situ* TEM imaging demonstrates its capability in providing new insights on the underlying physical phenomena giving rise to the unique electrical behavior of metal nanogranular films, with several implications for further developing of advanced materials with neuromorphic properties.

8:45 AM CH02.03.03
***In-Situ* TEM Study of Breakdown and Thermal Annealing Effects on Silver Nanowire for Memristive Applications**KatarzynaBejtka[1,2], MarcoAllione[1], GianlucaMilano[3] and FabrizioPirri[1,2]; [1]Politecnico di Torino, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]INRiM Istituto Nazionale di Ricerca Metrologica, Italy

Ag nanowires (NWs) are of interest among others, for memristive applications, including neuromorphic architecture based on self-assembled nanowire networks [1]. In the device the nanowire undergoes breakdown and then the switching behavior is based on creation and rupture of the filament lying across a gap. The experimental in situ observation of the breakdown behavior and reconfiguration of the filament is of high interest as it could provide better understanding of the switching mechanisms in these nanoobjects.
In this work, we investigate breakdown in single memristive Ag NWs, during voltage sweep stimulation, by in-situ TEM. Joule heating and electromigration are the two possible causes of fracture for metal wires during operation and in-situ observation sheds some more light on its mechanisms [2].
It is also of interest to investigate the temperature influence on the morphology and structure of the single NWs and of small networks of NWs. It was observed that the morphology of single Ag NWs starts changing at around 550 ºC with observable creation of humps and valleys, which indicate surface roughening. Eventually the NWs break at even higher temperatures. Once the NW undergoes breakdown the change in morphology proceeds following the crystalline orientations of preference. We report on the investigation of local structural and morphological evolution over time as a function of the temperature both for the NWs themselves and within the nanogap appearing after the wire breakdown. We also shed some light on the temperature influence on the morphology of the AgNW junctions within nanowire networks.

Atomic Resolved Mechanical Testing System and Approach of Synergy of High Strength yet Ductile Alloys XiaodongHan; Beijing University of Technology, China

How to characterize and measure the interface phenomena on the microscopic level is one of the most fundamental questions [1]. We report here the development of mechanical-thermal-electrical functional instruments to accommodate characterizing and measuring of plasticity properties of intra-grain and inter-grain dislocation activities at microscopic level, particularly at nano and atomic scale with the sub-A spatial resolution with time-resolved abilities [2]. By monitoring and measuring intra-grain and inter-grain plasticity at atomic level, it is discovered that: large angle unsymmetrical tilt grain boundaries slide by intrinsic dislocations climb and extrinsic disconnection slide [4]. The interactions of sliding extrinsic disconnections with intrinsic GB dislocations creates dislocation locks. The unlock and re-lock processes of the interacted GB dislocation-disconnection pairs accommodate GB sliding by GB atom transfers. For the TB, dislocations pin, pile up and cross-slip are directly revealed and uncovered. From these, new routes are proposed to develop advanced structural materials with synergy of high strength and ductility.

9:30 AM CH02.03.05
Single Nanocrystal Etching by 4D Graphene Liquid Cell Electron Microscopy SungsuKang[1,2] and JungwonPark[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

Etching of nanocrystals is a process in which surface-exposed atoms on nanocrystals are detached in specific chemical environments, predominating the structures and properties of nanocrystals, and occurs ubiquitously when nanocrystals are applied in applications such as thermal catalysis, electrochemical energy conversion, and drug delivery. However, surface structures of chemically-etched nanocrystals can differ from those of the bulk due to the high population of less-coordinated surface atoms and their preferential detachment during the etching. Structural transformations such as surface strains and phase transitions are predominant in crystals as small as a few nanometers and may further affect the structures of nanocrystals during etching. Thus, the structural changes in nanocrystal surfaces during etching should be understood beyond the scope established for bulk crystals. Here, we introduce a new method for investigating the atomic structure changes of single nanocrystals in liquid, namely "4D Brownian one-particle reconstruction" method, using graphene liquid cell (GLC) electron microscopy. We applied this method to track the atomic structures of Pt nanocrystals during their etching in an oxidative liquid medium. The reconstructed time-resolved three-dimensional (3D) atomic maps reveal that the Pt nanocrystals undergo a transformation from the ordered face-centered cubic (fcc) to a disordered structure. The transformation initiates on the surface via emerging hexagonal closed packed (hcp)-like disordered states, stabilizing less-coordinated surface-exposed atoms during the etching.

Near Surface Solution Structure Controls the Oriented Attachment of Metal Nanoparticles—Reactive Molecular Dynamics KristenA. Fichthorn; The Pennsylvania State University, United States

Oriented attachment (OA) of nanoparticles has been recognized as a common mechanism for crystal growth, affecting the micro- and macroscale morphologies for a large variety of materials. However, the role of environmental constraints such as pH, temperature, and ionic concentration in controlling the pathways and kinetics of OA remains unaddressed, which makes it difficult to control and exploit OA syntheses to create unique materials. Experimental studies with *in situ* liquid-cell and *ex situ* transmission electron microscopy indicated that the solution pH affects the OA of Pt nanoparticles. With pH varying from ~3 -1.5, the attachment facet of Pt nanospheres switches from {001} to {111}. The initial {001} attachment of ~2-5 nm nanoparticles leads to the formation of nanocubes (~50-200 nm), and the subsequent {111} attachment results in the extrusion of Pt nanorods from the surface of the nanocubes. Using molecular dynamics simulations based on a ReaxFF reactive force field fit to results from quantum density-functional theory, we simulated the approach of two Pt nanocrystals in HCl and C_{l2} solution under conditions of relatively low and high pH. Our studies confirm the experimental findings and reveal the key role of solution environment in controlling OA.

10:45 AM CH02.04.02
How Do Nanofillers Influence the Glass Transition Temperature of Polymer Nanocomposites?: Insights from Local Characterizations of Interfacial Adsorption KatelynRandazzo[1], SnehaSrinivasan[1], AbrahamJoshua[1], DanieleCangialosi[2], BiaoZuo[3] and RodneyPriestley[1]; [1]Princeton University, United States; [2]Consejo Superior de Investigaciones Científicas - Universidad del País Vasco, Spain; [3]Zhejiang Sci-Tech University, China

Polymers play a foundational role in shaping the modern world, with critical applications in healthcare, energy, and the environment. Their remarkable tunability affords avenues towards enhanced properties via the incorporation of a second phase. However, the consequences of introducing a second phase remain inadequately understood in several key aspects. Particularly, the effect of nanofillers on the glass transition temperature (Tg) of polymer nanocomposites remains unclear, with conflicting reports observing Tg enhancement, depression, or no perturbation. The underlying cause of these inconsistencies is unclear because conventional characterization techniques lack spatial resolution, preventing a comprehensive understanding of how nanofillers influence local polymer properties and, consequently, the overall system behavior.

One route towards understanding the phenomenon of perturbed Tg in nanocomposites is glassy physics. It has been reported in the framework of glassy physics that polymers annealed at elevated temperatures can irreversibly adhere to adjacent substrates, thereby forming adsorbed polymer layers. Once considered "dead" due to restricted chain conformations, adsorbed layers are now recognized as regions of active dynamics, as revealed by the occurrence of a glass transition in adsorbed 2D nanofilms. Conventional investigations of 2D adsorbed nanofilms are limited in their ability to distinguish perturbations between the substrate interface and the free interface, but these studies highlight the important implications of irreversible adsorption in polymer nanocomposites. Polymer nanocomposites are routinely prepared via high-temperature annealing and feature a large interfacial area. Accordingly, it can be expected that they feature a significant degree of overall chain adsorption at the polymer-nanofiller interface. Nevertheless, conventional techniques pose technical obstacles to understanding the evolution and impact of irreversibly adsorbed layers in nanocomposites, as approaches such as bulk differential scanning calorimetry provide data averaged across the entire system.

In this study, we present a novel and comprehensive approach that overcomes the limitations of conventional techniques, thereby allowing us to characterize the structural evolution and glassy properties of nanocomposites' adsorbed layers. Our approach leverages a stepwise assembly of nanocomposites: Nanoparticles are well dispersed within a polymer matrix, then annealed for various durations to induce interfacial adsorption from the matrix. Subsequent isolation of these nanoparticles allows for direct investigation of the adsorbed polymer structure through low-dose cryo-TEM imaging. Furthermore, by incorporating covalently attached fluorescent and dielectric labels into the adsorbed polymer, we can reintegrate them into an analogous unlabeled polymer matrix. This integration enables targeted in-situ measurements of the adsorbed layer properties within the nanocomposite. Importantly, our approach unravels the intricate relationships between local structure and properties in nanocomposites, elucidating the role of processing conditions that give rise to interfacial adsorption—an often overlooked factor with significant explanatory power for resolving discrepancies in the literature and for advancing material design strategies.

Direct Observation of Atomic Step-Assisted Stabilization of Polar Oxide Surface ZhipengWang[1], JinhoByun[2], JaekwangLee[3] and Sang HoOh[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Institute of Energy Technology, Korea (the Republic of); [3]Pusan National University, Korea (the Republic of)

Polar surface is intrinsically unstable and thus highly reactive due to the uncompensated surface charges. The charge compensation is accompanied by various surface reconstructions, establishing novel functionality for its applications. Our in-situ atomic-scale electron microscopy study directly shows that the atomic step and step-assisted reconstruction play central roles in the charge compensation of polar oxide surface. The flat $(LaO)^{+}$-terminated $LaAlO_3$ (001) polar surface, when annealed at high temperature in vacuum, transits to the (015) vicinal surface via the dynamic motion and interaction of atomic steps. While the (015) vicinal surface possesses zero polarization along the surface normal, the thermodynamic ground state is achieved when the in-plane polarization is fully compensated via the reconstruction of step edge atoms; the step edge La atoms are displaced from their ordinary atomic sites toward the adjacent Al step edge site, resulting in the formation of negatively charged La vacancy at the corresponding step edges. As confirmed by first-principles calculations, the observed step reconstruction of (015) vicinal surface can completely cancel both out-of-plane and in-plane electric fields. This hitherto unknown mechanism reveals the central role of step reconstruction in stabilizing polar surfaces, providing valuable insights for understanding the novel charge compensation mechanism accompanied by the step reconstruction.

Surface Dynamics of Hf- and Zr- based Thin Films During Oxidation Studied with *In Situ* STEM and SEM to Guide the Design of Innovative Electronic DevicesAlexandreFoucher, WouterMortelmans, RafaelJaramillo and FrancesM. Ross; Massachusetts Institute of Technology, United States

Transition metal dichalcogenides (TMDs) are increasingly under scrutiny for their implementation in novel nanodevices. More specifically, Hf- and Zr-based TMDs (HfS_2, ZrS_2, $HfSe_2$, and $ZrSe_2$) are promising materials for field-effect transistors. To that end, it is advantageous to oxidize the surface of the thin films to form an HfO_x or ZrO_x layer and ultimately obtain an oxide/TMD interface that will be crucial for next-generation nanodevices. However, the exposed surface's oxidation mechanism and structural changes have not been described in sufficient details for controlling the interface in these applications. In this work, *in situ* scanning transmission electron microscopy (STEM) analysis was simultaneously performed with *in situ* scanning electron microscopy (SEM) imaging. We show the impact of oxidation treatment parameters (temperature and pressure) on the ability to obtain a smooth and uniform oxide layer. We find that the surface of the oxide layer is smooth and homogeneous after a harsh oxidative treatment at low pressure. We also demonstrate that HfS_2 and ZrS_2 surface de-sulfurization occurs when the samples are oxidized. In contrast, segregation of Se in $HfSe_2$ and $ZrSe_2$ was observed upon oxidation, which explains the high compositional heterogeneities and leads to challenges in the control of the surface morphology. These structural changes provide valuable insights for designing a controlled oxide/TMD interface with high surface smoothness and will guide the improvement of efficient and stable nanostructures for electronic devices.

11:30 AM CH02.04.05
Insights into Nanoscale Adhesion via *In Situ* Transmission Electron MicroscopyAndrewBaker, SaiVishnubohtla, SanjanaKarpe, YahuiYang, GötzVeser and TevisJacobs; University of Pittsburgh, United States

Adhesion governs the performance of material interfaces, from large-scale applications such as the energy loss in an automobile engine to small-scale applications such as the stability of nanoparticles. An emerging technique for investigating nanoscale adhesion is performing nanoscale contact-and-separation tests via *in situ* transmission electron microscopy. In this work, we used this technique to reveal fundamental principles of nanoscale adhesion. First, we showed that nanoscale adhesion is governed primarily by strength-limited separation, rather than by fracture as previously believed. Here our adhesion tests of nanoscale contacts demonstrated the need for a different paradigm in interpreting nanoscale adhesion data. Next, we measured the nanoscale adhesion of noble-metal nanoparticles to their oxide supports, a critical parameter related to the efficiency and lifetime of nanoparticle technologies. In addition to validating our measurements with reported trends in adhesion energy, the flexibility of our technique enabled the characterization of new combinations of nanoparticles and supports. Finally, we demonstrated that the adhesive strength between a nanoparticle and its support is highly sensitive to the properties of the nanoparticles such as composition and size. Together, these results enable new fundamental insight into nanoscale adhesion that will inform the design of emerging technologies.

1:30 PM *CH02.05.01
Grain Boundary Migration, Triple Junction Dynamics, and Atomic-Scale Grain Rotation Mechanisms in Polycrystalline Materials: Insights from Novel TEM Studies XiaoqingPan; University of California, United States

Grain boundary migration, triple junction dynamics, and grain rotation are fundamental phenomena that profoundly influence the properties and behavior of polycrystalline materials. Understanding the mechanisms driving these processes is crucial for advancing materials science and engineering. This abstract presents two significant studies, shedding light on the intricate dynamics of grain boundary and triple junction migration, as well as the atomic-scale mechanisms underlying grain rotation.

The first study focuses on disconnection-mediated twin/twin-junction migration. By employing a combination of in situ high-resolution transmission electron microscopy (HRTEM) observations, molecular dynamics (MD) simulations, and disconnection theory, we investigate the coupling effect of grain boundary motion through disconnection motion and reactions at and adjacent to triple junctions. Specifically, we analyze twin/twin-junctions composed of coherent twin boundaries (CTBs) and a Σ9 grain boundary in copper. Experimental and simulated results reveal multiple modes and local mechanisms for CTB migration, including motion through pure steps driven by a chemical potential jump and stress-driven migration involving disconnections with non-zero Burgers vectors. Furthermore, we observe distinct migratory behaviors of different triple junction types, providing valuable insights into the coupling dynamics at these interfaces.

The second study focuses on the direct observation of atomic-scale grain rotation mechanisms. Utilizing in situ and four-dimensional scanning transmission electron microscopy with atomic resolution, we uncover compelling evidence of grain rotation taking place through the propagation of disconnections along grain boundaries in polycrystalline materials. The propagation of disconnections induces shear displacement across the grain boundary, correlating with grain boundary migration and grain rotation. These findings highlight the critical role of disconnections, analogous to dislocations in crystals, in determining the behavior of polycrystals. The observed mechanisms offer new quantitative insights into polycrystal dynamics, impacting grain growth kinetics, deformation mechanisms in nanocrystalline solids, and texture evolution.

Collectively, these studies provide significant advancements in our understanding of grain boundary migration, triple junction dynamics, and atomic-scale grain rotation mechanisms in polycrystalline materials. The insights gained from these investigations have broad implications for materials science, enabling the design and development of advanced materials with tailored properties for various applications.

2:00 PM CH02.05.02
Dynamic Changes in Intermetallic CuPt Catalysts Studied with *In Situ G*as-Heating STEM-EELS Analysis at 1 BarAlexandreFoucher[1], DanielJ. Rosen[2], ShengsongYang[2], Christopher B.Murray[2], AnatolyFrenkel[3] and EricA. Stach[2]; [1]Massachusetts Institute of Technology, United States; [2]University of Pennsylvania, United States; [3]Stony Brook University, The State University of New York, United States

It is crucial to develop and understand innovative nanocatalysts to improve the efficiency of major catalytic processes and reduce their cost. Intermetallic CuPt has been reported as a promising material as a catalyst for CO oxidation, but changes in structure in a reactive environment at high pressure and temperature are not well described. In this work, we performed an atomic scale *in situ* scanning transmission electron microscopy (STEM) analysis at 1 bar to track changes in the intermetallic CuPt phase upon oxidation and reduction. These conditions mimic the reactive environment when the CuPt particles are used for catalyzing CO molecules. The atomic structure of the intermetallic phase remained primarily unchanged in 1 bar of O_2 or H_2 at 800 °C, which explains the remarkable stability of the sample. *In situ* STEM-EELS showed some light oxidation of Cu on the edges of particles upon exposure to O_2 at 800 °C, which can be entirely re-reduced after treatment in H_2 at 800 °C. Thus, partial segregation and oxidation of Cu occur in an oxidative environment but remain limited and can be reversed through annealing. *In situ* XAS confirms the STEM-EELS results observed and shows that segregation and oxidation of Cu is a generalized trend not limited to the small number of particles studied with in situ STEM. Determining dynamic restructuring effects in CuPt catalysts is valuable information for the improvement and rational design of novel bimetallic catalysts.

2:45 PM CH02.05.03
***In-Situ* Liquid TEM Studies of Cu_2O-SnO_2 Catalysts during Carbon Dioxide Reduction Reaction**KatarzynaBejtka[1,2], MarcoFontana[1,2], Cecilia IreneGho[1,2], AlbertoLopera López[3], MariajoséLópez Tendero[3], SimelysHernandez[2], HilmarGuzmán[2] and AngelicaM. Chiodoni[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Torino, Italy; [3]Laurentia Technologies, Spain

The production of carbon-based chemicals and fuels by exploiting anthropogenic CO_2 is nowadays a topic of huge attention within the scientific community. Recently, CO_2 concentration in the atmosphere have exceeded 410 ppm, and its growth has remained constant since the 50s [1]. An advantageous method to reduce its concentration is to consider it as a valuable raw material for electrochemical reduction. Its reduction can result in value-added products and among many products that can be obtained, which depend on the catalyst characteristics, reaction conditions and electrolyte, the CO_2 reduction reaction (CO2RR) to carbon monoxide (CO) or formic acid (HCOOH) are up to now the economically most viable processes and can challenge conventional production routes [2]. Renewable and green approaches to CO_2 valorisation are aimed to minimize the worrying impact of its emission to the environment, and to drive the transition to a new circular economy approach in chemistry and energy production.
In this framework, efficient but abundant and inexpensive catalysts for the electroreduction of CO_2 are required. Among them, non-precious metal oxides like Cu_2O and SnO_2 can catalyse both CO or HCOOH. In addition, copper-based catalysts enable CO2-to-multicarbon product (C2+) conversion.
Here, we present an in-situ liquid phase transmission electron microscopy (LP-TEM) investigation of the morphological and structural dynamics during the life cycle of Cu_2O-SnO_2 catalysts for the CO_2 electroreduction to syngas, exploiting a Protochips Poseidon TEM electrochemical holder. The catalysts are prepared by wet precipitation, and the oxides formed have the shape of nanocubes and nanoparticles. For the LP-TEM, a dispersion of the catalyst in ethanol is drop casted on a Glassy Carbon working electrode in a microchip-based electrochemical set-up. This chip, together with an optimized prototype second chip, provided by Protochips, are used to compose the electrochemical cell. The catalyst was studied in 0.1M $KHCO_3$ saturated with CO_2. The electrochemical activity for the CO_2 reduction reaction was tested by means of Linear Sweep Voltammetry (LSV) and Chrono Amperometry (CA) analyses. In-situ LP-TEM helped to shed light on the changes the material undergoes during electrocatalytic activity, and thanks to improved cell we have been able to study this catalyst in relatively wide range of potentials, which are close to those of interest for the applications, even as low as -2.0V vs. Pt. The obtained results on the catalysts are of huge interest from the fundamental point of view, and, in addition, the optimised design of the LP flow TEM cell allowed to perform stability tests, which are of huge interest for the future application of these catalysts in real devices.
AKCNOWLEDGMENTS
The authors would like to sincerely thank Protochips for providing the prototype chips for the catalysts testing.
This work has received funding from the European Union's Horizon 2020 Research and Innovation Action programme under the Project SunCoChem (Grant Agreement No 862192).

3:00 PM CH02.05.04
Atomic-Scale Understanding of Cu-Ni Alloy Oxidation using *In-Situ* ETEM with Advanced Data QuantificationMengLi[1], JackG. McEver IV[1,2], WissamA. Saidi[1,3] and JudithC. Yang[1,2]; [1]University of Pittsburgh, United States; [2]Brookhaven National Laboratory, United States; [3]U.S. Department of Energy National Energy Technology Laboratory, United States

Understanding the complex interplay between multiple oxidizing alloy elements during oxidation is critical for fundamental understanding of alloy oxidation. Cu-Ni binary alloys, despite their wide industrial applications of Cu-Ni alloy, also serve as valuable model materials for studying binary alloy oxidation due to the mutual solubility of Cu and Ni and the non-mutual solubility of the formed oxides. In this study, we used in situ Environmental Transmission Electron Microscopy (ETEM) with advanced data quantification to investigate the initial oxidation processes of CuNi alloys and compared it with that of pure Cu [1-2].

Using a state-of-the-art in situ ETEM setup (Hitachi H9500), we examine the oxidation behavior of single-crystalline CuNi(100) alloy thin films at 300 C, under controlled O_2 gas pressure ranging from 0.1 to 1 mTorr. At atomic resolution, we observed the competing oxidation process of CuNi alloy. Specifically, we observed the nucleation and growth of NiO nano islands, followed by secondary nucleation and growth of Cu_2O nano islands are observed. Compared with the oxidation of pure Cu, the addition of Ni not only leads to the formation of NiO islands, but also altered the growth dynamics of Cu_2O islands. These observations highlight the complex dynamics during alloy oxidation. To elucidate the underlying mechanisms, correlated DFT simulations are performed, providing further insights into the role of Ni in the oxidation process.[3]

To further quantify the experimentally observed data, machine-learning enhanced advanced data analysis tools are developed. Currently, we are training neural networks to segregate and

quantify the Cu_2O and NiO islands, enabling more precise interoperation of the oxidation process. These innovative data analysis methods not only enhance our understanding of alloy oxidation but also hold potential for broader applications in *in situ* TEM studies.

In summary, our in situ ETEM study provides insights into the competing oxidation mechanisms in CuNi alloys and the impact of Ni on the oxidation behavior. The advanced data analysis tools developed in this work allow for a quantitative analysis of the experimental results, further deepening our understanding of alloy oxidation processes. These findings contribute to the fundamental knowledge of alloy oxidation and pave the way for future research in related fields.[4]

Oxide Reduction Continuously Quantified in Real Time by EELS and EDS Mapping BenjaminMiller and LiamSpillane; Gatan, Inc., United States

In-situ (scanning) transmission electron microscopy (S)TEM or in-situ TEM imaging are powerful techniques for observing the dynamics of oxidation and reduction reactions at the smallest scales. Many researchers combine these imaging techniques with spectroscopic characterization using electron energy-loss spectroscopy (EELS) or energy dispersive x-ray spectroscopy (EDS/EDX) to add complimentary information on the oxidation states or other compositional changes. Some have even performed continuous acquisition of EELS or EDS data [1], but continuous acquisition of spectrum images has been challenging and only possible using custom scripts [2]. Now, in the 3.6.0 version of the Gatan DigitalMicrograph software it is much easier to collect continuous spectroscopic data, including in-situ time series of spectrum images with live drift correction and real-time elemental quantification.

We will show data and screen capture videos of the acquisition of high-speed continuous spectrum imaging of the reduction of FeOOH to FeO with simultaneously acquired EELS and EDS data during in-situ heating to just over 850°C with a DENSsolutions Wildfire holder. Temperature data from the holder was also automatically captured and synchronized with the in-situ spectrum image data. While EDS would normally be impossible at such high temperatures, in this case an IR filter was used enabling the simultaneous collection of EDS spectrum image data all the way through the in-situ experiment. Live drift correction was also essential, since the sample moves during in-situ acquisition. Further precise drift correction can also be easily applied in post-processing. We will also discuss the live EELS quantification used as well as the format of the generated data, which can be easily processed further with built-in tools in the software, or analyzed via infinitely customizable Python scripting.

Liquid-Electron Microscopy: Making Waves in SARS-CoV-2 Research SamanthaM. Berry, Liza-AnastasiaDiCecco, JenniferL. Gray and DeborahKelly; The Pennsylvania State University, United States

In 2019, the emergence of the SARS-CoV-2 virus quickly spread across the global community. The resulting pandemic devasted health fields and economies throughout the world. In turn, viral research exploded as scientists rose to the occasion to develop novel therapeutics against SARS-CoV-2. Cryo-electron microscopy (EM) allowed researchers to characterize its viral structure, aiding in vaccine design. One limitation of this technique, however, is that the proteins must be vitrified and therefore are confined to static imaging. Protein regions can be highly flexible, and valuable data on protein-protein interactions and conformational changes could be lost through this technique. An emerging field known as liquid-electron microscopy solves this issue by enabling imaging in a fluid, near-native environment. By using liquid-EM, dynamic protein mechanisms can be captured in real-time at sub-angstrom resolution. In addition to capturing dynamic data, liquid-EM provides *in situ* experimental capabilities such as ramp heating and flow experiments to better characterize materials. In a biological sense, this technique can create hydrated, more biologically relevant imaging conditions in which to investigate protein structure.

In this work, we reveal a novel look into protein structure and dynamics of SARS-CoV-2 virions extracted from COVID-19 patient serum. Using liquid-EM, we deployed our innovative microchip sandwich technique to capture and image extracted SARS-CoV-2 virions. With this method, a thin liquid sample is sandwiched between a SiN chip and a carbon-coated gold grid and sealed using an autoloader clip. Samples can either be imaged instantaneously or stored for months without drying out, impressively. Another advantage to this technique is that a traditional single-tilt holder can be used, making it both accessible and affordable. When imaging our COVID-19 patient serum sample using this assembly, we discovered interesting protein behaviors in liquid. Over the course of a few days, SARS-CoV-2 virions appeared to begin self-assembling in round, heterogenous aggregates (~80 nm). Micrographs were obtained to render a 3D model of this behavior at 8.25 Å resolution. By imaging in a hydrated native environment, liquid-EM can provide us glimpses as to how SARS-CoV-2 interacts in the human body. In addition to observing the large aggregates, we also captured and modeled the spike (S) protein that is responsible for infection at 4.3 Å resolution using single particle analysis. Models revealed the presence of partial S protein trimers, suggesting how the body possibly fights off infection and degrades foreign virions. This work helps to elucidate structural features and functionality of authentic SARS-CoV-2 in a dynamic, near-native environment using liquid-electron microscopy.

3:45 PM CH02.05.07

Degradation of Quantum-Sized Semiconductor Nanocrystals Induced by Moisture Exposure through The Involvement of Amorphous Intermediates HyeonjongMa[1], SungsuKang[2], JungwonPark[2] and JiwoongYang[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Comprehending the mechanism underlying the degradation initiated by water in quantum-sized semiconductor nanocrystals holds significant importance for their practical utilizations, given their higher sensitivity to moisture compared to their bulk counterparts. *In-situ* liquid-phase transmission electron microscopy has emerged as a desirable method for investigating nanocrystal decomposition, and recent notable advancements have further enhanced its technological capabilities. This presentation will describe the degradation process of moisture-induced semiconductor nanocrystals, using graphene double-liquid-layer cells that provide precise control over reaction initiation. During the quantum-sized CdS nanorod decomposition, these advanced liquid cells enables clear differentiation between crystalline and non-crystalline domains due to their high-resolution imaging capability. Our observations enhance fundamental understanding on the degradation pathway, involving the formation of an amorphous phase, which stands apart from the traditional trajectories of nanocrystal etching. Notably, the decomposition process persists even in the absence of electron beam irradiation, indicating that the reaction is triggered by water exposure. This work unveils the remarkable pathways by which semiconductor nanocrystals degrade upon moisture exposure, a phenomenon elucidated through the involvement of amorphous intermediates.

4:00 PM CH02.05.08

Young's Modulus of Multiwalled Boron Nitride Nanotubes measured by *In-Situ* Nanoelectromechanical ResonanceJae-Won BryanSeo[1], Won-IlLee[1], KushalKumar Iyyapareddy[2], SooyeonHwang[3], EunkwangPark[4], JaewooKim[4], DavidHwang[2] and Chang-YongNam[1,3]; [1]Stony Brook University, The State University of New York, United States; [2]Stony Brook University, United States; [3]Brookhaven National Laboratory, United States; [4]NAiEEL Technology, Korea (the Republic of)

Boron nitride nanotubes (BNNTs) with alternating boron and nitrogen atoms arranged in hexagonal lattice in a tubular structural form factor are known to have excellent thermal and mechanical properties. However, in general it remains challenging to characterize mechanical properties of individual nanomaterials, such as BNNTs. In this study, we have characterized the nanomechanical properties of individual, multiwalled BNNTs using an in-situ nanoelectromechanical resonance method in transmission electron microscopy. BNNTs dispersed in isoprophyl alcohol were first drop-cast and dried on a Si substrate. The BNNTs on the substrate were then transferred and fixed to the tip of an electrochemically sharpened tungsten needle using silver paste, which was baked on a hot plate at 100 °C. Scanning electron microscopy (SEM) confirmed a successful sample preparation by visualizing individual BNNTs with one free end and the other firmly rooted on the tip. The tungsten tip was then loaded to an in-situ TEM holder with electrical feedthroughs. During TEM, while observing individual BNNTs, the tungsten tip was biased with respect to a counter electrode separated by vacuum using oscillating voltage wave input with peak-to-peak voltage of 10 V and frequency varied from 0 to 20 MHz. When the external frequency matched the natural mechanical resonant frequency of a given BNNT, the tube started to vibrate. A series of images taken at various frequencies around the resonance were analyzed to yield the vibration amplitude vs. frequency plot that enabled the determination of the resonance frequency and quality factor of the BNNT. By applying the Euler-Bernoulli beam theory, the measured resonance frequency then determined the Young's modulus of the given BNNT. We found that the measured Young's modulus of BNNTs was in the 1.6 – 224 GPa range. It was observed that the determined Young's modulus was increasing with increasing BNNT's outer diameter but also rendered lower when a BNNT had a larger hollow core. We also identified a reduced Young's modulus also had correlation with atomic structural defects, such as missing atoms and buckled tube surfaces. The study represents one of the first reports of the nanomechanical properties of individual BNNTs measured by the in-situ nanoelectromechanical resonance method. The results also highlight the importance of atomic structures on the resulting mechanical properties of BNNTs.

SESSION CH02.06: Characterizing Electronic, Magnetic and Energy Materials
Session Chairs: Madeline Dukes and Djamel Kaoumi

***In-Situ* and Cryogenic Electron Microscopy of Electrochemical Energy Material**YiCui; Stanford University, United States

Electrochemical energy materials often involve in dynamic movement of atoms and electrons simultaneously. To understand these materials down to the atomic scale resolution under intrinsic environment is a challenge. Here I report my lab's nearly two-decade long effort in developing electron microscopy methods to image battery electrode materials and electrocatalysts. I will show in-situ electron microscopy of electrochemical biasing during charging/discharging of battery materials and gas reaction of reactive materials. I will also share the breakthrough development of cryogenic electron microscopy for fragile energy materials and reveal novel knowledge not available previously.

8:30 AM CH02.06.02
Investigation of the Resistivity Switching Mechanisms of Different Types of Oxide Memristor Devices via *In Situ* STEM and EELSDiZhang[1], RohanDhall[2], ChengyuSong[2], JimCiston[2], MattSchneider[1], SundarKunwar[1], MichaelT. Pettes[1], RodneyMcCabe[2] and AipingChen[1]; [1]Los Alamos National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States

The resistive-switching (RS) phenomenon observed in a variety of transitional metal oxides (TMO) is of great research interest since it opens enormous opportunities for the next-generation electronic devices such as nonvolatile memory and neuromorphic computing units, etc. However, the RS mechanism for many TMO memristor devices are still unclear, not alone the distinction between filament-type and interface-type devices. In this project, we use *in situ* transmission electron microscopy (TEM) and Electron Energy Loss Spectroscopy (EELS) to investigate the RS mechanisms of different types of memristor devices. The high resolution STEM images captured during the *in situ* biasing experiment revealed the potential phase transition processes and polarized cations displacements, and the core EELS spectra confirmed the cations valene states change and the oxygen stoichiometry modulation during the RS processes. This study has shined great light on clarifying the RS mechanisms of different types memristor devices, which can be applied to the development of next-generation nanoelectronic devices towards advanced memory and neuromorphic computing units etc.

8:45 AM CH02.06.03
***In-Situ* Observation of Polarization Switching in Novel Ferroelectrics.**SebastianCalderon[1], JohnHayden[2], StevenM. Baksa[2], SamanthaJaszewski[3], JonF. Ihlefeld[3], IsmailaDabo[2], Jon-PaulMaria[2] and ElizabethC. Dickey[1]; [1]Carnegie Mellon University, United States; [2]The Pennsylvania State University, United States; [3]University of Virginia, United States

The discovery of ferroelectricity in HfO_2 [1] and wurtzite-based ternary materials such as AlScN [2] and AlBN [3] has attracted tremendous attention due to their compatibility with CMOS processes and their potential to be integrated in non-volatile memory devices. The origin of the ferroelectricity and the fundamental switching mechanisms in these materials is still under intensive investigation. Understanding the mechanisms that control and induce switchable states in these materials is an important goal to find solutions to the high coercive fields and avoid breakdown failures. We employ scanning transmission electron microscopy to observe the polarization of the films at atomic scale, by differential phase contrast, which allows simultaneous observation of light and heavy atomic columns. An internal electric field capable of switching these materials is attained by exposing them to long periods to the electron beam, provoking a positive charge accumulation due to the emission of secondary and auger electrons that are not compensated due to the insulating properties of these materials. STEM-DPC experimental images are acquired in a probe-corrected ThermoFisher Titan-Themis at 200kV, using a four-segment annular detector (DF4), a probe convergence angle of 18 mrads and a camera length that results in acceptance angles between 11 and 43 mrads. The experimental data are complemented with STEM simulations using Dr. Probe V1.9 software package [4]. Simulations are carried out using the frozen-phonon configuration method at 200 keV and 1 µm of spherical aberration. Our results show conclusively the pathway for the polarization inversion at the atomic scale in both wurtzite [5] and fluorite ferroelectrics, offering unprecedented insights into the mechanisms for ferroelectric switching. DFT calculations also support our finding, demonstrating the pathways for the polarization inversion.

4D-STEM & *In Situ* ec-TEM to Study the Lithiation Dynamics in Battery Cathode MaterialsArnaudDemortiere, NicolasFolastre, JunhaoCao, KevynGallegos Moncayo and GozdeOney; CNRS, LRCS Laboratory & RS2E Battery Network, France

This 4D-STEM method using ASTAR-ACOM system allows to build maps of crystalline phase and orientation, using scanning nano-diffraction with precession with nanometer resolution. The recent use of high-speed cameras, pixelated detectors such as CMOS cameras and hybrid-pixel detectors enabled larger areas to be scanned, and a higher resolution close to 1 nm with high SNR. The goal of our data preparation methods (ePattern suite) proposed here is to improve the quality of ASTAR pattern-matching using a dataset of diffraction patterns acquired with a CMOS Oneview camera. The high sensitivity of the CMOS camera and the data filtering developed here modify the diffraction images leading to a compromise between image quality and template matching result quality. In this work, we show that the mapping of crystal structures and orientations provides essential information for the determination of individual particle lithiation mechanisms of cathode materials for Li-ion and Na-ion batteries, as NaxMnV(PO4)3 and LiFe0.3Mn0.7PO4 was used in this study. In addition, this image processing method gives more confidence in phase determinations in such polycrystalline materials as well as local maps of strains and order parameters.

Deciphering Nanoscale Corrosion Mechanisms from 2D to 3D using Liquid-Phase TEM ZhihengLyu, LehanYao, SamyuktaShrivastav, DanielV. Krogstad, JessicaA. Krogstad and QianChen; University of Illinois at Urbana-Champaign, United States

As a ubiquitous phenomenon, corrosion has raised vital concerns globally as one of the major causes of infrastructure failure, leading to substantial financial losses and environmental damage. On the other hand, with careful control of reaction rate and selectivity, corrosion can also be utilized as a top-down method in material sculpting, tuning its size, shape, and component adapting to applications ranging from plasmonics, electronics, catalysis to biomedicine. Either prevention or utilization of corrosion requires fundamental understanding of reaction mechanisms, where in situ, high-resolution characterization techniques are necessitated for uncovering the localized, nanoscale processes. Recent advances in liquid-phase transmission electron microscopy (TEM) have shown its great promise in tracking the morphological and compositional change of materials during reactions with nanometer or even atomic resolution. With corrosion of carbon steel as an example, cavity generation and its anisotropic expansion were observed in real time using liquid-phase TEM, the process of which can be further correlated to strain distribution, crystal orientation, and component variation inside the steel. Advancing from two-dimensional projections to three-dimensional reconstructions, we also highlight our efforts in combining liquid cell with electron tomography to achieve a more comprehensive understanding of nanocrystal etching process. The intermediate shapes of core-shell or hollow nanocrystals at different stages into etching were captured and reconstructed, from which particle volume, surface curvature, and local etching depth were derived, unveiling the anisotropy in etching caused by structural and environmental heterogeneity. We hope these works could inspire more efforts devoted to in situ characterization of material shape transformation, enabling nanoscale observation and understanding of corrosion processes.

9:45 AM CH02.06.06
Probing Nanoscale Creep in Confined Dimensions MehrdadT. Kiani[1], QuynhSam[1], Yeon SikJung[2], Hyeuk JinHan[3] and JudyCha[1]; [1]Cornell University, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Sungshin Women's University, Korea (the Republic of)

The thermomechanical behavior of nanostructures can greatly diverge from their bulk counterparts due to their high surface area to volume ratio. In particular, diffusion-dominated creep at free surfaces and interfaces is greatly enhanced, enabling rapid deformation in short time scales. While traditionally considered a deleterious behavior in structural materials, enhanced creep at the nanoscale has been used to drive thermomechanical nanomolding (TMNM), where a bulk feedstock of a desired material is pressed through a nanoporous mold to form high aspect single crystal nanowires of metals, alloys, and intermetallics. For 1D nanowires, TMNM is thought to be driven by interfacial diffusion along the mold wall; however, there have been no *in situ* studies of TMNM confirming this mechanism. Furthermore, it is unknown whether interfacial diffusion still governs kinetics of TMNM for nanostructures other than 1D nanowires where other mechanisms may begin to dominate.
Here, we probe nanoscale creep during TMNM, focusing on fabrication of 2D nanostructures. Using a Si mold with 40 nm wide trenches, we successfully observe nanomolding of both nanoribbons and nanofins over wafer-length scales at back end of line compatible temperatures. In contrast to 1D TMNM, the final grain size of the nanostructure matches the grain size in the bulk, up to and including single crystal nanostructures. From nanoscale grain orientation mapping via 4D-STEM, we observe random grain orientations in the nanomolded samples. From the final microstructure and *in situ* TEM compression studies of nanomolding, we discuss possible diffusion-driven creep mechanisms at play and the importance of grain boundary diffusion in 2D TMNM.

SESSION CH02.07: Advances in In-Situ TEM
Session Chairs: Madeline Dukes and Djamel Kaoumi
Wednesday Morning, November29, 2023
Sheraton, Third Floor, Berkeley

10:30 AM *CH02.07.01
Imaging Ghosts with 4D-STEM: Diffuse Scattering, Vacancies and Vanishing Dislocations SeanMills[1], JennDonohue[1], YangYang[2] and AndrewM. Minor[1,3]; [1]University of California, Berkeley, United States; [2]Penn State University, United States; [3]Lawrence Berkeley National Laboratory, United States

In situ transmission electron microscopy (TEM) experiments are typically recorded either in real space or diffraction space [1]. However, it would be ideal to have both real and diffraction space for when transient events occur that cannot be repeated exactly (ie- defect generation or irreversible phase transformations). Real space imaging provides context for these transient events by spatially-resolving microstructural features to one another while diffraction space provides better structural clarity about phase identification and lattice parameters. Four-dimensional scanning transmission electron microscopy (4D-STEM) [2], can come close to providing both simultaneous real-space imaging and diffraction analysis during *in situ* testing. Here, we use 4D-STEM with high precision bullseye apertures [3] to map the nanoscale strain landscape during *in situ* cooling of a NiTi through the phase transformation from the high temperature B2 cubic austenite phase to the low temperature B19' monoclinic martensite phase. Using this method, we can map both the phase distributions and the strain as the sample approaches and then proceeds through the phase transformation, including the diffuse scattering ahead of the phase transformation.
4D-STEM also provides an opportunity to map vacancy distributions with nanoscale resolution. Our experiment using a model Au film demonstrates the 4D-STEM method for measuring vacancy concentration by closely following the differential thermal expansion method [4] of measuring concentrations of point defects [5]. In a more complicated scenario, we have used vacancy mapping with 4D-STEM to also help explain the mechanism behind a new type of one-dimensional corrosion in metals [6]. Lastly, this talk will also describe our recent results utilizing in situ 4D-STEM during nanomechanical testing to provide insight into multiscale deformation phenomena in the CrCoNi medium entropy alloy (MEA). 4D-STEM can provide both real-space imaging and diffraction analysis during *in situ* testing, making it possible to classify defects during in situ deformation before they disappear. These vanishing dislocations help to explain the correlation between SRO and planar defects during deformation of the CrCoNi MEA.

Machine Learning in Operando TEM—Let Me Count the Ways MitraL. Taheri[1,2]; [1]Johns Hopkins University, United States; [2]Pacific Northwest National Laboratory, United States

In recent years, applications of artificial intelligence (AI) and machine learning (ML) methods in microscopy have enabled utility of noisy data, monitoring of rare events, and even elucidation of metastable phenomena. Unfortunately, there is no one methodology that suits the wide variety of operando techniques, due in large part to the multiple data types and dimensions present in such experiments. This talk reviews the application of AI/ML to various data types, ranging from images to spectra, concentrating on the opportunities and challenges associated with their use. Also discussed is the possibility of generalizing such methods toward a more uniform approach to in situ and operando acquisition toward closed loop, intelligent or autonomous microscopy.

11:30 AM CH02.07.03
Novel Liquid Transmission Electron Microscopy Tools to Study Viral Pathogens Liza-AnastasiaDiCecco, LiamKaylor, JenniferL. Gray and DeborahKelly; The Pennsylvania State University, United States

Interest in the study of viruses has dramatically increased since the emergence of the deadly SARS-CoV-2 virus and its devasting impact in the United States and beyond. Globally, research has pivoted towards understanding such pandemic pathogens to identify new vaccines and drug therapies to save lives and curb viral transmission. To this end, traditional and cryo-transmission electron microscopy (TEM) methods have been primarily used to study virions and elicit key details of their structure; However, these methods lack the capacity to visualize necessary dynamic interactions that occur within these virions and their impact on treatment efficacy. Liquid-TEM tools are needed to visualize high-resolution viral interactions in real-time, giving researchers the capability to capture *in situ* dynamics and perform structural characterization of these important assemblies in native hydrated conditions.

Here in this presentation, we describe newly developed liquid-TEM methods for imaging human viruses that can be used in both liquid and cryo-TEM conditions using novel silicon nitride microchip sandwich assemblies. The hybrid liquid-TEM enclosures, composed of a SiN wafer clipped together with a carbon-coated gold TEM grid, are highly affordable and repeatable to use – providing accessible means for others to perform liquid-TEM. Bright-field TEM and high-angle annular dark-field imaging (HAADF) scanning TEM (STEM) are deployed in correlation in this proof-of-concept study to provide unparalleled insight into these structures, highlighting exciting new possibilities that liquid-TEM offers for the field of structural biology. Paired with automated workflows and low-dose imaging using direct electron acquisition, we highlight this method can effectively characterize the structures of viruses like Rotavirus and sub-viral SARS-CoV-2 assemblies with nanometer resolution. These efficient new toolsets offer a versatile way to study biological materials that could lead to meaningful contributions in the fight against future pandemic pathogens and may someday provide capabilities to visualize molecular dynamics *live*.

11:45 AM CH02.07.04
Pushing the Limits of Tunable Laser-Free Ultrafast Electron Microscopy SpencerReisbick[1], ChuhangLiu[1], AlexPofelski[1], Myung-GeunHan[1], EricMontgomery[2], ChunguangJing[2] and YimeiZhu[1]; [1]Brookhaven National Lab, United States; [2]Euclid Techlabs, United States

Typically, ultrafast electron microscopy (UEM) has been performed by photoexciting short electron packets from a TEM cathode with sub-picosecond laser pulses that are synchronized to an excitation on the sample. Adjusting the relative delay between the electron packets and the sample excitations allows time-resolved measurements that elucidate dynamics with picosecond resolution. Examples include the elucidation of dynamics relating to phonon propagation, electromechanical breathing, or magnetic domains. Here, I discuss a novel technique that removes lasers from the experimental setup by replacing them with RF compatible strip-line technology (referred to as the pulser). By doing so, we can expand the excitation space up to tens of gigahertz while retaining picosecond resolution. Additionally, the development of the pulser enables the entire setup to be contained within the TEM in a user-friendly environment. Unfortunately, covering a massively tunable domain in frequency, power, excitation type and applications cannot be contained in a simple solution, so I will discuss the necessary hardware, software and control that enables us to access such a wide variety of applications.

I will also discuss a few emerging applications that are becoming realized due to our laser-free UEM system. One such example is the excitation of spin-waves in rectangular permalloy stripes at frequencies near 5 GHz. We find transmitting RF near magnetic crosstie domains induces a modulation along the domain boundary which propagates into the magnetic domains. Further, we have fully characterized the wavelength and velocity as they propagate through the material. Another example is controlling phase transitions using electrical excitation in materials such as VO2 or TaS2. Both materials exhibit structural phase transitions near room-temperature that have been shown to occur with at least some effect due to an electrical excitation. In both instances, there is some controversy regarding whether the transition is purely electrically driven or if the current flow causes a temperature increase that induces the change. The tunability of our system enables us to conduct experiments at extraordinarily high frequencies the laser-driven UEM is incapable of. Therefore, we can lock the experimental systems into a resonance state and explore these systems knowing that the thermal excitation is long lived and reaches a steady state which can be ignored.

Understanding Heterogeneous Electrocatalytic CO_2 Reduction over Zn-Ag Bimetallic Electrocatalysts via *In-Situ* Liquid Phase Transmission Electron MicroscopyKholoudE. Abousalem and AhmedShehab; McMaster University, Canada

The electrocatalytic reduction of carbon dioxide (CO_2R) into valuable fuels is of urgent scientific importance to satisfy the sustainable carbon cycle, which remains a grand challenge. Due to the large energy barrier of CO_2R, the development of efficient catalysts is urgently required. On the other hand, understanding the mechanistic pathways of CO_2R will definitely introduce more opportunities to develop highly active catalysts. In this regard, several approaches have been used including *in-situ* characterization methods in order to get a deep insight into this kind of reaction. Herein, *in-situ* liquid phase TEM measurements have been systematically conducted to realize the electrocatalytic CO_2 reaction mechanism and track all dynamic changes concerning the electrocatalysts' composition and reconstruction under-investigated experimental conditions, which could affect the reaction pathway. Amongst the investigated electrocatalysts, Zn-based alloys have proved an outstanding selective CO production with high activity and enhanced stability. For this purpose, we have investigated the influence of Ag metal incorporation into porous Zn nanostructured electrodes on the product selectivity and stability of CO_2R. Bimetallic Ag-Zn alloys with different Ag ratios synthesized by the scalable electrodeposition approach have significantly promoted the electrode porosity and surface area, revealing high CO adsorption characteristics with improved selectivity over several electrocatalytic cycles; compared to bare Zinc electrocatalysts. Moreover, to investigate the mechanistic pathways of these reactions, TEM measurements including imaging and diffraction have been collected under CO_2 electrochemical reaction conditions "*in-situ*". Afterward, in order to investigate the activity and selectivity of these catalysts, the same CO_2 electro-reaction has been conducted without TEM measurements to quantify the formed products using the gas chromatography (GC) technique. Accordingly, the Ag- supported Zn electrocatalyst exhibits high faradic efficiency and improved current density at low overpotential, which suggests that Ag metal incorporation plays a crucial role in favoring the production of CO during the long-term operation over those reported by purely Zn metal catalysts. By combining both measurements with/without TEM, this study will produce some performance descriptors of the CO_2R, which will positively influence the catalyst development orientation in this field. Those findings could open further future suggestions on monitoring the *in-situ* catalyst performance during the CO_2 reduction process.

Surface Diffusion and Sintering of Single Metal Atoms on Graphene. KenjiYamazaki, MakotoMoriya and YunosukeIkeda; Hokkaido University, Japan

Single-atom catalysts consisting of single metal atoms dispersed on a supporting substrate are considered to be very advantageous in terms of both cost and catalytic activity due to their extremely large surface areas and quantum size effects and thus have attracted much attention. In particular, researchers have focused on the miniaturization of platinum (Pt) nanoparticles, which are used in many important chemical processes and solid-state fuel cells.We have achieved single Pt atoms adsorbed on graphene by plasma sputtering. We have shown that Pt atoms are dominantly adsorbed near the step edges of nanoscale graphene stacked on monolayer pristine graphene, which is called nanographene, and hardly adsorbed on the terraces. In addition, we found that the Pt 5dxy-orbital forms a bond to the step edge. However, Pt atoms may cause aggregation from single atoms into 2D clusters or 3D nanoparticles at high concentrations.
We analyzed the atomic structure and electronic states of single Pt atoms dispersed on N-doped graphene by plasma sputtering. We showed that the N atoms were dominantly adsorbed on nanographene. We achieved the atomic arrangement of Pt, N, and C at the step edge of nanographene and clarified that the N atom increases the population of the Pt 5dyz-orbital and enhances the stability of single Pt atoms. Exhaustive calculations have been performed to elucidate the major adsorbed structures of single Pt atoms bound to step edge. Similarly, it is important to perform exhaustive calculations on N-doped step edges. Moreover, we have revealed the components of the Pt 5d orbitals that contribute to binding. Both structural stability and high catalytic activity are important for monatomic catalysts. It is important to investigate the thermal stability of the structure and its activity in chemical reactions for application to catalysts. Thus far, the amount of single Pt atoms formed in graphene on a TEM grid has not been sufficient to test a catalytic reaction such as hydrogen evolution reaction (HER) or oxygen reduction reaction (ORR). In the near future, it will be necessary to experimentally clarify the relationship between the monatomic catalyst having these structures and catalytic performance. Detailed information about the highly reactive Pt 5d orbitals will be essential in studying these properties.
We also showed that Pt and gold (Au) single atoms dispersed on free-standing monolayer graphene were continuously observed via aberration-corrected scanning transmission microscopy (STEM), and the difference in the dynamic behavior of the single atoms on graphene underelectron beam irradiation was observed. Analysis was performed after the drift corrections to track the movement of the metal atoms from their binding sites with angstromorder accuracy. Approximately 70% of Pt single atoms traveled less than the nearest carbon atom distance of graphene (1.4 Å) during the observation interval (10 s). Thus, Pt was confirmed to be stably dispersed on graphene as single atoms. Au atoms could be dispersed on graphene by the same method as that used with Pt, and they were present at the nanographene edge, like Pt. However, the Au single atom mobility was larger than that of Pt. More than 40% of the particles traveled a distance exceeding the size of the sixmembered ring of graphene (2.8 Å) during the minimum observation interval (4 s), and the variation in moving distance during the observation time was large.Upon analyzing the three-dimensional structure of nanographene, we found that these single metal atoms were mainly present on more than three-layer nanographene, and almost no atoms were found on the terrace of first-layer graphene. One reason for this result is that the higher layer nanographene has many binding sites for metal atoms because it is structurally unstable and has many defects and edges compared with lower-layered nanographene.

8:00 PM CH02.08.03
***In-Situ* TEM Deformation of CrCoNi Medium Entropy Alloys**MadelynI. Payne[1,2], LilianVogl[1], PeterSchweizer[2], MingweiZhang[3], PunitKumar[2,1], MarkAsta[1,2], RobertRitchie[1,2] and AndrewM. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Davis, United States

The CrCoNi medium entropy alloy (MEA) is known for having exceptional properties at cryogenic temperatures, including the highest fracture toughness recorded in history. Even at room temperature these alloys are known to display microstructures including nanotwins and stacking faults that contribute to strain hardening. Defect structures such as, stacking fault tetrahedra and Lomer-Cottrell locks, introduced by sample processing temperatures and techniques can influence deformation processes. For example, studies have shown that cryogenic rolling of these alloys produce Lomer-Cottrell locks that enhance strain hardening at room temperature. In this study, we use advanced in-situ TEM techniques, to observe dislocation motion and interactions with existing microstructural features in differently processed CrCoNi bars pulled in tension. We perform in-situ TEM tensile deformation at room temperature and use image correlation to identify changes in structural features and local strain values.

8:00 PM CH02.08.04
Atomic Mechanisms Underlying The Phase Transformation in 2D CdSe Quantum Nanosheets Induced by Off-Stoichiometry HyeonjongMa[1], DongjunKim[2], JungwonPark[2] and

JiwoongYang[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

The phase transformation in semiconductor crystals have great potential for various applications, because intrinsic characteristics of materials primarily determined by their atomic arrangements. Nevertheless, the atomic-scale mechanisms governing phase transformations in quantum-sized semiconductors requires further understanding, particularly in smaller crystals where structural changes are more probable. This presentation will elucidate the phase transformation of two-dimensional (2D) CdSe quantum nanosheets triggered by changes in stoichiometric characteristics. *In-situ* transmission electron microscopy is used for observing the dynamic pathways of this transformation. Initially characterized by a wurtzite phase and atomically flat morphology, the CdSe nanosheets undergo a transformation into zincblende-CdSe nanosheets due to changes in stoichiometry. This transformation is investigated in detail using a combination of experimental and theoretical methods. The phase transformation is initiated within the reconstruction of (11-20) basal planes of the wurtzite-CdSe nanocrystals induced by the loss of Se atoms, resulting in the construction of zincblende-like basal planes. Moreover, we directly captured unconventional phenomena, including dynamic fluctuations in atomic arrangements, such as domain coalescence and separation, during the structural evolution. We envision that this study can enhance our fundamental understanding of phase transformation mechanisms in semiconductor nanocrystals, offering an intuitive perspective for various applications.

Structural Materials Characterisation for Hydrogen Systems PeterFelfer; Friedrich-Alexander-Universität, Germany

Due to increased demand for decarburization, the transport of hydrogen from low energy cost production locations to high energy cost locations of demand is rapidly moving into focus. Here, the costs are heavily influenced by the material costs for the required infrastructure. As a result, full utilisation of currently available structural materials under hydrogen and the development of new, cost effective materials is becoming increasingly important. Since all parts dealing with hydrogen under pressure or in cryogenic form are safety relevant, a deep understanding of the underlying mechanisms is highly desired. This demands the ability to recreate hydrogen loading and accelerated testing in the lab, characterisation of the effects of hydrogen on the material from the macro to the atomic scale and new theories on the failure mechanisms exhibited by hydrogen resistant materials.

In this talk, we will present the testing environment built up at the Friedrich-Alexander University Erlangen-Nuremberg (FAU) as well as a new development in the area of low-cost hydrogen resistant steels. In order to create a full materials development cycle for hydrogen resistant materials, we combine materials synthesis, materials testing and materials characterisation. At FAU, we are able to create new alloys through various powder and melt metallurgical means with associated hot deformation and heat treatment schedules. Materials testing under hydrogen is provided through electrochemical charging (in-situ and ex-situ) and through a high pressure autoclave station up to 1000 bar and 300°C. The latter is especially important for hydrogen resistant materials such as austenitic steels and Ni based superalloys due to their relatively low diffusion coefficients for hydrogen. Mechanical testing is then done ex-situ from the macro (tensile, fatigue) to the micro (pillars, cantilevers SEM-in-situ) scale. In order to understand the mechanical behaviour, characterisation is especially important. Here, hydrogen is especially challenging due to its relatively mobile nature.

At FAU, we have therefore built a special set of equipment to gain a deeper understanding of the microstructural response of structural materials under hydrogen. Besides standard materials characterisation equipment (SEM/EBSD, TEM, ...) this includes specialized equipment including a hydrogen capable titanium atom probe and a very high sensitivity titanium thermal desorption spectrometry (TDS) unit. Both of these instruments are UHV characterisation instruments built from titanium, in order to remove the usual hydrogen background found in UHV systems. For the atom probe, this enables the direct analysis of hydrogen at crystal defects without the use of tracers, as well as the analysis of hydrogen in materials using laser assisted atom probe tomography where typically even deuterium/tritium tracers are not suitable. The latter is especially important since analysis yields of hydrogen exposed materials are relatively low in voltage pulsed atom probe tomography. In the case of TDS, the drastically lower hydrogen background potentially allows for much smaller specimen sizes, increasing analysis dynamics and locality. The latter system is currently in the testing phase. Both systems are connected to a cryo-FIB system through a transfer suitcase in order to preserve hydrogen distributions.

In this talk we will also present the development of a novel, low cost class of hydrogen resistant steels. In these materials, we use high amounts of carbon to stabilise the austenitic phase. This has a major cost advantage over the use of Ni, Mn or N. These steels show no change of mechanical properties after exposure to hydrogen and provide good strength levels at a yield strength of 700 MPa and above. In the future, we hope to be able to develop these steels to mechanical properties under hydrogen of the highly cold worked Cr-Ni-Mo austenitic stainless steels currently used, at a fraction of the cost.

11:00 AM *CH03.01.02
Atomic Scale Analysis Reveals the Interplay between Grain Boundary Structure and Composition XuyangZhou[1], AliAhmadian[1], SourabhKumar[2], TilmannHickel[1,2], BaptisteGault[1,3], ColinOphus[4], ChristianLiebscher[1], GerhardDehm[1] and DierkR. Raabe[1]; [1]Max-Planck-Institut fuer Eisenforschung GmbH, Germany; [2]Federal Institute for Materials Research and Testing (BAM), Germany; [3]Imperial College London, United Kingdom; [4]Lawrence Berkeley National Laboratory, United States

Boron and carbon preferentially segregate at grain boundaries, i.e., two-dimensional defects between crystals with different orientations, to reduce the Gibbs energy of the system. The adsorption of these two elements can improve the cohesion of grain boundaries, making them important alloying elements for improving the mechanical properties of steels.

However, even for the simplest Σ5-grain boundaries, the atomic structure and composition of the grain boundaries are poorly understood. Several factors contribute to this difficulty: 1) representing the structure of grain boundaries requires more than five degrees of kinematic freedom; 2) the interplay between grain boundary structure and composition remains elusive, especially when it comes to imaging and quantifying light interstitial solutes, e.g. boron and carbon.
To address these challenges, we have designed special sample geometries that restrict the kinematic freedom of the grain boundary, allowing for a systematic investigation of the relationship between structure and composition. Additionally, we have developed custom software to quantify the solute composition and distribution along the grain boundary planes using atom probe tomography (APT). This information is then correlated with the atomic structure obtained by state-of-the-art differential phase contrast (DPC)–four-dimensional scanning transmission electron microscopy (4DSTEM), which allows direct imaging of both the light solute atoms and the heavier iron atoms at the grain boundaries.
Our combined results demonstrate that even a change in the inclination of the grain boundary plane with identical misorientation impacts grain boundary composition and atomic arrangement. It is the smallest structural hierarchical level, the atomic motifs, that controls the most important chemical properties of the grain boundaries.
Furthermore, when alloyed with boron, a grain boundary with the same crystallographic configuration can exhibit a nanoscale morphology transition from wavy to serrated. In-situ transmission electron microscopy (TEM) heating experiments demonstrate that at elevated temperatures, wavy or serrated grain boundaries tend to flatten. Interestingly, the presence of boron increases the temperature at which flattening occurs by at least 200 K. We attribute this difference to local grain boundary phase transformations triggered by boron atoms, as well as the pinning effect of boron-enriched nano-particles. Density functional theory calculations support the underlying mechanism of boron-induced local grain boundary phase transformation.
This work not only closes a missing link between the structure and chemical composition of such defects but also enables the targeted design and passivation of the chemical state of grain boundaries to free them from their role as entry gates for corrosion, hydrogen embrittlement, or mechanical failure.

11:30 AM CH03.01.03
Studying the Mechanisms of Hydrogen-Based Iron Oxide Reduction for Green Steel Making at the Atomic-And Nanoscale Using Atomprobe Tomography DierkR. Raabe, AymanEl-Zoka, BaptisteGault, IsnaldiSouza Filho and YanMa; Max Planck Institute for Iron Research, Germany

1.9 billion tons of steel have been produced last year, making it the most important material in terms of volume and environmental impact. Steel is a sustainability enabler, in lightweight vehicles, wind mills and magnets. However, its primary production is the oppposite. Iron is today reduced from oxide ores using fossil reductants, translating to about 2t CO_2 per ton of steel produced [1,2]. This stands for more than 30% of the global CO_2 emissions in manufacturing. These emissions can be reduced when replacing carbon by hydrogen or ammonia as reductants [1-4].
The lecture discusses some key mechanisms of hydrogen- and ammonia-based solid-state direct reduction and hydrogen-based plasma-based liquid state reduction from a near-atomistic perspective using atom probe tomography [3-5].
Our perception of such reactions has not only been limited so far by the availability of state-of-the-art techniques which can delve into the structure and near-atomic scale chemistry of the reacted solids, but we continue to miss an important reaction partner that defines the thermodynamics and kinetics of gas phase reactions: the gas molecules. We present here results from cryogenic-atom probe tomography to study the quasi in-situ evolution of iron oxide in the solid and gas phases of the direct reduction of iron oxide by deuterium gas at 700°C [6]. We observed several so far unknown atomic-scale characteristics, including, D2 accumulation at the reaction interface; formation of a core (wüstite)-shell (iron) structure; inbound diffusion of D through the iron layer and partitioning of D among phases and defects; outbound diffusion of oxygen through the wüstite and/or through the iron to the next free available inner/outer surface; and the internal formation of heavy nano-water droplets at nano-pores.

11:45 AM CH03.01.04
Ultra-Fine-Scale Observation of Trapped Hydrogen using Atom Probe Tomography Pang-YuLiu[1], RanmingNiu[1], Hung-WeiYen[2], JulieCairney[1] and EasonChen[1,2]; [1]The University of Sydney, Australia; [2]National Taiwan University, Taiwan

Hydrogen embrittlement poses a significant challenge to the durability of structural steels, a crucial factor in the advancement of the hydrogen economy. A potential remedy involves integrating hydrogen traps into the microstructure of steel. The efficacy of this approach is greatly influenced by the capacity of these hydrogen traps.

Theoretical models suggest carbon vacancies within metal carbide precipitates exhibit notable effectiveness as hydrogen traps in ferritic steels. In contrast, conventional structural defect traps such as dislocations and iron lattice vacancies have limited trapping energies and uncertain impact on countering hydrogen embrittlement. Therefore, enhancing the population of carbon vacancies within metal carbides holds significance. By introducing abundant metal carbides into steels, which can be feasibly achieved, the overall hydrogen trapping capacity can be substantially increased.

In order to validate this concept of material design, we produced two variants of titanium-microalloyed ferrite steels. The first variant contained stoichiometric titanium carbides (TiC) lacking carbon vacancies, serving as a reference. The second variant was an experimental steel infused with a small quantity of molybdenum (Mo). This addition led to the formation of Ti-Mo carbides, characterized by substitutional Mo atoms alongside carbon vacancies within the same TiC lattice.

We then used atom probe tomography to experimentally observe the hydrogen trapping behaviors of both the reference and Ti-Mo carbides. The outcomes demonstrate a shift in the hydrogen trapping mechanism within the metal carbide precipitates upon Mo addition. This alteration allows hydrogen to access the carbon vacancy traps within the carbide structure, causing a substantial escalation of trapping capacity. The identification of the influence of carbon vacancies on hydrogen trapping, achieved through a straightforward Mo addition, holds valuable implications for the development of carbide-strengthened steels with enhanced compatibility for hydrogen applications.

Atom Probe Tomography Analysis of Nano-Scale Precipitate Evolution in Ni alloyed Fe-Mn-Steel PradeepKonda Gokuldoss; Indian Institute of Technology Madras, India

The presence of Al in Fe-Mn-C based multi-component steels induces ordered precipitate formation and depending on the thermomechanical processing, the size of the precipitates can be varied from micrometer down to nanometer. Ni addition further promotes the formation of Ni-Al type B2 precipitates localized within the BCC matrix depending on the Mn content. This work therefore attempts to analyze correlatively the crystal structure of the nano-scale precipitates formed in a duplex (i.e. FCC matrix and embedded BCC phase) steel along with their precise local chemical composition in a high statistical manner.
To achieve the above, correlative SEM based microscopic techniques such as TKD and STEM is utilized while the precise local chemical composition at near atomic-resolution is obtained from the investigated volume using APT. This correlative methodology applied to as hot rolled and annealed conditions, provides deeper insights into the role of starting microstructures on the precipitation kinetics and hence to the final mechanical properties of the steel.

2:00 PM *CH03.02.02
Forensics at the Nanoscale: Mapping Elemental and Isotopic Distributions in Metallic Nuclear Fuels via Atom Probe Tomography ElizabethKautz[1,2], StenV. Lambeets[2], DanielPerea[2],

DallasReilly[2], VineetJoshi[2] and ArunDevaraj[2]; [1]North Carolina State University, United States; [2]Pacific Northwest National Laboratory, United States

Atom probe tomography (APT) provides a unique, 3D map of element and isotope distributions with near-atomic scale resolution that can enable improved understanding of nuclear material origin and process history, central to forensic investigations. The identification of material origin is a critical step needed to improve safety and security measures to prevent proliferation. Traditional forensic investigations rely on a variety of analytical techniques, including mass spectrometry methods, gamma spectroscopy, and electron microscopy. Recently, the application of APT in nuclear fuel processing and irradiation response has provided key insights into the role of impurity elements and fission products in phase transformations and material performance. APT has also been a critical tool in geochemical studies on age-dating. These related studies have paved the way for APT to be developed and utilized in forensic investigations. Here, two case studies will be presented and discussed, focused on understanding the origin of non-metallic inclusions and oxidation behavior of a uranium-molybdenum (U-Mo) alloy.
In cast U-Mo fuels, the mapping of both U enrichment and composition in nanoscale inclusions and the surrounding metallic matric are critical to identifying origin of non-metallic inclusions. Nanoscale elemental and isotopic mapping via APT has identified several possible sources of impurity elements (e.g., oxygen, carbon) that can lead to formation of oxides and carbides during solidification. Several pathways are possible for the production or retention of CO, CO_2, or O_2 including: (1) reaction of the U alloy with the crucible or the crucible coating, (2) exposure of the melt to trace CO_2, O_2 or H_2O from the atmosphere, and (3) small defects in the mold coating that can lead to the direct contact of the molten U with the graphite crucible. U enrichment measured via APT in all inclusions and the U-Mo matrix phases was approximately 20 at. % (consistent with nominal enrichment for LEU fuels), indicating that nonmetallic inclusions were formed in the casting process and not retained from raw materials.
In addition to mapping U enrichment, elemental distributions accompanying oxidation or corrosion of nuclear fuels are important to track to understand how fuels degrade in waste storage containers, or how U-bearing post-detonation debris ages in different environments of interest. U oxidation and corrosion can occur when U metal is exposed to environments such as those typical of material processing, storage, and waste disposal. The corrosion of U has been proposed to proceed through the advancement of two reaction fronts between: (1) a (pyrophoric) UH_3 and UO_2, and (2) the U metal and hydride. This corrosion mechanism is supported by prior atom probe tomography (APT) characterization that demonstrated a thin subsurface hydride layer is present between the U oxide and metal when U metal is exposed to water vapor environments. Recent work employing an in situ APT approach revealed that alloying and impurity elements also play an important role in the formation of an oxide film.

Overall, we find that the use of APT can enable signature discovery and insight into material origin and behavior in corrosive environments. Lastly, we highlight ongoing challenges and opportunities for APT in forensic investigations.

2:30 PM CH03.02.03
Atomic Scale Understanding of the Role of Alloying Elements in the Hydrogen Embrittlement of Austenitic Steels HeenaKhanchandani; FAU, Germany

High strength twinning induced plasticity (TWIP) steels are prone to oxidation and hydrogen embrittlement. They are austenitic and have high manganese (above 20 wt%) content. We studied the segregation of oxygen and hydrogen at the grain boundaries of a Fe 27Mn 0.3C (wt%) TWIP steel by atom probe tomography which also appears to be associated to the depletion of manganese. We observed that oxygen and hydrogen do not tend to segregate at the grain boundaries decorated with carbon. Motivated by this atomic scale study, we developed an austenitic steel with high carbon content and propose the stabilization of austenitic microstructure in steels by using carbon. The newly developed carbon austenitic steel did not show any embrittlement when it was exposed to the cathodic hydrogen charging. The role of alloyng elements in the hydrogen embrittlement susceptibility of the austenitic steels will hence be discussed in the talk along with the novel concept of carbon austenitic steels resistant to hydrogen embrittlement.

Atom Probe Tomography for Semiconducting Materials for Microelectronics and Optoelectronics Applications KatherineRice, YimengChen, IsabelleMartin, TyProsa, RobertUlfig, DavidReinhard and DavidLarson; CAMECA, United States

Atom probe tomography is one of the highest resolution techniques for elemental analysis at the nanoscale. The 3D data also provides a more complete picture of typical semiconductor structures which is challenging to obtain with other nanoscale characterization techniques. The semiconductor manufacturing industry has largely adopted the atom probe tomography technique, but this hasn’t come without challenges. Typically problems include yield or survivability of the sample through key regions of interest, sample throughput and speed of data acquisition, results matching between instruments, certainty in low-concentration measurements, and time-to-knowledge of critical data in the analysis process.
In this talk, technological and methodological innovations that CAMECA has adopted to support the semiconductor manufacturing industry specific to microelectronics and optoelectronics and tackle some of these challenges will be presented. Examples include automation, instrument matching, simultaneous voltage and laser pulsing, adoption of shorter wavelength lasers, and new reconstruction methods for closer feature fidelity. CAMECA has also initiated a large-scale collaboration effort with Interuniversity Microelectronics Centre (imec) as an independent semiconductor research institution to support the goals of applying atom probe to semiconductor manufacturing by creating test structures for semiconductor research.
Atom probe applications for semiconductors, power electronics, and optoelectronics are growing and driven by advances in instrument technology. Higher yield, automated reconstruction and analysis, and the ability to conduct design of experiments studies have all be recently enabled by technology development at CAMECA. In this presentation, we will discuss these developments and how we can enable the atom probe technology community in analysis of semiconductor materials.

3:45 PM CH03.03.02
Full-Dynamics Field Evaporation Simulation: Overcoming Limitations of Transition State Theory for Atom Probe Tomography JiayuwenQi[1], EmmanuelleMarquis[2] and WolfgangWindl[1]; [1]The Ohio State University, United States; [2]University of Michigan, United States

In atom probe tomography (APT), individual atoms or molecules are field-evaporated by an intense electric field from the surface of a needle-shape specimen. Following a linear projection law, APT allows for the reconstruction of a three-dimensional distribution of atoms within the specimen using recorded impact positions and the chemical identity information obtained from a mass spectrometer. However, due to the destructive nature of the field evaporation process, the verification of reconstruction results and quantification of their uncertainty necessitate atomic-scale forward modeling, where each atom can be traced.

Previous atomic-scale models in APT have implicitly relied on harmonic transition state theory (TST) [1]. However, TST is limited to predicting the rate of transition between states and fails to describe the underlying dynamics. Consequently, these models introduce ad-hoc assumptions, typically assigning a zero-launch velocity to evaporating atoms, which introduces biases in the calculation of atom trajectories and impact positions on the detector. As a result, many distinct features observed in field evaporation maps and reconstruction, arising from the full dynamics of atoms, cannot be faithfully reproduced or explained.

To overcome the limitations of TST in describing field evaporation, we employ molecular dynamics (MD) simulations with appropriate acceleration algorithms as an alternative. Our "ab-initio" field evaporation simulation method "TAPSim-MD" [2] integrates evaporation events as part of the MD simulation. This approach combines the classical finite-element field evaporation modeling from the TAPSim code [3] with the MD code LAMMPS [4]. In the resulting full-dynamics approach, atoms in the specimen are evaporated in an “ab-initio” way during the competition between the interatomic forces and the electrostatic forces. This eliminates the need for ad-hoc assumptions regarding activation energy or launch velocity.

By employing full-dynamics simulations, we successfully reproduce and explain the emergence of enhanced zone lines in field evaporation maps, which are dynamic features beyond the capabilities of TST-based models [5]. In a recent study, we revisited field evaporation in an [001] oriented γ-TiAl intermetallic compound, where experimental observations often exhibit mixed-layer reconstruction results due to the alternating Ti/Al layers. While traditional simulation approaches explained this artifact by assuming a higher evaporation field for Al compared to Ti [6], they failed to account for the distinct field evaporation maps obtained for Ti and Al, which should be inherently related to the dynamics. Through our full-dynamics approach, we accurately predicted the correct evaporation sequence in an [001] oriented γ-TiAl virtual tip and reproduced the mixed-layer artifact in reconstruction without any ad-hoc assumptions regarding the evaporation field of Ti or Al. Furthermore, we identified two distinct paths of bond breaking during the evaporation process: Ti initially breaks 4 Ti-Al bonds before breaking 2 Ti-Ti bonds (a two-step process), while Al-Al simultaneously breaks 4 Ti-Al and 2 Al-Al bonds (a one-step process). These two distinct bond-breaking paths elucidate the distinct evaporation

maps of Ti and Al, which also rationalizes the counter-intuitive higher evaporation field of Al, considering its generally weaker bonding ability.

Analysis of the Effect of Milling Temperature on the Antioxidation Behavior of Oxide-Dispersion-Strengthened Steel Won SangShin and Yoon-JunKim; Inha University, Korea (the Republic of)

Oxide-dispersion-strengthened (ODS) steel exhibits remarkable creep and oxidation resistance and therefore has potential for use in severe environments such as the core components of advanced nuclear reactors. The combination of appropriate factors and parameters such as nanometer-sized oxide features, milling methods, temperature and time enable the steels to withstand high-temperature degradation. Y-Ti-O nanometer-sized particles with a diameter of less than 5 nm play a key role in the properties of these materials. Therefore the oxidation resistance characteristics of ODS steel manufactured by ball milling at two temperatures were analyzed through various techniques via Atom-Probe tomography.
In this study, a comparative analysis was performed on the difference in the oxidation behavior of ODS steel according to the milling temperature. ODS steel were produced by mechanical alloying with milled Y_2O_3 powder in a ball mill at room temperature and cryotemperature (≈ -150 °C). Both samples were exposed to air for 6000 h at 800 °C for examining their long-term oxidation resistance at a high temperature. After long-term exposure both samples showed subsurface degradation occurred concurrently such as internal precipitation, phase formation, and phase dissolution.
The resulting oxide scaling kinetics were more sluggish for room cryotemperature compared to room temperature condition. On the basis of the reduction of the interfacial energies calculated by using the Gibbsian interfacial excess and the partial radial distribution functions of major alloying elements, Y atoms in room temperature condition were found to show a strong tendency to form Y–Ti–O nanoparticles (NPs), while N atoms did not form NPs on the surface. Analysis results showed that Y-Ti-O NPs were present at the grain boundaries at room temperature and that cryotemperature condition contained Y-Ti-O(N) NPs and sub-micrometer-sized TiN precipitates. Due to differences in the formed NPs, more Y atoms segregated at the matrix/oxide interface of room temperature compared to cryotemperature condition inhibited oxide growth. Therefore, the Y atom can be considered as a controlling factor for the oxidation rate at high temperature, and that the difference in oxidation resistance between the two samples is also related to this.

SESSION CH03.05: Atom Probe Tomography—Advanced Materials and Correlative Analysis

8:30 AM *CH03.05.01
Field Emission Physics and Correlative Microscopy within a Photonic Atom Probe LorenzoRigutti[1], AbrahamDiaz Damian[1], JonathanHouard[1], GeorgesBeainy[1], PradipDalapati[1,2], AngelaVella[1], FrançoisVurpillot[1], Jean-MichelChauveau[3], MaximeHugues[4], DenisLefebvre[4], GrzegorzMuziol[5] and HenrykTurski[5]; [1]University of Rouen Normandie, France; [2]Technological University, Singapore; [3]Université Paris Saclay, Université Versailles Saint Quentin en Yvelines, CNRS, France; [4]Université Cote d'Azur, CNRS, France; [5]Polish Academy of Sciences, Poland

The Photonic Atom Probe (PAP) allows for the measurement of Photoluminescence (PL) of a sample tip while it is being analyzed by Laser-Assisted Atom Probe. The femtosecond Laser pulse required for the La-APT measurement also serves to excite the free charge carriers, whose recombination provide the PL signal. As a consequence, it becomes possible to correlate the optical signature of the different parts of a complex structure with the 3D distribution of the contained chemical species [1].
We present an application of the PAP on III-nitride p-i-n junctions, namely a thick (> 1µm thickness) multi-layer structure containing InGaN quantum wells and a buried tunnel junction [2]. Plasma-assisted molecular beam epitaxy-grown structures, which were used in the study, are characterized by diverse doping concentrations in both p- and n-type regions. The PL spectra can be correlated with the 3D chemical information from APT [3]. The PL signals exhibit indeed a donor-acceptor pair (DAP) emission, whose spectral features can be related to the 3D distribution of the Mg dopants and of the InGaN heterostructures. These results open interesting perspectives for studies of light-emitting defects at the nanoscale.
Besides the interest of this instrument as a microscope [3], the particular conditions in which the optical signatures of localized light emitters are collected open intriguing possibilities for the study of field ion emission under high field and under laser illumination [4]. As an example, the PL spectral shift allows measuring the stress induced by the application of a strong electric field at the tip apex and its propagation through the tip. This has been evidenced both through the study of the stress-induced splitting of the zero-phonon line of the NV^0 center in diamond [5] and of the quantum well (QW) emission in a ZnO/(Mg,Zn)O system [6], allowing measuring stresss levels ranging from 9 GPa to ~1 GPa.

9:00 AM CH03.05.02
Correlative *In-Situ* Liquid Cell Electrochemistry TEM and Cryogenic APT of Liquid-Solid InterfacesShelly MicheleConroy, NeilMulcahy, JamesDouglas, LukasWolch, MaryRyan and BaptisteGault; Imperial College London, United Kingdom

Liquid cell transmission electron microscopy (LCTEM) allows for solution phase dynamic processes to be visualised and probed at the nanoscale at unprecedented temporal and spatial resolutions in comparison to other liquid microscopy techniques such as light and physical probe microscopes. Additionally, MEMS based biasing sample holder chip design has provided a platform to perform electrochemical experiments to replicate battery cycling experiments within the electron microscope.
While these experiments have been useful for gaining a micro and nanoscale in-situ understanding of electrochemical processes that occur at solid-liquid interfaces of battery materials, the current spatial resolution of liquid processes within the TEM is still not capable of resolving and quantifying complex dynamic nanoscale structures at atomic resolutions. As a result, the performance of electrochemical systems is currently limited due to a lack of understanding of complex interactions that occur between mobile species and electrode materials. Finding a

correlative high-resolution characterisation method which is compatible with both the liquid and solid component of the interface is of great importance to gain a fundamental understanding of these processes at an atomic level.
Cryogenic focused ion beam (FIB) preparation and atom probe tomography (APT) has allowed researchers to investigate the native liquid-solid interfaces of samples by vitrifying the liquid phase at the near to atomic scale. In this presentation we will present how one can combine in-situ electrochemistry LCTEM with site specific cryogenic atom probe tomography. We investigate Li based solid electrode interfaces and dendrites formed during the lithiation cycling.
While there have been numerous examples in recent years of room temperature correlative TEM and APT, there has been no such examples of correlative LCTEM-APT or correlative cryogenic TEM-APT. The primary reason for this is the difficulty in transferring, preparing, and maintaining specimens in **cryogenic conditions**. In this study, the liquid in the LCTEM chips are cryogenically vitrified following in-situ electrochemical LCTEM experiments, in order to allow APT needle samples to be created from the liquid-solid interface of interest. Recent advances in vacuum cryo transfer module technology, and cryogenic FIB site specific sample preparation workflows, have allowed for this type of correlative cryogenic multi-microscopy approach to be realised.

9:15 AM CH03.05.03
Design and Observation of Multiscale Defect Structures in Bulk Thermoelectric Materials Employing Atomic Resolution Scanning TEM and Atom Probe Tomography InChung; Seoul National University, Korea (the Republic of)

Nearly ~70% of total energy input is being lost as waste heat, and electrical energy is mostly generated by consuming fossil fuels such as coal and natural gas. Thermoelectric technology can simultaneously contribute to addressing these urgent energy and environmental crises that humanity faces. Thermoelectric materials can directly convert thermal and electrical energy reversibly without releasing undesirable chemical residues. Thermoelectric figure of merit, ZT, is a complex combination of charge and thermal transport properties. Because they are closely interrelated by the fundamental physics laws, it is extremely difficult to increase ZT by adjusting one of the constituents in the ZT formula. Very recently, designing and stabilizing defect structures have emerged as a new powerful strategy to increase ZT because they can decouple otherwise tightly bound physical quantities in ZT, thereby providing innovative and unconventional pathways for higher ZT materials. Until recently, formation mechanisms of defect structures and their effects on thermoelectric properties have not well understood mainly because of the technical difficulties. In this talk, I will present our recent works on designing multiscale defect structures in bulk inorganic crystal matrices by chemical composition controls to develop high performance thermoelectric materials. We directly observe the induced defect structures using atom probe tomography (APT) and atomic resolution spherical aberration-corrected scanning TEM (Cs-STEM). The achievements help understand how they affect bulk thermoelectric properties, thereby developing highly predictable defect design principles. This talk will highlight the importance of the combined utilization of ATP and Cs-STEM for a highly productive search for high performance thermoelectric materials.

10:00 AM *CH03.05.04
Understanding the Atomic Scale Mechanisms of Oxidation and Hydrogen Embrittlement of Nuclear Structural Materials using *In Situ* and Cryogenic Transfer Atom Probe TomographyArunDevaraj, DallinBarton, StenV. Lambeets, TingkunLiu, MarkWirth and DanielPerea; Pacific Northwest National Lab, United States

When nuclear structural materials, specifically stainless steel is subjected simultaneously to applied tensile stress and a corrosive, high-temperature water, interplay of hydrogen and oxygen interactions with the alloy microstructure are thought to lead to intergranular stress corrosion cracking (SCC). Despite decades of research on SCC mechanisms of stainless steel, crucial knowledge gaps remain about the atomic scale mechanisms responsible for intergranular oxidation and hydrogen embrittlement. To overcome these knowledge gaps, we used the novel in situ atom probe tomography (APT) experiments and cryogenic transfer workflow of steel samples after electrochemical hydrogen charging. These APT experiments were complemented by insights from atomic force microscopy, nanomechanical testing, synchrotron high-energy x-ray diffraction, ex-situ transmission electron microscopy, and computational simulations. Through this multimodal approach, we developed an atomic scale understanding of the mechanochemical coupling during SCC of Fe-Cr-Ni model alloys. This effort leveraged the Ferrovac Ultrahigh vacuum cryogenic transfer module, environmental transfer hub, and cryogenically cooled sample transfer carousal and the cryogenic transfer workflow developed in PNNL for a CAMECA LEAP 4000 XHR and a CAMECA LEAP 6000 XR. This talk will highlight the new scientific understanding of oxidation and hydrogen embrittlement mechanisms enabled by these unique experimental capabilities and expertise in PNNL.

10:30 AM CH03.05.05
Quantification of Dopants in Silicon using Atom Probe Tomography KarenDeRocher, MarkMcLean and FrederickMeisenkothen; National Institute of Standards and Technology, United States

The ever-increasing demand for semiconductor devices to shrink into the 3 nm regime without compromising computing power has made characterizing these materials incredibly challenging. In order to maintain device performance, there is a growing need to characterize these materials at device dimensions and accurately quantify and localize dopant atoms [1].

Atom probe tomography (APT) is currently the lone characterization technique with the ability to provide dopant distributions in semiconductor devices at device dimensions and in 3-dimensions. While APT can measure chemical information down to concentrations of 10's of µg/g (ppm_{at}), it has also been shown that, for some materials, analysis conditions can result in biased quantitative results [2, 3]. While the use of reference materials to calibrate data analysis is common in many characterization techniques, it is not generally used in APT. However, it has been shown that a standards-based approach to APT analysis can dramatically improve the accuracy of composition measurements [4, 5]. More recently, our work with phosphorous-doped silicon showed similar improvement in the accuracy of dopant quantification in the atom probe. In this work, we used a reference material with a known dose of phosphorous (NIST SRM 2133 [6]). We collected data from this material under a variety of analysis conditions and used that data to construct a calibration curve. We then performed similar analysis on a sample doped with a known concentration of phosphorous. After correcting our measurements using the calibration curve, reduced the relative error from 26% to less than 4% [7].

The reference material used for this work (NIST SRM 2133) was originally developed for use in secondary ion mass spectrometry (SIMS) and has a phosphorous concentration that varies with depth, with the total retained dose being the certified value. This required us to capture the entire doped profile in an atom probe experiment in order to use the results for our calibration curve. However, this introduces complexity both in sample preparation, and in the collection and analysis of the atom probe data. Therefore, we are also working to develop a research grade test material (RGTM) that is better suited for use with atom probe tomography. This material has a blanket film of P-doped Si at a constant composition, eliminating the need to preserve the precise sample surface during FIB sample preparation and speeding up acquisition times, as an entire doped profile no longer needs to be captured [8].

Successes and Challenges for Atom Probe Tomography of Small-Molecule Organic Materials JeramyD. Zimmerman, RolandBennett, PaulNiyonkuru and JaehyunSuh; Colorado School of Mines, United States

We will highlight several successes using atom probe tomography (APT) to analyze small-molecule organic materials and discuss challenges and opportunities for APT of these materials. Organic small molecule materials are used in a variety of applications, such as organic light emitting diodes (OLEDs); OLEDs are widely used in displays, yet there are many open questions about how molecular design ultimately impacts device properties. The light-emitting layer of an OLED is comprised of a co-deposited layer of two or more molecules, but little is known about how well these dissimilar molecules mix. A primary challenge with APT of organic molecules is that they are very sensitive to both electron-beam and ion-beam damage during conventional FIB-based tip preparation. We will review techniques to prepare and analyze these organic molecular materials,[1] including the development of large-radius APT tip coupons that enable fast sample preparation through thermal evaporation of materials onto the tips, entirely avoiding damage associated with FIB preparation and a quantitative model for understanding and predicting fragmentation of small molecules during APT measurement.[2] We will also address challenges associated with these materials, including low detector efficiencies, which can limit the

sensitivity of APT measurements. This research expands the capabilities of APT, enabling additional materials science of organic small molecule materials research.

Atomic-Level Investigation of Oxygen Distribution in Grain Boundaries in Yttria-Stabilized Zirconia using Graph-Order Parameter ParthDesai, PrachiGarg, BaishakhiMazumder and OlgaWodo; State University of New York at Buffalo, United States

Yttria-stabilized zirconia (YSZ) is a widely utilized ceramic material renowned for its remarkable mechanical and thermal properties. However, it is susceptible to low-temperature degradation (LTD), adversely affecting its long-term performance. This degradation process is hypothesized to be closely linked to the occurrence of oxygen vacancies within the crystal lattice. To understand the origins of LTD, Atom Probe Tomography (APT) is employed as a characterization technique to investigate the microstructure of YSZ. To analyze the sample and understand oxygen distribution, we translate the local atomistic environment characterization method from molecular dynamics into the APT field. The method is based on the graph representation of point cloud data coupled with the information theory entropy measures to capture the local environment's chaos/order and density. In this study, we learned that this method is highly sensitive to small changes in the number and connectivity of the oxygen ions. We unravel that grain boundaries are lean in the less connected oxygen ions compared to the grains, offering direct atomistic evidence of noticeable differences between grain and grain boundaries of zirconia. This knowledge contributes to developing strategies for enhancing the material's resistance to low-temperature degradation and optimizing its performance in diverse applications.

$L1_0$ FeNi Tetrataenite in Iron Meteorites: An Atom Probe Tomography Investigation FredericDanoix[1], RaphaeleDanoix[1], FabienCuvilly[1], JeromeGattacceca[2], ClaraMaurel[2], MathieuRoskosz[3] and MatthieuGounelle[3]; [1]CNRS Normandy University, France; [2]CEREGE, France; [3]MNHN, France

Metal matrix in siderites are iron based alloys containing up to 35at%Ni as well as other minor elements such as Co and P, at levels lower than 1at%, the microstructure of which keeps records of their thermal and mechanical history. The initial metal alloy was melted in the heart of planetesimals in the early days of the solar system. After formation, the planetesimal slowly cooled down, leading to the solidification of the metal alloy as FCC austenite. Due to the extremely slow cooling rate (between 1 and 100K/10^6 years), austenite grains could reach sizes up to several meters. During cooling, austenite experienced several solid-state transformations, starting with the precipitation of Widmanstätten ferrite, resulting in the development of the iconic microstructures of iron meteorites [1]. As it grows, ferrite rejects nickel, creating a Ni composition gradient in austenite, that extends over several hundred microns. This gradient, starts at more than 50% Ni at the interface with the ferrite, down to the initial Ni content, usually close to 7at%Ni. This naturally graded material makes it possible to explore the Fe rich part of the low temperature FeNi phase diagram [2]. In addition, due to the small cooling rate it possible to explore the reach full equilibrium conditions, at least for temperatures higher than approx. 300°C. In this work, we used atom probe tomography (APT), combined with electron backscattered diffraction (EBSD) and transmission Kikushi diffraction (TKD) on focused ion beam (FIB) lift outs for site specific specimen preparation, allowing investigation of the compositional and nanostructural features of this gradient material. The fine scale complexity of the final microstructures revealed in octaedrites and ataxites, two types of Ni rich iron meteorites, is discussed in the framework of the FeNi phase diagram. Of particular technological interest is Fe-36Ni alloy, also known as INVAR®, for which equilibrium phases can be described, providing an alternative investigation route to electron irradiation. Another technologically important phase present in iron meteorites is tetrataenite, an equiatomic FeNi $L1_0$ ordered variant of austenite. This phase, only present in meteoritic irons, is an extremely promising substitute to rare earth element (REE) based permanent magnet, as it exhibits very similar magnetic properties. Being REE free, and based on low cost and widely available elements, it would reduce dependence on toxic, environmentally harmful rare earth mines, and on China's multi-billion rare earth element monopoly. Understanding the formation path of tetrataenite is becoming a global geo-strategic issue of the next decade. Complex nanostructures containing tetrataenite are analysed by atom probe tomography, and some will be shown, in particular in the Santa Catharina meteorite.

SESSION CH03.06: Atom Probe Tomography—Minerals, Biominerals, and Oxides
Session Chairs: David Diercks and Pritesh Parikh
Tuesday Afternoon, November28, 2023
Sheraton, Third Floor, Dalton

1:30 PM *CH03.06.01
Atom Probe Tomography (APT) Analysis of Minerals AlbertoPerez-Huerta; University of Alabama, United States

The use of atom probe tomography (APT) in the analysis of minerals is becoming a powerful tool for geoscience applications. Most of the work has been focused on the study of isotropic minerals, mainly for geochronology and elucidating mineral formation under different temperature and pressure conditions. Thus, for the last ten years, we have been studying the different variables that control the quality of APT data for these minerals. The first part of the talk will be a summary of what we have learned so far about the influence of the crystallo-chemistry and physical properties of minerals (i.e., thermal conductivity) for the best outcomes of APT analyses. The second part will be centered around our most recent efforts in the analysis of layered, anisotropic minerals. We will be discussing challenges in sample preparation and 3D reconstructions of datasets, as well as potential applications of APT to the study of these ubiquitous minerals on Earth's crust and other planets. Finally, we will be talking about new directions in the use of APT for the characterization of geomaterials.

2:00 PM CH03.06.02
Ranging Atom Probe Spectra for Multi-Element Analyses FrederickMeisenkothen, DavidNewton, KarenDeRocher and MarkMcLean; National Institute of Standards and Technology, United States

Atom probe tomography (APT) is becoming an essential nano-characterization tool in a wide variety of fields. In principle, APT can deliver 3-dimensional chemically resolved images of nano-scale analysis volumes, thereby making the technique uniquely suited for applications requiring composition measurements at dimensions approaching atomic-scale (e.g., semiconductors) and nano-scale analysis in fields such as nano-geology. In practice, APT analyses can be hindered by two broad types of limitations – ion trajectory aberrations and composition measurement bias – leading to image distortions and erroneous chemical analysis results. However, these limitations are not constrained by physics, and thus should be possible to overcome through measurement science, technological advances, and application of standards. Ion ranging – i.e., how to properly attribute regions of interest in the spectrum to specific ion species – and associated measurement bias have long been topics of discussion within the APT community. APT spectra are complex, with peak forms often varying significantly between ion species and between data sets. No single model peak form can be applied universally to range spectra and there is no community-wide consensus on how best to range spectra, which can lead to erroneous analysis results and lack of reproducibility.
We have previously achieved accurate and repeatable single-element isotopic analysis results by employing a three-step analysis approach that relies on data filtering (artifact removal), adaptive peak fitting (assumes all isotopic variants within a given ion species have the same peak shape), and standards-based calibration (using known reference materials) [1-3]. However, this three-step approach cannot be used for complex multi-element analyses. In multi-element analyses, the peak forms often cannot be assumed to be identical, as required for adaptive peak fitting, and filtering the data to remove artifacts can introduce additional composition measurement bias. An alternative methodology must be developed.
We present the results of a systematic ion ranging study for multi-element analyses that compares about ten different APT peak sampling methodologies. A natural mineral specimen was chosen for the study since the material was characterized by multiple complementary methods and produced complex multi-element APT spectra with a high fraction of multi-hit detection events. Clear trends in the analysis results were observed for the measured element ratios of interest. The trends could be demonstrably associated with peak sampling bias and data interpretation artifacts. By applying a custom correction method to account for peak sampling bias, the analysis results improved significantly, with up to a 10-fold reduction in bias for the relevant peak ratios measured. Surprisingly, all APT ion ranging methodologies explored yielded similar analysis results, once peak sampling bias was accounted for. Further, the APT results largely agreed with the other complementary analysis methods employed for validation.

Imaging Interfaces and Interphases in Mineralized Tissues DerkJoester; Northwestern University, United States

Mineralized tissues are sophisticated materials with properties that include high toughness at low weight, outstanding fatigue life, self-repair capabilities, and sustainable synthesis. Often hierarchically structured, grain and interphase boundaries play an important role in the biosynthesis and final functional properties of mineralized tissues. However, the complex structure and phase composition, often with characteristic features at the nanoscale, the low atomic number of many physiologically relevant elements, and sensitivity to electron and X-ray beams creates significant challenges to the characterization of these biological materials.

I will discuss how UV-laser pulsed atom probe tomography (APT) has provided us with deep insights into compositional gradients at organic-organic interfaces in invertebrate teeth and bone-type tissues, helped us identify the role of an amorphous intergranular phase that acts as a cement in rodent enamel, and discover nanoscale gradients in hydroxylapatite crystallites in vertebrate tooth enamel.[1-5] I will further report on development of correlative elemental imaging using X-ray diffraction at the mesoscale (here: 0.25-20 µm) that allows us to extend the field of view beyond what APT can deliver.[6] Finally, I will provide a progress report on our characterization of a highly unusual biomineral, celestine ($SrSO_4$), that is found in single crystalline endoskeletal spicules in Acantharea, a class of marine zooplankton. This investigation is motivated by the high level of biological control over single-crystal growth evident in different Acantharea species, and because understanding how Acantharea selectively sequester Sr^{2+} over chemically similar ions present in seawater, is of interest for example for removal of ^{90}Sr from nuclear waste.

High Diffusivity Pathways in Human Dental Enamel XingchenZhao, DieterIsheim, XinqiChen and DerkJoester; Northwestern University, United States

Tooth enamel is an acellular, mineralized tissue with limited regenerative potential. Loss of enamel integrity and function, whether congenital, acquired, or environmental in origin, is irreversible, ubiquitous, and imposes great burdens on society [1]. Ions such as F^-, CO_3^{2-}, Na^+, Ag^+, Sr^{2+}, Fe^{3+}, and Mg^{2+}, are important determinants of enamel solubility; some are widely used in the prevention or treatment of defects. However, their mechanism of action and mode of transport in enamel remain poorly understood. This is at least in part due to the fact that the complex, hierarchical architecture of enamel was not taken into account in prior work studying diffusion in enamel under physiological conditions [2].

At the microscale, human enamel consists of rods that run from the dentino-enamel junction towards the external enamel surface and interrod enamel. Both are comprised of crystallites of hydroxylapatite (OHAp) that are highly elongated along the c-axis direction but display typical cross-sectional edge lengths of only 25-50 nm. Atom probe tomography (APT) and synchrotron X-ray microdiffaction revealed that crystallites are cemented together by an amorphous intergranular phase (AIGP) [3], are compositionally graded with a core enriched in minority components and a depleted shell [4], and that their average composition differs between rod and interrod enamel [5]. In the context of these recent insights, our long-term goal is to improve the understanding of transport processes in healthy enamel and enamel lesions as an integral step towards understanding the mechanisms by which lesions form and therapeutics act.

Herein, we describe a multi-scale correlative approach using depth profiling time-of-flight secondary ion mass spectrometry (ToF-SIMS) and X-ray photo-electron spectroscopy (XPS) to determine average concentration profiles for multiple rods and interrod enamel (~2500 μm^2) and APT to systematically determine effective diffusivities of F^-, Na^+, Ag^+, Sr^{2+}, Fe^{3+}, Zn^{2+}, and Mg^{2+}in the intergranular phase and, by extension, in rod and interrod enamel. For this purpose, ground and polished sections roughly parallel to the external surface of human premolars were treated with aqueous solutions of selected ions (0-1000 ppm, pH 7, 25 C, 24h). Concentration depth profiles (normal to the surface) were determined using ToF-SIMS and/or XPS. Chemical diffusivities were determined by fitting concentration profiles. Preliminary analysis suggest that diffusivities in rod and interrod enamel may differ by a factor of up to 30. Effective bulk diffusivities for both rods and interrods fell into the range between 10^{-16} to 10^{-19} cm^2/s and decreased in the following order: $Sr^{2+} = F^- > Mg^{2+} = Na^+ > Cl^- >> Ba^{2+} >> K^+$. Effective and absolute diffusivities at nanoscale level were acquired by fitting the APT reconstruction along with ion profiles from TOF-SIMS or XPS. APT analysis has been conducted on enamel treated with Na^+, Mg^{2+}, Ag^+, F^-, and Sr^{2+} compared with the original untreated enamel. Na^+ and F^- uptake by the AIGP can differ from crystallites by a factor of up to 100; Mg^{2+} and Sr^{2+} uptake by the AIGP was less than 10 times than from crystallites; Ag^+ barely infiltrates both crystallites and AIGP.

Multiscale Microscopic Insights into Low-Temperature Degradation in Zirconia: Enhancing Ceramic Stability PrachiGarg, PrathimaNalam and BaishakhiMazumder; University at Buffalo, The State University of New York, United States

Zirconia, a ceramic material known for its high fracture toughness, strength, and stability at elevated temperatures and pressures, is utilized in various applications such as solid oxide fuel cells, thermal barrier coatings, and sensors. Tetragonal zirconia, in particular, is highly desirable due to its unique properties, such as high fracture toughness, low thermal conductivity, and high melting temperature. Zirconia doped with 3-mol% Yttria helps stabilize the tetragonal phase and prevents its transformation to the monoclinic (t-m) phase at room temperature. However, extended exposure to extreme conditions, a process known as aging, has been observed to induce spontaneous phase transformations, leading to the development of microcracks and mechanical failure, referred to as low-temperature degradation (LTD). Our study hypothesizes that aging results in the preferential segregation of elements near the grain boundaries, initiating local phase transformations and altering the grain environment.
To investigate this hypothesis, a multi-scale microscopy approach, specifically employing Atomic Force Microscopy (AFM) and Atom Probe Tomography (APT) was utilized to examine the yttria-stabilized zirconia (YSZ) to provide fundamental insights into the degradation mechanisms. The investigation includes a comprehensive study of the material's response to artificial aging, including structural, crystallographic, and chemical analyses. Firstly, the Design of Experiments approach was employed to predict the process parameters necessary for artificially aging samples, relying on information collected from existing literature. AFM allowed us to examine surface topography and changes in grain size, providing detailed morphological changes that occur at the material's surface with aging. APT assisted in acquiring elemental distribution and segregation, offering 3-D compositional mapping with sub-nanometer resolution. The initial results show variation in grain size distribution and grain curvature at all stages of aging, i.e., among unaged, partially aged, and fully aged samples. We also observed preferential segregation of Aluminum and Silicon at certain grain boundaries. Additionally, a difference in Yttria concentration at the grain boundaries between the aged and unaged samples was observed, leading to a possible initiation of local phase transformation. These fundamental investigations enabled to generate novel insights for LTD mechanisms, which is a critical need for designing robust and durable ceramics for practical applications.

This work is supported by NSF award number DMR2114595. APT research was supported by the Center for Nanophase Materials Sciences (CNMS), which is a US Department of Energy, Office of Science User Facility at Oak Ridge National Laboratory. The authors thank Dr. Jonathan Poplawsky and Mr. James Burns for APT specimen preparations and conducting the APT experiments.

The Synthescope—An Approach for Synthesis at the Atomic Scale OndrejDyck, AndrewLupini and StephenJesse; Oak Ridge National Laboratory, United States

The scanning transmission electron microscope (STEM) is evolving from a workhorse instrument for materials characterization to an atomic-scale material manipulation platform. With its capability to image and characterize atomic-scale structural formation as it occurs, the STEM is being reconceptualized as a powerful instrument for fabrication and synthesis. By incorporating synthesis processes into the STEM, new transformations can be discovered and the atomic scale evolution of material growth can be better understood.

Within the STEM, there is a controlled environment with a focused beam of electrons that creates a highly localized perturbation of the sample. This perturbation can be considered a chamberless synthesis environment (CSE). Within this perturbed region of space, the sample environment is drastically different from regions outside the perturbation. The CSE can be moved around with great spatial precision and encounter a variety of different physical systems in a non-uniform sample. A reaction process can be prepared by adjusting global parameters without the intended process occurring until the CSE is created through e-beam exposure. When described in these terms, it can be seen that electron beam induced deposition (EBID) functions on the same principle. The e-beam dissociates molecular precursor gas molecules which become chemically reactive and bond with the substrate. This dissociative environment is created by e-beam exposure and can be considered to form a CSE within which the dissociation and growth of a new material occurs. The CSE concept, however, does not specify what reaction should occur, merely that the beam-sample interaction volume is a significantly different environment from that of the surrounding material.

With this idea in hand, we can begin to ask what environmental parameters could be varied such that *some* material transformation occurs within the CSE. A number of experimental results have shown that the positioning of single atoms in graphene is possible and that this could be extended to atomic scale patterning and writing if the sample environment could be better controlled, specifically the supply of various materials as is done in a synthesis chamber. To enable this capability, a prototype *in situ* evaporative delivery platform has been built. The basic functionality is demonstrated and test runs confirm the delivery of material down to the level of single atoms. With separate control over evaporation and substrate temperature, conditions were found where Sn atoms could be directly ‘written’ atom-by-atom into graphene.

The incorporation of synthesis processes in the STEM is opening up new possibilities for atomic-scale material manipulation and the discovery of new transformations. The concept of a chamberless synthesis environment (CSE) can lead to precise and controlled atomic-scale patterning and writing. With a prototype in situ evaporative delivery platform that can deliver material down to the level of single atoms, the future realization of the synthescope—a platform for synthesis and fabrication at the scale of an atom—shows great promise.[1]

8:45 AM CH04.01.02
Atomic Lattice Resolved Electron Tomography of a 3D Self Assembled Mesocrystal XiaoleiChu[1], AlexAbelson[2], CarolineQian[2], EthanM. Field[1], OlegIgouchkine[1], Kwan-LiuMa[1], MattLaw[2] and AdamJ. Moule[1]; [1]University of California, Davis, United States; [2]University of California, Irvine, United States

Complex 3D architectures of nanoscale building blocks can be created by self-assembly, but characterization of the atomic to mesoscale structure of such materials is limited by the difficulty of visualizing atoms across multiple length scales. Here, scanning transmission electron microscopy (STEM) and full-tilt tomographic reconstruction are used to image a single-crystalline region of a 3D epitaxially-fused PbSe quantum dot (QD) superlattice containing 633 QDs at a spatial resolution of 2.16 Å. The combined real-space and reciprocal-space analysis enables 3D mesoscale correlations of atomic lattice and superlattice order across hundreds of nanocrystals in 3D for the first time. Inhomogeneity in QD positional and orientational order reveals that the QD surface layers template the superlattice and that orientational entropy is higher in the interior layers than the surface layers. The measurement and analysis techniques presented here are applicable to a broad range of 3D nanostructured materials.

9:00 AM *CH04.01.03
Domain Configuration and Interface Characterization in Ferroelectric Oxides WanbingGe[1], DorinRusu[1,2], MarinAlexe[1], RichardBeanland[1] and AnaM. Sanchez[1]; [1]University of Warwick, United Kingdom; [2]University College London, United Kingdom

The rapid improvement in materials growth and processing techniques has produced novel structures with unique functionalities. Electron microscopy plays a key role in understanding the structure of these novel materials and controlling them at an atomic level. The development of spherical aberration correctors for electromagnetic lenses established a major improvement in the new generation of electron microscopes.
Using aberration-corrected scanning transmission electron microscopy (STEM), we analysed in detail the domain structure in bulk and thin film ferroelectric oxide materials. Two different case of studies will be presented:
(i) A dense domain structure alternating sawtooth and flat domains walls in flux-grown single crystal $BiFeO_3$ has been previously reported [1,2]. This intriguing ferroelectric structure of

domain walls has been controversial and the nature of these domains has remained ambiguous over the years. We demonstrated that although both type of domains are 180° their domain walls are different. (i) Flat walls, lying on (112) planes, have that head-to-head polarity. These flat domain walls are coincident with a 1/2[110] stacking fault, with a clear reconstruction visible in atomic resolution images [3]. (ii) Sawtooth walls are tail-to-tail with peaks elongated along the polar [111]axis. The formation and geometry of these sawtooth domain walls have been analysed in detail. These tail-to-tail domain walls form a crinkled 3D structure with three-faceted teeth consisting of a (11-2) facet allowing charge-free reversal of polarisation, and two facets close to (3-21) and (-321). Vortex structures are found at these domain walls .The neutral DW facets are Ising type and very abrupt, while the charged DW facets have mixed Néel/Bloch/Ising character with a chiral nature and a width of about 2 nm [4].
(ii) Ferroics can form vortices and skyrmions under particular boundary conditions. The formation of modulated ferroelectric vortices in $PbTiO_3$ sandwiched between two $SrRuO_3$ electrodes on $SrTiO_3$-buffered $DyScO_3$ (110) has been demostrated. The local structure is resolved using a combination of STEM and conventional TEM. Two orthogonal modulations were revealed. This incommensurate polar crystal may be an equivalent to the incommensurate spin crystals found in ferromagnetic materials.

10:00 AM CH04.01.04
Understanding Inherent Structural Defects and Chemical Distribution at Topological Superconductor-Semiconductor Interfaces and Heterostructures using Advanced Electron Microscopy RosaE. Diaz[1], RoyPeña[2], TianWang[3] and MichaelManfra[1]; [1]Purdue University, United States; [2]Universidad Nacional San Antonio Abad del Cusco, Peru; [3]Beijing Academy of Quantum Information Sciences, China

In the zoo of quantum systems that might disrupt the storage and manipulation of information, topological superconductors have received significant interest for their potential application in quantum computing, mainly due to their capacity to harbor non-Abelian states and provide fault-tolerant computation. One of the platforms proposed to host topological superconductivity is the interface between a superconducting metal and a semiconductor (SS)[1] with strong spin-orbit scattering[1] – where topological qubits are manifested. However, epitaxially interfacing two dissimilar materials, such a superconductor metal and a semiconductor heterostructure, inherent challenges emerge in the form of grain boundaries (black arrow in Fig. 1), grain misorientations (grains G1/G2 in Fig. 1), atomic distortions across the SS interface (white circle in Fig. 1), which might be detrimental to the device performance. Additionally, precise control of the semiconductor heterostructure interfaces and their chemical distribution across the interface is also needed to improve electron mobility and device performance. Thus, identifying and understanding these inherent structural defects at the multiple interfaces of this hybrid devices, and connecting our findings with growth process, might contribute to the performance improvement of topological qubits. Here we explore a combination of electron and ion microscopy together with advance image processing and mathematical modeling using Python libraries to understand structural properties at the SS interface, and quantify roughness and chemical distribution across the heterostructure interfaces. Our findings deliver metrology parameters to assess the quality of semiconductor heterostructure and highlight the relationship between such parameters and growth conditions.

10:15 AM *CH04.01.05
Atomic Structure Analysis of Metal Chlorides and Alkali Metals Intercalated in Bilayer Graphene Yung-ChangLin[1,2], MatsumotoRika[3], QiunanLiu[2], PabloSolís-Fernández[4], Po-WenChiu[5], HirokiAgo[4] and KazuSuenaga[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Osaka University, Japan; [3]Tokyo Polytechnic University, Japan; [4]Kyushu University, Japan; [5]National Tsing Hua University, Taiwan

Intercalation of metal species within graphene layers has attracted significant attention due to its potential for tailoring the electronic, magnetic, and optical properties of graphene-based materials. The precise characterization of the intercalation process and resulting atomic arrangements is crucial for understanding the fundamental interactions and the impact on material properties. In this study, we employ scanning transmission electron microscopy (STEM) to investigate the atomic structure of metal chlorides (AlCl3, CuCl2, MoCl5, FeCl3) and alkali metals (K, Rb, Cs) intercalated in bilayer graphene (BLG). Through STEM imaging, we have achieved high-resolution visualization and analysis of the atomic structure within the intercalated BLG samples. Our results reveal distinct patterns and arrangements of metal chloride and alkali metal atoms within the graphene lattice. We observe variations in interlayer spacing, local bonding configurations, and atomic ordering depending on the specific metal chloride and alkali metal employed. Additionally, we investigate the influence of intercalation on the electronic structure of the bilayer graphene using spectroscopic techniques.

SESSION CH04.02: Cryogenic Electron Microscopy

Probing the Atomic-Scale Internal Phases of Mutliferroic and Hyperferroelectric Domain Walls During Dynamics with *In-Situ* Biasining and Cryogenic STEMShelly MicheleConroy; Imperial College London, United Kingdom

Dynamic multiferroic domain wall topologies overturn the classical idea that our nanoelectronics need to consist of fixed components of hardware. To harness the true potential of domain wall-based electronics, we must take a step back from the device design level, and instead re-look at the subatomic internal properties. With recent advances in experimental characterization and theoretical calculation approaches, in the last 5 years reports of non-classic internal structures and functionalities within domain walls have become a common occurrence. As the region of interest is at the nanoscale and dynamic, it is essential for the physical characterization to be at this scale spatially and time resolved.

This presentation focuses on using the applied electric field of aberration corrected scanning transmission electron microscopy (STEM) probes to move domain walls, and thus investigate their dynamics while imaging at the subatomic scale. As the STEM probe can be controlled in terms of dose, probe size, direction and speed, a diverse set of experiments is possible without complicated sample preparation. Using a segmented STEM detector (or 4DSTEM CoM experimental set-up) any changes in deflection and thus the changes in polarisation for each domain, can also be investigated with controlled variants in applied field conditions. By controlling the incoming STEM probe direction, parallel domain walls could be moved around to form stable vertex junctions, thus switching from a neutral to charged state. Then in each frame by quantifying the atomic displacement per unit cell using our open-source python based TopoTEM software package,[1] the local polarisation at these charged topologies can also be monitored. Finally, we will show how changes in band structure can be monitored via ultrahigh energy resolution electron energy loss spectroscopy (EELS) as the domain walls switch from neutral to charge states. By combining the local atomic resolution structure, strain, charge density and band structure measurements we can resolve all the measurable parameters of interest within domain walls and thus start unravelling the fundamental physics governing their formation, dynamics and resulting functionality. We will show that this technique can be used for several different types of multiferroic oxide and oxy halide material systems, such as improper ferroelectric boracites and hyper-ferroelectric lead germanate. Additionally we will utilise new MEMS based cryogenic holder design to probe the low temperature phases of such materials and their topological features.

11:15 AM CH04.02.02
Exploring the Effects of Structural Defects on the Charge Density Wave Behavior of Rare-Earth Tritellurides SaifSiddique[1], JamesL. Hart[1], RatnadwipSingha[2], Myung-GeunHan[3], MichaelColletta[1], NoahSchnitzer[1], LenaF. Kourkoutis[1], YimeiZhu[3], LeslieSchoop[2] and JudyCha[1]; [1]Cornell University, United States; [2]Princeton University, United States; [3]Brookhaven National Laboratory, United States

Rare-earth tritellurides (RTe_3; R = rare-earth elements) are a family of layered compounds exhibiting charge density wave (CDW) order. They have rich phase diagrams involving other quantum phases, such as superconductivity and magnetism, providing an opportunity to understand the interplay between these phases by studying the mechanisms influencing the phase transitions. RTe_3 with lighter rare-earth elements (La-Gd) has a unidirectional CDW, while the ground state for the heavier rare-earths (Tb-Tm) has a second CDW at a lower temperature, and is orthogonal to the first with slighly larger wavevector, creating a bidirectional CDW. The direction of the charge and lattice modulations in the CDW state is governed by the orthorhombicity

of the crystal structure. The in-plane axes in these materials are nearly equal, but the presence of a glide plane only along one of the axes makes the unit cell orthorhombic, and the higher temperature CDW (for lighter RTe_3, the only CDW) emerges along this direction.
In this study, we use *in-situ* cryogenic scanning transmission electron microscopy (STEM) techniques to understand the influence of structural defects on the orthorhombicity and the CDW order in exfoliated flakes of $LaTe_3$, $GdTe_3$ and $ErTe_3$: two unidirectional and one bidirectional CDW system. Atomic-resolution STEM images in cross-section reveal the layer stacking in these materials to be disordered, with the disorder density increasing for heavier rare-earths in RTe_3. These layer stacking defects lead to the presence of glide planes along both in-plane directions rather than along only one in-plane direction, and hence the material loses orthorhombicity. Temperature dependent electron diffraction and 4D-STEM, down to 15 K and 120 K, respectively, are used to study the CDW phase transition behavior of these flakes that reveal the existence of in-plane domain walls. We observe that the loss of orthorhombicity and the presence of domain walls significantly affect the CDW order in these exfoliated flakes of RTe_3. Our results demonstrate the correlation of stacking defects and domain boundaries with the properties and dynamics of CDW phase transition.

Emerging Electron Microscopy Techniques for Probing Quantum Materials YimeiZhu; Brookhaven National Laboratory, United States

In this presentation I will give an overview of the recent work at BNL on advancements in electron microscopy characterization of quantum materials. I will focus on sample holder development, including holders designed for previously inaccessible microwave frequency range in TEM for in-situ RF excitation/ultrafast-dynamics and for liquid helium temperature cooling with temperature control and stability better than a few mK. I will also show our preliminary results on the evaluation of three direct electron detectors: Dectris Quadro, Quantum Directors Merlin (Medipix 3), and Gatan K3. The performance, especially at extremely electron low-dose and high acquisition speed, of these detectors installed on our aberration corrected JEOL ARM200FC and Laser-Free Ultrafast Electron Pulser will be compared. Applications on strongly correlated quantum materials and test results using these holders and detectors will be presented. The ability to probe materials dynamic responses under RF and microwave excitations at extremely low temperatures has promising applications for qubit devices and quantum information science.

Collaborations with S. Reisbick, X. He, C. Liu, MG Han, and L. Wu at BNL and C. Jing and R. Kostin at Euclid are acknowledged. Work at BNL was supported by the DOE-BES-MSE under contract No. DE-SC0012704.

SESSION CH04.03: Imaging Magnetic Materials

Real-Space Observation of Spontaneous Vortex-Antivortex Pairs and Their Topological Transitions Through Transmission Electron Microscopy XiuzhenYu[1], NaoyaKanazawa[2], XicaoZhang[3], KonstantinIakoubovskii[1], KiyomiNakajima[1], MasahitoMochizuki[3] and YoshinoriTokura[1]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan; [3]Waseda University, Japan

The spontaneous formation of vortex-antivortex pairs and their topological transitions have been extensively studied in various branches of physics, demonstrating their crucial role in phenomena such as superconductivity and quantum computing[1]. Unlike conventional magnets that typically exhibit collinear spin textures, helimagnets with non-centrosymmetric crystal structures offer additional degrees of freedom essential for manipulating noncollinear spin textures, such as a proper screw structure at zero field[2]. This unique characteristic makes helimagnets promising candidates for exploring and engineering topological states, such as a skyrmion lattice state, under specific conditions of temperature and external magnetic field[3]. However, achieving multiple topological magnetic states and their transitions within a single helimagnet presents a significant challenge due to the inherent topological protection associated with each state.
In this talk, I will present real-space observations of a spontaneous vortex pair composed of a meron and an antimeron, possessing topological charges of $N = \pm 1/2$, respectively, in a helimagnet $Fe_{0.5}Co_{0.5}Ge$ through advanced transmission electron microscopy. In addition, a meron pair, referred to as a bimeron (i.e., a vortex-antivortex pair), carrying a topological charge of $N = -1$, will also be presented. We successfully achieved the mutual transition between skyrmions and bimerons and the transformation of individual bimerons into a skyrmion lattice by carefully controlling the external magnetic field and electric current[4].
Overall, this research piece offers valuable insights into the manipulation of topological states, paving the way for potential future applications in fields such as spintronics and quantum technologies.

Multiscale Insights to the Origins and Dynamics of Chiral Magnetic Textures in Intercalated TMDs BeritH. Goodge[1,2], OscarGonzalez[1], LiliaXie[1] and DanielK. Bediako[1,3]; [1]University of California, Berkeley, United States; [2]Max Planck Institute for Chemical Physics of Solids, Germany; [3]Lawrence Berkeley National Laboratory, United States

Dynamically tunable properties such as magnetic textures have many potential applications for next-generation information and communication technologies ranging from spintronics to broadband resonators. One promising class of materials are intercalated transition metal dichalcogenides (TMDs), in which a wide range of electronic and magnetic phases which can be tuned by varying the host lattice or the species, amount, and ordering of intercalants. Chromium-intercalated TMDs, for example, stabilize low-temperature helical magnetic order with chiral winding along the *c*-axis of the crystal where the helical pitch is tunable by both spin-orbit coupling of the host TMD compound and by external in-plane magnetic fields. The extensive phase space of stoichiometry- and field-dependence of these textures provides a rich playground for real-space visualization of the interplay between atomic lattice and mesoscale magnetic order. Here, we leverage a combination of high-resolution and cryogenic imaging techniques in the (scanning) transmission electron microscope (S/TEM) to directly probe both atomic and magnetic (dis)order across multiple length scales. We reveal the dramatic impact of subtle changes in the atomic lattice on mesoscale magnetic textures and their dynamic evolution, and offer suggestions for more precisely-controlled synthesis of these compounds for future applications [1].

Three-Dimensional Inverse Scattering Problems Using Electron Ptychography: Atomic-Scale Imaging of Magnetization and Thermal Diffuse Scattering GeorgiosVarnavides[1,2], StephanieRibet[2], ReedYalisove[1,2], JoelMoore[1,2], ColinOphus[2] and MaryScott[2,1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Accelerated electrons passing through a thin sample acquire Aharonov-Bohm phase shifts due to sample interactions which scatter the incident electron wavefunction. These include coherent sources such as electrostatic scattering off atomic columns and scattering against a magnetic vector potential [1], as-well as incoherent sources such as thermal diffuse scattering and plasmon excitations [2,3]. Despite the large mechanistic differences between these scattering sources the fact that they are simultaneously collected as far-field diffraction intensities, as-well as the large order of magnitude difference in the acquired phase shifts, suggests the signals are hard to deconvolve. Reconstructing these various scattering sources from diffraction intensities is thus a high-dimensional non-convex inverse problem.

Electron ptychography is a recently rekindled phase-retrieval technique which attempts to solve this inverse problem using the redundant information in a set of converged-beam diffraction intensities with sufficient real-space illumination overlap [4], e.g., using a defocused 4DSTEM experiment [5]. Here, we introduce a general framework, implemented in the open-source analysis toolkit py4DSTEM [6], to reconstruct common coherent and incoherent scattering sources in materials using physically inspired forward and adjoint operators. We illustrate the utility of the framework by jointly reconstructing the coherent electrostatic potential and magnetic vector potential of an anti-ferromagnetically ordered NiO sphere with atomic resolution, as well as elucidating the real-space character of incoherent thermal diffuse scattering.

We demonstrate how the usual projection-limitation of electron microscopy can be overcome by solving a joint inverse problem for two orthogonal tilt-series directly to obtain the three-dimensional nature of scalar and vector scattering sources such as electrostatic and magnetic vector potentials, respectively. Finally, we investigate the role of optimizing common experimental parameters such as convergence angle, scan step-size, and illuminating probe defocus on the reconstruction quality.

Tracking Antiskyrmion Dynamics Induced by Nanosecond-Current Pulses Through Transmission Electron Microscopy YaoGuang[1], XichaoZhang[2], YizhouLiu[1], LicongPeng[1], FehmiS. Yasin[1], KosukeKarube[1], DaisukeNakamura[1], NaotoNagaosa[1], YasujiroTaguchi[1], MasahitoMochizuki[2], YoshinoriTokura[1,3,3] and XiuzhenYu[1]; [1]RIKEN Center for Emergent Matter Science (CEMS), Japan; [2]Waseda University, Japan; [3]The University of Tokyo, Japan

The collective behaviors of strongly correlated systems, such as the interaction of electronic states, demonstrate emergent phenomena and novel functionalities that are essential for developing quantum technologies and advanced materials.[1] Meanwhile, topological spin textures, which combine real-space topology and collective spins, have garnered significant attention in the field of electronic materials due to their emergent electromagnetic properties.[2] To understand the nature of topological spin textures, advanced transmission electron microscopy (TEM) serves as a privileged and efficient platform for direct observations and study with various stimuli, including heat, mechanical forces, external fields, and electricity. Recently, antiskyrmions, a type of spin texture in non-centrosymmetric magnets with D_{2d} and S_4 symmetries, showcase the abundant topological transition physics because of anisotropic Dzyaloshinskii-Moriya interaction.[3-5] However, the dynamics of antiskyrmions driven by electric current flows remain elusive and largely overlooked. Therefore, the purpose of this study is to investigate the dynamic behaviors and underlying physics of antiskyrmions with pulsed current stimulations.
In this work, we employ in-situ Lorentz TEM observations to reveal the dynamic behaviors of antiskyrmions under electric current flows in the presence of a helical texture background. Since helical stripes along [1-10] and [110] are energetically equitable due to the S_4 symmetry in $Fe_{1.9}Ni_{0.9}Pd_{0.2}P$, we can demonstrate the ability to control the directional motion of antiskyrmions along the stripes, regardless of whether they are confined by [1-10] or [110] stripes. The results show that the moving direction of antiskyrmions is parallel to the stripe direction, and the corresponding speed of antiskyrmions is linearly proportional to the current density. Notably, an enhancement of the antiskyrmion speed has been observed when the current flows vertically to the stripe, which is six times higher compared to the case when the current flows along the stripe. Our findings offer valuable insights into the development and advancement of quantum technologies and materials science.

Limits of Quantitativeness In DPC-STEM Studies of Charge Density MatthewJ. Coupin; University of Texas at Austin, United States

Differential phase contrast (DPC) based methods are increasingly popular for the characterization of electrostatic fields and charge densities in materials [1]. Unlike conventional diffraction-based techniques STEM-DPC methods can been used to probe the local environment surrounding defects [2, 3, 4, 5] which are very difficult to measure without the precise spatial resolution of microscopy techniques. 2D materials have been popular candidates for DPC-STEM due to their thinness and suitability for study in TEM; however, these methods can, with sufficient skill in sample preparation, be extended to bulk materials [6].

However, as the interest in these methods expands beyond the microscopy-focused community, it becomes increasingly important to acknowledge that there exist a wide range of deleterious experimental factors that degrade the magnitude of the measured properties, causing deviations from theoretically-predicted values. These include sample contamination, optical aberrations, partial coherence of the electron beam, stage-induced motion, and thermal and electron beam induced sample motion. Each of these factors can introduce uncertainty into the measurements and can lead to incorrect interpretation of experimental observations, especially because they may depend on spatial frequency, acting differently upon differently sized features within a given dataset. Under the influence of these deleterious experimental conditions it becomes challenging to perform quantitative DPC-STEM studies without relying on first principles physics to generate relaxed structural models for TEM simulation and to calibrate the magnitudes of the observed signal using the resulting DFT-derived potentials. Inevitably there will be situations where experiment and first-principles simulation cannot be brought into agreement, and this relationship between experiment and theory will break down. When novel physics is observed in TEM without complementary simulation, which should be believed?

This serves to motivate the development of new methods towards ‘blind’ quantitative STEM methods that do not rely upon existing frameworks for physics simulation. Although newer methods, such as those based off of iterative ptychography, can reduce the influence of lens aberrations, scan position uncertainty, and even dynamical scattering, there remain many possibilities for incorrect analysis of STEM data. The present work is a review of the challenges and common pitfalls associated with DPC-STEM based studies of electrostatic fields and charge densities, with a target audience beyond the core community of advanced TEM users.

Electron Beam Modification with an Electrostatic Phase Plate for Characterization of Quantum Materials StephanieRibet[1], StevenZeltmann[2] and ColinOphus[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Cornell University, United States

For Scanning Transmission Electron Microscopy (STEM) imaging, producing a high-resolution image generally requires focusing the beam to a fine point by eliminating aberrations and making a more uniform phase profile. However, further electron beam modification creates a myriad of opportunities to characterize material properties that are inaccessible through traditional methods. Existing phase modification devices often lack the necessary physical or phase stability to enable routine implementation of such experiments. In this presentation, I will share our design for an electrostatic phase plate that can be used for electron beam modification. Our phase plate is composed of many smaller apertures, each of which has a two terminal device that can be adjusted independently to impart a linear ramping or constant phase shift on the probe. The support bars for the electrostatic apertures ensure structural integrity, while the dynamic nature of the design enables spatial and temporal control over the electron beam. The electrostatic phase plate has implications for the characterization of quantum materials, such as through the creation of vortex beams that can be used to characterize chirality and magnetic ordering.

Multi-Modal Spectroscopic Characterization and Defect Identification in SnO_2 /Ga_2O_3 Nanostructures. PraveenaManimunda[1], João-LucasRangel[1], DidierHocrelle[1], FrancisNdi[1], EmilioNogales[2] and BianchiMendez[2]; [1]Horiba, United States; [2]Universidad Complutense, Spain

Semiconducting oxide nanostructures with a wide range of morphologies are emerging as a viable candidate for applications such as optical and mechanical resonators and solar cells. However, attaining effectively doped oxide nanowires with controllable conductivity is still a challenge. Designing semiconducting oxide nanostructures requires extensive understanding of their morphology and demands efficient multimodal characterization methods. Multimodal spectroscopy is the concept of combining several different spectroscopies onto one platform, thereby expanding the range of analytical capabilities available on that single platform. Besides the obvious benefit of cost reduction, having multiple analytical spectroscopies offers the added benefit of sample colocalization so that multiple complementary measurements can be made at the same location of the sample. The benefit of colocalization is particularly important as feature sizes get smaller, from a few microns to nanometers in size. In this study, Scanning Electron Microscope was integrated with cathodoluminescence (F-CLUE) and as a complementary information an external optical microscope coupled with photoluminescence (PL) and Raman spectroscopy were used to achieve co-localized high-resolution imaging and chemical mapping. Further shape engineered SnO_2 nanostructures grown on Ga_2O_3 nanowires were characterized in detail to understand the optical properties and defect characteristics. Panchromatic CL images identified the region of illumination on connected nanowires. The CL emission from Ga_2O_3 is composed of two components (3.3 and ~ 3.0 eV). However, the Ga_2O_3 nanowire tested had covered SnO_2 nanostructures and hence a weaker 3.3 eV emission, a stronger orange band (~ 1.94 eV) corresponding to the SnO_2 nanostructure was observed. The orange band was attributed to the oxygen vacancies in SnO_2. Photoluminescence and Raman mapping of the nanowires are carried out to understand the chemical nature of the local defects on SnO_2 /Ga_2O_3 nanostructures.

Imaging the Properties of Atoms and Fields at the Picometer Scale inside Quantum Materials DavidA. Muller; Cornell University, United States

Electron microscopes use electrons with wavelengths of a few picometers, and are potentially capable of imaging individual atoms in solids at a resolution ultimately set by the intrinsic size of an atom. Until very recently, the best resolution was more than an order magnitude worse than this limit. This was caused by two things – first the intrinsic aberrations in electron lenses are much worse than for optical lenses – comparable to using a beer bottle as a magnifying glass. Second, electrons are multiply-scattered inside the sample – a process described by Hans Bethe over 90 years ago. It's been a headache for electron microscopists ever since, but with recent advances in detector technology [1] and reconstruction algorithms, the resolution of the electron microscope is now limited only by the dose to the sample, and thermal vibrations of the atoms themselves [2], giving greater insight into the lattice contribution to exotic phases. These approaches have also allowed us to image the internal structures of both magnetic and ferroelectric vortices, skyrmions and merons, including their singular points that are critical for accurately describing the topological properties of these field textures [3,4]. [5]

9:00 AM *CH04.05.02
Large-Scale 3D Phase-Contrast Imaging from 4D-STEM Measurements PhilippM. Pelz[1], SineadM. Griffin[2], AlexZettl[3], PeterErcius[2], MaryScott[3,2], ColinOphus[2], DanielG. Stroppa[4] and MingjianWu[1]; [1]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [2]The National Center for Electron Microscopy (NCEM), United States; [3]University of California, Berkeley, United States; [4]DECTRIS AG, Switzerland

Spurred by the development and widespread availability of fast pixelated direct electron detectors (DEDs), scanning transmission electron microscopy (STEM) is undergoing a computational imaging renaissance. Experiments envisaged more than ten years ago can finally be realized with modern detector technology and reconstruction algorithms for 4D-STEM datasets.
We show the experimental demonstration of one such experiment relying on fast DEDs: ptychographic electron tomography at atomic resolution. Using ptychographic electron tomography, we have reconstructed an atomic-resolution 3D volume of a double-wall carbon nanotube encapsulating a complex core-shell $Zr_{11}Te_{50}$ structure from 34 million diffraction patterns [5]. From this volume, the atomic structure was determined using atom tracing methods known from annular dark-field atomic electron tomography [3]. Ptychographic electron tomography relies on the projection approximation, such that samples have to be ~10nm or less in thickness. Multi-slice ptychographic tomography [6] alleviates this constraint by modeling multiple scattering and allowing 3D atomic resolution phase-contrast imaging beyond the depth of focus limit. I will show first results using multi-slice ptychographic electron tomography to reconstruct samples with thickness beyond the depth of focus limit. With further technical developments, this method will be able to solve the 3D atomic structure of general TEM samples like FIB lamellas or needle specimens at atomic resolution in 3D. The datasets for these reconstructions were recorded with the 4DCamera, a direct electron detector capable of 87kHz frame rate. I will also present 3D imaging results using the DECTRIS ARINA DED, capable of 120kHz data acquisition and online data compression, alleviating large-scale 4D-STEM experiments. Finally, the limitations of current algorithms will be discussed, and developments towards imaging much larger volumes with 4D-STEM will be detailed.

10:00 AM *CH04.05.03
Optimizing the Analytical System to be Flexible yet Capable for Advanced Experimentation. JanRingnalda and LeeCasalena; Thermo Fisher Scientific, United States

Navigating the decision-making process for high-value instrumentation purchases has become increasingly complex and treacherous. While performance specifications play a crucial role in this process, it's important to avoid considering any single specification in a vacuum. Frequently, these specifications are tailored to highlight the superior performance of the advertised hardware, omitting key aspects/limitations that should be carefully considered in the decision-making process.
A new generation of ultra-high-brightness cold field emission guns (CFEGs) can deliver a current of more than 1 nanoamp into a sub-Angstrom sized beam. This level of coherent current performance is critical to meeting the demands of emerging camera and detector technologies, where short dwell times are needed for atomic resolution diffraction-based and analytical experiments.
Current detector technology poses challenges in meeting all requirements simultaneously. A trade-off must be made between selecting a fast detector or one capable of handling large currents.

Fast detectors tend to saturate quickly due to their limited current-handling capacity, while detectors capable of handling high currents tend to be slower. Rapid detectors that saturate at low currents fail to collect sufficient electrons for generating complete, low-noise images, often resulting in frames with negligible electron counts. This compromises the quality of the image or diffraction pattern obtained, making data processing more challenging. To address this, the concept of maximum usable imaging speed (MUIS [1]) has emerged, representing the fastest achievable detector speed that still produces the desired signal-to-noise ratio.
In this presentation, we will illustrate a few essential factors that should not be overlooked when deciding on instrumentation for conducting the widest range of experiments possible within the shortest timeframe. We will also illustrate the significance of selecting the appropriate electron source and sensors for specific experiments. Data will be presented using a microscope that can produce a coherent current exceeding 600 pA, coupled with a sensor capable of accommodating 1,000,000 electrons within a single pixel without saturation. Additionally, this sensor can handle ~20 nanoamps of current for a single frame readout. This combination provides the flexibility required for accurate quantification even at high beam currents, avoiding non-linear behavior and the challenges associated with frames containing only one or no electrons. The Maximum Usable Imaging Speed for such a complete system will be discussed, rather than just beam current, resolution or camera speed. New results of a flexible 30-300kV multimodal microscope system will be shown.

10:30 AM *CH04.05.04
Using Phase Contrast 4D-STEM to Solve 2D and 3D Nanostructures ColinOphus; Lawrence Berkeley National Laboratory, United States

Scanning transmission electron microscopy (STEM) has been successfully employed to image many materials at atomic resolution with techniques such as annular dark field (ADF), high angle ADF (HAADF), and annular bright field (ABF) imaging. Recently developed atomic electron tomography (AET) methods have been used to solve atomic resolution structures in 3D. However, these AET studies have relied on ADF imaging, which provides approximately linear and incoherent contrast. This makes the 3D tomographic reconstruction procedure robust and easy to apply, but it can only be used for materials with medium or high atomic numbers which can tolerate a high electron dose without damage, and can struggle to distinguish atoms with similar scattering profiles. Moving beyond these limitations will require more dose-efficient phase contrast imaging methods such as differential phase contrast (DPC) or ptychography, where computational imaging methods are used to solve for the complex probe in order to fully deconvolve it from the object. Ptychographic reconstruction algorithms can also correct for multiple scattering of the electron beam in order to reconstruct thicker samples which produce multiple scattering of the electron beam. In this talk, I will demonstrate the promise of ptychographic AET by solving the structure of a complex ZrTe nanowire embedded in a double walled carbon nanotube, and discuss how we can develop a general reconstruction framework incorporating any number of simultaneous measurement channels and performing joint reconstructions.

11:00 AM CH04.05.05
Unraveling Strain and Deformation in Two-Dimensional Materials: Insights from Nanobeam 4D-STEM YimoHan and ChuqiaoShi; Rice University, United States

Two-dimensional (2D) materials and their heterostructures have emerged as key components for innovative applications and exhibit unique properties distinct from bulk materials. Understanding the behavior of strain and deformation in 2D materials is crucial for their potential device applications and offers valuable insights into precisely engineering nano-scale strain in these layered materials. In this study, utilizing nanobeam four-dimensional scanning transmission electron microscopy (4D-STEM), we introduce novel approaches to investigate both in-plane and out-of-plane strain and deformation in 2D materials. Our findings reveal a new mechanism of strain relaxation in 2D materials through the formation of out-of-plane ripples. Additionally, we uncover how 2D materials employ long-range lattice rotation and confined nanoscale uniaxial strain to compensate for lattice mismatch, and we elucidate different stacking orders in van der Waals heterostructures mediated by interlayer strain effects.

11:15 AM *CH04.05.06
Optimized Detectors and Acquisition Modes for EELS, EFTEM and 4D-STEM Data Analysis RayD. Twesten and LiamSpillane; Gatan, United States

The number of electrons in a beam can be parsed in many ways, but the total flux of the beam is fixed. The finer you slice the time domain to increase acquisition speed, the fewer electrons you have at each data slice leaving you starved for counts. The same can be said for other data acquisition modes that parse the electrons into finer bins, such as increasing the energy dispersion to achieve better EELS resolution or reducing the energy selecting slit size to get sharper energy filtered images. The final limit of your experiment may not be the sensitivity or resolution of the hardware, but the Poisson or “shot” noise associated with counting discrete electron events. For a signal with N electrons in each bin, you can never have better noise than square root of N, which sets a limit to your data quality. Even for a perfect detector, if you want to double the signal to noise ratio of your data, you need to quadruple the number of electrons detected.

The advent of counting detectors for electrons has revolutionized electron microscopy in many ways, but they too cannot get around the Poisson limit. However, due to the fast readout rate, sharp point spread function and near zero added noise of these cameras, the traditional methods of acquiring electron microscopy data have been turned on their heads. In this presentation, we will discuss and illustrate the strategies for acquiring EELS, EFTEM and 4D STEM data using electron counting detectors to optimally use the fixed number of electrons available in the system. We will draw on examples from high-speed multimodal data acquisition and extreme low dose EELS fine structure analysis to demonstrate these strategies.

SESSION CH04.06: Four-dimensional Scanning Transmission Electron Microscopy II

1:30 PM *CH04.06.01
Exploiting Dynamical Scattering to Characterise Functional Materials JoanneEtheridge[1], WeiChao[1], WeilunLi[1], BryanEsser[1], EspenDrath Bojesen[2] and TimothyPetersen[1]; [1]Monash University, Australia; [2]Aarhus University, Denmark

Fast electrons interact strongly with the electrostatic potential of matter and are scattered “dynamically”. Put colloquially, this means that electrons scatter multiply within and between different scattering paths as they are transmitted within the specimen. Dynamical scattering can deliver a wealth of specimen information, such as the phase of a crystal structure factor, that is absent from experiments that are limited to single scattering.
Despite the complexity of dynamical scattering, under relevant conditions some properties of the specimen, such as electrostatic potential and symmetry, can be revealed in the distribution of scattered intensity as stable features, independent of experimental parameters, such as thickness or accelerating voltage. This is a consequence of mathematical structures, such as eigenvalue confluences, that are stable and embedded within the mathematics of dynamical scattering.

In this talk, we will explore how to exploit these features in the intensity distribution to measure different types of specimen information efficiently from various electron-optical configurations, including convergent beam electron diffraction (CBED) and four-dimensional scanning transmission electron microscopy (4D-STEM). We consider how to do this in different detection planes, providing access to coordinate, momentum and energy space and discuss the pros and cons in terms of information content, speed, and electron dose. We illustrate these approaches with applications to the measurement of structure, electronic structure and structural dynamics of functional materials, including photoactive and ferroic perovskites and plasmonic and semiconducting nanoparticle systems.

Fast 4D STEM with ARINA Hybrid-Pixel Detector DanielG. Stroppa; DECTRIS, Switzerland

characterization in both Materials Sciences and Life Sciences, particularly when beam-sensitive samples are involved [1]. The hybrid-pixel detector (HPD) concept [2] has the distinctive advantage of a flexible design with respect to the sensor material and electronics, allowing the direct electron detection and counting optimization for a range of TEM experimental parameters

(such as electron energy) and different applications.
Building on its successful HPD technology for X-ray detectors, DECTRIS fine-tuned its design to enable the precise detection of electrons. Its most recent development is an application-specific integrated circuit (ASIC) designed to allow read-out rates above 100 kHz and to perform electron counting up to 10 pA beam current per detector pixel with zero read-out noise [3]. ARINA detector combines this newly-designed ASIC with a flexible choice of sensor materials, an easy-to-use application programming interface (API), and a detector retraction mechanism, making it fit to most TEMs with electron energies from 30 to 300 keV and 4D STEM experiments requirements. Initial tests show that ARINA is suitable for flexible virtual STEM imaging with dwell time below 10 µs, allowing for flexible differential phase contrast (DPC) with atomic resolution, and electron diffraction experiments with high dynamic range for crystal phase/orientation mapping.

Atomic Resolution Inline Holography of Quantum Materials Jian-MinZuo[1], Hsu-ChihNi[1] and JiongZhang[2]; [1]University of Illinois-Urbana-Champ, United States; [2]Intel Corporation, United States

Characterization plays a critical role in the discovery of quantum materials, which is still challenging despite tremendous progress being made during past decades. Extending the study of point defects from 2D materials to crystals and thin films, probing novel charge states and complex structures, for example, are all difficult problems that require novel characterization approaches. Here we explore inline holography for quantitative defect imaging and defect analysis based on the collection and analysis of coherent convergent beam electron diffraction (CBED) patterns using an aberration corrected electron probe. At large convergence angles, the CBED patterns can be considered as Gabor's inline hologram formed by a spherical wave, while at smaller convergence interference between CBED disks provide phase information that forms the basis for electron ptychography[1,2]. With fast electron detectors, four-dimensional (4D, two-dimensional scan and diffraction pattern) diffraction data as in 4D-STEM can be collected efficiently with high signal/noise ratio[3]. All of these provide fertile ground for revisiting Gabor's original idea of inline holography. This talk will highlight our recent progress in developing atomic resolution inline holography using the combination of an aberration corrected STEM and EMPAD detector. Examples will be provided related to point defect detection in heavily doped semiconductors. The experimental study will be compared to dynamical diffraction simulations. The reconstruction algorithms will be proposed and discussed, as well as prospects[4].

4D-STEM Characterization of MBE-Grown Barium Titanate for Electro-Optic and Ferroelectric Devices AshleyCavanagh, LarissaLittle, CharlesBrooks, JulesGardener, JuliaMundy and RobertWestervelt; Harvard University, United States

Synthesis and characterization of thin film barium titanate is of great interest due to its promise for use in electro-optic modulators [1]. These devices require a thin film with a high electro-optic coefficient that can operate at low voltages and integrate into photonic circuits, so barium titanate's strong nonlinearity makes it an attractive candidate material. Barium titanate's ferroelectricity means that it is also of interest for applications in nonvolatile ferroelectric memories. To pursue these applications, we must understand how variations in film stoichiometry affect the electro-optic properties, local atomic structure, and ferroelectric structure of thin film barium titanate. In this work, we use four dimensional scanning transmission electron microscopy (4D-STEM) and high-resolution imaging techniques to analyze the crystal structure thin films of barium titanate grown via molecular beam epitaxy. 4D-STEM can detect small movements of an electron beam due to local electric fields and therefore image the ferroelectric domains in barium titanate. High-resolution electron microscopy imaging allows us to evaluate atomic-level variations in crystal structure, local defects, and polarization in thin films of barium titanate.

Understanding Antiferroelectric Thin Film Structure-Property Relationships with Emerging Scanning Transmission Electron Microscopy Techniques JamesM. LeBeau; Massachusetts Institute of Technology, United States

Although antiferroelectric materials have been studied for decades, they have gained renewed interest for potential applications in energy storage, actuation, and non-volatile memory. This is enabled by the polar behavior of AFEs, where the antiparallel alternation can be switched to lie in the same direction with a sufficiently strong electric field — i.e. an AFE to ferroelectric transition. Moreover, thin film growth of antiferroelectrics, including PbZrO3 (PZO) and Pb_2MgWO_6 (PMW), has been pursued to modify the properties of this transition and offers many new tantalizing opportunities to engineer the behavior of these materials. To further gain insights, direct investigations of the transformation mechanisms responsible will be key.

In this talk, we will highlight our results from ex and in situ aberration-corrected scanning transmission electron microscopy (STEM) studies of PZO and PMW thin films. In particular, we will focus on insights into the AFE-FE phase transformations during biasing of thin film PbZrO3. We will discuss the details of polarization switching and the evolution of domain structure, shedding light on the underlying mechanisms and defects governing the behavior. The role of strain, measured with cepstral analysis, and thin film growth orientation will also be explored to determine their impacts on the antiferroelectric/ferroelectric transition.

We will also highlight results from multislice electron ptychography to characterize chemical order and disorder in PMW, specifically at antiphase boundaries. By characterizing and mapping these boundaries, we gain a deeper understanding of their influence on local polarization and implications for polarization switching. Overall, STEM analysis provides critical insights into the defect/structure relationships and the impact of intrinsic and extrinsic factors on the behavior of antiferroelectric materials.

4:00 PM CH04.06.06
Joint Ptychographic-Tomographic 3D Reconstruction of Perovskite Nanowires in Carbon Nanotubes HannahDevyldere[1], GeorgiosVarnavides[1,2], StephanieRibet[2], YuxinJiang[1,2], ColinOphus[2], PeidongYang[1,2] and MaryScott[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Atomic-resolution electron tomography (AET) can be used to recover the 3D locations of atoms within nanomaterials without crystal priors from a set of 2D projections. However, AET requires precise subpixel alignments as well as exact tilt angles for each tomogram, limiting its applicability since these parameters are often not obtainable experimentally and must instead be solved for during the reconstruction process [1]. Additionally, experimentally-demonstrated atomic resolution tomographic reconstructions have thus far utilized high angle annular dark field projections - a dose inefficient imaging technique which limits the resolution for low scattering elements. Electron ptychography is a phase-retrieval technique capable of providing high resolution imaging of light elements at comparatively low dose [2]. Importantly, multislice electron ptychography has recently been shown to use the redundant information in overlapping illuminated regions to recover nonlinear information along the axis of projection [3]. The resolution along this "depth-sectioning" direction however, is limited by the lack of diverse angular information in a typical converged probe experiment, and thus not suitable for atomic resolution 3D reconstructions [4].

More recently, these two techniques have been combined in a serial fashion, whereby 2D ptychographic reconstructions are then utilized in 3D tomographic algorithms, enabling a unit cell averaged atomic resolution reconstruction of both low-z and high-z elements [5]. While this enables the efficient transfer of nonlinear information through the multislice propagator, it makes limited use of information redundancy across the tilt-series.

Conversely, the ptychography and tomography inverse problems can be solved jointly - reconstructing the volume directly from the tilt-series of 4D diffraction datasets. Here, we report on experimental results for a joint ptychographic-tomographic 3D reconstruction of perovskite nanowires encapsulated by carbon nanotubes [6]. We discuss the sensitivity of the technique in reconstructing the light carbon atoms of the nanotube and show how efficient regularization of the volume helps recover information in the missing wedge direction.

Development of Fast Direct Detectors for 4D STEM, *In Situ* TEM, and Other ApplicationsBarnabyD. Levin; Direct Electron LP, United States

Advanced transmission electron microscopy (TEM) techniques such as four-dimensional scanning TEM (4D STEM), and *in situ* TEM, require detectors with fast imaging speeds and single-electron sensitivity. Direct Electron has recently developed new fast direct detectors to meet the needs of these advanced applications.

Celeritas and Celeritas XS are 1024 x 1024 pixel detectors that are designed for extremely high frame-rate readout. The Celeritas XS detector can generate images at speeds of up to 87,000 frames per second, when reading out a small central region. For applications such as 4D STEM, this allows high-throughput data collection at speeds approaching conventional 2D STEM. Celeritas XS has recently applied to study the local ordering in amorphous materials such as molecular glasses [1], and metallic glasses [2]. When coupled with a programmable DE FreeScan scan generator, these detectors can be used to explore novel scanning techniques to collect data more efficiently.

The Apollo detector is a 4096 x 4096 pixel detector that has, to date, primarily been used for biological TEM imaging applications [3,4]. Apollo may also be promising for TEM imaging of beam sensitive materials such as polymers. Apollo uses a unique event-based readout method [5] to generate electron counting images with greater data efficiency than previous frame-based detectors, which helps to minimize coincidence loss, maximize detective quantum efficiency, and reduces the detector's cost.

Here, we will discuss the development of these detectors and a variety of potential applications, including 4D STEM and in situ TEM.

Multimodal Electron Microscopy for Unravelling Structure-Coherence Relationships in Superconducting Quantum Materials and Systems ThangPham[1,2], MatthewCheng[1,2], DominicGoronzy[1,2], CameronKopas[3], HilalCansizogu[3], JoshMutus[3], Robertodos Reis[1,4], MarkC. Hersam[1,1,1] and VinayakDravid[1,4,2]; [1]Northwestern University, United States; [2]Superconducting Quantum Materials and Systems (SQMS), United States; [3]Rigetti Computing, United States; [4]NUANCE-Northwestern University, United States

The quest to build quantum computers requires coordinated advances in materials science, device fabrication, and quantum architecture. Recently, superconducting qubits based on transmons have achieved coherence times on the order of hundreds of microseconds, but additional improvements are needed to achieve reliable and high-fidelity quantum computing that can outcompete conventional digital computing. The difficulties in understanding the structure-coherence relationships in transmons stem from the complex nature of different interfaces in the device, such as the metal-air, metal-dielectric, and metal substrate interfaces in Josephson junctions (JJs), which are believe to host two-level-system loss channels.
This talk will present our recent efforts to elucidate structure-coherence relationships using multimodal electron microscopy in two interfaces in JJs – namely the Al-AlOx and Al-Si substrate interfaces. We combine core-loss electron energy loss spectroscopy (EELS) and four-dimensional scanning transmission electron microscopy (4D-STEM) at cryogenic temperatures to investigate the chemical composition, bonding environment, and nanoscale structure of Al-AlOx and Al-Si interfaces. These electron microscopy findings are correlated with electrical characterization and theoretical calculations to provide a comprehensive understanding of the influences of atomic-scale quantum disorder on coherence time, which can help inform efforts to mitigate decoherence sources in superconducting qubit devices.

SESSION CH04.07: Electron Energy Loss Spectroscopy I

8:00 AM *CH04.07.01
Demystifying Quantum Phenomena at Functional Oxide InterfacesY. ErenSuyolcu[1,2], Yu-MiWu[1], NicolasBonmassar[1], GennadyLogvenov[1] and PeterA. Van Aken[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]Cornell University, United States

Quantum materials possess extraordinary properties making them highly promising for next-generation electronic devices and quantum information processing. Among these materials, transition metal oxide heterostructures provide a versatile playground for quantum phenomena, including high-temperature superconductivity, magnetism, and metal-to-insulator transition. The origin of these phenomena is the competition between different degrees of freedom, such as charge, orbital, and spin, which are interrelated with the crystal structure, the oxygen stoichiometry, and the doping dependence. Therefore, understanding the intricate structure-property relationship in these materials is crucial for harnessing their full potential.
The unique combination of aberration-corrected scanning transmission electron microscopy (STEM) and oxide molecular beam epitaxy (MBE) techniques allows the engineering of novel interface properties with precise control at the atomic scale[1]. Combining different oxide layers through heterostructural design opens access to interface physics and leads to engineering interface properties, where the degrees of freedom can be artificially modified. In this talk, I will focus on complex oxide interfaces with extraordinary structural quality and properties. We designed cuprate–manganite interfaces using oxide MBE and focused on interface superconductivity compared to cuprate–cuprate interfaces[2–4] and tuning interfacial magnetism[5]. The interfaces are extensively probed with STEM techniques, including high-angle annular dark-field (HAADF) and annular bright-field (ABF) imaging, electron energy-loss spectroscopy (EELS), and energy-dispersive X-ray spectroscopy (EDXS). High-resolution STEM investigations provide crucial feedback to improve structural quality and a detailed understanding of the properties.
Through different epitaxial designs, we demonstrate that *(i)* charge transfer and local magnetism can be tuned by epitaxial strain[5], *(ii)* sharper interfaces can be realized by pushing the interface superconductivity down to one monolayer thickness but with a cost of filamentary superconducting behavior[6] and, *(iii)* how superconductivity can be tuned via epitaxial integration of ultra-thin 214-manganate slabs[7]. Notably, our investigations further underline that the sharpness of interfaces requires a meticulous definition: Structurally perfect and coherent interfaces may exhibit dissimilar chemical sharpness, ascribed to the elemental intermixing that dominates the physical properties. In summary, our research showcases the remarkable potential of quantum materials and highlights the crucial role of STEM techniques in unraveling their properties and designing interfaces for next-generation electronic devices and quantum information processing systems[8,9].

8:30 AM CH04.07.02
Harnessing the Power of Defect Engineering: Unveiling Oxygen Vacancies in 2D Indium Oxide for Advanced Memory Regions and Pioneering 2D Materials Discovery Kuan-HungChen[1], Chang HsunHuang[1], Chen-ChihHsiang[1], Chia-YiWu[2], Yi-HsiangYen[1] and Yi-ChiaChou[1]; [1]National Taiwan University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

The rapid progress in the field of two-dimensional (2D) materials has revolutionized various industries and paved the way for exciting advancements in technology. These materials, with their unique properties and atomic-level thickness, hold immense potential for applications in electronics, optoelectronics, and beyond. To harness the full capabilities of 2D materials, it is crucial to develop effective fabrication techniques that enable their synthesis and manipulation. Among the range of techniques available for the fabrication of 2D materials, liquid metal printing (LMP) has emerged as an innovative approach. This method allows for fast, low-temperature, low-cost, and high-quality exfoliation of metal oxides with atomic-level precision.
One particular 2D material that has attracted significant attention is indium oxide (InO_x). InO_x is a wide bandgap material with remarkable structural stability and tunable electronic properties, making it highly desirable for applications in metal oxide semiconductors. However, the exploration of InO_x in 2D forms remains uncharted territory, presenting a compelling avenue for further development. In the realm of nanoscale memristive devices, the engineering of defects plays a critical role in tailoring the electronic performance. Conducting filaments in insulating oxides, which are essential for memristive behavior, rely on the field-induced migration of oxygen vacancies within the material[1]. Recent studies by Huang et al. shed light on the influence of printing temperatures on the electrical properties of 2D-InO_x. By altering the printing temperatures, they observed variations in the concentration of oxygen vacancies, leading to the presence or disappearance of memristive switching[2].
Building upon this prior research, the present study aims to investigate the defect characteristics of 2D-InO_x in more detail. To achieve this, X-ray photoelectron spectroscopy (XPS) and photoluminescence (PL) were employed. The results revealed that higher printing temperatures led to an increase in the concentration of oxygen vacancies, suggesting that the defect characteristics can be tailored through precise control of the fabrication process. Additionally, the microstructure and crystallinity of 2D-InO_x were analyzed using transmission electron microscopy (TEM) and selected area diffraction patterns (SADP). To gain further insight into the atomic arrangement and defect structures of 2D-InO_x, spherical aberration corrected scanning transmission electron microscopy (Cs-corrected STEM) and electron energy loss spectroscopy (EELS) were employed. STEM provides high-resolution images with atomic-level details, enabling the visualization and analysis of crystallographic features, grain boundaries, and defect structures. EELS measurements, on the other hand, offer information about the electronic properties and local chemical environment of the material. Notably, an observable shift in the In-$M_{4,5}$ and O-K peaks indicated a preferential segregation of oxygen vacancies at grain boundaries. Peak ratio calculations based on the EELS spectra also provided quantitative information about the defect concentration in 2D-InO_x. Surprisingly, the results suggested a higher defect concentration in 2D-InO_x printed at lower temperatures. The deeper insights gained from this study into the exact nature of oxygen defects and the ability to modify the concentration of oxygen vacancies in atomically-thin oxide films are of great significance. By tailoring defects, researchers can unlock the full potential of 2D-InO_x and pave the way for next-generation memory devices with enhanced performance, energy efficiency, and functional capabilities.

Lanthanide–Transition Metal Intermetallics Studied by Electron Energy Loss Spectroscopy EllisKennedy[1], TrentKyrk[2], SelinCetin[1], MoisesBravo[2], GregoryMcCandless[2], ColinOphus[3], JuliaChan[2] and MaryScott[1,3]; [1]University of California, Berkeley, United States; [2]Baylor University, United States; [3]Lawrence Berkeley National Laboratory, United States

The valence states of *f*-block elements strongly influence their magnetic quantum states. Lanthanide (Ln) transition metal (M) intermetallics in particular have been shown to host a variety of quantum properties, such as charge density waves, Kondo lattice behavior, fluctuating valency, and unconventional superconductivity[1]. These distinctive characteristics result from interplay between itinerant *d*-electrons and more localized *f*-electrons. While the basic model of Ln+M intermetallics consists of delocalized *3d* electrons interacting with localized *4f* orbitals, recent work shows that the tight binding description of *f*-electron materials is not accurate in some cases[2]. The ability to alter valency and *f*-electron itinerancy presents an opportunity to study magnetism in quantum materials as well as tune the degree of correlation. Furthermore, the breakdown of the tight binding model implies that crystal field interactions may play an important role in directing the properties of Lanthanide compounds[3]. The ability to modify the Ln valency through adjustments in composition, local coordination, or crystal phase therefore provides an excellent platform for the exploration and development of new materials with tunable and coexisting quantum properties.

Here, we probe the relationship between valency and crystal structure by coupling electron energy loss spectroscopy (EELS) with detailed structural characterization. We apply these methods to intermetallics with composition $Ln_2Co_3Ge_5$. Using *in-situ* monochromated EELS, we detect a strong dependence of the Pr valency in $Pr_2Co_3Ge_5$ as it undergoes a subtle structural transition from a monoclinic (m) to orthorhombic (o) phase. This alteration of the Pr environment from o-$Pr_2Co_3Ge_5$ to m-$Pr_2Co_3Ge_5$ is expected to influence the crystal electric field splitting of the Pr *4f* orbital, and therefore likely plays a role in the observed complex magnetic transitions in this material[4]. The density of unoccupied states of Co are redistributed during the phase transition as well, suggesting compensating behavior between the Co *3d* and Pr *4f* electrons. Similarly, we combine high resolution transmission electron microscopy and spatially resolved EELS measurements to determine the influence of twin boundaries in monoclinic $Sm_2Co_3Ge_5$. Although the deviation of the twins from the bulk crystal structure is not large, these local distortions of the crystal periodicity are shown to increase the hybridization of the delocalized Co *3d* electrons. As the magnetic moment of this material cannot be accounted for by Co alone, we expect that changes in Co hybridization at the twin boundaries will influence the bulk magnetic properties.

Our observations directly relate the electronic states of the Ln and Co ions in $Ln_2Co_3Ge_5$ compounds to their local crystal environment. These results directly show the relationship between the valency of the lanthanides and their local environment in the crystal structure, which are ultimately factors that direct their role in the material's quantum properties. Both of the observations illustrate the tunability of properties that is introduced by the complex behavior of *f*-electrons in the $Ln_2Co_3Ge_5$ of intermetallics, and point to the rich landscape of quantum phenomena available for exploration in these materials.

Backscattered Electron Energy Loss Spectroscopy with an Analytical High-Resolution Ultra-Low-Voltage SEM DanielRyklin[1], JochenKammerer[2] and RasmusSchroeder[1]; [1]Heidelberg University, Germany; [2]Queensland University of Technology, Australia

In scanning transmission electron microscopy (STEM) electron energy loss spectroscopy (EELS) is a well-established high resolution analytical characterization technique for a large range of materials and applications. However, the required sample dimension (i.e. < 100 nm thickness) is a limiting factor and often makes sample preparation rather challenging. Furthermore, beam-induced sample degradation at typical TEM electron energies is hampering the observation of beam-sensitive materials. The realization of EELS at very low electron landing energies on bulk materials, however, would definitely provide a completely new characterization tool – from simple materials identification to dynamic in-situ studies, such as plasmon excitations by electrons or light.

Using a prototype of an aberration corrected, ultra-low-energy SEM (Zeiss Delta-SEM [1]) modified with an electrostatic energy-selective detector, we show for the first time that it is possible to identify the excitation of states (e.g., plasmon and fluorescence excitations) in a SEM by their typical excitation energy loss signature in the energy spectrum of the backscattered electrons. We call this new analytical signal backscattered electron energy loss spectroscopy (bsEELS).

As initial model system we analyze the spectral data obtained from graphene on silicon wafer, materials where TEM-EELS measurements can serve as a reference [2,3]. The measured bsEEL spectra can be simulated in the framework of a naïve model which convolves TEM-EELS data with the energy response of the energy-selective detector. Although the energy resolution of our current experimental setup is limited (about 5 eV), we find good agreement of the experimental SEM-bsEELS spectral data to, e.g., the known characteristic surface plasmon signal of

graphene. This is the first experimental evidence that backscattered electrons carry specific material information resulting from their elastic and inelastic interaction with the sample. Applying this to an organic PBDB-T:ITIC blend for solar cells we can use the plasmon loss signals in the bsEEL spectra to identify and distinguish the two materials inside the blend to create a surface map of the material distribution.
Using bsEELS relaxes constraints on the sample preparation (thickness, size) while aberration correction allows to use ultra-low electron landing energies, comparable to energies usually used for high-resolution EELS. We show that contrast and imaging quality are significantly improved for electron energies below 500 eV (as far down as 20 eV) – while retaining high spatial resolution (< 1 nm at 100 eV).
To prove the high sensitivity of this novel imaging modality we study organic samples such as DNA and DNA labelled with fluorophores. The results show that at ultra-low electron energies beam damage is minimized and that contrast is strongly increased for organic, low atomic number materials. First results of bsEELS on DNA origamis with 12 covalently bound fluorophore molecules reveal a pronounced signal for the DNA's UV absorption as well as the excitation signal of the fluorophores.

HAADF-STEM and EELS Characterization of Stoichiometry and Defects in the Pyrochlore Quantum Magnet $Tb_2Ti_2O_7$MargaretA. Anderson, JohannaNordlander, IsmailEl Baggari, CharlesBrooks and JuliaMundy; Harvard University, United States

Quantum spin liquids, highly entangled magnetic materials which lack a long-range symmetry-breaking ordering transition down to absolute zero, host anyonic quasiparticles that are promising platforms for quantum computing. The quantum spin liquid state results from magnetic frustration, which relies on a careful balance of magnetic interactions. Defects in the crystal structure disrupt this balance and may obscure the intrinsic spin liquid behavior in candidate materials. Using reactive-oxide molecular beam epitaxy, we synthesize a series of thin films of the pyrochlore quantum spin liquid candidate $Tb_2Ti_2O_7$ with varying composition on YSZ (111) substrates. We use scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) to observe and characterize point and extended defects in this composition series. We present the first atomic-resolution EELS maps that directly show excess titanium incorporated via 'antistuffing' on the terbium site as both Ti^{3+} and Ti^{4+} along {1 1 1} antiphase boundaries. Using multivariate curve resolution (MCR), we map out changes in valence and in the titanium *L*-edge structure across these defects. In contrast, we find that terbium-rich films exhibit mainly {2 -1 -1} antiphase boundaries. Using phase lock-in analysis, we reveal quasi-periodic dislocations along the film-substrate interface that act to relieve strain in nominally stoichiometric films. Finally, we characterize the films' magnetic behavior with SQUID magnetometry. While none of the films exhibit a magnetic transition down to 1.8 K, the magnetization is impacted by the presence of defect spins in the off-composition films.

Wavefront Shaping in the TEM: What Promise Does it Hold for Materials Characterisation?JohanVerbeeck and Chu-PingYu; EMAT, University of Antwerp, Belgium

Wavefront shaping or the ability to freely change the phase of a coherent wave is a powerful concept in diverse areas of science ranging e.g. from light optics, telecommunication, radar, acoustics and seismology. The ability to freely shape the wavefront of a coherent electron wave in transmission electron microscopy has become a recent possibility with our 48 pixel array of electrostatic phase shifters that cen be placed in an aperture position of a modern electron microscope. This changes the paradigm from attempting to make ever smaller probe sizes for spatial resolution to create a large basis set of orthogonal quantum states to interact with a sample. We discuss several potential applications of this new tool with proof of concept implementation and simulations. Such applications can include increased selectivity in probing EELS excitations based on symmetry selection, adaptive optics providing high contrast images while dynamically correcting aberrations and bringing out relevant (eg phase) contrast. It also helps for inverse problems in ptychography and diffraction problems where the phase control over the incoming beam can break point symmetry and make it easier for inverse algorithms to converge to a single solution.

Advances in High Energy and Spatial Resolution STEM EELS DemieKepaptsoglou[1,2], KhalilEl Hajraoui[1,2], MatthieuBugnet[1,3], GuillaumeRadtke[4], MicheleLazzeri[4], VladoLazarov[2], JanRusz[5] and QuentinRamasse[1,6]; [1]SuperSTEM, United Kingdom; [2]University of York, United Kingdom; [3]Institut National des Sciences Appliquées de Lyon, France; [4]Sorbonne Université, France; [5]Uppsala University, Sweden; [6]University of Leeds, United Kingdom

Engineering the structural or chemical architecture of functional materials at the nano or even atomic level enables emergent properties that rely on the interplay between fundamental properties of matter such as charge, spin and local atomic-scale chemistry. Thanks to advances in monochromators, state-of-the-art electron energy loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM), offers nowadays the ability to map materials and atomic structures with an angstrom size electron beam and an energy resolution for EELS under 5meV. (Krivanek *et al.*, 2014) These capabilities have allowed to probe the spectroscopic signature of phonons down to the single atom level. (Hage *et al.*, 2020) Here, we present strategies for high spatial and energy resolution STEM-EELS experiments to interrogate proximity effects of heterostructure materials at the atomic scale and present opportunities for new experiments using monochromated electron probes.
Bi_2Se_3 is a topological insulator (TI) with topologically protected helical two-dimensional surface states and one-dimensional bulk states associated with crystal defects, in proximity with graphene. The strong spin-orbit interaction and proximity effects result in subtle and controllable electronic band structure changes at and near the interface, with exciting potential for spintronic applications. Here we probe at high energy resolution the interfaces in a system consisting of Bi_2Se_3 films grown by chemical vapor deposition on epitaxial graphene/SiC(0001), where the number of carbon layers can be carefully controlled to tune possible proximity effects between the film and the substrate. In addition to a direct interrogation of the chemical bonds (Bugnet *et al.*, 2022) between the layers via their vibrational response, these observations are linked to the interplay between the various phonon modes and the Dirac plasmons in the TI layers, whose dispersion is mapped in momentum space with nm spatial sensitivity using a recently developed methodology for nanoscale momentum-resolved spectroscopy.
Magnonics is an emergent field within spintronics utilizing the ability to generate and propagate controllably a spin-wave in nm-sized magnetic structures, with a view to build a new generation of devices for data processing and storage. It was also recently demonstrated that magnons can be utilized to convert spin to charge (or charge to spin) currents, a critical step for integration of spin and charge devices. STEM EELS is proposed to be a leading candidate technique to attempt the detection of magnons at the nanoscale, perhaps down to at the atomic scale, thanks to a recently developed theoretical calculation framework and preliminary experimental investigations (Lyon *et al.*, 2021). Here, we report on progress in designing experiments building on these initial steps using in-situ STEM-EELS. The prototypical spin-to-charge conversion system considered for this proof of principle attempt consists of Yttrium Iron Garnet (YIG)/platinum (Pt) bilayer, a widely used materials combination where a magnon created by a thermal gradient creates spin accumulation at the YIG/Pt interface, which subsequently diffuses into the nonmagnetic Pt, and via inverse spin Hall effect (ISHE) creates a voltage signal in the Pt layer.

Vibrational and Electronic Structure of Superlattices using Monochromated Electron Energy-Loss spectroscopy EricR. Hoglund[1], De-LiangBao[2], HarrisonWalker[2], Mahmut SamiKavrik[3,4], GeeminKim[5], MattLaw[5,5,5], PatrickE. Hopkins[6,6], SokratesT. Pantelides[2,2] and JordanA. Hachtel[1]; [1]Oak Ridge National Laboratory, United States; [2]Vanderbilt University, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]University of California, San Diego, United States; [5]University of California, Irvine, United States; [6]University of Virginia, United States

Many quantum phenomena emerge from reducing the size of materials and therefore increasing the discretization of quantum states. When multiple materials of reduced size are combined into heterostructures, their interaction results in new emergent states at the interface between the materials that can be as prevalent as bulk-like state that are intrinsic to the lattice of the parent materials. These interface states can result in new optical, thermal, or electronic properties. Herein, we demonstrate structure-vibration and structure-electronic relations resulting from the formation of superlattices using scanning transmission electron microscopy (STEM) imaging combined with monochromated electron energy-loss spectroscopy (EELS) and density-

functional-theory calculations.

To design properties dictated by atomic vibrations at interfaces in an informed manner, we need to probe vibrations with lateral spatial resolution to resolve the local vibrations. We connect the localized vibrational response of interfaces in $SrTiO_3$-$CaTiO_3$ superlattices observed with EELS to the structurally diffuse interfaces observed with integrated differential-phase contrast. As the layer thickness of the superlattices decrease, the interface structure extends further into the layers and the related vibrations. The progression of the local atomic structure and interface vibrations come to determine the vibrational response of an entire superlattice, which explains new infrared activity and crossovers from incoherent to coherent thermal transport observed in the superlattices.

In ferroelectric superlattices phonon modes linked with static atomic displacements can spatially vary, in particular at the interfaces. Here we will show that the structurally non-equivalent interfaces in a period are also vibrationally non-equivalent as a result of different coupling between the lattice and electronic structure at the different interfaces.

Lastly, we will concentrate on the emergence of new electronic states in self-assembled quantum dot superlattices. Quantum dots can exhibit unique excitonic behavior and quantized electronic states that result from the limited number of atoms in the material. Recently, epitaxially fused superlattice of PbSe QD film show delocalized states, which are not derivative of bulk materials. However, this “confined” but “connected” structure results in new electronic behavior that is sensitive to defects in different length scale lattices, such as missing or undercoordinated QDs (superlattice) and point defects in the necks between fused QDs (atomic). We will show the connection between the electronic and structural properties across both length-scales and the impact of defects using cryogenic high-spatial and spectral resolution STEM-EELS.

Probing Excitations and Structures by Ultrafast Electron Microscopy ClausRopers[1,2] and Jan-WilkeHenke[1]; [1]Max Planck Institute for Multidisciplinary Sciences, Germany; [2]University of Göttingen, Germany

Providing the most detailed views of atomic-scale structure and composition, transmission electron microscopy serves as an indispensable tool for structural biology and materials science. The combination of electron microscopy with pulsed electrical or optical stimuli allows for the study of transient phenomena, involving magnetization dynamics, strain evolution and structural phase transformations. Ultrafast transmission electron microscopy (UTEM) is a pump-probe technique, in which non-equilibrium processes can be tracked with simultaneous femtosecond temporal and nanometer to atomic-scale spatial resolutions.
This talk will cover recent methodical developments and applications in UTEM based on laser-triggered field emitters, including real-space imaging [1] and ultrafast nanobeam diffraction [2] of structural phase transitions. Moreover, the mechanisms involved in free-electron beams interacting with optical fields at photonic structures will be discussed, emphasizing quantum effects. In particular, recent progress in the coupling of electron beams to whispering gallery modes [3] and integrated photonic resonators [4] will be presented. Finally, using event-based electron spectroscopy, the preparation and characterization of electron-photon pair states [5] and Coulomb-correlated electron number states [6] will be discussed.

2:00 PM *CH04.08.02
STEM Developments: Atomic-Resolution SE Imaging, Fast 4D STEM, Ultrahigh Energy Resolution TracyC. Lovejoy[1], NikalasDelby[1], ChrisMeyer[1], MichaelHoltz[1], JoelMartis[1], AndreasMittelberger[1], BenPlotkin-Swing[1], StevenQuillin[1] and OndrejKrivanek[1,2]; [1]Nion R&D, United States; [2]Arizona State University, United States

A modern STEM can achieve atomic-scale spatial resolution (1.1 Å) and phonon-scale energy resolution (2.6 meV) at 20 keV primary energy [1], and improved spatial but worsened energy resolutions at higher keV. These capabilities come from advanced electron-optical instrumentation, such as monochromators, correctors, and spectrometers. In parallel developments, many researchers are turning attention to combining advanced electron-optical capabilities with new developments in, detectors, software, and operating modes.

A new type of secondary electron (SE) detector designed by Nion for a modern STEM combines SE detection with an atom-sized probe in the operating range 20-200 kV, clean (metal-sealed and bakable) UHV vacuum conditions, and state-of-the-art electron energy loss spectroscopy (EELS) and 4D-STEM capabilities [2,3]. Running experience reveals that common S/TEM samples (e.g. MoS2 or metal nanoparticles on a carbon film) that give atomic-resolution annual dark field (ADF) images initially show only surface contamination in the SE signal. We use multiple methods for UHV surface cleaning, including resistive heating of the whole sample in a side entry holder (e.g. Protochips) and direct laser illumination of a small spot (20 µm x 40 µm). Direct laser illumination is particularly interesting because the laser light modulates the SE signal in some samples by changing the local charge distribution on the surface [4].

After cleaning, atomic-resolution SE signals are readily visible. Expanding on previous work with atomic-resolution SE imaging [5], lower operation voltage in a modern STEM avoids knock-on damage and enables atomic-resolution SE studies of 2D materials. We will show an example combining atomic resolution ADF, SE, and 4D-STEM to study monolayer MoS2 with intentional Vanadium dopants at 60 keV primary energy.

4D-STEM and especially EELS experiments on 2D materials have traditionally been complicated by slow detectors and readout noise. The latest direct detectors avoid readout noise and achieve high DQE and dynamic range with speed approaching that of traditional single-channel detectors (>10,000 frames/second). Combining these detectors with powerful open-source software for smart acquisition/compression and live processing makes multi-frame (time series) 4D-STEM or EELS imaging possible, bringing significant advantages when changing the sample environment (e.g. heating, cooling, light-, or gas-injection) causes sample drift that makes longer exposures impractical.

Doing these experiments in an instrument capable of <5 meV energy resolution opens the door for synergistic experiments such as mapping the absolute temperature of the sample in and around the spot illuminated by a laser using electron energy gain spectroscopy [6], and measuring the presence and local bonding configuration of hydrogen in the sample by detecting the “infrared absorption” signal of the H bonds with vibrational EELS [7]. Phonon spectroscopy of surface dopants visible in the SE signal is also very promising.

Momentum-Resolved Electron Spectroscopy of Kagome Crystal YCr_6Ge_6BabafemiS. Agboola, JonahGautreau, GraemeLuke and Maureen JoelLagos; McMaster University, Canada

The YCr_6Ge_6 Kagome crystal exhibits unique electronic band structure like flat bands[1] which drive quantum properties (e.g. flat band ferromagnetism, superconductivity). YCr_6Ge_6 can also sustain plasmons and their behavior is driven by the complex electronic structure of the Kagome crystal. Material synthesis and characterization of structural and plasmonic properties are challenging and in progress. Here we report on the synthesis of YCr_6Ge_6 Kagome crystals and on the dispersion behavior of anisotropic bulk plasmons using momentum-resolved EELS.

We grew single crystals of YCr_6Ge_6 with the flux method and TEM/STEM methodologies (e.g., diffraction and imaging) were used to obtain structural information. The electron diffraction patterns obtained from different micrometer-sized regions revealed a single crystalline phase. Furthermore, atomic-resolution imaging was performed in STEM mode to spatially identify the hexagonal close pack crystal structure and the Kagome lattice structural profile. We also conducted spatially resolved core-loss EELS experiments to identify the chemical composition of the crystal and valence states of the Kagome crystal. EELS spectrum images were collected at different ionization edge energies (e.g. Cr $L_{2,3}$), revealing different degrees of scattering delocalization.
We studied the dispersion of bulk plasmons along the orthogonal ΓA and ΓM dispersion directions, accessing plasmon behavior beyond the first Brillouin zone. We found anisotropic response of bulk plasmons, dispersing with different velocities along the high symmetry directions. Anomalous non-linear dispersion is also visualized suggesting a complex behavior of valence electrons. Our work represents progress towards understanding the complex electronic behavior of anisotropic plasmons sustained in quantum materials.

3:30 PM *CH04.09.01
Recent Advances in Cathodoluminescence Spectroscopy and in-TEM Light Injection ChristianMonachon; Attolight AG, Switzerland

Cathodoluminescence spectroscopy is a technique consisting in the analysis of the light emitted in the UV-IR range by a material upon its excitation with an electron beam. This technique is particularly useful in semiconductors, where it allows local probing of the material properties such as quantum well properties, dopant concentration, or alloy composition. Another of its exciting prospects is plasmonics, where it allows direct modal probing of nanostructures.

Several new developments and technical improvements make it more flexible than ever, and open the way for unparalleled light injection densities. This contribution will treat the technological choices made at Attolight in order to foster ever better and more consistent results, in particular in terms of mirror architecture vs collection efficiency, as well as field of view. Necessary constraints on the electron microscope will also be reviewed and explained in order to outline the capabilities as well as limits of light injection and collection in a STEM.

4:00 PM *CH04.09.02
Time Resolved Cathodoluminescence of InGaN/GaN Quantum Well in an Ultrafast Transmission Electron Microscope CléoSantini[1], LuizTizei[2], DelphineLagarde[3], RobinCours[1], SebastienWeber[1], AlexeiV. Sakharov[4], AndreyF. Tsatsulnikov[4], AndreyE. Nikolaev[4], ArnaudArbouet[1], MathieuKociak[2], AndreaBalocchi[3], NikolayCherkashin[1] and SophieMeuret[1]; [1]CEMES/CNRS, Netherlands; [2]Université Paris-Saclay, France; [3]LPCNO, France; [4]Ioffe Institute, Russian Federation

Cathodoluminescence is the emission of visible light when an electron interacts with matter. It is a powerful technique to study the luminescence properties of semiconductors below the diffraction limit of visible light. The development of time-resolved Cathodoluminescence (TR-CL) in a scanning electron microscope enabled the measurement of the lifetime of excited states in semiconductors with a sub-wavelength spatial resolution. It was used for example to measure the influence of stacking faults on the GaN exciton [1], to probe the role of a silver layer on the dynamics of a YAG crystal[2] or to show the influence of stress on the optical properties of ZnO nanowires [3]. These results demonstrate that TR-CL is essential to study the correlation between semiconductor optical and structural properties (composition, defects, strain…). While all these pioneering studies were done using a scanning electron microscope, the improvement of the spatial resolution and the combination with other electron-based spectroscopies offered by transmission electron microscopes has been a step forward for TR-CL. Indeed, we recently succeed to do the first time-resolved cathodoluminescence experiments within an ultrafast transmission electron microscope [4], followed soon after by Ye-Jin Kim et al [5]. Our TRCL experiment are performed in a unique electron microscope, based on a cold-FEG electron gun [6]. This technology allows among other things to reach a spatial resolution of a few nanometers, essential for the study of III-V heterostructures.
In this presentation we will discuss the advantage and inconvenient of TRCL in a UTEM and present our results on the study of charge carrier dynamics in a 4 nm $In_{0.3}Ga_{0.7}N$/GaN quantum well with a resolution below 10 nm. We studied the QW emission dynamic both along and across the quantum well and correlate the results with strain map and high resolution HADF images.

4:30 PM *CH04.09.03
Effects of Coupling in Atomically-Thin Transition Metal Dichalcogenides Revealed by Electron Spectroscopies SteffiY. Woo[1], FuhuiShao[1], AshishArora[2,3], RobertSchneider[2], BenjaminJ. Carey[2], JohannA. Preuß[2], SteffenMichaelis de Vasconcellos[2], F. JavierGarcía de Abajo[4], RudolfBratschitsch[2], AndreaKonečná[5] and LuizTizei[1]; [1]Université Paris-Saclay, France; [2]University of Münster, Germany; [3]Indian Institute of Science Education and Research, India; [4]ICFO-Institut de Ciencies Fotoniques, Spain; [5]Brno University of Technology, Czechia

Understanding and controlling the interlayer coupling in van der Waals homo- and heterostructure devices containing transition metal dichalcogenides (TMDs) has been an ongoing effort in the two-dimensional material community. Due to the reduced Coulomb screening at atomic thicknesses, TMD optical properties are extremely sensitive to their local dielectric environment. This contributes detrimentally to the exciton linewidth due to inhomogeneous broadening [1], but also provides opportunities for tuning of the electronic gap and exciton binding energy [2] or neutralization of charged exciton emission [3] as demonstrated previously with graphene. Obtaining exciton linewidths towards the homogeneous limit for TMD monolayers in both optical absorption and emission (by photoluminescence) has been made possible by encapsulation in hexagonal boron nitride (*h*-BN).

A monochromated electron microscope is the ideal platform with capabilities for analogous measurement on such 2D materials at the nanoscale, including cathodoluminescence and electron energy-loss spectroscopy (EELS). Until recently [4-6], freely suspended TMD layers have long suffered broad EELS exciton linewidths and have easily succumbed to electron-beam damage. Incorporating *h*-BN encapsulation has put electron spectroscopies on a level playing field as well-known optical measurements, with supplementary structural and chemical information down to the atomic-scale [4,6].

In the first part of this presentation, the influence of two dielectric materials (Si_3N_4 and *h*-BN) in various TMD monolayer configurations (suspended, supported, and encapsulated) is explored using EELS coupled with electron diffraction to measure the layer roughness [5]. Surprisingly, interfacial cleanliness and substrate-induced charge inhomogeneity/trapping predominate the influence on absorption linewidth more than monolayer flatness, which is significantly improved by the atomically flat *h*-BN. In the second part, complementary EELS (absorption) and CL (emission) measurements offer valuable insight into the coupling behavior in monolayer WSe_2/graphene heterostructures (encapsulated in *h*-BN). This includes evidence for Coulomb interactions modified by the graphene, namely a redshifted neutral exciton emission energy and reduced exciton binding energy from absorption [7]. Spectral differences with mixed *h*-BN and/or graphene encapsulation with increasing graphene layer thickness will also be discussed.

10:30 AM *DS01.01.01
Flexible Automation Accelerates Materials Discovery CurtisP. Berlinguette; The University of British Columbia, Canada

Automated systems perform repetitive tasks quickly and consistently with minimal human intervention. These characteristics are particularly effective in manufacturing, where speed and reproducibility drive down cost and increase quality. In materials science laboratories, however, automation is rarely used. The diverse experimental workflows used in materials science often require highly customized automation that is not commercially available. Even when automated tools for materials synthesis or characterization are available, they are often linked together by manual steps. “Flexible automation” is changing this situation because of the recent emergence of safer, cheaper, and more user-friendly robotics. I define flexible automation as the concept of using robotics to create reconfigurable automated experiments. A powerful feature of flexible automation is the ability to program multiple experimental procedures together into fully automated workflows. These experimental procedures can be performed by commercially-available or customized hardware modules that operate on samples either serially or in parallel. Flexible automation platforms can be readily reconfigured to the changing needs of the experiment. It is for these reasons that flexible automation can accelerate the unique experiments characteristic to materials science. As a proof-of-principle set of experiments, I will show how Ada, our self-driving laboratory for thin-film materials, discovers and optimizes high-performance, low-cost hole-transport materials for use in advanced solar cells. I will also showcase how Ada’s modular design (see below) can enable the automated and autonomous discovery of materials for other clean energy technologies.

11:00 AM DS01.01.02
Autonomous Chemical Reactions in High Resolution Scanning Probe Microscopy NianWu[1], MarkusAapro[1], AlexanderIlin[1], DrostRobert[1], PeterLijeroth[1] and AdamFoster[1,2]; [1]Aalto University, Finland; [2]WPI Nano Life Science Institute, Kanazawa University, Japan

High resolution Scanning Probe Microscopy (SPM) not only enables visualizing material structures at atomic resolution, but also provides an opportunity to manipulate individual atoms or molecules [1]. More recent studies have even harnessed the capability of SPM to selectively form and break bonds as a method for controlling chemical reactions in on-surface molecular synthesis [2]. In general, the SPM manipulations are predominantly controlled via parameters of the tip position, bias voltages and tunneling conductance. However, the selection of proper parameters requires extensive domain knowledge, which is not necessarily transferable to new systems. Improper parameters could lead to manipulation failure and even damage to the tip through a crash. Therefore, it is of great value to develop efficient and autonomous SPM techniques with an excellent control system for manipulation to both optimize experiments and explore non-intuitive manipulation pathways. Recent research combining machine learning algorithms with SPM has allowed the automation of a wide range of challenges, including image quality assessment, tip conditioning, tip functionalization, lateral manipulation and vertical manipulation, and nanofabrication [3].
In this work, we build on our deep reinforcement learning atomic manipulation approach [4] to automate a chemical reaction by the controlled removal of an atom from a molecule and selectively reattaching it. To achieve the objective, we split the challenging task into three major parts as follows: 1) selection of manipulation regions, detection of atoms and identification of elements toward SPM scanning images at atomic resolution; 2) learning manipulation parameters to dissociate chemical bonds; 3) learning lateral manipulation parameters to separate atoms or molecules and perform selective recombination.

11:15 AM DS01.01.03
Towards AI-Controlled Continuous Flow Chemistry and Polymerizations RigobertoC. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

The study of structure-composition-property (SCP) relationships in soft matter is of high interest since advances in simulation and the use of statistical optimization methods have been widely used. The macroscopic properties can also be defined by the processing methods and therefore more finite element analysis (FEA) methods have found wide utilization. The use of artificial intelligence and machine learning (AI/ML) in polymer materials has appended the ability to rapidly optimize synthetic routes and manufacturing. The use of Bayesian and statistical methods enables the application of logic-derived design and regression analysis into an otherwise trial-and-error approach in polymer synthesis, fabrication, and characterization. We demonstrate in this talk the use of continuous flow reaction chemistry and polymerizations to enable unit operation optimization and the possibility of autonomous design and synthesis with a hierarchical approach and learning. There is a high possibility that a combination of P, V, T, and flow rate control enables new methods of copolymerization and the ability to use kinetics as a handle for optimized macromolecular properties and design for controlled yield. The automation for online monitoring is a possibility with improved instrumentation and the development of a feedback loop learning for possible deep learning (DL) development.

AI-Guided Discovery of the Hidden Life of Oxides in Extreme Environments StevenR. Spurgeon[1,2], BethanyMatthews[1], JennaBilbrey[1], ArmanTer-Petrosyan[1], ChristinaDoty[1], ChristopherBarr[3], KhalidHattar[4], LeWang[1], YinggeDu[1], RajendraPaudel[5], RyanComes[5] and SarahAkers[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]Sandia National Laboratories, United States; [4]The University of Tennessee, Knoxville, United States; [5]Auburn University, United States

Directing the evolution of functional oxides in extreme environments is a longstanding challenge that requires new approaches to precision synthesis, characterization, and analytics. Our present inability to acquire, interpret, and act on multi-modal signatures limits our control of oxide-based devices, such as fuel cells and neuromorphic computing architectures, particularly in high-radiation environments. Here I will show how we are operationalizing machine reasoning to induce, probe, and model oxide degradation pathways more richly than ever before. I will describe a bespoke instrument and analytics workflow that combines on-machine sparse data-guided control with cloud-based analytics, which together yield better out of distribution model performance, improved capacity for discovery, and more interpretable analysis of fast-evolving phenomena. I will show how this new approach can accelerate the discovery and design of oxide-based devices for extreme environments.

11:45 AM DS01.01.05
Bayesian Optimization of Wet-Impregnated Co-Mo/Al_2O_3 Catalyst for High-Yield Carbon Nanotubes Sang SuShin and JaegeunLee; Pusan National University, Korea (the Republic of)

Carbon nanotubes (CNTs) have become a significant component for various fields because of their outstanding electronic and mechanical properties. To meet the requirement of specific applications, CNTs synthesis with controlled properties is significantly required. Chemical vapor deposition (CVD) using solid supported catalysts is considered an attractive approach for controllability of the nanostructure and large scale production. Since the early 2000s, many researchers have used mono-metallic catalysts to control CNT properties, but it was hard. To overcome these limitations, bi- and tri-metallic catalysts are being studied. However, there are a variety of possible combinations of multi-metallic catalyst systems. In addition, the development of multi-metallic catalysts requires a more complicated optimization than that of mono-metallic catalysts.
In this presentation, we introduce our research efforts to implement Bayesian optimization (BO) in optimizing a bimetallic catalyst for the CVD growth of CNTs. BO, one of a machine learning processes based on Bayes' theorem that finds the optimum value of a black-box function, could quickly optimize parameters of less than 20 dimensions. BO consists of two main components: surrogate model and acquisition function. The surrogate model is a model that performs probabilistic estimation of the shape of a black-box function based on the investigated input-output values ($(x_1, f(x_1)), \ldots, (x_n, f(x_n))$). The acquisition function is a function that recommends input values for the next experiment based on the probabilistic estimation of the surrogate. Specifically, we attempted to optimize the wet impregnation of Co-Mo/Al_2O_3 catalyst. Co-Mo is one of the famous bimetallic system because of their ability to synthesize chirality-specific single-walled CNTs. Here, we optimized the experimental variables to maximize the CNT yield. Four input parameters were chosen: total wt% of catalyst, ratio of Co and Mo of catalyst, drying temperature, and calcination temperature. To compare the performance of two types of acquisition functions: Expected improvement (noise-free) and One-shot knowledge gradient (with noise), we parallelly performed two BO processes. As a result, both the acquisition functions successfully optimized the CNT yield with similar performance. The contour plot established by the surrogate model that predicts black-box function show that addition of Mo has negative effect on CNT yield. This study demonstrates the potential of BO in the material synthesis.

SESSION DS01.02: Innovations in Autonomous Experimentation II

1:30 PM *DS01.02.01
SARA—Autonomous Agents for High-Throughput Exploration of Composition/Time/Temperature Processing Space by Lateral Gradient Laser Spike Annealing MichaelO. Thompson; Cornell University, United States

The coupling of fast, high-throughput, automated experiments with autonomously directed protocols, based on active learning (AL) agents, promises to dramatically accelerate both the exploration and exploitation of new material systems. SARA, a Scientific Autonomous Reasoning Agent, was developed to manage efficient exploration of the complex composition, time, and temperature phase processing space enabled by non-equilibrium laser spike annealing. Integrating robotic materials synthesis and characterization with a hierarchy of AI methods, SARA has demonstrated efficient exploration of processing phase maps in unary, binary and ternary oxide systems.
Lateral gradient laser spike annealing (lgLSA), coupled with focused X-ray synchrotron sources, generates and characterizes over a thousand unique processing conditions per minute, with upwards of 100,000 conditions on a single ternary compositional library plate. To autonomously manage the search at a commensurate rate, SARA utilizes a hierarchical set of characterization and decision algorithms based on nested active learning cycles and machine learning models incorporating the underlying physics and end-to-end uncertainty quantification. To enable specific phase exploitation as well as exploration, a probabilistically quantitative, multi-phase labeling algorithm has been incorporated to provide full in-loop structural information to the AI agents, including quantitative lattice distortions from composition or strains, peak broadening and grain size, and probability estimates of likely multi-phase combinations.
We demonstrate the efficacy of SARA by autonomously mapping processing/synthesis phase boundaries in several unary and binary oxide composition spread systems, with orders-of-magnitude acceleration over exhaustive searches previously used.[1,2] With this search acceleration, we also demonstrate the ability of SARA to implement a two-stage objective function, switching between exploration and exploitation modes based on uncertainty of the material processing space with structurally labeled phase fields. Finally, I will discuss future directions enabled by the autonomous search, including the potential to track also kinetic parameters through time-resolved characterization directed by SARA.
While demonstrated for mapping of processing phase maps, SARA has the potential to be incorporated into numerous high-throughput workflows, and can be equally used to provide physical knowledge to train machine learning models for accelerated materials discovery.

Automated Microscopy for Physics Discovery—From High-Throughput to Hypothesis Learning-Driven Experimentation YongtaoLiu[1], RamaK. Vasudevan[1], MaximZiatdinov[1] and SergeiV. Kalinin[2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

In this work, we explore the ferroelectric polarization switching in relation to the applied pulse bias (i.e., bias voltage and time) in an automated manner in scanning probe microscopy (SPM). We perform (1) high-throughput experimentation for a comprehensive understanding of the relationship between pulse biases and ferroelectric domain growth, (2) autonomous experimentation driven by machine learning (ML) algorithm to optimize experimental conditions based on real-time experiment results.

SPM has been a powerful tool for manipulating and visualizing ferroelectric domains at the nanoscale. Investigations of ferroelectric domain size and stability can advance understandings of ferroelectrics application in memory devices, such as operating time, retention time, bit size, and so on. However, these SPM measurements have traditionally been time-intensive and dependent on experienced researchers for monotonous operations and real-time decision-making of measurement parameters, e.g, researchers determine and manually tune the parameters for next iteration of experiment according to the previous results. Here, we perform automated experiments in SPM to explore the mechanism of ferroelectric polarization. First is a high-throughput experiment of writing ferroelectric domains by applying various bias pulse conditions and subsequently conducting piezoresponse force microcopy to image the written domain structure. The high-throughput experimentation enables systematically varying the bias pulse parameters, therefore comprehensively understanding the relationship between the bias parameters and the resulting domain structures. In this experiment, we discovered different polarization states that show up upon different bias conditions. Second, we implement a hypothesis active learning (HypoAL) algorithm to control the SPM for ferroelectric domain writing. The HypoAL is based on structured Gaussian process (sGP), which analyzes the relationship between the bias pulse parameters and the written domain size during operating experiments, and subsequently determines the bias pulse parameters for the next experiment. The HypoAL aims to establish the best physical model from a hypothesis list for the material's behaviour within the smallest number of experiment step. The HypoAL indicates that the domain growth in a $BaTiO_3$ film is ruled by kinetic control. We anticipate the established approaches here can be extended to microscopy methods other than SPM in the future to accelerate materials and physics discovery.

Acknowledgement: This work (high-throughput experimentation) is supported by the Center for Nanophase Materials Sciences, a US Department of Energy Office of Science User Facility. This work (HypoAL experimentation) is partially supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences Energy Frontier Research Centers program

Active Learning for Efficient Parameter Space Mapping—A Case Study with using Quantum Dots JeffXu[1], KatherineYoung[2], LoganKeating[1], AjitVikram[3], MoonsubShim[1] and PaulKenis[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Purdue University, United States; [3]Merck & Co Inc, United States

Autonomous workflows have increasingly been implemented across disparate facets of materials research to accelerate materials discovery or materials optimization. One application of autonomous workflows is the generation of accurate parameter space maps of synthesis spaces. These accurate parameter space can then be probed by subject matter experts to generate deeper insight and propose new hypotheses for further research.

Building an accurate parameter space map requires efficient sampling of the parameter space, which can be done effectively with active learning. Active learning algorithms involve both a surrogate model to fit existing data and an acquisition function to decide the next experiment(s) based on some pre-defined heuristic. Presently the selection of surrogate models and acquisition functions relies on human intuition and requires both an understanding of statistical learning fundamentals and the nature of the material systems studied. Increased adoption of active learning, however, requires a set of heuristics regarding the selection of surrogate models and acquisition functions that is beginner friendly: scientists should be able to build effective active-learning algorithms without prior machine learning experience.

This talk will report on a generalized modular active learning approach to combine various surrogate models and acquisition functions for mapping the synthesis parameter space of quantum dot (QD) synthesis. We tested different surrogate models, acquisition functions, and batch sizes using simulated data and digital twins of real experiment data and compared their relative performances in terms of accuracy and computational resources required. We then experimentally applied these active learning algorithms on an automated QD synthesis platform on different synthesis chemistries to test the generalizability of our approach. Results from this endeavor generated useful heuristics for building active learning algorithms that will help future scientists who wish to use machine learning to accelerate their automated online or manual offline workflows. The modular approach for implementing active learning also provides a useful framework for analyzing and assessing new active learning approaches.

Modeling and Design of Heterogeneous Hierarchical Bioinspired Spider Web Structures using Deep Learning and Additive Manufacturing WeiLu, NicLee and MarkusJ. Buehler; Massachusetts Institute of Technology, United States

Spider webs are incredible biological structures, comprising thin but strong silk filament and arranged into complex hierarchical architectures with striking mechanical properties (e.g., lightweight but high strength, achieving diverse mechanical responses). While simple 2D orb webs can easily be mimicked, the modeling and synthesis of 3D-based web structures remain challenging, partly due to the rich set of design features. Here we provide a detailed analysis of the heterogenous graph structures of spider webs, and use deep learning as a way to model and then synthesize artificial, bio-inspired 3D web structures. The generative models are conditioned based on key geometric parameters (including average edge length, number of nodes, average node degree, and others). To identify graph construction principles, we use inductive representation sampling of large experimentally determined spider web graphs, to yield a dataset that is used to train three conditional generative models: 1) An analog diffusion model inspired by nonequilibrium thermodynamics, with sparse neighbor representation, 2) a discrete diffusion model with full neighbor representation, and 3) an autoregressive transformer architecture with full neighbor representation. All three models are scalable, produce complex, *de novo* bio-inspired spider web mimics, and successfully construct graphs that meet the design objectives. We further propose algorithm that assembles web samples produced by the generative models into larger-scale structures based on a series of geometric design targets, including helical and parametric shapes, mimicking, and extending natural design principles towards integration with diverging engineering objectives. Several webs are manufactured using 3D printing and tested to assess mechanical properties.

3:15 PM DS01.02.05
Autonomous Thin-Film Materials Synthesis by Machine Learning and Robotics KazunoriNishio[1], AkiraAiba[1], ShigeruKobayashi[2], RyoNakayama[2], RyotaShimizu[2] and TaroHitosugi[2,1]; [1]Tokyo Institute of Technology, Japan; [2]The University of Tokyo, Japan

Accelerating the development of new materials is indispensable for a sustainable society. However, new materials development in laboratories involves repeated cycles of conception, synthesis, and characterization, manually performed by researchers. Under such circumstances, the inclusion of machine learning, robotics, and big data into these cycles promises to revolutionize materials research.
Recently, we have designed and built a closed-loop system that combines Bayesian optimization, automatic synthesis, and automatic physical property evaluation for inorganic thin-film materials. This system implements a concept; lab equipment and instruments should be Connected, Autonomous, Shared, and operate in a High-throughput manner. With this approach, we have already achieved a proof-of-concept of autonomous material synthesis, which was demonstrated by autonomously optimizing the synthesis conditions specified by Bayesian optimization to minimize the electrical resistance for Nb-doped TiO_2 thin films fabricated via the sputtering method [1]. We present an expanded system to evaluate various physical properties: X-ray diffraction, scanning electron microscope/energy dispersive X-ray spectroscopy, Raman spectroscopy, and UV-Vis spectroscopy. Coevolution with such technologies, researchers work on more creative research, accelerating materials science research.

3:30 PM DS01.02.06
Machine Learning-Guided Precision Synthesis of Colloidal Nanocrystals YugangZhang[1], Hyeong JinKim[1], FangLu[1], MatthewCarbone[1] and KristoferG. Reyes[2]; [1]Brookhaven National Laboratory, United States; [2]University at Buffalo, The State University of New York, United States

Colloidal nanocrystals, also knowns as 'artificial atoms', offer a new avenue for packing atoms and interfaces, which are essential for catalysis, photonics, and energy storage. Over the past several decades, tremendous advancements have been made in the synthesis of colloidal nanocrystals with controlled size, shape and composition. However, conventional synthesis methods largely depend on Edisonian (trial-and-error) approaches, which are both labor-intensive and time-consuming. In this talk, we will showcase our experimental work on machine-learning-assisted synthesis of nanocrystals. This machine learning strategy allows for rapid and efficient exploration of the synthetic space, leading to the successful synthesis of targeted nanocrystals with a high degree of control over size and size distribution.

3:45 PM *DS01.02.07
The NIST Autonomous Formulation Laboratory—Accelerating Liquid Formulation and Reaction Landscape Exploration with AI and X-Ray/Neutron Scattering PeterBeaucage, DuncanSutherland and TylerMartin; National Institute of Standards and Technology, United States

Liquid formulations are ubiquitous in products ranging from deicing liquids and fuels/lubricants to biologic drugs, shampoo, and food/beverage ingredients. All these products require precise tuning of 10s-100s of components to produce a desired product: viscosity modifiers, surfactants, dyes, fragrances, flammability inhibitors, etc. This large number of components often precludes rational mapping between component fractions, structure, and product stability. Multimodal characterization and machine learning (ML) tools promise to greatly reduce the expense of exploring the stability boundaries of a particular, desirable phase in highly multicomponent products. This talk will describe the development of the Autonomous Formulation Laboratory, a highly adaptable platform capable of autonomously synthesizing and characterizing liquid mixtures with varying composition and chemistry using x-ray and neutron scattering. Highlights will include closed-loop AI-guided exploration of composite nanoparticle synthesis for coatings development and bioformulation exploration incorporating neural networks into scattering pattern classification. I will further discuss our ongoing efforts to incorporate a multimodal suite of secondary measurements such as optical imaging, UV-vis-NIR and capillary rheometry to provide greater-than-sum-of-parts materials characterization.

4:15 PM DS01.02.08
Autonomous Synthesis of Sputtered Nitride Thin Films with Controlled Cation Composition DaviM. Febba, KevinR. Talley, KendalJohnson, StephenSchaefer, SageBauers, JohnS. Mangum, RebeccaSmaha and AndriyZakutayev; National Renewable Energy Laboratory, United States

Autonomous experimentation has emerged as an efficient approach to accelerate the pace of materials discovery. Although instruments for autonomous synthesis have become popular in molecule and polymer science, solution processing of hybrid materials and nanoparticles, examples of autonomous tools for physical vapor deposition (PVD) are scarce yet important for the semiconductor industry.
Although some of the few existing reports of autonomous PVD focused on the optimization of material properties such as resistivity and crystallinity, precise control of cation and anion

composition in inorganic thin films is of paramount importance. For example, it has been theoretically predicted and experimentally demonstrated that short-range ordering tunes the optical absorption edge in the long-range disordered alloy $(ZnSnN)_{1-x}(ZnO)_{2x}$ at a very specific composition of x = 0.25. Also, the resistivity and bandgap of ternary nitrides and their alloys depend mostly on cation composition.
In this presentation, we will discuss the design and implementation of a closed-loop autonomous workflow for sputter deposition of thin films with controlled composition, leveraging a highly automated sputtering reactor custom-controlled by Python, optical emission spectroscopy (OES), and Bayesian optimization. By fabricating $Zn_xTi_{1-x}N_y$ thin films with simultaneous monitoring of optical emission lines from the co-sputtering of elemental targets, we will show that cation composition, spanning a wide range, can be expressed as a linear function of emission lines.
Informed by OES, a control algorithm with Bayesian optimization as its decision-making agent can effectively optimize the power on each sputtering source, achieving deviations from the targeted cation composition within relative 3.5 %, even for 15 nm-thick films, which demonstrates that the methods described in this work can reliably synthesize thin films with specific composition and minimal human interference.
Moreover, we will show that our approach can enhance reproducibility in the synthesized films by assuring that the desired composition will be achieved regardless of the N_2/Ar mixture and total power applied on elemental targets. Finally, we will also discuss how substrate effects and chamber pressure affect the calibration of the current approach and suggest future improvements of its accuracy.

This presentation will be based on the following preprint: https://arxiv.org/abs/2305.11122

4:30 PM DS01.02.09
ML-Assisted Fully Autonomous Robotics for High-Throughput Performance Optimization of Organic Mixed Ionic–Electronic Conductors YahaoDai[1], HenryChan[2], AikateriniVriza[2], FredrickKim[2], SihongWang[1] and JieXu[2]; [1]University of Chicago, United States; [2]Argonne National Laboratory, United States

Machine learning (ML) has revolutionized the way materials research is performed nowadays by intelligently navigating to vast experimental design space and identifying promising material candidates with desired properties, thereby reducing the time and cost associated with traditional trial-and-error approaches. Recently, a novel category of materials: organic mixed ionic–electronic conductors (OMIECs) attract considerable attention for simultaneously facilitating highly efficient electron/hole and ion transport, and thereby are widely adopted in signal processing, sensing, and energy storage devices. Among these, the organic electrochemical transistor (OECT) is of particular interest due to its high transconductance (G_m), which is essential for enabling biosensing with high sensitivity. To gain the high G_m, high [μC^*] needs to be achieved, which is determined by the intrinsic morphology and energy profile of OMIECs that can be tunned by vast processing conditions and molecular design strategies, resulting in a large searching space. Therefore, ML can play an important role in not only accelerating the OMIEC exploration but also uncovering the underlying knowledge. However, to realize this, it requires built-in fully autonomous robotics for acquiring high-fidelity source data, and a well-designed ML algorithm and workflow for enhancing exploration efficiency. Herein, we build the fully autonomous Polybot system to carry out the closed-loop workflow for screening out the best processing conditions of OMIECs. The entire system is monitored in real-time by a built-in live streaming platform providing imaging and data analytics tools. During the ML-guided experimentation, we identify the optimal processing conditions of our model OMIEC with improved [μC^*] by over 2 folds. Interpretability techniques were also employed during the process to facilitate a deeper understanding of the materials' mixed conducting behaviors and unveil fundamental relationships between [μC^*] and processing conditions.

4:45 PM DS01.02.10
Autonomous Synthesis of Thin Films with Pulsed Laser Deposition Enabled by *In Situ* Diagnostics and CharacterizationSumnerB. Harris, ArpanBiswas, ChristopherM. Rouleau, AlexanderA. Puretzky, Seok JoonYun, GyulaEres, MinaYoon, RamaK. Vasudevan, DavidB. Geohegan and KaiXiao; Oak Ridge National Laboratory, United States

Synthesis of thin films has traditionally relied upon slow, sequential processes conducted with substantial human intervention, often using a mix of experience and serendipity to optimize material structure or discover properties. With recent advances in autonomous systems which combine automated synthesis, characterization, and artificial intelligence (AI), large parameter spaces can be explored autonomously at rates beyond what is possible by human experimentalists, promising to greatly accelerate our understanding of synthesis science. In this talk, I will discuss the infrastructure development of two highly versatile, autonomy-capable pulsed laser deposition (PLD) platforms: one based on real-time and *in situ* gas-phase and optical diagnostics and the other based around *in vacuo* robotic transfer for characterization. I will then show how we incorporated *in situ* and real-time diagnostics and characterization, a high-throughput methodology, and cloud connectivity to enable an autonomous synthesis experiment with PLD. We grew ultrathin WSe_2 films using co-ablation of two targets with real-time laser reflectivity for thickness control and showed a 10x increase in throughput over traditional PLD workflows. Bayesian optimization with Gaussian process regression was used with *in situ* Raman spectroscopy to drive synthesis and autonomously discover the growth window with a sparse sampling of only 0.25% of a broad 4D parameter space. Moreover, the process-property relationship predicted by the Gaussian process surrogate model suggests two different growth regimes and offers a more global understanding of the synthesis space than a human experimenter could gain without machine learning, information that is crucial for simultaneous, cooperative refinement of both synthesis experiments and theory. Any material that can be grown with PLD can be autonomously synthesized with our platforms and workflows, enabling AI-driven synthesis and accelerated discovery of a vast number of materials. This work was supported by the U.S. DOE, Office of Science, Materials Sciences and Engineering Division and was performed at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

SESSION DS01.03: From Self-Driving Labs to an Accelerated Research Ecosystem
Session Chairs: Milad Abolhasani and Keith Brown
Tuesday Morning, November28, 2023
Sheraton, Third Floor, Fairfax B

8:00 AM *DS01.03.01
Exploiting Diverse Knowledge Sources for Autonomous Materials ResearchA. GiladKusne[1,2], IchiroTakeuchi[1,2], HaotongLiang[2], FelixAdams[2], AustinMcDannald[1], BrianL. DeCost[1] and MikkLippmaa[3]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]The University of Tokyo, Japan

Autonomous research systems seek to accelerate materials exploration and discovery by placing materials synthesis and characterization under control of machine learning. For such systems, machine learning controls experiment design, execution, and analysis, thus accelerating knowledge capture while also reducing the burden on experts. The system-driving machine learning algorithms can be dramatically enhanced by integrating knowledge from varied sources including theory, computation, and human intuition. In this talk I will discuss NIST's diverse set of autonomous systems, including autonomous control over user facility measurement systems, and their improved capabilities by drawing on new sources of knowledge.

8:30 AM *DS01.03.02
A-Lab—An Autonomous Laboratory for the Accelerated Synthesis of Novel Inorganic Materials GerbrandCeder; University of California, Berkeley/Lawrence Berkeley National Laboratory, United States

We will present the development and initial successes of A-lab: an autonomous facility for the closed-loop synthesis of inorganic materials from powder precursors. All synthesis and characterization actions in A-lab, including powder mixing and grinding, firing, characterization by XRD and SEM, and all sample transfers between them are fully automated, leading to a lab that can synthesize and structurally characterize novel compounds within 10-20 hrs of initiation. The A-lab leverages ab-initio computations through an API with the Materials Project, historical data sets that are text-mined from the literature, machine learning for optimization of synthesis routes and interpretation of characterization data, and active learning to plan and interpret the outcomes of experiments performed using robotics. Over 17 days of continuous operation, the A-Lab successfully developed synthesis routes for 41 novel compounds from a set of 58 targets that were identified using large-scale ab-initio phase stability data from the Materials Project and Google Brain. Synthesis recipes were proposed by natural language models trained on the literature and optimized using an active learning approach grounded in thermodynamics. Analysis of failed syntheses provide direct and actionable suggestions to improve current techniques for materials screening and synthesis design. The high success rate exemplifies the new paradigm of autonomous materials discovery and motivates further integration of computations, historical knowledge, and robotics into AI-driven, closed-loop platforms.

9:00 AM DS01.03.03
Object-Oriented Software Architecture (control-lab-ly) to Control Automated Workflows—A Case Study of Quantum Dot Ligand Cocktails Chang JieLeong[1], JayceJ. Cheng[1] and KedarHippalgaonkar[1,2]; [1]Institute of Materials Research and Engineering, Singapore; [2]Nanyang Technological University, Singapore

Given the multitude of ways to produce new materials, such as altering composition and processing parameters, the state space in materials research is vast, and AI algorithms are vital in

exploring the space and reducing discovery time. To accelerate the collection of copious amounts of experimental data required for these algorithms, many research groups are increasingly turning to automated and autonomous workflows.

Within the community, significant strides have been made in creating flexible and reconfigurable setups by using modular hardware. However, less thought is put into the software that controls these workflows, which are usually custom setups. Bespoke software is typically written to orchestrate actions and communicate between components in the setup. Once working, code is commonly left untouched, which does not leverage on the flexibility and reconfigurability afforded by having modular hardware. This has two complications. First, code is not easily reusable. For a group setting up a new workflow, it is difficult to adapt code from a previous project or from another group. Second, changing a component in the workflow requires substantial rework of the code, since abstractions of how different components interact have not been established. These serve as barriers to teams that intend to set up a new automated workflow or update its components during the course of a campaign.

In this work, we propose a modular software architecture that controls automated experimentation setups, and we use it in our study to improve the charge mobility of quantum dot (QD) thin films by investigating the combinatorial space of multi-ligand passivation of QDs. Effective passivation of QDs can be achieved by matching the appropriate ligand type with each QD facet and we examine combinations of up to five different ligands. Fabricating spin-coated thin films was the major bottleneck in our workflow, as making just one sample already takes multiple spin steps, each having considerable wait times. Evolution of our thin-film fabrication tools was enabled by the proposed software architecture, implemented as a Python package. The package (*control-lab-ly*) exposes available actions for each tool in a standard manner for its particular category. For example, tools with the same function of moving items around a workspace are given identical methods, regardless of form (e.g. gantry vs articulated robots). The modular nature of the package also allows for extension via user plugins, so drivers for new equipment can easily be written and integrated.

9:15 AM DS01.03.04
Machine Learning-Assisted High-Throughput Robot for Electrocatalytic Seawater Splitting MasanoriKodera and KazuhiroSayama; National Institute of Advanced Industrial Science and Technology, Japan

The expected shift from fossil fuels to H_2 as the main renewable energy carrier inspires the search for inexpensive, reliable, and green H_2 production methods such as seawater electrolysis. However, the noble metal-based catalysts used for electrolytic H_2 production are costly and should be replaced by cheaper non-noble metal–based ones. Effects of the composition of electrocatalysts have been widely investigated while the search space is too large to investigate manually. For example, reports on electrocatalysts that contain more than three cations are still very limited.
Here, a high-throughput automatic robot was used to prepare Co-Mn-Fe-Ni–based composite-oxide anodic electrocatalysts and characterize their ability to promote the selective and stable production of O_2/HClO at the anode during the electrolysis of model seawater (aqueous NaCl). This robot can deal with 88 samples in a single run from preparing to measuring.
First, the pipetting arm dispenses and mixes up to 10 different metal ion–containing solutions. Then, mixed solutions were deposited onto conductive substrates with a size of 5 mm × 30 mm and dried on a hotplate. The samples are transported to an electric furnace using the transfer arm and calcined to obtain electrodes with different compositions. Subsequently, the measuring sequence starts with the following procedures. The pick-up arm, which has two pins connected to a potentiostat and functions as a working electrode, transfers each electrode to an H-type cell for electrochemical measurements. Finally, the pipetting arm dispenses a small amount of the solution from the cell, mixes it with a coloring reagent, and measures the absorption using a plate reader to quantitate the generated HClO. After each measurement, the solution is automatically replenished from the tank behind the robot.
This robot can perform several electrochemical measurements such as cyclic voltammograms, chronoamperometry, and chronopotentiometry. Therefore, current density at 2.0 V vs. the Ag|AgCl reference electrode, reaction selectivity (faradaic efficiency of HClO formation (FE_{HClO}) for a charge of 0.2 C (1 mA for 200 s)), and the ratio of current densities at 2.0 V vs. Ag|AgCl after 1000 and 100 s (stability) were calculated from these results. It was revealed that a wide range of FE_{HClO} values could be controlled by composition tuning. Co-Fe-Ni–based catalysts such as $Co_{0.6}Fe_{0.3}Ni_{0.1}O_x$ exhibited high current densities for HClO production and good stability, whereas Co-Mn-based catalysts such as $Co_{0.2}Mn_{0.5}Ni_{0.3}O_x$ showed superior O_2 evolution performance and relatively high stability.
Moreover, machine learning–assisted composition optimization was performed using a Bayesian optimization framework. The dataset of the four-element Co-Mn-Fe-Ni system with 286 samples was used. The explanatory and target variables were composition and current density at 2.0 V vs. Ag|AgCl, respectively. The initial 10 points were selected using a D-optimal design, and 10 candidates were suggested after Bayesian optimization. Then, 10 measured samples were added to the initial points. Gaussian process regression was performed to suggest another 10 points, and this cycle was repeated until all samples with top-ten current density were searched. As a result, compositions with high current densities were successfully found after examining 40 out of 286 data points. Furthermore, the best composition was found after examining 30 samples. Thus, Bayesian optimization-based composition optimization worked well in our system and could be applied to a larger feature space.
In summary, we developed a high-throughput robot for electrocatalyst screening that performs from preparing to measuring samples. Bayesian optimization-assisted screening further improved the effective optimization of electrocatalysts composition. The adopted approach is not limited to electrocatalysts and thus accelerates research and development in the field of materials chemistry.

Delocalized Close-Loop Discovery to Rapidly Access Functional Organic Molecules—Process Scale-Up to Support the Campaign JasonHein; University of British Columbia, Canada

Delocalized closed-loop discovery represents a ground-breaking approach that revolutionizes the exploration of synthesis, optimization, property testing, and scale-up synthesis of functional organic molecules. This step-by-step process distinguishes itself by employing geographically isolated labs, each with unique hardware architectures and capabilities. Together, these labs cover the entire life cycle of design, synthesis, testing, and scale-up required to advance a molecule from inception to tested material. By integrating iterative cycles of synthesis, analysis, and property evaluation, this approach enables rapid exploration of the chemical space, leading to the discovery of novel molecules with desired properties. Additionally, delocalized closed-loop discovery connects geographically isolated research groups, leveraging their specialized skills, equipment, and capabilities to achieve collective objectives.

This presentation aims to highlight the advantages and benefits of delocalized closed-loop discovery, providing insights into how the process was executed to develop novel organic laser candidates. The delocalized exploration process expedites synthesis optimization by offering real-time feedback and adjustment based on property evaluation, enabling specialized members to contribute asynchronously, following the canonical design-make-build strategy. This iterative approach significantly reduces the time and resources required for optimization, facilitating the discovery of high-performance organic laser molecules. Moreover, the delocalized closed-loop approach plays a critical role in improving scalability by considering scale-up synthesis considerations early in the discovery process, ensuring the feasibility of large-scale production of synthesized molecules.

This presentation emphasizes the value of delocalized closed-loop discovery as a comprehensive approach for the exploration of synthesis, optimization, testing, and scale-up of organic laser molecules. Its step-by-step process facilitates the discovery of functional organic molecules by iteratively refining their properties. The advantages of employing this approach include accelerated synthesis optimization, enhanced property control, and improved scalability. Furthermore, the inclusion of case studies serves to exemplify the effectiveness of delocalized closed-loop discovery in advancing the field of organic laser molecule development.

Making an Accessible Automation Tool Autonomous RobertW. Epps[1], RossKerner[1] and JosephJ. Berry[1,2,2]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

Automated and autonomous experimentation is most effective when it can be easily adopted by a diverse range of researchers. In this light, the company Opentrons has developed a library of low-cost, user-friendly robotic tools that have recently been leveraged in material science and chemistry. The OT-2 offers an extremely low barrier of entry in robotics accelerated research through facile liquid handling and simple job automation software. However, this platform lacks two critical features necessary for closed-loop studies. First, there are no simple metrology tools for process characterization. The number of compatible metrology techniques in literature are limited on biological applications, and Opentrons does not officially support any developed methods. In the typical workflow, human users are required to transfer prepared samples to an ex-situ monitoring system before data can be collected. This inhibits the rate of data generation, produces imprecise reaction time features, and prevents efficient algorithm driven research. Second, the OT-2 system does not have a simple machine facing API. The instrument is controlled through individual jobs that are uploaded onto the machine itself then executed. This can be done easily by a human using the instrument software or SSH commands; however, for a computer to identify and select experiments, additional steps are necessary. Accessing the API indirectly would enable the OT-2 to be paired with offline computational power and to be more easily integrated into larger closed-loop and automated systems and algorithms.
In this work, we present an open-access and user-friendly strategy for adapting the OT-2 robot for closed-loop, autonomous research. The system features a generalizable sample aliquoting tool which has been combined with absorption spectroscopy, machine-facing control of the OT-2 API, and a single user interface for sampling, liquid handling, and experiment selection algorithm specification. We applied the tool toward the exploration of perovskite solar cell ink compositions in order to gain insight into material combination dynamics through active learning and algorithm-based feature prediction.

The aliquot system operates by collecting samples from the OT-2 through a low volume funnel connected to microfluidic tubing. Samples are pulled from the funnel using a positive displacement pump and sent through an optical flow cell where absorption spectra are collected. While this work leverages absorption spectroscopy, alternative techniques, including destructive and non-destructive characterization methods may be easily included. This tool can be used outside of closed-loop systems to facilitate precise time resolved data collection and more efficient experimentation.
The OT-2 is algorithmically controlled through automated experiment scripting, upload, and execution. With each new set of experimental conditions, the algorithm arranges a set of instructions along with the system features in the language specified by the OT-2 Python API and saves them to a new Python script. This submission is then pushed to the OT-2 server along with the command to execute the script. This method automates a process that otherwise requires a human to manually program the experiment script, upload it to the OT-2, and send the execution command. By algorithmically interacting with the OT-2 through the Opentrons supported API, users can easily leverage the actively developed library of modules without manually implementing updates.
The software and techniques presented in this work will enable users without extensive programming or robotics experience to implement their own closed-loop reaction explorations and optimization. Further development of the modules available for sampling and similar user friendly and low-cost autonomous tools will improve the rate of adoption of autonomous technologies by the broader scientific community.

10:45 AM *DS01.03.07
Discovery of New Materials using Chemputation LeeCronin; University of Glasgow, United Kingdom

Chemputation' is a universal approach to explore chemical reactivity, discovery of new reactions, and molecules / materials, as well as program chemical synthesis that allows us to translate all procedures, manual or automatic, into a executable chemical programming language that can run the processes on a chemputer. This code is written in the world's first universal programming language for chemistry and materials: χDL (pronounced Chi-DL). This new approach maps into a universal programming language for chemistry that is accessible to ALL synthetic chemists and will work on ALL robotic systems (subject to suitable specification). We demonstrate that the process is universal, and by analogy with computation, we call systems capable of universally turning code into reliable chemistry and materials processes *Chemputation*.

11:15 AM DS01.03.08
A Distributed and High-Performance Compute Cluster and Data Science Framework for Handling Materials Data—CRADLE TM 3.2 ArafathNihar, RounakChawla, PawanK. Tripathi, YinghuiWu, VipinChaudhary and RogerH. French; Case Western Reserve University, United States

The foundation of materials data science capabilities is well curated datasets, often of disparate types such as tabular data, images, movies and unique data formats from distinct instruments combined with data science models and their metadata. We present the Common Research Analytics and Data Lifecycle Environment (CRADLE™), a groundbreaking research computing infrastructure that seamlessly integrates Hadoop Distributed Computing with High-Performance Computing (HPC) capabilities to store, query, and process FAIRified, structured and semi-structured materials data including XCT, XRD, Pyrometry, spectroscopy and high-speed camera images at terabyte scales. We outline a structured data pipeline used to transform large volumes of tabular data into the efficient Apache Parquet file format and store it in the Hadoop Distributed File System (HDFS). For non-tabular, semi-structured data such as images, we leverage Apache Ozone for highly scalable, distributed storage for analytics. Additionally, we utilize Apache Spark for Data Ingestion (the distributed version of traditional Extract, Transform, Load (ETL)) jobs and Apache Impala for distributed analytical queries, ensuring comprehensive data processing capabilities within the CRADLE™ distributed computing environment. This data lifecycle environment is integrated in a large-scale multi-node HPC environment with thousands of CPU and GPU cores for parallel data processing. Finally, to simplify the dependency management of our numerous materials data science modeling tools and their associated scientific investigations, we use containerized Singlurity environments. We utilize Continuous Integration/Continuous Deployment (CI/CD) principles to automatically build Singularity containers in our container registry and deploy them in our HPC compute environment. We securely integrate the Hadoop cluster with the Singularity containers in the HPC cluster via the HDFS client, Spark client, and ODBC (Open Database Connectivity) for Impala with full Kerberos authentication compatible with NIST 800-171 cybersecurity requirements. The result is a massive yet flexible research computing infrastructure with petabyte-scale storage and thousands of CPU and GPU cores, allowing researchers to process billions of data points in seconds, and train hundreds of thousands of models in minutes. This innovative approach to computing infrastructure development has the potential to transform research across various domains, opening up new possibilities for scientific exploration and discovery. This material is based upon research in the Materials Data Science for Stockpile Stewardship Center of Excellence (MDS3-COE), and supported by the Department of Energy's National Nuclear Security Administration under Award Number(s) DE-NA0004104.

11:30 AM *DS01.03.09
ARES™ Autonomous Experimentation for Accelerated Research BenjiMaruyama, RahulRao and RobertWaelder; Air Force Research Laboratory, United States

The current materials research process is slow and expensive; taking decades from invention to commercialization. The Air Force Research Laboratory pioneered ARES™, the first autonomous experimentation system for materials development. A rapidly growing number of researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of making research progress orders of magnitude faster than today. We will discuss concepts and advances in autonomous experimentation in general, and associated hardware, software and autonomous methods.

We will distinguish between non-iterative AI/ML approaches that use large data sets (e.g., CNN, LLM) and small data, iterative approaches that strive to identify & confirm scientific hypotheses using AI reasoning.

We consider the impact of autonomous experimentation on human scientists and the scientific enterprise: Changing roles for humans and robots, expectations. In the future, we expect autonomous experimentation to revolutionize the research process, and propose a "Moore's Law for the Speed of Research," where the rate of advancement increases exponentially, and the cost of research drops exponentially. We also consider a renaissance in "Citizen Science" where access to online research robots makes science widely available.

Analyzing Machine Learning Models to Forecast Hybrid Perovskites' Dynamic Response to Environmental Stressors MarinaS. Leite; University of California, Davis, United States

Machine learning (ML) can significantly accelerate the discovery of materials for clean energy. Hybrid perovskites (an emerging class of materials for photovoltaics and light-emitting diodes) encompass an enormous chemical composition space, resulting in a hyperparameter space that is nearly impossible to be interrogated via traditional trial-and-error methods. Thus, there has been a pressing need within the materials research community to identify ML models that can be implemented to inform the physical and chemical behavior of the perovskites. Here, we apply distinct ML models (mostly based on recurrent neural networks) to classify and forecast physical properties encompassing electrical conductivity, photoluminescence response, the power conversion efficiency of photovoltaic devices, etc. Specifically, we use automated, *in situ* optical measurements to predict the optical response of a series of perovskites for 50+ hours, upon materials' exposure to moisture. We quantitatively compare linear regression, echo state network, and seasonal auto-regressive integrated moving average with eXogenous regressor algorithms and achieve accuracy of >90% for the latter. Demonstrating the ability of this model to capture non-linear features. Our high-throughput measurements and ML-assisted data analysis exemplifies the potential of ML to diagnose and forecast hybrid perovskites' response with a variety of chemical compositions.

2:00 PM DS01.04.02
Machine-Learning Assisted Global Optimization of Equivalent Circuit Parameters in the Field of Electrochemical Impedance Spectroscopy CarlP. Klemm[1,2]; [1]TU-Darmstadt, Germany; [2]Rhd-Instruments GmbH, Germany

In this paper, we introduce a machine-learning regression system for initial-parameter guessing for optimization of Electrochemical impedance spectroscopy equivalent circuit parameters. In Electrochemical impedance spectroscopy, the fitting of equivalent circuits models to experimental data is the standard technique for data interpretation. The currently used techniques and tools for solving this global optimization problem require the user to guess starting parameters, which degenerates the problem into a local optimization problem, or apply an expensive stochastic optimization algorithm with performance characteristics that are incompatible with large scale automated data analysis. To help alleviate this deficiency, a Machine-learning

regression stage for initial-parameter guessing is proposed and implemented.

2:15 PM DS01.04.03
Exploration of Machine Learning (ML) Methods for Determining Unit Cell Parameters from Powder XRD Patterns ElyssaHofgard[1], VanessaOklejas[2], DavidMittan-Moreau[2], AriaMansouri Tehrani[1], DanielPaley[2], AaronBrewster[2] and TessSmidt[1]; [1]Massachusetts Institute of Technology, United States; [2]Lawrence Berkeley National Laboratory, United States

We investigate different machine learning (ML) methods to determine unit cell parameters and classify Bravais lattices from powder X-ray diffraction (XRD) data. Traditional powder indexing algorithms encounter errors when dealing with noisy experimental data and overlapped regions from multiple phases. The dominant zone problem also causes errors, arising when certain crystal planes significantly overshadow other planes in the diffraction pattern due to differences in the magnitudes of unit cell axes. This causes complications in accuracy of peak identification, peak intensity measurements, and subsequent crystal structure determination [1-3]. ML methods offer the potential to surpass time-consuming conventional techniques through their ability to learn complex patterns from diverse datasets and provide fast inference speeds.
Previous research has primarily addressed lattice type classification using ML models with decreased accuracy for lower symmetry crystal structures [4-7]. A recent publication on unit cell parameter regression showed that 1-D convolutional neural networks (CNNs) could predict unit cell lengths across all crystal systems but struggled to predict unit cell angles for monoclinic or triclinic systems [8]. However, CNNs assume translational invariance in the input data, which is absent in powder XRD data.
Therefore, we explore the effectiveness of ML models specifically designed for identifying 1D patterns in sequential data. We train and test these models on established crystallographic databases and assess their performance on Bravais lattice classification and unit cell parameter regression. We also consider other essential factors such as regression targets, spectrum complexity, data augmentation techniques to improve performance with large unit cells or dominant zones, and the use of physically meaningful loss functions. Ultimately, our goal is to integrate these models with powder XRD analysis software such as GSAS-II or TOPAS to accelerate crystal structure determination for complex or challenging systems.

Interpreting *In Situ* 4D-STEM Data for Accurate Measurement of Ferroelectric Polarization using Machine Learning TechniqueJinhoByun, LeeKeeyong, Geun HoGu and Sang HoOh; Korea Institute of Energy Technology, Korea (the Republic of)

Ferroelectric materials, such as barium strontium titanate ($Ba_{0.5}Sr_{0.5}TiO_3$, BST), exhibit tiny amounts of ionic displacement under an electric field, which is challenging for reliable detection by STEM based imaging techniques due to the limited precision (typically ~4 pm). Recent progress in 4D-STEM have made it possible to measure these small polarizations with a high degree of accuracy in the reciprocal space as the diffraction intensity varies very sensitively with ionic displacement. However, the quantitative interpretation of the diffraction intensity in 4D-STEM data is challenging due to the unavoidable dynamical diffraction effects included in most 4D-STEM data. In this study, we present a practical machine learning technique to interpret the in-situ 4D-STEM data obtained from 20 nm-thick BST thin film capacitors under electric fields, which allows accurate measurement of the tiny ionic displacements induced by the applied electric field. Our results demonstrate the effectiveness of this approach in accurately detecting and measuring the field-induced ionic polarization in high-κ oxide thin film devices. This breakthrough opens up new avenues for studying not only ferroelectric materials but also piezoelectric and flexoelectric materials. The methodology presented in this study has the potential to revolutionize the field of ferroelectric materials research, enabling researchers to detect and measure tiny amounts of polarization with greater accuracy and efficiency.

3:15 PM *DS01.04.05
Co-Development of Experiment Automation and Data Science for Accelerated Materials Discovery JohnM. Gregoire[1], JoelA. Haber[1], DanGuevarra[1], LanZhou[1], DiChen[2], ShufengKong[2], FrancescoRicci[3], JeffreyB. Neaton[3] and CarlaP. Gomes[2]; [1]California Institute of Technology, United States; [2]Cornell University, United States; [3]Lawrence Berkeley National Laboratory, United States

As materials discovery efforts increasingly expand in high-order composition spaces and/or far-from-equilibrium syntheses, efficient exploration requires both automation of experiments and advancement of data science to interpret and plan experiments. We will discuss the automation of experiments for research modalities including exploratory experimentation, validation of theory predictions, and incorporation of artificial intelligence for accelerating both experiment design and data interpretation. In the area of solar fuels materials discovery, these modalities have been prolific for discovery of (photo)electrocatalysts. Furthermore, the interplay of experiment, theory, and data science has inspired the development of new artificial intelligence methods for materials research, including prediction of electronic structure to accelerate computational screening (Mat2Spec) as well as the integration of physical constrains in deep learning models, which enables super-human analytic capabilities for inference of phases in x-ray diffraction patterns via Deep Reasoning Networks (DRNets).

3:45 PM DS01.04.06
Neural Networks Trained on Synthetically Generated Crystals can Extract Structural Information from ICSD Powder X-Ray Diffractograms HenrikSchopmans, PatrickReiser and PascalFriederich; Karlsruhe Institute of Technology, Germany

Machine learning techniques have successfully been used to extract structural information such as the crystal space group from powder X-ray diffractograms, especially in self-driving lab settings [1,2]. However, training directly on simulated diffractograms from databases such as the ICSD is challenging due to its limited size, class-inhomogeneity, and bias toward certain structure types. We propose an alternative approach of generating synthetic crystals with random coordinates by using the symmetry operations of each space group [3]. Based on this approach, we demonstrate online training of deep ResNet-like models on up to a few million unique on-the-fly generated synthetic diffractograms per hour. For our chosen task of space group classification, we achieved a test accuracy of 79.9% on unseen ICSD structure types from most space groups. This surpasses the 56.1% accuracy of the current state-of-the-art approach of training on ICSD crystals directly. Our results demonstrate that synthetically generated crystals can be used to extract structural information from ICSD powder diffractograms, which makes it possible to apply very large state-of-the-art machine learning models in the area of powder X-ray diffraction. We further show first steps toward applying our methodology to experimental data, where automated XRD data analysis is crucial, especially in high-throughput settings. While we focused on the prediction of the space group, our approach has the potential to be extended to related tasks in the future.

4:00 PM DS01.04.07
Metrology and Characterization of Defects in Transition Metal Dichalcogenides using Scanning Tunneling Microscopy with Machine Learning DarianSmalley[1,1], StephanieD. Lough[1,1], LukeHoltzman[2], MadisenHolbrook[2], JamesHone[2], KatayunBarmak[2] and MasahiroIshigami[1,1]; [1]University of Central Florida, United States; [2]Columbia University, United States

The electronic and optical properties of transition metal dichalcogenides (TMDs) are influenced by the presence of atomic point defects within the crystal lattice. Identifying the quantity and nature of these point defects is important for engineering TMD synthesis, ensuring TMD device consistency, and verifying single photon emission sources. Scanning tunneling microscopy (STM) can determine the nature of such point defects by correlating their electronic structure with atomic-scale spatial properties, which is typically done manually. However, manual identification, counting and measurement of point defects in STM images is painstakingly slow and unreliable, causing reported point defect densities to have large experimental uncertainty, preventing directed refinements of synthesis and controlled reduction in TMD point defect density. We address this problem by processing our STM data with a machine learning algorithm and show atomic-scale defect metrology in scanning tunneling microscopy images of tungsten diselenide using an ensemble of U-Net-like convolutional neural networks. Using this technique, we determined the coordinates, densities, and real space properties of over 3000 defects with statistical significance. Our results demonstrate that STM data analysis aided by machine learning can be used to rapidly determine the quality of TMDs and provide much needed quantitative input to systematically improve the synthesis process. As such our machine learning enhanced

STM can impact many two-dimensional materials researchers.

4:15 PM DS01.04.08
Assisting the Design of Chiral Metal Halide Semiconductors with Machine Learning RuilongWang, HaofengZheng and ShaocongHou; Wuhan Univerisity, China

Chiral metal halide semiconductor (CMHS) can directly resolve circularly polarized light and has high carrier mobility and strong defect tolerance, which is highly promising for applications in quantum communication, asymmetric catalysis, medical diagnosis, and so on. However, the tortuous and costly experimental process of designing high-performance CMHS is detrimental to the application of CMHS. Therefore, there is a need to find efficient methods for the design of CMHS.
Here, we built the map between the structure, composition, and chiral intensity of CMHS efficiently using machine learning. Then, we performed SHAP analysis on the established model and calculate the chirality intensity of 1080 potential chiral CMHSs through high-throughput screening. By combining the result of SHAP analysis and prediction, we infer that $1NEA^+$ in A-site, Cu^{2+} in B-site, and Cl^- in X-site are positively related to the chirality intensity of CMHSs. Furthermore, we successfully synthesized unreported material, such as $1NEA_2PbCl_4$ with a g_{CD} of 0.00805, which further validates the credibility of our predictive model. Our work provides an in-depth understanding of combining machine learning and experimentation and helps accelerate the development of CMHS.

4:30 PM DS01.04.09
Autonomous Robotic Experiments Accelerate Discovery of Multi-Components Electrolyte for Rechargeable Lithium-Metal Batteries ShoichiMatsuda; National Institute for Materials Science, Japan

Artificial intelligence (AI) driven approach for materials discovery, has attracted significant recent attention even in the field of rechargeable batteries. Instead of relying on the experience and intuition of researchers for exploring new materials, the approach employs data scientific techniques that can, in principle, reduce the time and cost of the discovery of new materials with superior battery performance and predict cycle life. Actually, an automated robotic experimental system was recently developed by our group for discovering new multi-component electrolytes for lithium-metal based rechargeable batteries, which exhibited superior energy density compared with conventional lithium-ion batteries (ref.1). Although superior searching throughput analyzing more than 1000 samples per day was achieved, adequate experimental design is essential to realize high-throughput exploration of electrolyte composition from large searching space. For example, when considering a combination of selecting 5 types from 20 types of chemicals, the candidates are over 10^7. Thus, it is not realistic to comprehensively evaluate all the possible combination even through such robotic experiments. Therefore, a specific electrolyte composition that realizes a superior battery performance must be determined with only a limited number of experimental trials.
In the present study, the effectiveness of a data-driven automated robotic experiments was investigated to discover multi-component electrolyte additives for lithium-metal based rechargeable batteries. Established machine-learning methodologies using Bayesian optimization were employed to solve optimization problems for analyzing datasets obtained from the automated robotic experiments, thereby minimizing the number of trials required to identify the ideal electrolyte composition. As results, we identified the specific electrolyte composition (1.5 M LiNO3, 0.1 M LiTFSI, 0.1 M LiBr, 0.5 mM LiCl, and 10 mM LiBOB in dimethylamide, with 5 vol.% 1,3-dioxolane) that enhanced the cycle life of the lithium-oxygen rechargeable batteries (ref.2). In additions, we also put our attention for the development of the orchestration system to realize a closed loop between AI searching algorithms and robotic experiments. Generally, different searching algorithms are utilized depending on the motivation of a materials exploration task and the procedure for controlling the devices largely depends on the characteristics of the robotic systems. Thus, the control software has far been developed on a case-by-case manner, limiting the widespread use of searching algorithms for robotic experiments. Based on these considerations, we recently developed the NIMS-OS to implement a closed loop of AI and robotic experiments for automated materials exploration (ref.3). Notably, NIMS-OS treats each AI algorithm and each robotic system as separate modules, resulting in the implementation of a closed loop with any combination of these modules. When modules for new AI algorithms or robotic systems are prepared, new closed-loop systems can be easily controlled via NIMS-OS. We believe that the such generic control software is the advantageous for NIMS-OS as standard platform for autonomous materials exploration with robotic experiments.

Deep Learning-Based Terahertz Inspection Technique for Internal Defect Detection in Ceramic, Polymer and Metal Composites Tae WanKim, Sang-IlKim, You-GwonKim, Heon-SuKim and Hak-SungKim; Hanyang University, Korea (the Republic of)

Abstract
: In this study, internal defects in composites composed of ceramics, polymers, and metals were inspected using terahertz technology in combination with a convolutional neural network (CNN) model and anomaly detection employing a generative adversarial neural network (AnoGAN) model. The defective specimens were intentionally fabricated in the hole and edge regions of the polymer layer, which are vulnerable regions in the composites. The defect region in the polymer layer of the composite was detected in the THz scanning image due to the scattering of THz waves.
The THz scanning image dataset was constructed based on the presence or absence of defects in different regions using a terahertz time-domain spectroscopy (THz-TDS) system. The CNN model was trained to determine the scanning regions (hole, edge) of the composites, while the AnoGAN model was trained to detect defects in the THz images. The CNN model demonstrated a 95% accuracy in classifying the THz scanning regions, and the AnoGAN model achieved a 95% accuracy in detecting defects in the composites. This technique enables automated, real-time inspection for detecting internal defects in semiconductor composite products.

Rapid Analysis of Secondary Phases and Prediction of Photovoltaic Performance in Multinary Chalcogenides ChristianUtama[1], LeoChoubrac[2] and ThomasUnold[3]; [1]Freie Universität Berlin, Germany; [2]Université de Nantes, France; [3]Helmholtz-Zentrum Berlin, Germany

Multinary chalcogenide thin film technologies are interesting for various energy conversion related applications, such as photovoltaics, photocatalysis or thermoelectrics. Due to the large degrees compositional and structural degrees of freedom of this multicomponent materials class, the establishment and control of single-phase deposition routes and material homogeneity is a challenging task, while the detection of secondary phases with X-ray diffraction, electron microscopy and Raman spectroscopy can be tedious and time-consuming. Using the model system of combinatorially-deposited Cu2ZnSnSe4 thin film libraries we demonstrate how rapid hyperspectral optical reflection measurements in conjunction with machine-learning can be used to predict the presence of secondary phases in these material libraries covering a large region of the Cu2Se-ZnSe-SnSe2 ternary phase diagram with high accuracy. The advantages and limitations of different machine-learning algorithms for secondary phase prediction will be discussed. Extending this approach to include hyperspectral photoluminescence measurements, we show how photovoltaic performance can be predicted on a 575 sample library within a 2-hour measurement/analysis cycle.

8:00 PM DS01.05.03
Bayesian Inference in High-Dimensions for Root Cause Analysis of Underperformance BasitaDas[1], ZekunRen[2], AlexanderE. Siemenn[1], ThomasKirchartz[3] and TonioBuonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]National University of Singapore, Singapore; [3]Forschungszentrum Jülich GmbH, Germany

In any solar cell, the root cause for underperformance could be manifolds, arising from recombination in different layers and interfaces, low mobility of the transport layers etc. Traditionally different characterization and data fitting techniques are used to analyze underperforming devices and are often slow as well as destructive to the device. Also, most often the data is fitted to simple rate equations which does not give enough information about the system. Ideally one can try to fit more complex device models to the characterization data, but the sheer number of parameters that usually goes into a device simulator, and the correlation between the parameters make the problem intractable. To infer unknown parameters from higher dimensional spaces, we make use of Bayesian inference.
Bayesian inference methods have been previously used in the field of solar cells for well-studied solar cell technologies like Si solar cells, which are already well studied such that a lot of material parameters are well known. It has also been used for material systems like SnS solar cells where the number of unknown parameters is small [1-3]. However, in previous implementations there were the following challenges :(1) not easily scalable to higher dimensions, (2) solution depending on the initialization condition of the sampler, and (3) the speed of operation was also limited by the device model.
In this presentation we will address these challenges and discuss the strategies we have implemented to overcome them. We take the following strategies to solve the challenges.:
(1) We solve the problem of scalability by using the state-of-the-art Markov chain Monte Carlo (MCMC) sampling technique.
(2) However, even though MCMC makes Bayesian inference scalable to higher dimensions, the solution is highly sensitive to the initialization condition of the samplers. To solve this problem, we introduce a hybrid MCMC method coupled with optimization algorithms such that our solution is reproducible from one run to another. This method of initialization is also robust at finding multiple minima/maxima in case of multi modal solution space.
(3) To achieve performance beyond that limited by the speed of the device model we also incorporated a neural network based surrogate model[4] to replace the device model.
Overall, as an effect of the three improvements, we achieve improvement in scalability, reproducibility, and speed. We show
(1) scalability and reproducibility of our algorithm to up to 10 dimensions,
(2) 15 times faster convergence of MCMC in 10 dimensions, and
(3) 10-100x [4] performance boost from introduction of NN surrogate model.
We also show that the improvements discussed have a overarching impact on high dimensional parameter estimation in both multimodal space as well as needle-in-haystack like situations.

Artificial Neural Networks for Predicting Springback of aa6061 Sheet Based on Environmental and Forming Data Obtained from Smart Sensors ChanheeWon and HyejinLee; Korea Institute of Industrial Technology, Korea (the Republic of)

This research mainly proposes the artificial neural network (ANN) model for predicting the springback of AA6061-T6 sheet using manufacturing process and environmental data, which are collected by temperature, vibration, and force smart sensors. Heat-treated high-strength aluminum alloys, such as AA6061-T6 and AA7075-T6, exhibit low formability and high springback at room temperature, and they are typically formed at elevated temperatures. It is highly necessary to control the elevated temperature of the aluminum sheet before the forming process, as its strength degrades due to the annealing effect at specific temperatures above 250°C. The influencing factors contributing to temperature reduction include ambient temperature, wind speed, and transportation time, among others. Additionally, forming conditions such as forming speed, holding force, and dwell time interact in a complex manner with the environmental conditions to determine the amount of springback in the final product.
To obtain a large dataset for training the ANN model, we newly developed an empirical testing system to simulate the actual warm forming process. This feasibility testing system allows for the systematic application of various combinations of process parameters, such as heating temperatures, transportation time, external wind speed, ambient temperature, and forming conditions. It also enables the attachment of smart sensors to monitor the process status and interconnection. We suggest specific variables from the environmental sensing data as input parameters, along with the forming load-depth curves and vibration data. Various environmental data, including the target temperature, transportation time, wind speed, and duration of exposure to external wind, are used to analyze the characteristics of temperature reduction in the elevated temperature of AA6061-T6 before the forming process. The material properties, maximum forming force, duration time of the maximum force, slope of the load-displacement curve, and FFT analysis of vibration data are used to determine the main influencing factors on the amount of springback in terms of the springback angle of U-channel.
To examine the effect of each input parameter, the performance of each input parameter was evaluated in terms of mean squared error. To confirm the prediction accuracy of the proposed ANN model, the obtained dataset was divided into two subsets: a training dataset and a test dataset, with 30% of the data utilized for the test dataset. Additionally, the proposed ANN model was compared with other conventional machine learning algorithms such as linear regression, decision trees, lasso regression, and ridge regression. Various error statistics, including mean absolute error (MAE), root mean squared error (RMSE), and R-square, were analyzed. The proposed ANN model exhibited remarkable performance in the prediction of the springback angle, which makes it possible to apply in feedback control in the manufacturing process to obtain quick dimensional accuracy when the manufacturing environment undergoes rapid changes.

Function Space Representations for Complex Material Workflows KiranVaddi, KacperLachowski, Huat ThartChiang, KarenLi and LiloD. Pozzo; University of Washington, United States

Self-driving laboratories (SDL) are primed to improve the pace of material discovery and provide tangible solutions to emergent energy, health care, and sustainability applications using a combination of robotic agents and machine learning tools. They replace the traditional, time-consuming experimental-based ideate-synthesize-characterize loop with a more efficient set of agents that accelerate them in all aspects by being able to autonomously make decisions consistent with the physics and chemistry of the underlying system. Data-driven methods are the primary workhorse for developing autonomous agents and have been successfully applied in various applications ranging from closed-loop mapping of synthesis-property relationships to material retrosynthesis of semiconductors, nanoparticles, and 3D printed structures. However, unlike other autonomous agents developed elsewhere, SDL generates a data set of different modalities ranging from scalar outputs (e.g.: efficiency) to a function (e.g.: spectroscopy measurement). I will describe the challenges associated with building models for knowledge extraction and autonomous decision-making using functional data generated to study the nanoscale structure of colloidal and polymer materials and provide a tractable mathematical framework using the differential geometry of function spaces.

Optimization of Silicon Particle Milling Process for Lithium Secondary Battery Anode Using Deep Learning and Bayesian Optimization Jong HoKim; Research Institute of Industrial Science and Technology, Korea (the Republic of)

Lithium rechargeable batteries are developing rapidly in response to the rapid growth of electric vehicles. Electric vehicle batteries require high energy density to increase performance and ensure the ability to drive long distances. Conventional lithium-ion batteries use graphite as the anode material, and recent results have shown that silicon can increase the energy density. However, silicon has been shown to deteriorate due to volume expansion during charge and discharge, and nanoscale particles have been proposed to overcome this problem. In this study, we optimized the milling process to produce silicon particles through deep learning and Bayesian optimization. It was found that the size of silicon particles varies depending on the type of milling process and variables, which in turn changes the characteristics of the battery. Image analysis using deep learning and Bayesian optimization using a Gaussian process have the effect of shortening the analysis and reaching the target size in the silicon particle manufacturing process.

Machine Learning-Based Prediction of Crystal Structure Proportions in Ag-TiO_2 Nanofibers for Enhanced Photocatalytic Activity Yin-HsuanChang[1], Rei-YangLi[1], Ying-HanLiao[1], Ting-HanLin[1] and Ming-ChungWu[1,2]; [1]Chang Gung University, Taiwan; [2]Chang Gung Memorial Hospital at Linkou, Taiwan

In the past decade, mechasim learning has suraged a revolution in the field of materials science and bringing about advancements in predicting materials properties, materials discovery, and materials characterization. Due to the remarkable activity, stability, and non-toxic nature, TiO_2 has emerged as a highly promising photocatalyst for pollutant removal and self-cleaning paints. The diverse crystal structures inherent in TiO_2 play a cricial role in modulating in its energy band structure, thereby enhancing its photocatalytic activity. However, the precise determination of

optimal conditions for multi-phase TiO_2 poses a challenge, as it necessitates a thorough and time-consuming analysis of the quantitative crystal structure.
To overcome this difficulty, we embarked on developing a robust model for predicting the proportion of crystal structures in multi-phase TiO_2. Prior to build a reliable model, we assembled a collection of Raman spectra encompassing various proportions of anatase and rutile phases for serving as database of machine learning. Over the past decade, our research team has focused on investigating metal-doped TiO_2 nanofibers (NFs). Among the studied compositions, silver doped TiO_2 NFs (Ag-TiO_2 NFs) exhibits the highest photocatalytic performance. Excepet for the interaction between inceidnet light and self-precipitated sliver nanoparticles, the phase composition of TiO_2 photocatalysts is also an influential factor for their photocatalytic activity. Although the anantase-to-rutile phase transition occurs at 900 to 1,100 °C in pristine TiO_2 NFs, the senerio is toltally different as a dopant induced into TiO_2 NFs. How to precisely control metal dopant and anatase-to-rutile phase transition in TiO_2 NFs still remains an ongoing challenge.
Herein, we employed the "Variational Autoencoder" machine learning model to perform unsupervised learning and extract meaningful characteristics from the Raman spectra. After thorough inspection and verification, we successfully applied the model to predict the proportion of crystal structures in Ag-TiO_2 nanofibers with different calcination temperatures. By employing innovative and efficient methods, our research offers valuable insights into the correlation between quantitative crystal structure and photocatalytic activity. Notably, our model achieved a mean absolute error of 2.33% and a root mean square error of 0.0291, demonstrating its high predictive accuracy.
By leveraging machine learning techniques, our study provides a powerful tool for predicting crystal structure proportions in multi-phase TiO_2, specifically focusing on Ag-TiO_2 NFs. This enables researchers and practitioners to efficiently analyze the relationship between crystal structure and photocatalytic activity, paving the way for the design and optimization of advanced TiO_2-based materials with enhanced performance in pollutant removal and self-cleaning applications.

Automated EXAFS and Nanoindentation Analysis using Artificial Intelligence in Addressing Reproducibility Challenges MinLong[1], Miu LunLau[1] and JeffreyTerry[2]; [1]Boise State University, United States; [2]Illinois Institute of Technology, United States

We have developed a novel, artificial intelligence-based methodology that can be utilized to reliably analyze experimental results from Extended X-ray Absorption Fine Structure (EXAFS) measurements and other spectral analyses. This development will help to address (1) the reproducibility problems that slow research progress and inhibit effective technology transfer and manufacturing innovation in these scientific disciplines and (2) ultimately a challenge in obtaining the best model fitting parameters from the large and growing quantities of real-time materials characterization data produced by modern instruments, with minimal human intervention.
The existing EXAFS analysis approach relies on a human analyst to suggest a potential set of chemical compounds in the form of feff.inp input files that may be present, which can cause reproducibility issues. The situation is made even worse with advances in instrumentation that have been enabled to produce data 2-3 orders of magnitude more rapidly than it can be analyzed. Instead, we applied a machine learning approach to the analysis of EXAFS spectroscopy measurements collected using a synchrotron radiation facility. Specifically, for the first time, we developed a genetic algorithm (GA) for fitting the measured spectra to extract the relevant structural parameters. The algorithm attempts to determine the best structural paths from these compounds that are present in the experimental measurement. It starts with a population consisting of a number of temporary fittings and looks for the primary EXAFS path contributors from the potential compounds. It calculates goodness of fit value that can be used to identify the chemical moieties present. To improve the accuracy and efficiency of finding an optimized final solution, evolutionary-inspired operators (e.g., crossover, mutator) are applied to each solution throughout subsequent generations. The advantage of using GA is that it can explore large and complex parameter spaces for model solutions and does not require computation of the derivatives of the functional objectives, nor assumptions of continuity and convexity for the objective functions and constraints.
The analysis package is called EXAFS Neo and is open-source and written in Python. It requires using Larch and Feff to calculate the initial EXAFS paths. We have recently extended the code to make use of Feff8.5lite so it can calculate the paths needed for populating the analysis from within the EXAFS Neo package. We have also expanded the Neo to fitting Nanoindentation, the analysis of core-level photoemission, and spectral fitting in other fields like X-ray astronomical data and published the analysis results.

Rapid Mechanical Property Prediction and *De Novo* Design of Three-Dimensional Spider Webs Through Graph and GraphPerceiver Neural NetworksWeiLu, ZhenzeYang and MarkusJ. Buehler; Massachusetts Institute of Technology, United States

Spider webs feature advanced structural performance due to the evolutionary success of over hundreds of millions years, including lightweight design, and exceptional mechanical properties. Spider webs are appealing for bio-inspired design since web designs serve multiple functions including mechanical protection and prey catching. However, high computational cost and limited quantified web properties render extensive spider web studies challenging, in part due to the high structural complexity and randomness of fiber arrangements in 3D webs. Here we report a computational method to relate spider web graph microstructures to effective mechanical properties, focusing on strength and toughness, upscaling from the microscopic to the mesoscale level. The dataset is developed based on experimentally determined spider web graphs, through sheet laser tomography. The new computational framework uses deep neural networks, trained on graph-structured *Cyrtophora citricola* spider web mechanical data, in order to capture complex cross-scale structural relationships. Three different models are developed and compared. First two Graph Neural Network (GNN) models, a Graph Convolutional Network (GCN) and a Principal Neighborhood Aggregation (PNA) method. Second, a GraphPerceiver transformer model that is fed similar input data as provided to the GNN approach, but within a natural language modeling context using self-attention mechanisms. The GraphPerceiver model can achieve similar performance as the GNN model, offering added flexibility for building deep learning models of diverse hierarchical biological materials. As an application of the model, we propose a computational optimization tool for synthetic web design that is used to generate synthetic, *de novo* spider web architectures. Finally, multi-objective optimization enables us to discover web structures that meet specific mechanical properties as design objectives.

8:00 PM DS01.05.10
Machine Learning Analysis and Predictions of PAMBE III-Nitride Growth AndrewS. Messecar, RobertMakin and SteveDurbin; Western Michigan University, United States

There is considerable interest in applying machine learning techniques to aid in rapidly identifying optimal process parameters for materials growth. For example, Bayesian optimization has been employed to optimize the molecular beam epitaxy synthesis of $SrRuO_3$ and TiN thin films, and random forest classifiers have been applied to predict monolayer coverage for MoS_2 thin films. Here, we explore how supervised machine learning (ML) techniques can be applied to understand and predict the relationship between the plasma-assisted molecular beam epitaxy (PAMBE) growth parameter space and both the crystalline quality and structural properties of thin-film binary compounds of GaN and InN by utilizing over a decade's worth of detailed film growth records for the same system.

Data from over one hundred PAMBE growth runs of GaN and InN (each) have been organized into material-specific data sets, and includes substrate temperature, metal source effusion cell temperature, plasma source gas pressure, and plasma source RF power. These variables were selected for model training as they are the direct system parameters an ML model would control. Each film growth experiment was performed using a Perkin Elmer model 430 MBE system equipped with an Oxford Applied Research HD–25 RF plasma source, and custom effusion cells and substrate heater from E-Science. Reflection high-energy electron diffraction (RHEED) was used as the primary quality metric, with crystallinity represented for the initial study by a binary numerical value (1 for monocrystalline and 0 for polycrystalline). Images were acquired using a k-Space Associates model 400 system. The values of the growth variables were then mapped to RHEED data and other structural properties measured ex-situ to perform both inference and prediction using a range of supervised learning algorithms, in order to determine which techniques performed the best on the datasets. The methods applied include classical machine learning methods of state vector machines, k-nearest neighbors, quadratic discriminant analysis, linear discriminant analysis and naive Bayes classifiers, as well as the deep learning techniques of neural networks.

Prior to training each model, K-fold cross-validation was performed for each model in order to determine optimal parameter to be used during training. All of the supervised learning algorithms were subsequently trained on the synthesis data and used to predict the crystallinity and other metrics including the Bragg-Williams order parameter across a broad range of possible process variables. Across most models, the resulting machine learning predicted growth spaces, when adjusted to machine agnostic parameters such as as flux using calibration data from specific growth runs in the machine, agreed with conventional experimental wisdom for PAMBE growth of nitride semiconductors, while also providing new insight on the processing space for these materials. This the work re first step towards developing a more general model for rapid optimization of PAMBE growth parameters for new materials-based discovery applications. Ultimately such generalized models can be combined with models for similar techniques to further enhance the material discovery process.
This work was supported in part by NSF grant DMR-203581.

8:00 PM DS01.05.11
An Adaptive Method Based on Machine Learning for the State-of-Charge and State-of-Health Estimation of Lithium-Ion Batteries BenWenig and BabakKasmaei; American University, United States

The accurate estimation of the state-of-charge (SOC) and the state-of-health (SOH) of lithium-ion batteries is crucial for reliability assurance and maintenance of the energy systems in various applications including electric vehicles, cell phones, and aerospace satellite missions. Due to the complicated and nonlinear nature of the physical mechanisms involved in these batteries and their dependence on several variables, in the past few years, various algorithms based on machine learning have been used for the SOC/SOH estimation. One of the challenges is that the estimator models need to be adaptive for different batteries, application scenarios, and environmental parameters. We present a novel adaptive method for SOC/SOH estimation of lithium-ion batteries based on techniques in machine learning. We apply the proposed method on real datasets of battery operation, and we compare the performance of various algorithms used in this

context. Our findings contribute to the growing field of efficient battery management systems and facilitate creating effective maintenance schedules and enhancing the reliability and safety of battery-powered applications.

8:00 PM DS01.05.12
Enzeptional: Enzyme Optimization via a Generative Language Modeling-Based Evolutionary Algorithm Yves GaetanNana Teukam[1,2], FedericoZipoli[1], TeodoroLaino[1], MatteoManica[1] and FrancescaGrisoni[2]; [1]IBM Research Europe, Switzerland; [2]Technische Universiteit Eindhoven, Netherlands

Enzymes are molecular machines optimized by nature to allow otherwise impossible chemical processes to occur. Besides the increased reaction rates, they present remarkable characteristics to enable more sustainable reactions: mild conditions, less toxic solvents, and reduced waste. Billion years of evolution have made enzymes extremely efficient. However wide adoption in industrial processes requires faster design using in-silico methodologies, a daunting task far from being solved. The majority of methods operate by introducing mutations in an existing amino acid (AA) sequence using a variety of assumptions and strategies to introduce variants in the original sequence. More recently, machine learning and deep generative networks have gained popularity in the field of protein engineering by leveraging prior knowledge on protein binders, their physicochemical properties, or the 3D structure. Here, we cast the problem of enzyme optimization as an evolutionary algorithm where mutations are modeled via a generalized autoregressive language model trained on fragments of AA sequences from UniProtKB. Relying on a pre-trained language model, we apply transfer learning and train a Random Forest as the scoring model on a dataset of biocatalysed chemical reactions to drive the optimization process. With our approach, using the least amount of assumptions, we can adapt active sites to perform new reactions. Our methodology allows designing enzymes with higher predicted biocatalytic activity, emulating the evolutionary process occurring in nature by sampling optimal sequences modeling the underlying proteomic language.

SESSION DS01.06: Novel Learning Strategies for Materials Discovery
Session Chairs: John Gregoire and Kedar Hippalgaonkar
Wednesday Morning, November29, 2023
Sheraton, Third Floor, Fairfax B

8:30 AM *DS01.06.01
Revamping Robotic Minds—Unleashing Bias-Free Machines JasonR. Hattrick-Simpers; University of Toronto, Canada

Over the past five years, the emergence of materials science self-driving labs (SDL) has witnessed a remarkable surge. Although their implementation is not yet widespread, recent substantial federal investments aim to establish dedicated SDL user facilities, aimed at eliminating obstacles around access to equipment and data across various subdomains. Key among the shared challenges faced by SDLs is the influence of human bias, which permeates activities such as building predictive models, extracting knowledge from data, and planning experiments or calculations. The reliance on data selected by risk-averse topical experts, generation of ground truth labels made through heuristic decisions, and the influence of years of choice made through “solid physical intuition” raise important questions: How can we ensure that SDLs do not repeat our mistakes and have the potential to discover truly novel insights?
In this talk, I will present compelling examples from our recent work, where we have encountered biases and developed innovative methods to overcome them. Specifically, I will delve into (1) the identification and mitigation of bias in large materials datasets, (2) the development of bias-free tools for analysis in electrochemical impedance spectroscopy, and (3) bridging the trust gap between AI and experimental experts when the model suggests unconventional paths that challenge intuition. As an example I will show how for specific regression tasks as much as 95% of data available in large data sets can be dropped without degradation of their predictive power.

9:00 AM DS01.06.02
Efficient Bayesian Reaction Optimization Guided by Graph Neural Networks for Quantifying Difficulty of Chemical Synthesis YoungchunKwon, Jin WooKim, JoonhyukChoi, SeungminBaek and Youn-SukChoi; Samsung Advanced Institute of Technology, Korea (the Republic of)

Synthetic reaction planning is an inevitable tool for expediting the exploration of groundbreaking drugs and materials. In order to achieve the synthesis of a newly conceived molecular structure that meets the desired properties, it becomes imperative to optimize a multitude of experimental condition parameters such as catalyst, solvent, ligand, etc. To rapidly find the optimal reaction conditions is one of the key factors that can reduce the long cycle of new drug and material discovery. Because synthetic experiments are required very high financial costs, time, and domain experts. Therefore, the many different types of methods such as design of experiments (DOE) and Bayesian optimization(BO) have been employed to solve this optimization tasks. However, BO has a cold-start problem, which necessitates conducting crucial initial experiments to train the surrogate model. Moreover, assessing the feasibility or difficulty of synthesis encounters a challenge where the search space inefficiently expands due to variations arising from individual human’s knowledge and experience.
In this study, we propose to solve the trade-off problem of chemical reaction optimization by combining machine learning approaches and Bayesian optimization techniques using accumulated experimental data to efficiently define the search space using by a generative model. We also quantify the difficulty of experiments with our uncertainty-aware yield prediction model and construct an optimization strategy, and dynamically reflect the results of repeated experiments into the strategy.
In first research focus is to effectively reduce the wide range of parameters using by our generative model to predict the best combination of conditions, not just a classification model. Second research aims to predict yield of a chemical synthesis reaction along with the uncertainty of the prediction results. The utilization of uncertainty models enables us to estimate the likelihood and challenges associated with the process of synthesis. By considering the constrained search space, the difficulty of synthesis, and a chemical reaction yield prediction model, we devised an approach to tackle the optimization trade-off problem effectively, facilitating efficient execution of optimization experiments.
We verified the effects of our proposed framework-based optimization algorithm with various existing approaches. In this study, we successfully found condition combinations that achieved the target yield with the least number of experimental trials compared to other optimization algorithm. To further validate the performance of proposed study in comparison to synthesis experts, we conducted additional verification using a high throughput experimentation.

9:15 AM DS01.06.03
Improved Carbon Nanotube Growth via Autonomous Active Learning of Catalyst Metal Oxide Phase Transition by Jump Regression RobertWaelder[1,2], ChiwooS. Park[3], JenniferCarpena-Núñez[1,2], JoshYoho[1,2], RahulRao[1] and BenjiMaruyama[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc, United States; [3]Florida State University, United States

Nanoparticle catalyst control is critical to carbon nanotube (CNT) growth and scaling their production. In supported catalyst CNT growth, the reduction of an oxidized metal catalyst enables growth, but its reduction also leads to catalyst deactivation via Ostwald ripening, agglomeration, and other effects. Here, we conducted autonomous experiments guided by a hypothesis-driven machine learning planner based on a novel jump regression. This planning algorithm iteratively builds a model to identify discontinuities in the experimental response surface, such as those created by a material phase change, and selects further experiments to better identify those discontinuities. This approach led us to identify input conditions that resulted in the greatest CNT yields as a function of the driving forces of catalyst reduction in a fraction of the time and cost of conventional experimental approaches. Specifically, by varying temperature and the reducing potential of the growth atmosphere, we identified a discontinuous jump in CNT growth resulting in the largest observed yields at a critical thermodynamic equilibrium between metallic iron and iron oxide for two different thicknesses of thin film iron catalysts. In addition to the greatest overall yields, we observed the longest growth lifetimes and a greater degree of diameter control at the jump, compared to other regions in the search space. We believe that conducting CNT growth at the jump identified in thermodynamic space optimizes catalyst activity, since the presence of oxidized species inhibits Ostwald ripening-induced deactivation, thereby keeping catalyst nanoparticles smaller and more numerous. This work identifies optimal thermodynamic conditions for the production of small diameter single-walled CNTs using a supported iron catalyst, establishes a thermodynamic framework for a generalized understanding of other metal catalysts in CNT growth, and demonstrates the capability of iterative, hypothesis-driven autonomous experimentation to greatly accelerate materials science.

10:00 AM *DS01.06.04
Accelerating Materials Discovery via Bayesian Optimization—“A Case Study in High-Performance Polymers” and its Possible Future Improvement JayH. Lee[1] and MujinCheon[2]; [1]University of South Carolina, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Bayesian optimization (BO) has emerged as a powerful technique for accelerating materials research, both in academic and industrial settings, due to its exceptional data efficiency in black-box optimization problems. This presentation will give a comprehensive overview of BO, its underlying principles, and its application in the pursuit of high-performance materials. Furthermore, we highlight the limitations of conventional BO approaches, specifically their myopic nature and vulnerability to local minima, and propose one possible novel solution using reinforcement learning (RL)-based BO.
Bayesian optimization (BO) combines statistical modeling and sequential design to efficiently explore and optimize objective functions with limited evaluations. Unlike traditional Design of

Experiments (DoE) methods, which require a pre-defined grid or set of samples, BO adaptively selects new candidate points based on previous observations, dynamically refining its search towards promising regions of the design space. This adaptive nature of BO allows it to allocate experimental resources more efficiently, resulting in significant time and cost savings compared to DoE approaches. Furthermore, BO incorporates uncertainty estimation, enabling effective decision-making in the face of noisy or scarce data. These key principles make BO particularly well-suited for accelerating materials research, where data collection can be noisy and time-consuming, and the design space is often high-dimensional.
In collaboration with Kolon, Inc., we conducted a case study aimed at discovering a high-performing polymer with minimal experimentation. The problem had 15 dimensional search space, and 4 measured output properties. Our objective we chose was to maximize the values of output properties 2 and 3, while adhering to specific constraints associated with each output property. Initially, the company provided us with 32 initial data points to kick-off BO iterations.
Remarkably, after just the first iteration of the Bayesian optimization, we discovered a polymer that satisfied all the imposed constraints and aligned with the company's specific requirements. This accelerated discovery showcased the efficiency and effectiveness of BO in navigating the high-dimensional design space while optimizing for multiple objectives and constraints. The successful outcome of this case study illustrates the potential of BO for expedited material discovery, significantly reducing the number of required experiments.
However, traditional heuristic Bayesian optimization algorithms do not provide a universally good solution for every system. Conventional BO approaches, such as PI, EI, and UCB, tend to prioritize short-term gains within a single step, often resulting in being trapped in local minima and failing to explore the wider landscape of undiscovered possibilities. To overcome this limitation, we propose RL-based BO, which offers a non-myopic perspective. By integrating RL algorithms into the BO framework, we enable more intelligent exploration and exploitation strategies. By considering the future utility of exploration in current decision-making, RL-based BO actively seeks out unexplored regions, facilitating the discovery of high-performing materials.
In this abstract, we present a narrative that highlights the potential of various BO techniques in expediting materials discovery. Our case study exemplifies the power of BO-assisted experimentation in accelerating materials research. Additionally, we introduce RL-based BO as a promising approach to overcome the limitations of conventional BO. This presentation aims to inspire researchers, and industry professionals to leverage the synergistic relationship between AI and materials science.

10:30 AM DS01.06.05
Physics Inspired Batch Bayesian Optimization for Autonomous Polymer Electrolyte Discovery JurgisRuza[1], MichaelStolberg[1], JeffreyLopez[2], SawyerCawthern[3], AbrahamHerzog-Arbeitman[3], Ha-KyungKwon[4], DanielSchweigert[4], RafaelGómez-Bombarelli[1], YangShao-Horn[1] and Jeremiah A.Johnson[3]; [1]DMSE, MIT, United States; [2]Northwestern University, United States; [3]Massachusetts Institute of Technology, United States; [4]Toyota Research Institute, United States

Polymer electrolytes have been identified as a promising alternative to liquid electrolytes in Li-ion batteries due to their potential for improved stability and enhanced mechanical properties. At the core of a successful candidate is the selection of a symbiotic pair of a salt, polymer, and the salt concentration in the polymer. However, the vast number of possible salt and polymer combinations hinders the discovery of new polymer candidates. Machine learning has proven essential in the search for new polymer electrolytes. Prior research on polymer electrolytes in existing literature can be used as a resource for discovering new and interesting polymer-salt combinations. Machine learning methods can be trained on this data as a starting point for suggesting new experiments and guiding them until best composition is found.
In this work, we propose a physics-inspired batch Bayesian Optimization (BO) model to guide the discovery of new and optimal salt-polymer combinations. To achieve this, we used a previously developed model for predicting the ionic conductivity Arrhenius parameters, which was trained with ionic conductivity data from literature, as a surrogate model for BO with ensemble uncertainty estimation. The latent embedding space of the polymer-salt candidates constructed by the machine learning model was used as the sampling space for batch BO. This approach ensured chemical diversity for each experimental run. Our results show that this model efficiently explores the search space by reducing model uncertainty in unexplored regions while quickly reaching the optimal ionic conductivity limit.

10:45 AM DS01.06.06
Towards Better Guided Experiments and Adaptive Learning with Human-AI Collaborated Bayesian Optimized Active Recommender System ArpanBiswas[1], YongtaoLiu[1], Yu-ChenLiu[2], Jan-ChiYang[2], SergeiV. Kalinin[3], MaximZiatdinov[1] and RamaK. Vasudevan[1]; [1]Oak Ridge National Laboratory, United States; [2]National Cheng Kung University, Taiwan; [3]The University of Tennessee, Knoxville, United States

Optimization for different tasks like material characterization, synthesis, and functional properties for desired applications over multi-dimensional control parameter and function spaces need a rapid strategic search through active learning. However, in all cases prior to optimization, the target structure-material property relationship to be explored are assumed known, with the ability to shift the trajectory of the optimization based on human-identified findings during the experiment is lacking. This can be critical for running expensive experiments on new materials, when the experimental results are fuzzy for any scientific outcomes due to improper target setting, ultimately wasting time and cost. The failure rate and cost are even higher over exploring on multi-target space, where we want to learn the pareto among multiple properties, to jointly optimize during material synthesis for desired applications. To address the challenge and highlight the best of both machine learning and domain experts with appropiate balance between accelerated and meaningful scientific discoveries, here we introduce the human-AI collaborated active recommender system which aims to design and shape the target property to explore “on the fly” with real time visual assessment during the course of Bayesian optimized sequential experiements, ultimately bypassing the need to define any target scalarizer prioir to the optimization process. The proposed approach allows to seamlessly combine the human input at the policy of the ML agent during the early explorations (when prioir knowledge is minimal) to refine the target to explore, and with future adaptive explorations, the preferences shifts completely towards artifical intelligence to accelerate the learning with human assessed goal. The approach has been demonstrated to peizoresponse force spectroscopy of a ferroelectric thin film, exploring (finding symmetric hysteresis loops) with different kernels and acquisition functions, and finally extended the proposed tool to explore over human assessed multi-target (jointly exploration of symmetric loops and higher left loop) spaces (Pareto frontier). This work shows an advancement towards human-AI collaborated automated experiments, simulateneoulsy steering optimization trajectories and accelerating the path to optimal learning with human guidance and AI-driven experimentation.

Advanced Gaussian Process Function Approximation for Uncertainty Quantification and Autonomous Experimentation MarcusM. Noack; Lawrence Berkeley National Laboratory, United States

The fields of machine learning (ML) and artificial intelligence (AI) have transformed almost every aspect of science and engineering. The excitement for AI/ML methods is in large part due to their perceived novelty, as compared to traditional methods of statistics, computation, and applied mathematics. But clearly, all methods in ML have their foundations in mathematical theories, such as function approximation, uncertainty quantification, and function optimization. Autonomous experimentation is no exception; it is often formulated as a chain of off-the-shelf tools, organized in a closed loop, without emphasis on the intricacies of each algorithm involved. The uncomfortable truth is that the success of any ML endeavor, and this includes autonomous experimentation, strongly depends on the sophistication of the underlying mathematical methods and software that have to allow for enough flexibility to consider functions that are in agreement with particular physical theories, knowledge, and intuition. We have observed that standard off-the-shelf tools, used by many in the applied ML community, often hide the underlying complexities and therefore perform poorly. In this talk, I want to give a perspective on the intricate connections between mathematics and ML, with a focus on Gaussian processes for uncertainty quantification and autonomous experimentation. Although the Gaussian process is a powerful mathematical concept, it has to be implemented and customized correctly for optimal performance; it is often criticized for unrealistic uncertainty quantification and poor scaling when used in its standard setup. The reason, however, is often not the method itself but missing flexibility and domain awareness of the underlying prior probability distribution. I will start this talk by discussing some recent examples in which GPs were applied to various approximation and decision-making problems; we will discover, by example, where the challenges, intricacies, and complexities of this methodology lie, and subsequently, how they can be addressed to yield improved performance. We will continue this thought process by focusing on how the right customizations can improve autonomous experimentation. I will present several simple toy problems to explore these nuances and highlight the importance of mathematical and statistical rigor in autonomous experimentation, uncertainty quantification, and ML.

Inverse Design for Printable Photovoltaics—Improving Efficiencies through Single Experiment Optimisation Enabled by High-Throughput Experimentation and Machine Learning LeonardNg Wei Tat[1], Na GyeongAn[2], JeungeunKim[2], LukeSutherland[2], YinhuaZhou[3], LiuYang[3], Dong WookChang[4], TawfiqueHasan[5], MeiGao[2] and DoojinVak[2]; [1]Nanyang Technological University, Singapore; [2]Commonwealth Scientific and Industrial Research Organisation, Australia; [3]Huazhong University of Science and Technology, China; [4]Pukyong National University, Korea (the Republic of); [5]University of Cambridge, United Kingdom

Roll-to-roll (R2R) printed photovoltaics (PVs) can reduce solar energy costs with their flexible form factors and manufacturing footprint. Machine-learning techniques and high-throughput experimentation have enabled multiple opportunities to accelerate materials discovery to break previous power conversion efficiency (PCE) records. Here, we demonstrate a `MicroFactory', a high-throughput, autonomous and modular research platform for R2R printed PVs that enables inverse design. Consisting of an R2R fabricator, characteriser, and a cloud database, we use the MicroFactory to fabricate, characterise and record manufacturing parameters of an unprecedented 11,800 non-fullerene acceptor (NFA) organic photovoltaic devices (OPV) devices in a single

24-hour experiment. We further demonstrate how a rich dataset of 649,055 data points across 54 features collected in a single experiment can be used for inverse design to generate new input parameters that can produce enhanced devices. This is done firstly by solving an optimisation problem, making predictions on simulated data whose results can be measured to real-world performance, and then taking the generated inputs from the simulated data to produce printed PVs with enhanced PCEs. Using this process, we make a set of 1,200 enhanced devices that outperformed our initial experiments and achieved a PCE of 9.35%, an 87% improvement from a previous record efficiency of 5% for printed R2R PVs. This established heuristic presents an opportunity to accelerate materials discovery with the assistance of AI that is transferrable to other research platforms and material classes.

Enhancing Active Learning Framework for Material Discovery and Optimization Through Incorporation of Physical Insights and Multimodal Data Ming-ChiangChang[1], SebastianAment[1], MaximilianAmsler[1,2], DuncanSutherland[1], HongruiZhang[1], LanZhou[3,3], JohnM. Gregoire[3,3], CarlaP. Gomes[1], LouisaSmieska[1], ArthurR. Woll[1], R.B. Van Dover[1] and MichaelO. Thompson[1]; [1]Cornell University, United States; [2]University of Bern, Switzerland; [3]California Institute of Technology, United States

Recently, artificial intelligence (AI) and active learning (AL) have been adapted by the experimental material science community for on-the-fly decision making and experiment planning, enabling autonomous research. Although researchers have demonstrated the ability of AL to efficiently explore materials spaces and identify compositions with extraordinary properties, existing methods mostly "learn" from the experimental data without significant physical insight. Additionally, inputs to the AI are typically based on single characterization data (unimodal). These constraints limit the physical reasoning ability of current AL agents. The incorporation of specific physical characteristics from the experiments as inputs to the AI models, and including data not directly related to the objective properties, has the potential to significantly improve the overall exploration and exploitation efficacy.

In this work, we demonstrate these improvements through two case studies. In the first, we incorporate concurrent probabilistic labeling of complex XRD patterns generated during laser spike annealing of composition gradients. A new phase labeling algorithm provides quantitative identification of potential multiphase structures with probabilistic assessment that is used by the AL agents to develop full temperature/time/composition phase processing maps. This has enabled us to readily expand the active learning AI from simple phase space exploration tasks to the more complex task of searching for specific targeted phase(s). We demonstrate the utility of this approach in the Bi-Ti-O system where phase maps for multiple structures were autonomously generated during an X-ray synchrotron run, with the AI transitioning from exploration mode to exploitation mode mid-experiment to optimize the anatase structure.

Second, we have incorporated additional "low-cost" measurements (e.g. optical microscopy) as indirect indicators of the objective property into the data analytic workflow, further accelerating the property optimization process. Using these additional data sources, the AI efficiency is shown to be significantly enhanced with minimal experimental overhead. In the first demonstration, this additional data was used to more efficiently utilize limited X-ray synchrotron time to maximize the AI learning. In second work, these data enable optimal use of more complex experimental protocols such as contact-mode electrical measurements. For both examples, we carefully examine the efficacy of the data processing and active learning methods, and demonstrate that the inclusion of these elements indeed improves the overall autonomous workflow.

Battery Charge Curve Prediction via Feature Extraction and Supervised Machine Learning LaisuoSu[1], ShuyanZhang[2], AlanMcGaughey[2], B. ReejaJayan[2] and ArumugamManthiram[1]; [1]The University of Texas at Dallas, United States; [2]Carnegie Mellon University, United States

Real-time onboard state monitoring and estimation of a battery over its lifetime is indispensable for the safe and durable operation of battery-powered devices. In this study, a methodology to predict the entire constant-current cycling curve with limited input information that can be collected in a short period of time is developed. A total of 10,066 charge curves of LiNiO2-based batteries at a constant C-rate are collected. With the combination of a feature extraction step and a multiple linear regression step, the method can accurately predict an entire battery charge curve with an error of < 2% using only 10% of the charge curve as the input information. The method is further validated across other battery chemistries (LiCoO2-based) using open-access datasets. The prediction error of the charge curves for the LiCoO2-based battery is around 2% with only 5% of the charge curve as the input information, indicating the generalization of the developed methodology for predicting battery cycling curves. The developed method paves the way for fast onboard health status monitoring and estimation for batteries during practical applications.

Autonomous Multimodal Optimization of Surfactant Solutions Utilizing The AFL Platform DuncanSutherland, PeterBeaucage and TylerMartin; National Institute of Standards and Technology, United States

Biological formulations such as protein therapies, vaccines, insulin solutions are complex mixtures of a variety of carefully balanced components, for example surfactant stabilizers, anti-microbial agents, buffer salts, and the active biological component. Such solutions are optimized for shelf life, potency, and efficacy of the biologic. Neutron scattering techniques are a critical but costly tool for understanding the solution structure and interplay between the insipient and excipient components. A naïve grid search over each independent component results in an increasingly intractable space due to a span of resource limitations. (experiment and analysis time, cost of reagents, beamline availability, etc.) The autonomous formulation lab (AFL) was developed to conduct an optimized and iterative search of such spaces utilizing neutron scattering. While sensitive to the underlying structure, the neutron scattering is not capable of measuring all the desired properties of the end formulation. Previous work indicates successful exploration through large dimensional spaces but operates only on identifying solution morphology boundaries in the scattering data. A solution that becomes turbid indicates aggregation, a non-starter in biomedical formulations, and can be detected by simple image processing techniques. The combination of both structure information and turbidity can reduce the number of experiments in exploring *useful* solution composition space, lowering the overall resource cost. Here we present the recent results of combining two sources of information, Gaussian process classification of the neutron scattering patterns and gaussian process regression over the optical turbidity, in active learning campaigns trialing different acquisition functions and search strategies. We benchmark independent source learning with a joint optimization scheme that explore the space via the uncertainty in the classification model while exploiting the expected turbidity of the regression model. This accelerated the exploration and optimization of solutions containing a PS188 surfactant, and two preservative and antimicrobial components benzyl alcohol and phenol in a sodium phosphate buffer.

2:15 PM DS01.07.03
Demonstration of Iron-Based Superconducting Magnet through Complemental Researcher- & Bayesian-Driven Process Design and Twinning Network Graph Analysis AkiyasuYamamoto[1,2], ShotaIshiwata[1], ShinjiroKikuchi[1], YutaHasegawa[1], ShinnosukeTokuta[1,2], AkimitsuIshii[3,2], AkinoriYamanaka[1,2], YusukeShimada[4,2], ZimengGuo[5,2], SatoshiHata[5,2], TakutoKojima[6,2], KentaroKutsukake[7,2], HiroakiKudo[6,2] and NoritakaUsami[6,2]; [1]Tokyo University of Agriculture and Technology, Japan; [2]JST-CREST, Japan; [3]NIMS, Japan; [4]Tohoku University, Japan; [5]Kyushu University, Japan; [6]Nagoya University, Japan; [7]RIKEN, Japan

122 phase iron-based high temperature superconductors show high upper critical field with small electromagnetic anisotropy[1)] and large critical grain boundary angle[2)], and therefore is a promising material for applications in polycrystalline form. Foreseeing magnet applications, Weiss et al. have reported demonstration of trapped field of 1 T for K-doped $BaFe_2As_2$ (Ba122) polycrystalline bulks synthesized by hot isostatic pressing[3)]. In this study, K-doped Ba122 bulks were synthesized from mechanochemically synthesized precursor which was prepared by high-energy ball-milling of elemental metals with the molar ratios of Ba:K:Fe:As = 0.6:0.4:2:2 in a Ar glove box [4), 5)]. The precursor powder was then spark plasma sintered. Two approaches to optimizing the processing conditions were considered: optimization by researchers' experience and intuition and by data driven process based on machine learning[6)]. Bayesian optimization was applied to find the best input parameters that maximize the target output property, critical current density (J_c) under magnetic field of 3 Tesla, on the experimentally available range of processing conditions with pre-optimization data by researchers using a software BOXVIA[6)]. High J_c value exceeding 10^5 A/cm^2 was developed by both experiments guided by researchers and Bayesian optimization process. Doubled trapped magnetic field exceeding the previous record by Weiss et al. [3)] was measured. Detailed trapped magnetic field properties of Ba122 bulk magnets and the key microstructural features revealed by 3-dimensional multiscale analysis[7)], precession electron diffraction (PED) nano-orientation STEM analysis and the twinning network graph analysis[8)] will be discussed.

Generative Design and Validation of Inorganic Crystals KedarHippalgaonkar[1,2]; [1]Nanyang Technological University, Singapore; [2]Institute of Materials Research and Engineering, Singapore

We present a generative model framework for rapidly discovering inorganic materials. By leveraging deep generative models and a property prediction target learning branch, the model efficiently explores the chemical space and identifies materials with desirable properties (in this case, formation energy and synthesizability[1]). The generative model consists of constructed latent space representation from known materials and generating new materials by sampling from this space. The main ingredient is our newly designed reconstructable Wyckoff site based crystal representation that includes symmetry considerations.

Beyond reducing reconstruction loss, to validate the generated materials, Density Functional Theory has been performed in addition to high-throughput synthesis and validation of the generated compounds.

In summary, our generative model framework offers a promising approach for accelerated inorganic materials discovery. Its integration with robotic, high-throughput workflows and self-driving labs ensures efficient validation of the generated materials, facilitating their successful translation into real-world applications.

Continuous Flow Synthesis of Pyridinium Salts Accelerated by Multi-Objective Bayesian Optimization with Active Learning JohnH. Dunlap[1,2], JeffreyG. Ethier[1,2], AmeliaA. Putnam-Neeb[1,3], AbigailG. Doyle[4], TimothyM. Swager[5], ChristopherA. Crouse[1] and LukeA. Baldwin[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States; [3]National Research Council, United States; [4]University of California, Los Angeles, United States; [5]Massachusetts Institute of Technology, United States

We report a human-in-the-loop implementation of the multi-objective experimental design via Bayesian Optimization platform (EDBO+) towards the optimization of butylpyridinium bromide synthesis under continuous flow conditions. The algorithm simultaneously optimized reaction yield and production rate (or space-time yield) and generated a well defined Pareto front. The versatility of EDBO+ was demonstrated by expanding the reaction space mid-campaign by increasing the upper temperature limit. Incorporation of continuous flow techniques enabled improved control over reaction parameters compared to common batch chemistry processes, while providing a route towards future automated syntheses and improved scalability. To that end, we applied the open-source Python module, nmrglue, for semi-automated NMR analysis, and compared the acquired outputs against those obtained through manual processing methods from spectra collected on both low-field (60 MHz) and high-field (400 MHz) NMR spectrometers. The EDBO+ based model was retrained with these four different datasets and the resulting Pareto front predictions provided insight into the effect of data analysis on model predictions. Finally, quaternization of poly(4-vinylpyridine) with bromobutane illustrated the extension of continuous flow chemistry to synthesize functional materials.

4:15 PM DS01.07.06
Improvement of Extrapolative Prediction Performance by Quantum Chemical Calculations for Machine Learning Predictions of Flow-Synthesized Binary Copolymers. ShogoTakasuka[1], ShuntoOikawa[1], TakayoshiYoshimura[2], ShoIto[1], YosukeHarashima[1], TomoakiTakayama[1], ShigehitoAsano[3], AkiraKurosawa[3], TetsunoriSugawara[3], MihoHatanaka[2], TomoyukiMiyao[1], TakamitsuMatsubara[1], Yu-yaOonishi[3], HiroharuAjiro[1] and MikiyaFujii[1]; [1]Nara Institute of Science and Technology, Japan; [2]Keio University, Japan; [3]JSR Corporation, Japan

The properties of polymers are highly dependent on the combination and composition ratio of the monomers used to prepare them; however, the large number of available monomers makes an exhaustive investigation of all the possible combinations difficult. In the present study, five binary copolymers were prepared by radical polymerization using a flow reactor, and the prediction performance of a machine learning model was evaluated in the interpolation and extrapolation regions for the estimation of the monomer conversion and monomer composition ratio in the polymer, which were used as objective variables. The prediction model was constructed using the process variables during polymerization and additional molecular descriptors (i.e., molecular flags (one-hot encoding), fingerprints or quantum chemical calculation values) related to the monomer type as explanatory variables. In the interpolated regions where all monomer types used were included in the training data, the prediction accuracy was high irrespective of the molecular descriptors. In the extrapolation region, the model that included explanatory variables corresponding to quantum chemical calculation values representing the energy related to the radical reactions such as energies of transition states and radicals, showed a high prediction accuracy for each objective variable. We found that quantum chemical calculation are important factors in the search for new binary copolymers. Besides, we will make a presentation about Bayesian optimization to synthesize a desired copolymer by optimizing the process variables.

Chemist-Intuited Atomic Robotic Probe for Intelligent Synthesis of Magnetic Nanographenes JieSu[1], JialiLi[1], XiaonanWang[2] and JiongLu[1]; [1]National University of Singapore, Singapore; [2]Tsinghua University, China

Atomic-scale manufacturing of carbon-based quantum materials with single-bond precision holds immense potential in advancing tailor-made quantum materials with unconventional properties, which are crucial in developing next-generation spintronic devices and quantum information technologies. To date, on-surface chemistry approaches, including surface-assisted synthesis and probe-assisted manipulation, while demonstrating huge potential in fabricating these materials, are impeded by the challenges of reaction selectivity control, or restricted by scalability and production efficiency, severely hindering their practical deployment. Herein, we demonstrate the concept of the chemist-intuited atomic robotic probe (CARP) by integrating probe chemistry and artificial intelligence, allowing for conducting precise molecular surgery, aiming for the on-demand synthesis and comprehension of the elusive carbon-based quantum matters with single-bond precision. Such a concept is validated by a novel multi-bond molecular surgery to fabricate open-shell magnetic nanographenes, known as single-molecule quantum π-magnets (SMQMs), with tunable topology and spin multiplicity triggered by site-selective probe chemistry. Our deep neural networks not only transform such a complex probe-chemistry issue into machine-understandable tasks but also provide valuable chemist-intuition into elusive reaction mechanisms by extracting the critical chemical information within the data. A joint experimental and theoretical investigation demonstrates that a voltage-controlled two-electron-assisted electronic excitation enables synchronous six-bond transformations to extend the zigzag topology of SMQMs, triggered from the phenyl *sp2* -CH bond activation, aligning with initial conjectures given by the deep neural models. Our work represents a significant leap from autonomous fabrication to intelligent synthesis with unparalleled levels of selectivity and precision beyond the current synthetic tools, thus creating a major paradigm shift in the on-demand manufacturing of novel organic quantum materials for on-chip integration

9:15 AM DS01.08.02
Bayesian Optimization with Experimental Failure for High-Throughput Materials Growth YukiK. Wakabayashi[1], TakumaOtsuka[2], YoshiharuKrockenberger[1], HiroshiSawada[2],

YoshitakaTaniyasu[1] and HidekiYamamoto[1]; [1]NTT Basic Research Laboratories, Japan; [2]NTT Communication Science Laboratories, Japan

Recent developments in materials informatics leveraging machine learning methods, including Bayesian optimization (BO) and artificial neural networks, have been accelerating materials research [1,2]. However, appropriate handling of missing data caused by experimental failures has been a common but significant challenge for the application of machine learning and automation technologies, such as BO and robotic experimentation, toward efficient high-throughput materials synthesis.
BO is a sample-efficient approach for global optimization. In this presentation, we will introduce a novel BO algorithm that effectively handles missing data. Missing data instances arise when the target material is evasive due to inadequate synthesis parameters [3]. Our algorithm aims to complement and address this issue, enabling more robust and efficient optimization even in the presence of missing data. Though one may restrict the parameter search space to avoid experimental failures, this approach can exclude good parameters for the target material. In contrast, our algorithm can fully search complex parameter spaces by substituting the evaluation value for the missing data to the worst evaluation value available at that time. First, we show the efficacy of the BO method in handling experimental failures by utilizing simulated data. Subsequently, we validate its performance by implementing real materials growth data, namely machine-learning-assisted molecular beam epitaxy (ML-MBE) [4,5] of itinerant ferromagnetic perovskite $SrRuO_3$ thin films. We used the residual resistivity ratio (RRR) as the evaluation metric. The growth conditions, specifically the Ru/Sr flux ratio, growth temperature, and ozone flux rate, of $SrRuO_3$ thin films on $DyScO_3$ substrates were optimized for achieving high RRR values. The optimization process uses five random initial growth parameters and measured experimental RRR values for the updated Gaussian process regression model that predicted RRR values at unseen growth parameters using the past observations. We achieved the RRR of 80.1, the highest ever reported among tensile-strained $SrRuO_3$ films. We explored a wide three-dimensional parameter space, while complementing missing data within only 35 MBE growth runs. Our tensile-strained $SrRuO_3$ thin films stabilized by epitaxial strain show higher Curie temperature than bulk or compressive-strained films [6]. The proposed BO method is capable to properly handle experimental failure and will play an essential role in the growth/synthesis of various materials.

Towards Self-Driving Laboratory for Perovskite Ceramics: An Automated Rapid-Sintering and Dielectric-Analysis Platform (ASAP) MojanOmidvar[1], AchinthaA. Ihalage[1], HangfengZhang[1], TheoG. Saunders[1], HenryGiddens[1], MichaelForrester[2], SajadHaq[2] and YangHao[1]; [1]Queen Mary University of London, United Kingdom; [2]QinetiQ, United Kingdom

The convergence of machine learning (ML) and automated experimentation offers promising avenues for advancements in materials and manufacturing. As a result, an entirely integrated automated process facilitates the creation of the autonomous "self-driving laboratory" (SDL) for material discovery.[1] Yet, challenges remain in creating comprehensive maps connecting the Process-Structure Properties (PSPs) of materials, largely due to the intricate relationship between a material's microstructure and its manufacturing process, as well as associated costs and energy consumption of trial-and-error experimentation. One exemplar is the Solid-State Reaction (SSR), a standard method for producing 3D bulk ferroelectrics. This method requires significant energy, driving up both costs and environmental impact, particularly with the need for prolonged high-temperature sintering and subsequent reheating for dielectric characterization of ML-predicted compositions.[2] Addressing these challenges, we introduce the Automated Rapid Sintering and Dielectric Analysis Platform (ASAP), designed to streamline the dielectric characterization process of 3D tunable perovskites and the discovery of new disordered layered materials. This platform adopts a holistic approach to sample production, sidestepping potential bottlenecks, particularly in operations carried out by robotic arms connected to off-the-shelf lab equipment. Validated successfully with previously known samples, ASAP drastically reduces processing times to minutes compared to traditional methods that can span hours or days. Moreover, ASAP's capabilities extend to the efficient validation of innovative perovskite solutions, as demonstrated with samples from the barium family, particularly $(Ba_xSr_{1-x})CeO_3$ identified using ML-based combinatorial chemical space screening presented in our previous publication.[3] We used ASAP to create relation between sintering condition and Phase structure of these particular unknown samples. In addition, the ASAP characterisation tool monitored the dielectric performance of number of ferroelectric (such as: BST and BTS samples) rapidly sintered samples over the frequency range of 0.2 to 3GHz with no sample surface modification required. Using this probe, the robot recorded resonance frequency, permittivity and temperature tunability for each sample. Looking ahead, we anticipate a growing trend towards user-friendly automation, open sourcing, and the use of collaborative robots (cobots) in laboratories. These advancements will undoubtedly accelerate the adoption of automation, enabling more efficient exploration in materials science.

Machine Learning Models for Predicting the Morphology of Chalcogenide Thin Films IsaiahA. Moses and WesleyReinhart; The Pennsylvania State University, United States

2D materials are growing in popularity due to their unique and intriguing properties that make them promising for technological applications in areas including electric and optoelectronic, energy, and sensing. The synthesis of these materials involves careful tuning of a number of independent design variables which determine the success of the growth and/or the properties of the synthesized materials. The optimization of the growth recipe usually entails intuition-based experimentation with different process variables, which requires a large investment of time, effort, and resources before high quality materials are obtained. Developing machine learning models to predict suitable conditions for materials growth is therefore essential for more timely design of these technologically relevant materials. We study synthesis recipe optimization including dimensionality reduction, latent feature representation using transfer learning, and the evaluation of various machine learning model architectures as applied to a dataset produced in-house at the 2D Crystal Consortium, a Materials Innovation Platform housed at Penn State. Given that a limited volume of experimental data will be typical of the 2D materials design process, different data augmentation and training schemes are evaluated to build robust models. As a case study, we predict MoS_2 thin film morphology based on the growth temperature. High validation accuracy shows that our models and training protocols are suitable for this and similar predictive tasks for accelerated 2D materials discovery.

Autonomous In-Silico Accelerated Design of Novel Energy Materials Ivano EligioCastelli; Technical University of Denmark, Denmark

The development of automated computational tools is required to accelerate the discovery of new functional materials to speed up the transition to a sustainable future. Here, I address this topic by designing new electrodes with controlled interfaces for different applications which accelerate the transition to a sustainable future. These workflows are implemented in the framework of Density Functional Theory, using MyQueue and the Atomistic Simulation Environment (ASE). In the first part, I describe a fully autonomous workflow, which identifies materials to be used as intercalation electrodes in batteries based on thermodynamic and kinetic descriptors like adsorption energies and diffusion barriers [1]. A substantial acceleration for the calculations of the kinetic properties has been obtained due to a recent implementation of the Nudged Elastic Bands (NEB) method, which considers the system's symmetries to reduce the number of images to calculate. Moreover, we have established a surrogate model to identify the transition states, which can further reduce the computational cost to at least one order of magnitude [2, 3]. We have applied this workflow to discover new cathode materials for Mg batteries as well as solid-state electrolytes for Li, Na, and Mg all-solid-state batteries [1, 3]. In the second part of my talk, I discuss how engineering the interface can positively impact surface properties. I show this concept using two examples. In the first one, I nanostructure materials to increase the Li-storage capacity in C-anodes or to adjust the change in volume during charge/discharge in Si-anodes for Li-ion batteries [4]. In the second example, I apply strain engineering and external stimuli to switch the material’s polarization to decrease the reaction overpotential in oxynitride materials for the oxygen evolution reaction [5, 6].

A Tutorial on Functional Data Analysis for High-Throughput Experiments KiranVaddi[1,2]; [1]University of Washington, United States; [2]eScience Institute, United States

In this tutorial, I will describe a novel mathematical framework called 'Function Data Analysis' that combines tools from Statistics and Riemannian differential geometry to analyze data of a functional form. Functional data are ubiquitous in material science such as Spectroscopy, X-ray scattering, and Diffraction to list a few examples. Analyzing functions using traditional 'vector-based' methods is challenging as information is encoded in both the x-axis (warping or phase) and y-axis (intensity or amplitude). Intuitively, we analyze functional data such as those listed above using a notion of 'shape' that is hard to capture and analyze in a statistical sense. This tutorial will cover a basic introduction to performing statistics on Riemannian manifolds, relations between multi-variate and functional data analysis, and a few example applications to high-throughout polymeric material design and discovery problems. We will also include some code walkthroughs using synthetic datasets. Attendees will learn about performing tasks such as dimensionality reduction and clustering and have the opportunity to try them on a dataset of their own choice.

SYMPOSIUM DS02

Automated Experimentation with Synchrotrons, Neutrons and Microscopes

Machine Learning Analysis and Automation in High-Resolution Scanning Probe Microscopy AdamFoster[1,2]; [1]Aalto University, Finland; [2]Kanazawa University, Japan

Scanning Probe Microscopy (SPM) has been the engine of characterization in nanoscale systems in general, and the evolution of functionalized tips as a reliable tool for high-resolution imaging without material restrictions has been a breakthrough in studies of molecular systems. In parallel, machine learning (ML) methods are increasingly being applied to data challenges in SPM. In particular, the success of deep learning in image recognition tasks has led to their application to the analysis of SPM images, especially in the context of surface feature characterisation and techniques for autonomously-driven SPM [1].

In this work, we explore the potential for using ML approaches to aid in the analysis of high resolution Atomic Force Microscopy (AFM) and Scanning Tunnelling Microscopy images. Building upon a deep learning infrastructure that matches a set of AFM images with a unique descriptor characterizing the molecular configuration [2-4], we further develop a workflow that takes experimental images of complex molecular systems and revises initial ML structure predictions with neural network potential simulations. In this context, we discuss the challenges of handling experimental data and possible data augmentation strategies. Alongside this, we show how ML approaches can be used actively during SPM experiments to aid in both tip functionalization [5] and in the construction of nanostructures through atomic manipulation [6], while also highlighting approaches towards automated construction of complex systems.

Automated Nano-Metrology with AI-Assisted AFM for High-Resolution Material Research Sang-JoonCho; Park Systems Corp., Korea (the Republic of)

The Atomic Force Microscope (AFM) has been a powerful instrument in nanoscale imaging, manipulation, and material property characterization. The capability of AFM allows repeated and reliable surface topography measurements in three dimensions with subnanometer resolution. Additional information, such as nanomechanical, electrical, magnetic, or even chemical information, can be obtained simultaneously, yielding a vast array of data from a single instrument with minor hardware and electronic system variations and adding software features. However, AFM is also known to be complex in operation and analysis. There are too many parameters to control and variables to influence the data. Tip-sample interactions are affected by the tip's material and shape and the environmental conditions such as vibration, temperature, humidity, noise, vibration, and system leveling. However, the importance of AFM analysis is growing due to the vital necessity to investigate and characterize innovative nanomaterials. Finding new materials with innovative characteristics at the nanoscale has helped guide many industries to grow. The newly found materials have contributed to breakthroughs in energy, the semiconductor industry, and life science, to name a few. Recently introduced artificial intelligence and robotics solutions could greatly simplify the complex operation of AFM and help upgrade the quality of AFM data. AFM must be robust and easy to use in many areas to expand its use. To do that, AFM operation and data management should be automated and categorized by AI to expand its usability further. We introduced the various AFM automation technologies, including probe exchange, probe identification, beam alignment, sample location, tip approach, and possible AI applications. In addition, the new optomechanical design increases data quality and measurement precision. The automation of AFM could open the door to new ways to control the development of the material's facets, dramatically boost its productivity, and drive innovation across the field of nanometrology.

11:30 AM DS02.01.03

Image Interpretation Methods for High-Resolution SPM LauriKurki[1], NikoOinonen[1], OndrejKrejci[1], ShigekiKawai[2,3] and AdamFoster[1,4]; [1]Aalto-Yliopisto, Finland; [2]University of Tsukuba, Japan; [3]National Institute for Materials Science, Japan; [4]Kanazawa University, Japan

Scanning tunnelling microscopy (STM) and atomic force microscopy (AFM) functionalized with a CO molecule on the probe apex are methods capable of capturing sub-molecular level detail of the electronic and physical structures of a sample [1]. While high-resolution STM is a widely adopted method in materials science, the produced images are often difficult to interpret due to the convoluted nature of the signal. In this work, we propose image interpretation tools to extract physical information directly from STM images using machine learning.

In recent years, there has been rapid development in image analysis methods using machine learning, with particular impact in medical imaging. These concepts have been proven effective also in scanning probe microscopy (SPM) in general and in particular for extracting sample properties from AFM images [2,3,4]. Leveraging these developments, we extend these models to demonstrate the extraction of atomic positions directly from STM images. We also further explore how the accuracy of these predictions varies with the use of a simultaneous AFM signal and finally establish the limits of the approach in an experimental context by predicting atomic structures from STM images of silico-organic compounds [5].

SESSION DS02.02: Cutting-Edge Automation and Machine Learning Approaches in Microscopy II
Session Chairs: Adam Foster, Yongtao Liu and Steven Spurgeon
Wednesday Afternoon, November29, 2023
Sheraton, Third Floor, Dalton

1:30 PM *DS02.02.01
Programmatic and Deep Learning Analysis Pipelines for 4D-STEM Materials Science Experiments ColinOphus; Lawrence Berkeley National Laboratory, United States

Many materials science studies use scanning transmission electron microscopy (STEM) to characterize atomic-scale structure. Conventional STEM imaging experiments produce only a few intensity values at each probe position. However, modern high-speed detectors allow us to measure a full 2D diffraction pattern, over a grid of 2D probe positions, forming a four dimensional (4D)-STEM dataset. These 4D-STEM datasets record information about the local phase, orientation, deformation, and other parameters, for both crystalline and amorphous materials. However, 4D-STEM datasets can contain millions of images and therefore require highly automated and robust software codes to extract the target properties. In this talk, I will introduce our open source py4DSTEM analysis toolkit, and show how we use these codes to perform data-intensive studies of materials over functional length scales. This includes measurements of macroscopic properties such as crystal phase, orientation, and local deformation maps, and microscopic properties such as atomic structures in 2D and 3D measured with ptychography and other phase contrast imaging mode. I will also demonstrate some applications of modern machine learning tools, to perform measurements on electron diffraction patterns where property signals have been scrambled by multiple scattering of the electron beam. All our analysis, simulation, and machine learning codes and datasets are freely available for download, as we try to adhere to FAIR data principles.

2:00 PM *DS02.02.02
AI/ML Analytics Suite for the Automated Interpretation of Scanning Transmission Electron Microscopy Data JennaBilbrey, SarahAkers, ArmanTer-Petrosyan, ChristinaDoty, BethanyMatthews and StevenR. Spurgeon; Pacific Northwest National Laboratory, United States

With the rise of automated experimentation, the topic of few-shot and semi-supervised learning techniques are increasingly relevant in the context of creating adaptable AI designed for flexibility in both analytics and data acquisition. We have developed a platform with a custom central controller that automatically utilizes these techniques for both quantitative characterization and adaptive sampling in scanning transmission electron microscopes (STEM). We previously developed a flexible, semi-supervised few-shot machine learning approach for segmentation of STEM images that uses a small support set of canonical examples across a material system to detect and quantify discrete regions. We expand our previously developed few-shot approach to include multiple modalities by incorporating energy dispersive X-ray spectroscopy (EDS) data, which allows both lattice structure and elemental composition to be taken into account during segmentation. We also demonstrate methods for unsupervised clustering using similarity graphs and semi-supervising clustering to automate support set generation. High-throughput characterization though rapid and accurate image classification and unsupervised microstructural feature mapping take us one step closer to truly autonomous microscope platforms.

3:30 PM *DS02.02.03
Towards Femtogram-Scale Materials Discovery using Scanning Probes as a Self-Driving Lab KeithA. Brown; Boston University, United States

This work explores recent progress in transforming scanning probe systems into platforms for materials discovery studying samples approaching the femtogram scale. There is a need to discover advanced materials to address the pressing challenges facing humanity, however there are far too many combinations of material composition and processing conditions to explore using conventional experimentation. One powerful approach for accelerating the rate at which materials are explored is by miniaturizing the scale at which experiments take place. Scanning probe lithography has the dual benefits of being capable of patterning nanoscale features and providing a system for measuring their properties at a commensurate scale. However, before this potential can be realized, methods must be developed for controllably patterning and mixing samples at the nanoscale. Thus, the focus of this talk is recent progress in developing new methods for ultra-miniaturized combinatorial materials research using scanning probes. To begin, we describe the use of inertial sensing as a path to quantifying the amount of fluid on the probe and thus the amount of fluid transferred when patterning. This method allows us to study the fluid transport between a tipless scanning probe and a surface to develop relationships that allow for predictable control over feature size. This process is used to realize closed-loop patterning of fluids with better than 1% mass accuracy. This level of control also allows us to attach metal-organic framework (MOF) crystallites to probes and study MOF-polymer interactions with high throughput. Following these innovations, we explore the use of ultrafast probes together with spherical tips that allow for patterning of fluids down to the femtogram scale. Finally, we show that these methods allow one to mix fluids on a surface to realize compositional gradients of materials. We close with a demonstration of a combinatorial experiment in which a scanning probe is used to prepare a gradient of polymer composition and then perform mechanical testing to functionally read out these materials. Taken together, these advances set the stage for scanning probes to function as a single system for materials discovery.

4:00 PM *DS02.02.04
Reinforcement Learning for Electron Microscopy Automation JamesM. LeBeau; Massachusetts Institute of Technology, United States

Theory, synthesis, and characterization are essential components of the materials informatics cycle. While significant emphasis has been placed on theory and synthesis, comparatively limited progress has been made in materials characterization. Initial efforts to apply machine learning to characterization have mainly focused on the backend data analysis, but capturing reproducible data in a statistically significant way remains a major challenge. Although electron microscopy can provide atomic-level structural measurements of materials to unravel structure-property relationships, some critical limitations to the current workflow severely limit the current usage and future potential for materials informatics. The largely manual nature of the technique requires a significant amount of time to characterize an extremely small volume of material. This makes it challenging to collect extensive enough datasets that truly represent the material, especially when the material is inhomogenous or contains various defects. Moreover, the human input in collecting images and spectroscopic data inherently has bias and random error that is undesirable for any comprehensive and systematic study.

In this talk, we will highlight the application of reinforcement learning (RL) techniques in automating and optimizing operations within electron microscopy. RL has proven its capabilities in surpassing human performance in complex systems, including high-skill games. In the context of electron microscopy, RL offers a reliable approach to enhance and automate materials characterization through instrument control. While significant progress has been made in theory and synthesis within the materials informatics cycle, materials characterization remains

challenging with comparatively fewer advancements. Current workflows suffer from limitations such as manual data collection, time-consuming processes, and inherent biases and errors. We present machine learning-assisted electron microscopy to address these challenges. By creating a virtual RL environment, we develop a network capable of autonomously aligning the electron beam without prior knowledge. Through extensive simulation and experimental validation, we showcase the robustness and effectiveness of our approach, emphasizing the significance of appropriate virtual environments. The results highlight the potential of RL in streamlining electron microscopy workflows, reducing algorithm design complexities, and facilitating the integration of machine learning techniques for accelerated discovery.

4:30 PM *DS02.02.05

Autonomous Elucidation of Structure-Property Relationships in Ferroelectrics via Humanin the Loop Bayesian Optimization, Reinforcement Learning and Scanning Probe Microscopy RamaK. Vasudevan[1], SaiM. Valleti[1,2], YongtaoLiu[1], ArpanBiswas[1], BenjaminSmith[2], StephenJesse[1], BharatPant[3], YeCao[3], SergeiV. Kalinin[2] and MaximZiatdinov[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States; [3]The University of Texas at Arlington, United States

Recent progress in the areas of autonomous experiments, particularly at major user facilities, has ushered in a new paradigm over traditional human-based operations, thereby enabling new experiments that were hitherto impossible via traditional operations. To date, however, most autonomous systems in materials characterization and synthesis facilities rely on straightforward Bayesian optimization where targets are pre-defined by the user, and no subsequent interactions between the operator and the instrument are expected.

Here, we will discuss autonomous experiments performed on scanning probe microscopes (SPM) at the Center for Nanophase Materials Sciences. We first show that using human in the loop models, where the operator is presented with a subset of the experimental results that can be voted on, is an effective strategy for leveraging the best features of human-based curiosity along with machine learning -based optimization. This is implemented in the form of a Bayesian optimization active recommender system model, on a functioning scanning probe microscope to investigate relationships between the local domains structure and the characteristic features of ferroelectric hysteresis.

Next, we explore the use of automated and autonomous SPM platforms for (a) developing surrogate models of domain wall dynamics, and (b) training and deploying reinforcement learning (RL) agents to automatically manipulate domain wall structures towards desired morphologies. Of note, these surrogate models are validated via phase-field simulations and reveal peculiar features including effects of local wall stresses on functional responses. The RL agents are implemented on the working instrument, and challenges and future directions of this strategy towards autonomous manipulation of materials is discussed. Overall, this work shows that utility of automated and autonomous SPM platforms, that enable qualitatively new types of experiments and additional physical insights that are difficult to capture through non-autonomous means. This work was supported by Center for Nanophase Materials Sciences (CNMS), which is a US Department of Energy, Office of Science User Facility at Oak Ridge National Laboratory.

5:00 PM DS02.02.06

Autonomous Defect Analysis of 3D Atom Probe Microscopy Data using Machine Learning PrachiGarg[1], KristoferG. Reyes[2,1] and BaishakhiMazumder[1]; [1]University at Buffalo, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

Tetragonal yttria stabilized zirconia (t-YSZ) is a ceramic material that exhibits excellent mechanical strength, fracture toughness, thermal shock resistance, and high ionic conductivity. Its unique combination of properties has led to its widespread use in oxygen sensors, dental restorations, solid oxide fuel cells, and other applications that require exceptional performance and reliability. To increase the tetragonal phase stability of the material, a critical vacancy concentration is desired. Annihilated vacancies, or the presence of excessive vacancies in oxide materials, can result in material degradation and reduced performance. Vacancy serves as a diffusion pathway for atomic species resulting in unwanted atomic arrangements and phase transformation. To mitigate these issues, vacancy mapping and detection are significant. While conventional microscopy tools have limitations in detecting vacancies, advanced characterization techniques such as Atom Probe Tomography (APT) can provide valuable information for predicting local structure including vacancies. APT is a powerful 3D nano-analytical tool that provides atomic positions, structural information, and chemical composition with exceptional spatial resolution. It works by field-evaporating atoms from the surface of a sample and detecting them individually, allowing for precise atom-by-atom reconstruction of the material. While APT can provide valuable insights into the atomic-scale structure, its capability for directly detecting vacancies is limited. This motivates us to complement APT data analysis with an advanced machine learning model to detect vacancy concentration and reconstruction.
To detect vacancies in the microscopic 3D positional data, we build, train, and deploy a deep learning (DL) model, using architectures common in computer vision and image processing tasks. The DL model detects structural features in 3D voxelated images. To train this model on large data, synthetic dataset with known vacancy positions and associated structural and chemical information is simulated using an empirical ball-and-spring model. The learnt DL model is applied on the real APT data for automated vacancy mapping and detection in t-YSZ. By predicting the local structure, including vacancies, the model can provide insights into the defects in the material. This information can help optimize the phase structure and stability of t-YSZ and guide the design of improved oxygen sensors and solid oxide fuel cells.
This approach of combining deep learning with APT data analysis holds great potential for advancing our understanding of vacancy detection and its impact on the mechanical stability of oxide materials like t-YSZ.

5:15 PM DS02.02.07

Automating Convergence of STM Controls using Bayesian Optimization GaneshNarasimha, SabanHus, ArpanBiswas, RamaK. Vasudevan and MaximZiatdinov; Oak Ridge National Laboratory (ORNL), United States

Scanning Tunneling Microscopy (STM) is a widely used tool for atomic-scale imaging of novel materials. However, the tip optimization is a tedious process due to the extremely complex nature of the tip-surface interaction, and thus limits the throughput efficiency. Here we demonstrate a Machine Learning (ML) based framework to realize the automated optimization of the scan controls for high quality STM imaging of graphene. We deploy a Bayesian Optimization (BO) method on the STM controls in real-time to enhance the imaging quality, given by the peak intensity in the Fourier space. The BO prediction is dynamically incorporated into the microscopy controls, i.e., the current setpoint and the tip bias, to rapidly optimize the imaging conditions. We present strategies to either selectively explore or exploit across the parameter space. As a result, suitable policies are developed for autonomous convergence of the control-parameters. The ML-based framework serves as a general workflow methodology across a wide range of materials.

SESSION DS02.03: Poster Session: Leveraging Machine Learning for Materials Design and Characterization II
Session Chairs: Yongtao Liu and Steven Spurgeon
Wednesday Afternoon, November29, 2023

8:00 PM DS02.03.01

Real-Time and Absolute Quantification of Infectious Pathogens using Wide-Field Imaging-Based Droplet Analysis System SunghyunKi[1] and Dong-KuKang[1,2,3]; [1]Incheon National University, Korea (the Republic of); [2]Research Institute of Basic Sciences, Korea (the Republic of); [3]Bioplastic Research Center, Korea (the Republic of)

Droplet-based microfluidic (DMF) system has been widely used as molecular diagnostic tool for digital analysis with absolute quantification and high-resolution. Especially, droplet digital analysis is useful and powerful diagnostic tool because droplets are worked as chemical and biological containers to partition biomarkers, such as virus, bacteria and nucleic acid, in single molecule manner. Due to coronavirus disease 2019 (COVID-19) pandemic, digital analysis is becoming more important as a next-generation diagnostic platform to monitor infectious pathogens affecting human health. For example, droplet digital PCR (ddPCR), the third-generation PCR, has been used because it can provide more accurate and sensitive results for monitoring infectious pathogens at a single-molecule manner comparing real-time PCR, the second-generation PCR. However, commercialized-digital analytical systems (ddPCR, digital ELISA and digital Cell Analyzer) require expensive and complex optical systems to detect droplets containing target molecule such as DNA, RNA, protein and bacteria. Even commercialized imaging systems also have a small field of view because of high-magnification lens. Examples include high-performance optical, fluorescence and confocal microscopes. To address these issues, we have developed an analytical system that combines a wide-field imaging system with DMF system to capture and quantify target droplets (we called the DropVIST, Droplet analysis system with Vast Imaging and Statistical Tools). In this approach, first of all, droplets are encapsulated with microfluidic devices and incubate for chemical reaction. Then, reacted droplets are imaged and quantified with the DropVIST for absolute quantification and high-throughput assay. In this work, droplets were encapsulated within flow-focusing structure of microfluidic devices made of polydimethylsiloxane (PDMS) material using soft-lithography technology. To setup the DropVIST, this system was composed of a simple optical system using a 50.2-megapixel CMOS image sensor-based DSLR camera and a 100mm macro lens to obtain wide-field images with high-resolution. A MATLAB-based software, called the dFinder software, was also made for absolute quantification of target droplets. In this study, the DropVIST was identified with the dFInder software that simultaneously analyzes eight individual colors for multiplexed and absolute quantification from a single image. Then, a size of detectable droplet was characterized to be over 30 μm in diameter. Also, it can be analyzed using the dFinder software that a droplet image with a minimum size of 32 pixels in a field of view of 201.8 cm^2 (The focal length of camera was 65 cm). The DropVIST allowed a field of view from a

minimum of 11.48 cm^2 to a maximum of 201.8 cm2 and theoretical total sample volume of droplets were calculated from 69.65 µL to 1224 µL when droplets are encapsulated at 91 µm in a diameter. We demonstrated with the DropVIST that digital proliferation assay and digital colony forming unit (CFU) assay were performed to identify more rapid and accurate analysis than conventional assays (microbroth dilution and CFU assays). In these cases, bacterial cells were used at concentrations ranging from 10^6 cells/µL to 0.1 cells/µL and a limit of detection (LOD) was 0.1 cells/µL when used the DropVIST. In the future, this system will be utilized as a diagnostic tool for rapid and accurate droplet digital analysis such as digital antimicrobial susceptibility test and real-time digital nucleic acid amplification test.

8:00 PM DS02.03.02
3D Reconstruction of Polycrystalline Microstructure of Iron-Based Superconductors using Deep Learning YoshikiNishiya[1], TakahiroHosokawa[1], YuHirabayasi[1], HarukaIga[1], ShinnosukeTokuta[1], YusukeShimada[2] and AkiyasuYamamoto[1]; [1]Tokyo University of Agriculture and Technology, Japan; [2]Tohoku University, Japan

Image analysis to identify the constituent phases from microstructural images is an important topic in understanding the mechanism of functional materials and in applying to informatics techniques. Classic automatic thresholding methods are well known as a phase segmentation tool of functional polycrystalline materials and quantification of microstructural factors. On the other hand, polycrystalline materials often contain characteristic microstructural defects and secondary phases, and those electron microscopy images are affected by artifacts that occur during sample preparation and observation, making it challenging to achieve high phase segmentation accuracy. In this study, we focused on semantic segmentation by deep learning, which is successfully applied to medical images [1] and automatic driving [2]. Secondary electron images from the iron-based polycrystalline superconductor Ba122[3] were acquired in three dimensions by 3D FIB-SEM [4] and segmented by a deep learning model. A high IoU value over 90% was obtained [5, 6] for the images captured from the same sample and observation condition. Moreover, ty tuning the learning conditions and adopting data augmentation, we have succeeded in significantly improving the segmentation accuracy of electron microscopy images of samples with different chemical compositions and observed under different conditions than the learned images.

SESSION DS02.04: Exploring Physics and Simulation with Machine Learning
Session Chairs: Sijia Dong, Ayana Ghosh, Yunseok Kim and Daniela Uschizima
Thursday Morning, November30, 2023
Sheraton, Third Floor, Dalton

8:15 AM *DS02.04.01
Physics-Informed Machine Learning Workflows Connecting Electron Microscope to Atomistic Simulations AyanaGhosh; Oak Ridge National Laboratory, United States

In recent years, artificial intelligence, and machine learning (AI/ML) methods are being rapidly adapted in physical sciences to gain comprehensive understandings of material structures, properties, system evolutions over spatial-temporal resolution, processes involving phase transitions across various time- and length scales. With the emergence of efficient algorithms and advancement in electron microscopes, there is a scope to utilize theoretical models to guide, perform experiments while refining the parameters in both spaces, to establish a continuous feedback-loop. Instrument specificity, implementation complexity, information transferability by addressing fundamentally different latencies of imaging and simulations, remain the primary challenges. This presentation will focus on how deep learning (DL) frameworks are employed to extract atomic level information from 2D systems such as graphene followed by first-principles based studies to develop comprehensive understanding of the materials physics. These enable seamless deployment of several DL algorithms on-the-fly for appropriate feature finding, property predictions in combination with atomistic simulations to explore underpinning causal mechanisms, suited for guiding next set of experiments. A discussion on extending such workflows for other functional materials with targeted properties on-the-fly will also be included.

This effort (machine learning) is based upon work supported by the U.S. Department of Energy (DOE), Office of Science, Office of Basic Energy Sciences Data, Artificial Intelligence and Machine Learning at DOE Scientific User Facilities, INTERSECT Initiative as part of the LDRD Program of Oak Ridge National Laboratory.

8:45 AM *DS02.04.02
The Multi-Tiered Iterative Projection Framework for Solving Complex Inverse Problems from Experimental Data JeffreyDonatelli; Lawrence Berkeley National Laboratory, United States

Recent upgrades at experimental facilities throughout the world are enabling several new experiments to capture the properties and behavior of important biological objects and materials that were not previously possible to study. However, a major barrier in enabling new scientific breakthroughs from these experiments is the capability to accurately, efficiently, and robustly solve the inverse problem of reconstructing information about the sample from increasingly complex, fast, large, and sensitive detector measurements. There is a critical need to develop new math and algorithms that can accurately solve these inverse problems from new and challenging data.

I will present a new general mathematical and algorithmic framework capable of overcoming many of these challenges in inversion. This framework, called Multi-Tiered Iterative Projections (M-TIP), is based on exploiting the multi-tiered structure inherent in many inverse problems, by breaking them up into several tiers of underdetermined subproblems, each of which can be solved efficiently via mathematical projection operations that are applied iteratively. This property allows M-TIP to leverage optimal mathematical solutions for the subproblems to improve speed, robustness, convergence, and accuracy of the overall inversion. I will demonstrate the application of this M-TIP framework in solving several important open problems in inversion from challenging data for experiments including fluctuation X-ray scattering, coherent surface scattering imaging, and more.

9:15 AM DS02.04.03
Embedding Theory, Classification and Decision in Variational Autoencoders for the Transmission Electron Microscope JonathanHollenbach and MitraL. Taheri; Johns Hopkins University, United States

In-situ Electron Energy Loss Spectroscopy (EELS) is an instrumental technique in understanding how processing materials changes local structure and composition, but acting on the transient changes occurring at high temporal resolutions requires new artificial intelligence frameworks for characterization and analysis to match the data rate of the detector. We demonstrate a machine learning framework for rapid assessment and characterization of operando EELS data, informing decision frameworks and updating process changes. Variational Autoencoders (VAEs) have been proven ideal for encoding the complex relations of chemical changes to latent representations. By incorporating both experimental data and a sparse library of simulated data linked to theory-based structures into a single, cohesive latent embedding, this framework seeks to not only classify spectroscopy but also update input controls on edge. Pairing on edge decision with operando control of the electron beam, laser processing, and other instrument controls enables a feedback loop capable of autonomous materials processing within the Transmission Electron Microscope (TEM).

9:30 AM *DS02.04.04
Human-In-The Loop Automated Experiment (hAE)—Explainable ML for Physics Discovery in Microscopy SergeiV. Kalinin[1], YongtaoLiu[2], KevinRoccapriore[2], ArpanBiswas[2], RamaK. Vasudevan[2] and MaximZiatdinov[2]; [1]University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Rapid advancements in machine learning over the last decade have attracted broad attention of scientific community towards the possibility of automated and autonomous experimentation (AE) in areas spanning synthesis, characterization, and microscopy. For microscopy, this interest is driven both by the opportunity to automate the often repetitive and tedious process of operation and data collection, and also capitalize on the fact that for many imaging modalities the intrinsic limits for microscope operation are considerably faster than human decision making and response times. Even for imaging, the achievable sampling sizes can exceed the depth of human perception by orders of magnitude, whereas addition of microscopy optimization and spectroscopy measurements opens infinite vistas for ML-driven workflow developments. In AE, the machine learning agent is interacting with the instrument driving the sequence of the

operations, either autonomously (no human in the loop) or with human oversight. However, the incorporation of the AE requires significant changes in the human-machine interaction and in particular requires introduction or adoption of fundamentally new concepts describing the experiment planning and execution. In this presentation, I introduce the description of the AE workflows in microscopy and the fundamental concepts necessary for their development including rewards, policies, explainability, and strategies for human in the loop monitoring and intervention. I will illustrate several scenarios for automated microscopy for characterization of ferroelectric and electrochemically active materials including supervised learning, identification of microstrucutres responsible for desired responses, and autonomous physical discovery. I further pose that the emergence of the user facilities and cloud labs necessitate development of universal frameworks for workflow design, including universal hyper-languages describing laboratory operation, reward functions and their integration between domains, and policy development for workflow optimization. These tools will enable knowledge-based workflow optimization, enable lateral instrumental networks, sequential and parallel orchestration of characterization between dissimilar facilities, and empower distributed research.

Accelerating Simulations of the Excited States of Molecules and Materials Through Machine Learning and Automation SijiaDong; Northeastern University, United States

Automated experimentation can be informed and directed by on-the-fly first-principles simulations. However, accurate first-principles simulations of the electronic excited states of molecules and materials are usually computationally expensive, especially those that involve strong correlation or excitons. In this talk, we will discuss 1) a strategy to accelerate many-body perturbation theory through machine learning for efficient simulation of the excited states of macromolecules and extended systems, and 2) a strategy to automate multireference methods for the simulation of molecules with strong correlation.

11:00 AM DS02.04.06
Comparison and Investigation of Mobility in BDT Trimers by DFT Simulating of Inelastic Neutron Scattering—The Impact of Fluorination FarahnazMaleki[1], MakenaDettmann[1], DanielVong[1], LukeDaemen[2], JohnAnthony[3] and AdamJ. Moule[1]; [1]University of California, Davis, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Kentucky, United States

Fluorination of conjugated organic molecules is known as a way of enhancing charge mobilities in organic semiconducting materials. The tri(n-hexyl)silylethynyl benzodithiophene (BDT) trimer is an example of a molecule that has shown significant high mobility. Although the mobility in both non-fluorinated and fluorinated structures is high, the fluorinated one exhibits significantly larger mobility. To better understand the impact of fluorination on mobility, we used our DFT-based open-source Davis Computational Spectroscopy (DCS) workflow to analyze phonon spectra of anti and syn isomers of these materials. These results were also verified using inelastic neutron scattering (INS) measurements. We employed a novel method to analyze the INS spectra for each atom in the structure. By comparing the INS spectra of similar atoms in different isomers of both non-fluorinated and fluorinated structures, first we can gain insights into the reflection of isomerism in INS spectra and second influence of fluorine atoms on the INS spectra of other atoms.

11:15 AM *DS02.04.07
Pushing the Boundaries of Waste Heat Recovery—Novel Approaches at the Intersection of Phonon Theory and Experiments MingdaLi; Massachusetts Institute of Technology, United States

Every year, over 2/3 of the global generated energy end up as waste heat. Phonons are major carriers of heat in semiconductors and insulators, and play an indispensable role in global decarbonization. However, phonon calculations experience high computational cost, while phonon measurements with momentum resolution often have high technical barrier and limited resources. The broadband nature of phonons further impedes the acquisition of phonon mode-resolved information from experiments.
In this lecture, we introduce three of our recent efforts aiming to acquire phonon properties with the aid of machine learning that integrates with experiments. Besides introducing the immediate topic, we highlight why the research challenges naturally lead to the solutions.

Phonon Density-of-states: First, we introduce a predictor that takes in crystal structures as input and phonon density-of-states – a key property to determine specific heat – as output [1]. With very limited training data, symmetry argumentation in a graph neural network plays a key role reaching high-quality density-of-states prediction but with much reduced computational cost. This enables a search for alloys for superior thermal transport.

Phonon Transport: Second, we introduce an integrated experimental-computational framework that can extract frequency-resolve phonon relaxation and transmittance and relaxation time. Ultrafast diffraction offers high-dimensional data in time-momentum space where phonon thermal transport is reflected on the atomic vibrations and thereby diffraction intensities, and data-free scientific machine learning is used to solve an inverse thermal transport problem and extract those frequency-resolved phonon transport information [2].

Full Phonon Bandstructure: Finally, we introduce our latest work on predicting phonon spectra at arbitrary k-points, by designing a generically applicable approach that can augment graph neural networks, termed virtual node graph networks [3]. It overturns the conventional wisdom that graph nodes represent real-space atoms but instead build the needed reciprocal space. The method enables rapid and high-precision calculation of full phonon bandstructure calculations in nearly arbitrarily complex materials, such as alloys, interfaces, amorphous materials, or materials with very large unit cells. We conclude with a number of applications in thermal energy storage, thermoelectric energy harvesting, and alloy designs.

Autonomous Laboratory for Bespoke Synthesis of Nanoparticles Sang SooHan, Hyuk JunYoo, NayeonKim and DonghunKim; Korea Institute of Science and Technology, Korea (the Republic of)

The demand for bespoke synthesis of nanoparticles (NPs) has significantly increased in various applications due to their tunable properties depending on the synthesis process conditions. And, an autonomous laboratory based on AI and robotics has been rapidly employed for the time-consuming and labor-intensive NP synthesis. This approach accelerates the NP synthesis with the target properties and readily helps to understand the synthesis process-property relationship through experimental data. In this talk, we will introduce our homemade autonomous laboratory for the bespoke synthesis of commercial Ag NPs, focusing on optical properties. Bayesian optimization with an earlystopping process greatly improves the efficiency for the bespoke synthesis, in which five experimental variables are considred. Also, the data analysis and visualization help us to understand the AI-based syntheitic route without human intuition. Furthermore, we can readily discover a new chemical knowledge regarding the synthesis of Ag NPs. This study show that autonomous laboratories can accelerate materials discovery and readily help to find new knowledge.

Towards an Artificial Intelligence-Driven Automated Workflow for Battery Material Synthesis MargaretLund, SarahAkers, DerekHopkins, PedroRodriguez Fernandez, HeatherJob, YangangLiang and StevenR. Spurgeon; Pacific Northwest National Laboratory, United States

The realization of breakthrough energy storage technologies depends on design of new battery materials, informed by high-throughput synthesis and characterization pipelines. Here we present an artificial intelligence (AI)-driven workflow that harnesses the predictive capabilities of machine learning to optimize electrolyte solutions for improved battery materials design. In this closed-loop automated workflow, a robotic synthesis platform is integrated with two diagnostics systems (UV-vis / electrochemical impedance [EIS]) using an analysis and experimental

design feedback loop. An analysis program, written specifically for this work, reads diagnostic spectroscopy data for a plate of samples and studies absorbance or impedance spectra. Standards are used to fit an absorbance vs. concentration curve, to identify the range where the model has high confidence in its predictive capability, and this is used to predict concentrations for all samples. These predicted concentrations are fed into a machine learning optimizer that automatically determines dilution amounts for the next plate of samples. The automated workflow continues, with the robot initiating the next round of sample preparation, synthesis, and diagnostics. Using AI-driven analysis platforms such as this, we can guide synthesis and characterization of electrolytes to improve design and performance and streamline our path to game-changing research breakthroughs. 2:45 PM DS02.05.07
Missing Wedge Correction Without Ground Truth—Unsupervised Sinogram Inpainting for Nanoparticle Electron Tomography (UsiNet) LehanYao, ZhihengLyu, JiahuiLi and QianChen; University of Illinois at Urbana-Champaign, United States

Complex natural and synthetic materials, such as subcellular organelles, device architectures in integrated circuits, and alloys with microstructural domains, require characterization methods that can investigate the morphology and physical properties of these materials in three dimensions (3D). Electron tomography has unparalleled (sub-)nm resolution in imaging 3D morphology of a material, critical for charting a relationship among synthesis, morphology, and performance. However, electron tomography has long suffered from an experimentally unavoidable missing wedge effect, which leads to undesirable and sometimes extensive distortion in the final reconstruction. Here we develop and demonstrate for the first time Unsupervised Sinogram Inpainting for Nanoparticle Electron Tomography (UsiNet) to correct missing wedges. UsiNet is the first sinogram inpainting method that can be realistically used for experimental electron tomography by circumventing the need for ground truth. We quantify its high performance using simulated electron tomography of nanoparticles (NPs). We then apply UsiNet to experimental tomographs, where more than 100 decahedral NPs and vastly different byproduct NPs are simultaneously reconstructed without missing wedge distortion. The reconstructed NPs are sorted based on their 3D shapes to understand the growth mechanism. Our work presents UsiNet as a potent tool to advance electron tomography, especially for heterogeneous samples and tomography datasets with large missing wedges, e.g. collected for beam sensitive materials or during temporally-resolved in-situ imaging.

3:30 PM *DS02.05.03
Deep Learning Sub-nm Resolution Crystallographic Mapping of Polycrystalline Doped Hafnium Oxide Thin Films Young-MinKim; Sungkyunkwan University, Korea (the Republic of)

Deep learning (DL)-assisted analysis of electron microscopy datasets has revealed promising prospects for automated interpretation and signal enhancement with high fidelity, offering an unparalleled ability to address complex challenges in electron microscopy. Four-dimensional scanning transmission electron microscopy (4D-STEM)-based diffraction has been proposed as a potential approach for correlating crystal symmetries and orientations with nanograin distribution when integrated with DL. This DL-assisted crystallographic analysis is expected to demonstrate significant potential for resolving structural issues in the polycrystalline thin film domain, as it can provide crucial information for the advancement of nanoelectronics at reduced dimensions down to 1 or 2 nm.
In this study, we present a deep learning-based method for mapping crystal phases and orientations in polycrystalline oxide thin films composed of similar polymorphs. As a representative system, polycrystalline hafnium zirconium oxide ($Hf_{0.5}Zr_{0.5}O_2$, HZO) thin films with a thickness of approximately 10 nm were investigated, which are expected to play a critical role as a ferroelectric switching component in future ultrathin field effect transistors.
Incorporating 4D-STEM (position-averaged) convergent beam electron diffraction ((PA)CBED) with a hybrid deep neural network for automated feature clustering and classification enables efficient management of extensive CBED datasets acquired from polymorphic nanograins oriented arbitrarily in polycrystalline HZO thin films. This facilitates expeditious mapping of crystallographic characteristics and their geometric configuration throughout the films. The precision of this method is commensurate with zone-axis STEM imaging on an atomic scale, and its effective spatial resolution for symmetry determination can reach below 0.5 nm^2, surpassing existing diffraction-based phase mapping techniques in terms of efficiency, accuracy, and spatial resolution.

4:00 PM DS02.05.04
Automated Determination of Electron Affinity from Low-Energy Inverse Photoelectron Spectra using Machine Learning YukiKusano and HiroyukiYoshida; Chiba University, Japan

Introduction
The edges of the valence and conduction bands are essential for the operation of semiconductor devices. The energy of the conduction band edge with respect to the vacuum level is the electron affinity (EA). The precise measurement of EA became possible by the development of low-energy inverse photoelectron spectroscopy (LEIPS) in 2012 [1]. In LEIPS spectra analysis, the spectral onset is usually determined from the intersection of fitted lines to the baseline and the rising edge of the spectra. However, this method requires expertise and is time-consuming. As the LEIPS instruments are commercialized and widely used, quick and reliable analysis by non-experts is highly demanded. This study demonstrates an automated analysis method for LEIPS spectra based on machine learning.

Method
So far, machine learning analysis of photoemission yield spectroscopy (PYS) spectra has been reported [2]; to determine the ionization energy, the spectral onset is determined using Random Forest (RF) and Gradient Boosting (GB) models. We also use these models in this work. Many machine learning studies on spectral analysis use simulated data because large numbers of data are required. However, there is no theoretical model for the spectral shape of LEIPS. Moreover, the simulations do not include the variations in spectral line shape owing to different film preparation methods or material-specific variations. Therefore, we utilized a dataset of 253 experimental LEIPS spectra of 28 organic semiconductors measured in our laboratory.
The intensity for each energy was used as the explanatory variable, and the EA values determined by a skilled analyst (referred to as the analysis values) as the objective variable. The data set was divided into 80% training data set and 20% test data set. The model was trained on the training data and then validated on the test data. The predicted EA was output by inputting the LEIPS spectra into the trained model. The EA values predicted by each trained model were compared to the analytical values as a validation method.

Results and Discussion
The results show that both RF and GB satisfactorily predict EA. For example, the differences between the analytical and the predicted values were only 0.04 eV and 0.00 eV for the C60 spectra, respectively. The differences between the analytical values and the predicted values (residuals) of the two models are summarized for all the test data: for RF and GB, 61% and 51% of the test data were predicted within ±0.1 eV, and 78% and 73% when the predicted values were extended to ±0.2 eV. The R^2 values were 0.915 and 0.856 for RF and GB, respectively. For some spectra, machine learning shows large deviation from the analytical values. We analyze the reason and propose the preprocess method to improve the precision.

A Deep Learning Framework for the Spatiotemporal Feature Extraction and Statistical Characterization of Terabyte-Scale XCT Datasets ThomasCiardi, PawanK. Tripathi, BenjaminPalmer, JohnLewandowski and RogerH. French; Case Western Reserve University, United States

Materials science faces a bottleneck in the ability to analyze large-scale image data. Datasets produced by modern imaging modalities such as X-Ray Computed Tomography (XCT) at synchrotrons output Terabytes of data per sample. Traditional approaches that use commercial software fail to effectively scale, while classical machine learning requires labeled data which can be impossible to obtain depending on the expertise required and volume of features present. As a result, analysis is reduced to hand-crafted features and small subsets of data which introduce human bias and only captures region-specific defect interactions as opposed to sample-wide behavior. To solve this, we have developed a framework that leverages distributed and high performance computing and machine learning (ML) to build an automated pipeline for the translation of 2D XCT images into 3D spatiotemporal graph representations of all microstructural features of interest. This graph-based representation provides a full statistical characterization of all defects within a given sample volume and enables additional downstream analyses.

We apply this spatiotemporal graph (st-graph) framework to XCT scans characterizing stress corrosion cracking (SCC) in Al-Mg alloys during a slow-strain tension test. The tests were conducted with collaborators at the Diamond Light Source on field-retrieved Al-Mg plate material. Samples had experienced 42-years of real world exposure to determine the effects of long-term service on stress corrosion cracking. Our st-graph pipeline 1) segments all fractures, precipitates, and pores on Terabytes of scans 2) provides a complete statistical characterization of all features of interest 3) constructs a spatiotemporal graph representation of the microstructural defect profile. We demonstrate the ability to extract over 150,000 features in a single scan, build a complete microstructural feature profile, and derive novel insights into degradation patterns from the interactions of features across a sample.

4:30 PM DS02.05.06

Semantic Segmentation and Feature Extraction from X-Ray Computed Tomography of Aluminum Bond Wires Using Deep Learning and Image Processing PawanK. Tripathi[1,2], MalieshaSumudumalie[2], ThomasCiardi[2,2], PhilipJ. Noell[3], JamesGriego[3], LauraBruckman[1,2], RogerH. French[1,2,2] and AlpSehirlioglu[1,2]; [1]Case Western Reserve University, Cleveland, Ohio, USA, United States; [2]Case Western Reserve University, United States; [3]Sandia National Laboratories, United States

Advancements in X-Ray Computed Tomography (XCT) techniques have reached a stage where high-resolution data can be rapidly acquired. However, analysis of XCT scans, particularly in the context of semantic segmentation and feature extraction, remains a challenging task. The traditional segmentation methods are no longer practical due to their time-consuming nature and the substantial volume of data generated, necessitating the development of automated data pipelines capable of handling complex 3D images. In this study, we present an automated characterization pipeline that can efficiently process a batch of XCT scans of Aluminum wires exposed to a saline environment over an extended period resulting in pitting corrosion, to perform semantic segmentation and feature extraction. The developed pipeline leverages deep learning and image processing to accurately identify and segment different regions within the XCT scans, such as the wire, pitting corrosion sites, and droplets. The dataset is used to train a UNet model, specially designed for segmentation tasks, to accurately classify and segment features of interest. The automated analysis provided by this pipeline offers valuable insights into the statistical feature extraction at the voxel level, and corrosion evolution, including information on the location, size, and severity of pitting corrosion sites.

SESSION DS02.06: Automated Experiments and Machine Learning Approaches in Synchrotron and Neutron Sources-I

8:30 AM *DS02.06.01
Understanding Lithium Metal Plating and Stripping using High-Resolution X-Ray Tomography and Semantic Segmentation IrynaZenyuk[1,1,1], YingHuang[1], JermoneQuenum[2,3] and DanielaUschizima[2,3,4]; [1]University of California, Irvine, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States; [4]University of California, San Francisco, United States

This scientific study presents a novel computational approach to inspecting and quantifying the durability of batteries using high-resolution X-ray data obtained from the Argonne National Laboratory Advanced Photon Source (ANL APS) and Lawrence Berkeley National Laboratory Advanced Light Source (LBNL ALS). The focus of the investigation was on lithium metal batteries (LMB), which are prone to lithium dendrite formation, impacting battery efficiency and posing safety hazards. The study employed in-situ and operando imaging techniques, including 3D microtomography, to detect battery defects and monitor the dynamics of lithium plating during cycling experiments. A multiclass semantic segmentation method based on the Iterative Residual U-net architecture was proposed for accurately identifying lithium plating dynamics. The computations were performed using the NERSC Perlmutter high-performance systems, exploiting both CPU, GPU, and large memory nodes. The results demonstrated the successful application of the proposed computational tool, batteryNET, for semantic segmentation and classification of different phases in the battery after cycles of charge and discharge. The analysis included volume quantification of different phases, spatial correlation among different components at different points during the cycling and renderings of the semantic segmentation results, showcasing the effectiveness of the approach. Ongoing and future work includes exploring larger datasets and new semantic segmentation algorithms based on vision transformers and other transformer-based deep learning architectures for the detection of battery defects using semantic segmentation techniques.

9:00 AM DS02.06.02
Acceleration of Time Resolved X-Ray Imaging using Deep Learning Techniques EshanGanju and NikhileshChawla; Purdue University, United States

Quantifying the three-dimensional (3D) microstructure of materials is vital across various domains, including materials science, condensed matter physics, and semiconductor research. Despite the efficacy of traditional characterization methods such as optical microscopy, electron microscopy, and serial sectioning, these techniques tend to be dimensionally limited, destructive, and require a significant time investment. Over the past few decades, advancements in synchrotron and lab-scale 3D x-ray tomography (XCT) have drastically enhanced researchers' capacity to uncover complex 3D microstructures across numerous materials and fields of research. Specifically, lab-scale XCT systems have facilitated the broader utilization of 3D characterization methods among diverse researchers. Despite their advantages, 3D XCT techniques also present substantial challenges, including but not limited to extended experimentation time, substantially large datasets compared to 2D methods, and high computational demands associated with analyses of the 3D tomography data. These limitations are exacerbated in lab-scale systems, which have flux limitations compared to their synchrotron-scale counterparts. The challenges are further intensified when working with time-resolved 3D tomography or 4D datasets. Applying deep learning, which excels at handling large datasets, offers a potential solution to these challenges. Deep learning can significantly optimize the most time-consuming aspects of lab-scale 4D experimentation—data collection and data analysis or segmentation. In this study, we have utilized Generative Adversarial Networks (GANs) to filter, enhance, and segment low-dose Absorption Contrast Tomography (ACT) and Diffraction Contrast Tomography (DCT) datasets captured using a lab-scale x-ray microscope (XRM). In our GAN-based approach, we adopted the U-Net++ network architecture to improve the quality of the 3D datasets captured at the lab scale. Our study encompassed two model samples: hyper-spherical Aluminum (Al) particles dispersed in a resin matrix and micro-scale Silicon (Si) cubes dispersed within a resin matrix. The Al particles were scanned under low and high x-ray doses (controlled by the exposure time and the number of X-ray projections) and resolutions. The Al particle datasets were used to train our GAN network to filter and enhance the low-dose and low-resolution scans, respectively. The results from this approach demonstrated clear improvements in image quality and significant savings in scan time. Our approach was also carried out on Diffraction contrast tomography (DCT) scans of single-crystal Si cubes to obtain diffraction spots with varying noise levels. The high-dose diffraction spots were manually segmented, a process that is both time-consuming and labor-intensive, and this segmented data was used to train our GAN network to segment the diffraction spots from the low-dose DCT scans directly. The manual and GAN-based segmentation results were used to reconstruct the 3D grain structure of the Si cubes using a forward modeling approach. The reconstructions from the GAN-based and manually segmented datasets were compared to assess the accuracy of the GAN segmentation and quantify the time savings achieved with this approach. The deep learning-based approach outlined in this study helps advance our ability to perform 4D material characterization and analysis at the lab scale. Integrating deep convolutional neural networks into lab-scale 4D material characterization can accelerate data collection and analysis, automate the characterization of materials and open up new avenues for analyses of diverse material classes at an expedited rate.

9:15 AM DS02.06.03
Pair-Variational Autoencoders (PairVAE) for Linking and Cross-Reconstruction of Characterization Data from Complementary Structural Characterization Techniques ShizhaoLu and ArthiJayaraman; University of Delaware, United States

In materials research, structural characterization often requires multiple complementary techniques to obtain a holistic morphological view of the synthesized material. Depending on the availability and accessibility of the different characterization techniques (e.g., scattering, microscopy, spectroscopy), each research facility or academic research lab may have access to high-throughput capability in one technique but face limitations (sample preparation, resolution, access time) with other technique(s). Furthermore, one type of structural characterization data may be easier to interpret than another (e.g., microscopy images are easier to interpret than small angle scattering profiles). Thus, it is useful to have machine learning models that can be trained on paired structural characterization data from multiple techniques (easy and difficult to interpret, fast and slow in data collection or sample preparation), so that the model can generate one set of characterization data from the other. In this talk, we demonstrate one such machine learning workflow, PairVAE, that works with data from Small Angle X-Ray Scattering (SAXS) that presents information about bulk morphology and images from Scanning Electron Microscopy (SEM) that presents two-dimensional local structural information of the sample. Using paired SAXS and SEM data of newly observed block copolymer assembled morphologies [open access data from Doerk G.S., et al. Science Advances. 2023 Jan 13;9(2): eadd3687], we have trained our PairVAE. After successful training, we have demonstrated that the PairVAE can generate SEM images of the block copolymer morphology when it takes as input that sample’s corresponding SAXS 2D pattern, and vice versa. This method can be extended to other soft materials morphologies as well and serves as a valuable tool for easy interpretation of 2D SAXS patterns as well as an engine for generating ensembles of similar microscopy images to create a database for other downstream calculations of structure-property relationships.

9:30 AM DS02.06.04

Machine Learning-Based Interpretation of Spectroscopy and Diffraction Data for Materials Characterization DanielE. Vizoso and RemiDingreville; Sandia National Laboratories, United States

A wide variety of spectroscopic and diffraction techniques are commonly used for the identification and characterization of materials in many fields of study. Traditional interpretation of diffractograms or spectral profiles relies on the practitioner's ability to accurately and systematically featurize these profiles and make comparisons to reference profiles or correlate changes in these measurements to some material characteristic of interest. However, several studies have shown that traditional human-identifiable features such as peak positions and widths can be unreliable metrics depending on the methods used to identify them, particularly when the material deviates significantly from pristine, defect-free states or when the feature of interest is similar in magnitude to experimental noise. To address these challenges, machine learning methods have been used for the classification or featurization of simulated and experimental profiles for the purposes of rapid materials characterization and identification. In this presentation, we propose a reliable protocol based on supervised manifold learning meant for the extraction of meaningful features from simulated vibrational density of states as well as simulated X-ray diffraction data as exemplar data captured via spectroscopic or diffraction techniques, respectively. Using the extracted features (both separately as well as a combined feature set from the simulated vibrational density of states and simulated X-ray diffraction), we present accurate and robust regression models that are able to disentangle complex overlapping material states from individual profiles, demonstrating comprehensive decoding of profiles beyond classical peak analysis.
Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy National Nuclear Security Administration under contract DE-NA0003525.

9:45 AM DS02.06.05
Predicting the Number of Grains Contributing to 2-D XRD Patterns of Ti-6Al-4V Using Deep Neural Networks Trained by Ab-Initio XRD Simulations Mohommad RedadMehdi[1,2], WeiqiYue[1,2], EthanFang[1,2], PawanK. Tripathi[1,2], MatthewA. Willard[1,2], VipinChaudhary[1,2], DanielJ. Savage[3], DonaldW. Brown[3], RogerH. French[1,1,2] and FrankErnst[1,2]; [1]Case Western Reserve University, United States; [2]Materials Data Science for Stockpile Stewardship: Center of Excellence, United States; [3]Los Alamos National Laboratory, United States

Beamline X-ray diffractometry, where a high-energy X-ray beam is transmitted through a material and sequences of 2D diffractograms (diffraction patterns) are obtained on X-ray detectors, provides a wealth of data, including crystal structure, phase composition, and microstructure. While containing information similar to that in 2D (e.g. light-optical) images, comprehensive quantitative evaluation of information from diffractograms is less intuitive. One example is the number of grains in the field of view, which is straight-forward to determine in an image, but less obvious in a diffractogram.
Using this example, we present a novel approach to determine the number of grains contributing to sequences of diffractograms recorded during in-situ experiments. Our approach uses deep learning, based on neural networks that are trained by ab-initio simulations of 2D diffractograms. The simulations incorporate the relevant material and diffractometry parameters, allowing us granular control over the features in the simulated diffractograms. Using large numbers of simulated diffractograms, we train several DNNs (deep neural networks), designed using various architectures and appropriate hyperparameters. These DNNs are capable of learning significant features from the simulated diffractograms, which allows them to predict the number of grains in the irradiated volume with good accuracy. The effectiveness of our approach will be validated by applying it to real-time evaluation of experimental beamline 2D diffractograms obtained during additive manufacturing of Ti-6Al-4V.

10:30 AM *DS02.06.06
Streamlined Curation and Mining for Synchrotron Multi-Modal Microscopic Study of Battery Materials YijinLiu; The University of Texas at Austin, United States

As modern material science moves beyond the homogeneous model system and towards research into real-world materials under realistic conditions, it usually requires using high spatial resolution probes to survey a relatively large sample, preferably in 3D and within an acceptable time frame. The research of lithium-ion batteries is a typical example. The prolonged operation of a lithium-ion battery could lead to redox heterogeneity, local phase transformation, surface passivation, particle cracking, and local domain deactivation. All these processes critically affect the electrochemical behavior and cell performance. The characterization of these processes is an important research area and synchrotron analytic methods stand out as a suite of effective approaches. The technical challenge is further amplified by the desire to integrate X-ray probes in different modalities that offer different sensitivities to various material properties. In this talk, I will discuss our efforts to utilize high-resolution, high-throughput diffractive imaging and spectro-imaging methods to investigate a few different types of battery cathode materials. I will present a few case studies that highlight the leverage of computational developments to streamline the data curation and mining. Finally, I will briefly discuss our perspective on the future developments that could be applicable to the application of X-ray inspection for industrial manufacturing of battery components and cells.

11:00 AM DS02.06.07
Leveraging Deep Neural Networks for Feature Extraction from 2D XRD Diffractogram Movies Acquired at the NSF CHESS Synchrotron Beamline PawanK. Tripathi[1,2], WeiqiYue[2,2], EthanFang[2,2], Hoang HaMy Le[2,2], DonaldW. Brown[3], MatthewA. Willard[1,2], VipinChaudhary[2,2], FrankErnst[1,2] and RogerH. French[1,2,2]; [1]Case Western Reserve University, Cleveland, Ohio, USA, United States; [2]Case Western Reserve University, United States; [3]Los Alamos National Laboratory, United States

Analysis of 2-D X-ray diffraction (XRD) diffractogram movies acquired at synchrotron beamlines such as the Cornell High Energy Synchrotron Source (CHESS) beamline plays a crucial role in understanding the temporal changes in the atomic-scale structure and crystallographic properties of polycrystalline materials such as the Ti-6Al-4V (Ti-64) as they undergo heat treatment and related grain growth. By combining automated image preprocessing pipelines to standardize the diffractogram image sequences, we can then use pre-trained deep neural networks (DNNs) to harness the temporal coherence present in image sequences obtained during in-situ XRD experiment of heat treatment. DNNs have demonstrated their importance in learning complex patterns and extracting insights from sequential image data. The temporal coherence present in image sequences contains information about evolving features of the material's microstructure, such as the Ti-64 α to β phase transition and grain growth.
These 2D XRD diffractogram image sequences are massive and rich with information, yet could be overwhelming, becoming a bottleneck for extracting research insights due to their terabyte sizes. Therefore, we use automated analysis pipelines on FAIRified datasets, implemented in our CRADLETM Distributed and High-Performance Computing Cluster, where we can ingest, and perform image pre-processing to remove bias in the XRD patterns and perform DNN model training. The 2-D XRD patterns were directly used for DNN learning, instead of the typical down-sampled, dimension-reduced 1-D XRD peak patterns typically analyzed using GSASII. To identify the role of neural network architecture in learning from 2-D XRD movies, we trained 168 DNNs with different architecture and hyper-parameters using an experimental dataset acquired over multiple samples and beamline runs that contains 3,012 2048x2048 pixel Ti-64 XRD images and we evaluated their performance on an image test set of 1,102 Ti-64 XRD images, achieving a mean square error (MSE) of 0.076%. Using the trained DNN models, we can predict the titanium beta phase volume percentage during the thermal heat treatment.

This material is based upon research in the Materials Data Science for Stockpile Stewardship Center of Excellence (MDS3-COE), and supported by the Department of Energy's National Nuclear Security Administration under Award Number(s) DE-NA0004104.

Computational Reverse Engineering of Scattering Experiments (CREASE) Method for Interpreting Structure in Soft Materials ZijieWu, ChristianHeil and ArthiJayaraman; University of Delaware, United States

In this talk, we will describe 'Computational Reverse Engineering of Scattering Experiments (CREASE)', a computational method that we have developed for analysis of small angle scattering profiles and interpretation of the structure in soft materials. CREASE is useful to interpret structural detail at a range of length scales for soft materials without relying on fitting small angle scattering profiles with off-the-shelf analytical models that may be too approximate for novel polymers and/or unconventional assembled structures. We will share multiple examples of how we have applied CREASE to experimental small angle X-ray scattering (SAXS) and neutron scattering (SANS) profiles obtained from different classes of soft materials [e.g., methylcellulose fibrillar structures (*Macromolecules* 2022, 55, 24, 11076–11091), micelles in amphiphilic polymer solutions [*ACS Polymers Au*, 2021, 1, 3, 153–164], and segregation in binary nanoparticle mixtures [*JACS Au*, 2023, 3, 3, 889–904 and *ACS Central Science*, 2022, 8, 7, 996–1007]. Through these examples we will show how CREASE can be used to test various hypotheses regarding the assembled domain shapes and sizes within the materials' structure and identify the relevant structural dimensions. Besides identifying relevant structural dimensions, the structures' representative 3D configurations that CREASE outputs can also serve as an input for other computational methods that predict macroscopic properties (e.g., color, reflectance profiles) thus serving as a valuable tool for predicting structure-property relationships [e.g., *Science Advances* 2023, 9, 21, eadf2859; *ACS Materials Letters* 2022, 4, 9, 1848–1854] Machine

learning enhanced CREASE also enables fast automated analyses of high throughput SAXS or SANS data facilitating future automation in soft materials structural characterization. Interested readers can find more information about CREASE on these two links:
https://crease-ga.readthedocs.io/en/latest/ and https://github.com/arthijayaraman-lab/crease_ga .

11:30 AM DS02.06.09
Combining Synchrotron Imaging with Artificial Intelligence—The Key for Elucidating Bone Multi-Scale Fracture Origin FedericaBuccino[1], ZhaoQin[2], MiladMasrouri[2], GiulianaTromba[3], GiuseppeBanfi[4] and Laura MariaVergani[1]; [1]Polytechnic University of Milan, Italy; [2]Syracuse University, United States; [3]Elettra Synchrotron, Italy; [4]IRCCS Galeazzi Orthopaedic Institute, Italy

The detection and diagnosis of early fractures pose a challenging goal due to the complex and intertwined nature of bone structures. In this context, the field of healthcare is embracing deep learning and artificial intelligence as a means to overcome the subjectivity associated with clinicians' analysis of medical images. However, the current utilization of neural networks is primarily focused on the macro-scale of bone structures, limiting their ability to comprehend the initial stages of crack formation. To gain a better understanding of crack occurrence, it is crucial to adopt a multi-scale perspective and investigate the micro-scale, where the presence of a dense network of lacunae could indicate the initiation or deviation site of a crack. Unfortunately, speculations at this scale can only be made with the assistance of high-resolution imaging techniques, which are time-consuming when it comes to analyzing output images. In this research, we aim to combine an understanding of the mechanisms behind micro-crack propagation with the promising application of convolutional neural networks (CNNs) and coarse-grained simulation for mechanics prediction.
Trabecular samples obtained from healthy and osteoporotic human femoral heads are considered for this study. These samples are subjected to image-guided failure assessment inside a synchrotron, which emits a monochromatic beam at an energy of 25.6 keV, with a resolution of 1.6 µm. For the detection of cracks and lacunae, a CNN is implemented based on the Keras VGG16 built-in model. During the training and validation stages of the CNN, a total of 648 images are utilized, with a split of 20% for validation and 80% for training. In terms of lacunae identification, the input set consists of three different samples, each containing three images.
The designed CNN demonstrates a high level of accuracy in automatically detecting lacunae and micro-cracks at different compression levels. With the baseline setup, the networks achieve accuracy levels exceeding 0.99 for both cracks and lacunae, with a meanIoU validation metric of over 0.87. This result is particularly encouraging, considering the complexity of the scanning procedure and the challenges encountered when micro-cracks coalesce into larger meso-cracks.
The CNN proves successful in identifying cracks at their initial stages. These cracks become visible and progress further as the applied displacement increases. However, in the final compression stages, cracks are difficult to highlight using the implemented algorithm due to the complete collapse of the bone structure. From a diagnostic standpoint, the higher accuracy in detecting the initial stages of cracks is of great interest, as meso- and macro-scale cracks already represent a critical stage for the subject. Regarding lacunae detection, the CNN achieves optimal results, reducing the computational cost associated with manually segmenting these micrometric elliptical features.
Additionally, experimental images are converted into CG models and then LAMMPS is exploited to run fracture test of the trabecular biological material, which architecture is particularly complex and needs for repeating tests for extrapolating the deviation range. Here, we combined this tool with the up-to-date generative imaging methods to massively generate reasonable artificial phase images and test their fracture, so to get a reliable range of the mechanical properties without actually scanning or testing all of them.
The adopted approaches and methodologies hold promise for developing powerful classifiers and recognition systems to study the microdamage initiation and progression and the mechanical response prediction of bone tissue. Ultimately, this paves the way for the application of machine learning in the study of bone micromechanics.

SYMPOSIUM DS03

Emerging Challenges and Opportunities in Materials by Design
November27 - December5, 2023

Synthesis Predictions in AI-Based Materials Design YousungJung; Seoul National University, Korea (the Republic of)

Chemical research is primarily focused on discovering new molecules and materials that possess desired properties. To improve this process, an effective strategy involves utilizing all accessible knowledge and data to strategically design future materials using computers. However, a notable hurdle in digital discovery is that many molecules and materials designed computationally are often impractical to synthesize in the laboratory. In this presentation, I will delve into the synthesizability of molecules and materials, including the prediction of synthesis pathways (retrosynthesis) and chemical reactivity. Additionally, I will explore several challenges and opportunities that await further advancements in accelerated chemical platforms.

11:00 AM DS03.01.02
A Three-Dimensional Generative Framework for Designing High Performance Complex Material Structures ZhengyangZhang, HanFang and YanmingWang; Shanghai Jiao Tong University, China

Generative design for materials has recently gained significant attention due to the rapid evolution of generative deep learning models. There have been successful demonstrations of molecular-level generative design, including conditional generation based on specific criteria[1]. In the realm of macroscopic structures, voxel representations of two-dimensional[2,3] and three-dimensional[4] structures have been extensively studied. However, the challenge lies in the insufficient resolution of these models, hindering their ability to accurately represent real structures. Various other approaches based on point cloud[5,6], mesh[7], and neural radiance fields (NeRF)[8–10] have been explored but have yet to be introduced in the fields of material science. In this study, we aim to address these issues with a novel framework consisting of a mesh-based 3D structure generator and physics-informed functions. We utilize non-linear mapping networks as soft constraints to capture the complex nature of 3D material structures. The incorporated physics-based methods are capable of evaluating the performances of generated structures in real-time. The composition of the loss function considers these evaluation results to drive active structure optimization. Our framework endeavors to achieve high-resolution 3D structures generation

guided by desired material properties, expected as a significant step forward toward the inverse design of novel functional materials.

CrystalGAN—Crystal Generative Adversarial Network for Periodic Materials Discovery DivyaSharma[1], CharlieGuan[2], MargaretQuinn[3] and PauletteClancy[1]; [1]Johns Hopkins University, United States; [2]Northwestern University, United States; [3]DC Energy, United States

There are several online databases available that make available the periodic structure of a wide variety of crystal structures. These can play a crucial role in generative tasks to produce new, previously undiscovered periodic materials. Such a generative task can be achieved by using a Generative Adversarial Network(GAN) on ‘crystal images’, a representation built from other various voxel-based data that comprises of the 3D-fractional coordinates of each element in the crystal structure, that are stored in a separate ‘channel’, similar to the RGB representation of conventional images. We use a Wasserstein GAN to generate new materials, learning from Materials Project data. To take advantage of a larger subset of the MP dataset, we learn on all ternary materials and predict the lattice vector and the elemental identity of each channel of a given structure. We also preserve periodic, rotational, and translational invariance by also performing data augmentation. The trained GAN will allow us to reconstruct new materials from the different generative and prediction heads of the network.

11:30 AM DS03.01.04
Bispectral Analysis of Local Atomic Environments in Metal-Organic Chalcogenide Assemblies and Related Material Classes TuongPhung, AriaMansouri Tehrani and TessSmidt; Massachusetts Institute of Technology, United States

In this talk, we explore the use of bispectra as a tool to analyze and cluster local atomic environments, enabling the identification of geometric trends across different material classes. The local environments in a material play a significant role in determining its overall properties. Understanding the complex interplay between local environment geometries and material properties is crucial to designing next-generation materials with desired properties. Bispectra are well-suited to characterizing local environments due to being a rotationally invariant, smooth, invertible (modulo a global rotation), and fixed-length descriptor. We define the bispectrum in this context as the scalars and pseudoscalars resulting from the triple tensor product of a local environment's spherical harmonic expansion with itself.

We apply the bispectra to compare the local environments of a new class of hybrid inorganic-organic materials called MOChAs with those found in other transition-metal and chalcogen-containing materials from the Materials Project and Cambridge Structural Database. MOChAs, or Metal-Organic Chalcogenides Assemblies, are self-assembled hybrid crystals in which low-dimensional transition metal chalcogenide structures are scaffolded by organic ligands. The structural diversity of organic ligands leads to a wide range of possible local environments in MOChAs, which are effectively captured by bispectra. These bispectra can be visualized and clustered, ultimately guiding the design and discovery of new MOChAs.

11:45 AM DS03.01.05
Strategies for Assessing and Improving the Diversity and Utility for Generative Models for Material Structure AlexanderNew[1], MichaelPekala[1], ElizabethPogue[1], NamQ. Le[1], JannaDomenico[1], ChristinePiatko[1] and ChristopherStiles[1,2]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

Generative machine learning (ML) models can use computational and experimental materials databases to create large quantities of novel material structures. Via additional property-prediction models, generated materials can be assessed for suitability in design tasks. Identified materials can be studied in detail, synthesized, and characterized. Here, we assess how one state-of-the-art generative model, the physics-guided crystal generation model (PGCGM), can be used as part of the inverse design process. We show that the PGCGM's learned latent space is not smooth with respect to variation in model inputs and output material properties, making material optimization difficult and limited. We also demonstrate that most of its generated structures are predicted to be thermodynamically unstable by a separate property-prediction model, partially due to out-of-domain data challenges in stability-prediction. Our findings suggest strategies and mechanisms for improving the effectiveness of generative models for inverse design. In particular, we implement and evaluate some of these suggested strategies, such as developing smoother latent spaces and more generalizable property-prediction models.

Inverse Crystal Structure Prediction AronWalsh; Imperial College London, United Kingdom

What set of chemical elements can adopt a given three-dimensional crystal structure? This question is challenging to answer, especially for multi-component solids where the compositional search space across the periodic table is vast. I will discuss routes by which we are attempting to tackle this, including rules-based chemical filters and data-driven statistical measures, implemented in the SMACT package [1]. Recent advances will be presented including the use of chemical similarity metrics to match compositions to prototype crystal structures, and symmetry descent down the crystallographic Bärnighausen tree to explore both metastable and ground-state configurations [2]. Finally, metrics to assess the stability and synthesisability [3,4] of the resulting materials will be covered.

High-Throughput Screening of Symmetry-Breaking Reconstructions at Vacancies in Oxides SeánR. Kavanagh[1,2], IreaMosquera-Lois[1], DavidO. Scanlon[2], AronWalsh[1] and YuKumagai[3]; [1]Imperial College London, United Kingdom; [2]University of Birmingham, United Kingdom; [3]Tohoku University, Japan

Point defects are a universal feature of crystalline materials, whose identification is often addressed by combining experimental measurements with theoretical models. The standard approach of simulating defects is, however, prone to miss the ground state atomic configurations of defects, due to energy-lowering reconstructions from the idealised crystallographic environment.[1–4] Missed ground states severely compromise the accuracy of calculated properties.

To address this issue, we report an approach to efficiently navigate the defect configurational landscape using targeted bond distortions and rattling.[5] In this study, we apply our defect structure-searching method (implemented in ShakeNBreak[6]) in a high-throughput methodology to oxygen vacancies in over 200 metal oxides, building on the work of Kumagai et al.[7]

Our results reveal energy-lowering reconstructions missed by the standard modelling approach in ~50% of cases, demonstrating the widespread prevalence of this phenomenon. Analysis of this large defect dataset allows us to correlate the host material properties with the likelihood of defect symmetry-breaking and the motifs observed. Finally, we extend this analysis by re-training a graph neural network force-field on this large dataset of defect relaxations and applying it to a much wider oxide dataset (~1000 oxides), demonstrating the future potential of machine learning methods to accelerate defect calculation workflows.

Towards Atomistic Phase Diagrams for Surface Reconstructions and Nanoparticle Responses to Adsorbates using Machine-Learned Dynamics CameronJ. Owen[1], NicholasMarcella[2], GengnanLi[3], ChristopherO'Connor[1,4], YuXie[1], ClareY. Xie[1], AndersJohansson[1], Jin SooLim[1], LixinSun[1], ChristianReece[1,4], AnibalBoscoboinik[3], AnatolyFrenkel[5,3], RalphNuzzo[2] and BorisKozinsky[1,6]; [1]Harvard University, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Brookhaven National Laboratory, United States; [4]Rowland Institute, United States; [5]Stony Brook University, The State University of New York, United States; [6]Robert Bosch LLC Reseach and Technology Center, United States

Metal surfaces have long been known to reconstruct in both facile and activated fashions, exhibiting substantial influence in their resulting catalytic and mechanical performance. We provide an unbiased simulation method by which surface reconstructions can be studied with atomistic resolution under the effects of temperature and chemisorption of adsorbates. A machine-learned force field (MLFF) is trained from *ab initio* (first principles) calculations that can capture each of the low-index mesoscopic surface reconstructions of Au (e.g., the Au(111)-`Herringbone,' Au(110)-(1x2)-`Missing-Row,' and Au(100)-`Quasi-Hexagonal' reconstructions) using large scale molecular dynamics (MD) simulations. Additionally, we present another independent MLFF that can provide proper description of the Pt(100)-(1x1) to ‘hex’ reconstruction, as well as subsequent lifting via exposure to CO.

Analysis of these MD trajectories yields direct atomistic understanding of the dynamic evolution of these surfaces from their initial facets, providing previously inaccessible information such as nucleation timescales under the effects of strain, local deviations from the original stoichiometry, and adsorbate exposure. Both MLFFs can also be used to study surface reconstructions and responses to adsorbates on Au or Pt nanoparticles (NPs) under similar environmental stimuli. These methodological advancements set a new standard for determining surface reconstructions along the axes of surface stoichiometry, mechanical strain, and adsorbate exposure without bias and with atomic resolution, thus providing a comprehensive picture of the nucleation environments and time-scales for such phenomena and moving the surface science community towards surface phase diagrams for these complicated mesoscopic systems.

Code, Data and Infrastructure Gaps in Machine Learning for Materials Science Shyue PingOng; University of California, San Diego, United States

Machine learning has emerged in recent years as a powerful new tool in the study and design of materials. Nevertheless, significant challenges remain to the application and dissemination of machine learning models and architectures. In this talk, I will share my perspectives on the gaps in code, data and infrastructure for machine learning in materials science. I will highlight the Materials Virtual Lab’s efforts toward addressing some of these gaps in collaboration with the broader computational materials science community.

3:00 PMBREAK

3:30 PM *DS03.02.05
Overcoming the Limits of Approximate Electronic Structure Models in Machine Learning Accelerated Materials Discovery HeatherJ. Kulik; Massachusetts Institute of Technology, United States

Machine learning (ML)-accelerated discovery of transition metal containing materials such as light-harvesting chromophores, phosphors, and other photoactive complexes holds great promise. Nevertheless, the open shell d electrons that impart many of the desirable properties to these systems also make them notoriously challenging to study with conventional electronic structure techniques such as density functional theory (DFT). Thus, when ML is used to accelerate computational screening, it often inherits the biases of the underlying method used to generate training data. I will describe our recent efforts to overcome these limits through three complementary approaches. First, I will describe how we have developed machine learning models trained directly on experimental reports of iridium phosphors, leading to the development of ML models that can predict experimental emission energies and lifetimes with superior or equivalent performance to conventional methods such as time-dependent DFT but in a fraction of the computational time. Next, I will describe how we overcome limits of DFT uncertainty in screening for light harvesting chromophores with earth abundant 3d metals by incorporating method insensitivity into a multi-objective optimization workflow, requiring a consensus of functionals to agree on a property in order for a material to be selected as optimal. These workflows accelerate materials discovery by at least 1000-fold. Finally, I will describe our development of a density functional "recommender" that can identify which DFT functional is most predictive to obtain accurate vertical spin excitation energies in transition metal complexes.

4:00 PM DS03.02.06
Finding Stable Zintl Phases using an Upper-Bound Energy Minimization Approach Manish KumarKothakonda[1], Cheng-WeiLee[1], JeffLaw[2], QianYang[3] and PrashunGorai[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States; [3]University of Connecticut, United States

Thermodynamic phase stability is a prerequisite in the search for novel functional materials. Density functional theory (DFT) has been the workhorse for phase stability predictions but is computationally expensive for large search spaces. In this context, machine learning models have become powerful in predicting phase stability and material properties. In particular, graph neural networks (GNNs) have outperformed more traditional ML models in phase stability predictions. In GNNs, the periodic crystal structures are converted into graphs with atom positions represented by nodes and bonds with edges connecting the nodes. In materials searches, often, hypothetical structures are created either by chemical substitutions in prototype structures or other strategies. The resulting hypothetical structure needs to be relaxed before it can be used as an input to a GNN for predicting stability. Such relaxation requires expensive DFT calculations or is achieved with machine-learned interatomic potentials. To address this challenge, we have recently proposed an upper-bound energy minimization approach (UBEM) that finds very stable structures that lie deep in the convex hull, without having to perform structural relaxations [1]. We demonstrate the efficacy of this approach by discovering novel Zintl phases that possess complex structures, and are located between saltlike compounds and intermetallic phases with a combination of ionic and covalent bonding. Although Zintl phases represent a chemically and structurally diverse family of materials, only a limited number of such phases are currently known. The potential for discovering new Zintl phases remains largely untapped and traditional experimental approaches are resource-intensive and slow. We performed a search over ~100,000 hypothetical Zintl phases using UBEM and discovered 2,140 stable Zintl phases. We have validated these predictions with DFT. Furthermore, we compared our predictions with M3GNet, which utilizes machine-learned interatomic potentials to explicitly perform structural relaxations and predict phase stability[2]. Further investigation of the thermoelectric performance of the predicted stable phases and experimental validation are currently underway.

4:15 PM DS03.02.07
Estimating and Correcting DFT Error of Metal-Organic Frameworks Through Molecular Derivatives YeongsuCho and HeatherJ. Kulik; Massachusetts Institute of Technology, United States

Metal-organic frameworks (MOFs) are composed of metal clusters linked by organic molecules, forming a porous structure that is suitable for a range of applications, including catalysis, hydrogen storage, and CO_2 capture. While an accurate theoretical analysis is crucial for characterizing and designing functional MOFs, the presence of transition metals makes MOFs exhibit strong static correlation and considerable errors in their density functional theory (DFT) calculations. Additionally, post-DFT methods are computationally prohibitive for MOFs due to the large number of atoms per unit cell. We estimate the magnitude of static correlation of MOFs using low-cost multireference diagnostics based on finite-temperature DFT, which is the first time they are applied to solid-state systems. By comparing the behavior of the diagnostics on MOFs and their molecular derivatives, we demonstrate that the DFT-based multireference diagnostics are equally applicable to solids as to their molecular derivatives. Moreover, we show that estimates provided by multireference diagnostics of a MOF have a good correlation with those of its molecular derivatives, which can be calculated much more affordably in comparison to those of the full MOF. The additivity of the multireference character discussed here suggests the set of molecular derivatives to be a good representation of a MOF, allowing it to be utilized to extract empirical parameters. Therefore, we propose to determine the Hubbard U

parameter by fitting DFT results of molecular derivatives to their theoretical benchmark, and apply the same parameter to DFT+U calculations of MOFs to effectively correct the multireference error. The quality of fitted U parameters was evaluated on the adsorption energy of N_2, O_2, and CO_2 gas molecules. The ability to perform high-level calculations for molecular systems and the low cost of DFT+U make this procedure a practical strategy for designing MOFs with improved accuracy and efficiency.

4:30 PM DS03.02.08
High-Throughput Identification of Quantum Defects in Semiconductors YihuangXiong[1], NatalyaSheremetyeva[1], WeiChen[2], WeiruChen[1], DianaDahliah[2], CélineBourgois[2], SineadM. Griffin[3,4], AlpSipahigil[5,4,3] and GeoffroyHautier[1]; [1]Dartmouth College, United States; [2]Universite Catholique de Louvain, Belgium; [3]Lawrence Berkeley National Laboratory, United States; [4]Lawrence Berkeley National Laboratory,, United States; [5]University of California, Berkeley, United States

Color centers, or quantum defects, in semiconductors are emerging as promising candidates for the spin-photon interface—an indispensable building block that combines the memory capability of a spin with the information transfer capabilities of photons. This interface holds significant potential for the realization of various quantum technologies. However, the challenge remains in building a database documenting tens of thousands of quantum defects due to the complexities of accurately describing their electronic structures in an efficient manner. In this talk, we will present our work on a high-throughput search for promising spin-photon interfaces using first-principles computations. We will discuss our approach for addressing the prescribed issue by employing single-shot hybrid computations, as well as our strategies for designing defects that emit at technologically relevant wavelengths. Our results suggest promising candidates and shed light on strategies for designing novel spin-photon interfaces.

4:45 PM DS03.02.09
Machine Learning of Density Functionals for Accurate, Large-Scale Materials Simulations KyleW. Bystrom, StefanoFalletta and BorisKozinsky; Harvard University, United States

We have recently developed the CIDER formalism for machine learning exchange-correlation functionals, with a particular emphasis on using nonlocal features to achieve hybrid density functional theory (DFT) accuracy at semilocal DFT cost for large solid-state simulations. In this talk, we will cover current directions being pursued to further improve CIDER functionals, including training full exchange-correlation functionals for applications to heterogeneous systems and improving the accuracy of CIDER functionals for band gap and charge transfer-related problems. We will also discuss how CIDER can be used to overcome cost-accuracy trade-offs for materials science applications where both large system sizes and hybrid DFT accuracy are required, such as the calculation of charged point defect properties in semiconductors.

8:30 AM *DS03.03.01
Predictive Materials Design and Discovery with Causal Machine Learning AyanaGhosh; Oak Ridge National Laboratory, United States

Applications of machine learning/deep learning (ML/DL) methods have become common in a variety of scientific disciplines. However, capabilities of such techniques are yet to be fully realized in fundamental physical disciplines due to limited access to labeled data, lack of extensibility, and robustness of traditional ML models. More importantly, the intrinsically in-built correlative nature of ML models does not capture the causal hypothesis-driven nature of physical sciences. The interpretability and explainability of large parameter-dependent deep networks also pose significant challenges for fashioning more informative and physically intuitive data-driven approaches. As a result, current ML approaches for materials design fail to provide quantitative and reliable predictions about structure/property relationships, useful for theory-based design workflows for targeted synthesis/characterization to accelerate time-to-solution and reduce expensive laboratory costs. This talk will focus on how causal ML models can be exploited in combination with generalized materials representation to solidify our understanding of governing fundamental atomistic mechanisms with direct ties to experimental observables. While the family of perovskite oxides remain at the center of this exploration, discussion on extending such frameworks to other material classes with real-life applications in energy, catalysis, photovoltaics, drug design, reaction mechanisms mapping, will also be incorporated in the presentation.

This research is sponsored by the Laboratory Directed Research and Development Program of Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the U. S. Department of Energy.

Efficacy of Materials Representations on Prediction of Superconductor Properties VictorLeon[1], AlexanderNew[1], MichaelPekala[1], ElizabethPogue[1] and ChristopherStiles[1,2]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

The search for high temperature superconductors with mechanical flexibility is motivated by critical applications in healthcare (magnetic resonance imaging), MAGLEV vehicles, and reduction in power line transmission energy waste. The discovery of novel superconductors is hindered experimentally and computationally by the huge numbers of combinations of possible elements and crystal structures. In recent years, significant interest has been directed towards using machine learning and materials informatics for inverse design of materials. However, there is no standard way to represent materials for inverse design problems. An ideal material representation would keep the most predictive power for the design application relevant materials properties. In this study, we conduct a systematic evaluation of the predictive power of various materials representations (e.g. Roost, Magpie descriptors, element-fraction) with a variety of distance measures (e.g. Euclidean, earth movers distance). We compare their performance as inputs to a variety of machine learning algorithms (e.g. k-nearest neighbors regression, neural networks) to predict relevant superconductor materials properties (e.g. critical temperature, elastic modulus). We present a systematic comparison between these representation methods and algorithms for the application of superconductor property prediction.

Physics-Informed Deep Learning Framework for Material Discovery MaitreyeeSharma Priyadarshini, OluwaseunRomiluyi, YiranWang, KumarP. Miskin and PauletteClancy; Johns Hopkins University, United States

The lack of efficient discovery tools for advanced functional materials is a major bottleneck to enabling future-generation energy, health, and sustainability technologies. One main factor contributing to this inefficiency is the large combinatorial space of materials which is very sparsely observed. Searches of this large combinatorial space are often biased by expert knowledge and clustered close to material configurations that are known to perform well. Moreover, experimental characterization or first principles quantum mechanical calculations of all possible materials are extremely expensive leading to small available data sets. As a result, there is a need for the development of computational algorithms that can efficiently search this large space for a given material application. Here, we introduce, PAL 2.0, a method that combines a physics-informed belief model with Bayesian optimization. Every material is characterized by physical and chemical properties of components of the material in a complex manner but *a priori* knowledge of the identity of the important properties is often lacking. The key contributing factor of our proposed framework is the creation of a physics-based hypothesis using XGBoost and Neural Networks. The generated hypothesis provides a physics-based prior to the Gaussian process model which is then used to perform a search of the material space. Our method is unique since it picks out the physical descriptors that are most representative of the material domain making the search unbiased toward expert knowledge, which in many cases is unknown. The model also provides valuable chemical insight into the domain that can be used to develop new materials that were outside the domain that was initially searched. Some materials that we have tested our approach on include metal halide perovskites and thermoelectric semiconductors. More recently our approach is being used in a closed-loop setup with experimentalists to discover high-temperature shape memory alloys.

Funding acknowledgment: MSP, OVR and PC acknowledge support from the U.S. Department of Energy (DOE), Basic Energy Sciences (BES), under award DE-SC0022305. Kumar Miskin thanks Johns Hopkins University for his support. The authors acknowledge the support afforded by access to the computing 376 facilities at the petascale Advanced Research Computing at 377 Hopkins (ARCH) facility (rockfish.jhu.edu), supported by the 378 National Science Foundation (NSF), Grant Number OAC 379 1920103, for providing the extensive computational resources needed here. Partial funding for the infrastructure for ARCH was originally provided by the State of Maryland.

Machine-Learning-Driven Advances in Modeling Inorganic Materials VolkerL. Deringer; University of Oxford, United Kingdom

Understanding the connections between atomic-scale structures and macroscopic properties is among the most important research challenges in solid-state and materials chemistry. Computer simulations based on the laws of quantum mechanics have played a key role in this – but they are computationally demanding, and therefore they will inevitably reach their limits when materials with highly complex structures are to be studied. Machine learning (ML) based interatomic potentials are a rapidly emerging approach that helps to overcome this limitation: being "trained" on a suitably chosen set of quantum-mechanical data, they achieve comparable accuracy whilst giving access to much larger-scale simulations – with thousands or even millions of atoms.

In this presentation, I will showcase some recent advances in the modeling and understanding of inorganic materials that have been enabled by ML-driven molecular dynamics (MD) simulations. I will argue that ML potentials are particularly useful for modeling structurally complex inorganic solids, such as non-crystalline (amorphous) phases that are difficult to characterize experimentally. I will survey recent work that ranges from structural studies of amorphous elements at ambient and high pressure to the modeling of materials for practical applications – for example, of disordered carbon phases for lithium- and sodium-ion battery anodes, or phase-change memories for digital data storage. I will discuss perspectives for combining these increasingly popular ML-driven simulation tools with first-principles electronic-structure computations and chemical-bonding studies, as well as possible new synergies with experimental approaches – with a vision to more fully understand, and ultimately to design, complex inorganic materials on the atomic scale.

ChIMES—Enabling Accurate Modeling of Complex Reacting Systems on Large Spatiotemporal Scales RebeccaK. Lindsey; University of Michigan, United States

For decades, atomistic modelers interested in studying condensed phase reacting systems have been forced to choose between highly predictive yet computationally expensive first principles methods, and parametric "force field" approaches affording greater computational efficiency at the expense of accuracy and predictive power. But now, modelers have a third option in machine-learned interatomic potentials (ML-IAP), which can yield models approximating quantum-based potential energy surfaces with computational expense that scales linearly with system size. These ML-IAPs have had a transformative effect by enabling "quantum accurate" simulations on previously inaccessible scales; however (1) their development for systems of more than a few atom types (especially those for which molecular chemistry is involved) necessitates large volumes of high expense (e.g., quantum) training data, and (2) they remain significantly more computationally intensive than classical "force field" models. In this presentation, we discuss ChIMES, a ML-IAM and artificial intelligence-driven generation framework designed to overcome these challenges. Recent advances and applications to complex reacting systems are overviewed.

11:00 AM DS03.03.06
GPU-Accelerated Simulations of Thermal Transport using Machine Learning Force Fields AndersJohansson, JenniferCoulter, AndreaCepellotti and BorisKozinsky; Harvard University, United States

Controlling thermal conductivities of materials is important for a wide range of applications, from thermoelectrics for clean energy generation to electronic devices and thermal barrier coatings. The thermal conductivity is commonly estimated using molecular dynamics simulations within the Green-Kubo formulation. This requires a force field that is both 1) an accurate estimate of the interatomic interactions and 2) fast enough to allow simulations with sufficiently large length and time scales. An accurate force field can also be used to accelerate the calculation of force constants for transport simulations via the Boltzmann transport equation.

In this work, we employ the Gaussian Process-based FLARE force field, which automatically learns the interactions of more complex materials than empirical force fields. The resulting model can then be mapped to a low-dimensional, computationally efficient model. Through GPU-acceleration with LAMMPS and the Kokkos library, we achieve excellent performance and obtain well-converged estimates for the thermal conductivity with Green-Kubo molecular dynamics. Our newly developed transport code, Phoebe, computes the thermal conductivity with force constants calculated by FLARE. The data efficiency of FLARE reduces the total number of DFT calculations required, and Phoebe has been highly optimized to solve the Boltzmann transport equation efficiently on GPUs using the Kokkos and cuSOLVER libraries.

Exploring Self-Assembly Models and Transformation Pathways of Complex Crystal Structures JuliaDshemuchadse[1], HillaryPan[1], MayaMartirossyan[1] and MatthewSpellings[2]; [1]Cornell University, United States; [2]Vector Institute for Artificial Intelligence, Canada

The emergence of ordered structures from simple building blocks is as ubiquitous as it is mysterious. The process of how long-range ordered structures—whether complex or simple, universal or unique—emerge from short-range interactions, remains poorly understood and an area ready for exploration with computational approaches. We model crystallization with molecular dynamics simulations of particles that interact via isotropic pair potentials: by exhibiting multiple features that represent competing length scales, these simple models have been shown to enable the self-assembly of a large variety of crystal structures. On the basis of these systems, we study which crystal structures can be self-assembled from isotropic interactions alone and how such phase transitions proceed on the particle-by-particle level. We employ rational forward design to target the assembly of varied structures, and we classify different local environments in the observed phases via high-dimensional, machine-learning-enabled order parameters (using principal component analysis and Gaussian mixture models). Through these investigations, we gain insights into processes that occur on time and length scales typically inaccessible to direct observation, and we hope to develop models for different types of interactions that enable the assembly of a wide variety of structures. Ultimately, we envision a framework within which the driving forces and mechanisms of crystal growth and self-assembly are causally linked to the types of phase transitions and emergent ordered phases that will enable the design of new materials.

Meta-Learning—Efficient Force-Field Parameterization for Accurate Molecular Simulations AdityaKoneru[1,2], HenryChan[2] and SubramanianSankaranarayanan[2,1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Accurate interatomic potentials in molecular dynamics are crucial for predicting the behavior of materials, enabling exploration of the vast materials landscape. This study focuses on the application of meta-learning techniques for force-field parameterization. Traditional approaches to force-field parameterization rely on global or local optimization strategies, often requiring extensive sampling to achieve satisfactory results when the parameter space is large. However, by leveraging meta-learning techniques, we can minimize the need for extensive sampling by acquiring knowledge about the specific regions in the parametric space that align with the desired properties. Meta-learning involves capturing the experience of navigating the parametric space automatically. For example, to capture multiple material properties like local and global structural features, energetics, mechanical and thermal properties, it is important to understand their mapping to the force-field parameter space. In this research, we have successfully applied meta-learning to various force-fields, enabling accurate descriptions of multiple polymorphs and diverse material properties. The results highlight the effectiveness of meta-learning in improving force-field parameterization for enhanced modeling and simulation of molecular systems.

Learning the Interatomic Potential of Ionic Liquids and Salt-In-Ionic Liquids with Machine Learning ZacharyA. Goodwin, NicolaMolinari, AlbertMusaelian, SimonBatzner and BorisKozinsky; Harvard University, United States

Ionic liquids are a promising class of electrolytes for battery and supercapacitor applications, as well as universal solvents for chemical reactions. In their pure form, these two-component liquids have complex molecular environments and their disordered structures can have large length scales. Moreover, how these electrolytes behave at interfaces, how they transport ions and how additives, such as Li-based salts or/and water, affect their properties is challenging to study using empirical interatomic potentials due to their limited accuracy. Here we develop machine learning interatomic potentials, based on the equivariant graph neural networks with NequIP [1], for representative ionic liquid and salt-in-ionic liquid [2]. As capturing the complex intermolecular interactions is subtle, training a potential for this system is not as straightforward as a simple solid-electrolyte, for example, and we highlight some of the challenges encountered with this process. In addition, we study the question of model transferability across the composition space of salt-in-ionic liquids, the effect of long-range interactions and uncertainty of the model.

The Second Decade of the Materials Genome Initiative JamesA. Warren; National Institute of Standards and Technology, United States

Two years ago, the US Materials Genome Initiative (MGI) released an updated strategic plan that outlined the priorities and tactics for this multi-agency effort to accelerate the discovery, design, development, and deployment of new materials into manufactured products. The means to achieve this overarching goal is the Materials Innovation Infrastructure, a federated, yet tightly knit, interplay of computational, experimental and data resources. In this presentation I will briefly review the MGI's progress to date and explore the new strategic plan, especially its focus on data and artificial intelligence. I will then focus the remainder of the talk exploring the variety of social, technical, and intellectual challenges that have both made the MGI an ambitious and exciting undertaking as well as providing a number of sobering lessons in the reluctance of the R&D community to adopt paradigm shifts.

2:00 PM DS03.04.02
Machine Learning-Guided Materials Discovery—How Fast and How Novel?MichaelPekala[1], ElizabethPogue[1], AlexanderNew[1], BrandonWilfong[2], GregoryBassen[2], KyleMcElroy[1], TyrelM. McQueen[2] and ChristopherStiles[1,2]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

Discovery is central to the advancement of science but the rate of discovery and the novelty of discovery associated with individual methods is rarely quantified. While machine learning (ML) approaches have accelerated experimental materials research, the ability of different sampling and ML approaches to discover fundamentally new classes of materials with desired properties has not been fully evaluated. Ultimately, ML is limited by existing data even in a closed-loop framework. Questions remain regarding how effectively these methods can truly generalize beyond the limited training data. In existing materials datasets, high-performance families of materials tend to be over-represented and “negative data” is often missing or sparse. When designing ML for material discovery, these effects are likely to be magnified because the goal is often to discover promising novel families of materials far from the training dataset. This requires generalization of the ML model to regions where optimal sampling strategies are less straightforward. Adaptive sampling strategies add data to databases in ways that enable tradeoffs between model fidelity and training set breadth but this has not been widely explored systematically or quantified in the materials discovery context. Here, we use a combination of the Supercon Database and Materials Project to simulate the needle-in-a-haystack material discovery problem to compare the ability of several adaptive sampling strategies to rediscover promising superconductor families like the cuprates and iron-based superconductors when those are excluded from the training data. This framework allows for quantification of the rate of discovery and the novelty of predictions associated with individual ML and adaptive sampling approaches, which extends beyond the superconductor discovery to any discovery problem.

2:15 PM DS03.04.03
polyBERT—A Large Language Model to Make Ultrafast Predictions of Polymers ChristopherKuenneth[1,2] and RampiRamprasad[2]; [1]University of Bayreuth, Germany; [2]Georgia Institute of Technology, United States

Polymers play a crucial role in our daily lives, offering a wide range of applications. The vast polymer cosmos possesses both exciting opportunities and significant challenges when it comes to identifying suitable candidates for specific applications. Here, we show an end-to-end polymer informatics pipeline that searches this vast space for suitable candidates at unprecedented speed and accuracy. The pipeline includes a large language model-based fingerprinting capability called polyBERT. polyBERT acts as a “chemical linguist”, treating the chemical structure of polymers as chemical language. A multitask learning approach maps the polyBERT fingerprints to a variety of polymer properties. In comparison to manually designed fingerprinting schemes, our polyBERT pipeline achieves a remarkable speed improvement of two orders of magnitude while maintaining accuracy, making it a highly promising candidate for deployment in scalable architectures, including cloud infrastructures.

2:30 PM DS03.04.04
Non-Centrosymmetric Materials Discovery for Nonlinear Optic and Ferroelectric Applications Using Phonon Database LouisAlaerts[1], JingyangHe[2], YuWang[2,2], VictorTrinquet[3], VictorSanni[1], RomainClaes[3], RowanKatzbaer[2], EvanKrysko[2], RaymondSchaak[2,2,2], Gian-MarcoRignanese[3], GeoffroyHautier[1], ZhiqiangMao[2,2] and VenkatramanGopalan[2,2]; [1]Dartmouth College, United States; [2]The Pennsylvania State University, United States; [3]UCLouvain, Belgium

Materials belonging to non-centrosymmetric point groups, i.e. lacking an inversion center, can exhibit a series of important physical properties such as ferroelectricity (FE) or nonlinear optical (NLO) response. This leads to potential applications in low-power electronic devices, transducers or beyond von-Neumann computers for FE and in lithography and spectroscopy for NLO materials. Discovering new classes of non-centrosymmetric materials is therefore of great interest. Over the last couple of decades, density functional theory (DFT) has become a method of choice for the high-throughput search of new materials thanks to the considerable increase in computational power. Notable early successes of DFT for materials discovery include cathode for electrochemical storage, electrocatalysts or thermoelectrics. Nowadays, properties that used to be computationally-intensive are routinely calculated and in particular, phonons.
Starting from a phonon database, materials with polar imaginary phonon modes are identified as being dynamically unstable. Following the eigenmodes associated with these phonon instabilities, we can assess the energy stability of all the distortions (limited to 2x2x2 supercell) to find out whether the true structural ground-state is polar or not. This method was already applied to the discovery of new ferroelectric materials. Here, I will present some results about the discovery of new classes of non-centrosymmetric material with a focus on a new family with general chemical formula MBa3(B3O6)3 (M=Sc, In, Y, Lu, Eu). Previously reported as belonging to the centrosymmetric space group $P6_3/m$, our calculations show that the structural ground-state is actually P3 or $P6_3$. The compound EuBa3(B3O6)3 (EBBO) was subsequently synthesized and characterized using XRD and SHG, demonstrating that indeed, it forms into the non-centrosymmetric space group P3. This work shows that new class of NLO and possibly FE materials can be identified through the use of phonon databases.

2:45 PM DS03.04.05
Scientific Understanding of Materials using Multi-Explanation Graph Attention Network JonasTeufel, LucaTorresi, PatrickReiser and PascalFriederich; Karlsruhe Institute of Technology, Germany

Explainable artificial intelligence (XAI) methods are expected to improve trust during human-AI interactions, provide tools for model analysis and extend human understanding of complex scientific problems [1]. Explanation-supervised training allows to improve explanation quality by training self-explaining XAI models on ground truth or human-generated explanations. However, existing explanation methods have limited expressiveness and interoperability due to the fact that only single explanations in form of node and edge importance are generated. To that end we propose the novel multi-explanation graph attention network (MEGAN) [2]. Our fully differentiable, attention-based model features multiple explanation channels, which can be chosen independently of the task specifications. We first validate our model on a synthetic graph regression dataset. We show that for the special single explanation case, our model significantly outperforms existing post-hoc and explanation-supervised baseline methods. Furthermore, we demonstrate significant advantages when using two explanations, both in quantitative explanation measures as well as in human interpretability. Finally, we demonstrate our model's capabilities on multiple real-world datasets [3,4]. We find that our model produces sparse high-fidelity explanations consistent with human intuition about those tasks and at the same time matches state-of-the-art graph neural networks in predictive performance, indicating that explanations and accuracy are not necessarily a trade-off.
A interactive version of the trained model is available on https://megan.aimat.science

3:30 PM *DS03.04.06
Revisting the ”I” in FAIR: Opportunities and Challenges ClaudiaDraxl; Humboldt-Universität zu Berlin, Germany

Advanced machine learning (ML) and, more generally, artificial intelligence (AI) algorithms have entered many fields of research, also successfully predicting new materials with improved

properties. However, one drawback remains that almost all of these investigations are based on data sets that have been created or adapted for the specific purpose. Therefore, ML results are mainly interpolations rather than out-of-the-box predictions. To change this situation, data from different sources must be brought together. Leveraging the knowledge created by the entire community promises major breakthroughs in AI for materials research. This raises the issues of veracity and variety, two of the 4V challenges of big data. Both have a strong impact on the FAIRness of materials science results, especially the "I" - interoperability. One challenge here is to introduce metrics to assess the conditions under which data can be shared. Of course, this also depends on the specific research question. Again, AI can help speed up the process. In this talk, I will first focus on how to compare data, how to "define" data quality, and how to select data suitable for a given purpose. I will illustrate of how seemingly the "same" data can behave differently when used in a given context. I will discuss challenges related to data from the computational materials side as well as from experimental characterization techniques. For the theoretical side, I will also present ML approaches that are able to extrapolate results from computations with computational settings used in daily practice to highly converged results. The availability of such tools is a big step towards the interoperability of computational data.

4:00 PM DS03.04.07

High-Throughput Computational Search for New Solar Absorbers Taking into Account Defect Tolerance ZhenkunYuan[1], DianaDahliah[2,3], MuhammadR. Hasan[4,5], GideonKassa[1], AndrewPike[1], RomainClaes[2], CierraChandler[6], SitaDugu[7], ShahamQuadir[7], YihuangXiong[1], VictoriaKyveryga[4,5], PhilipYox[4,5], Gian-MarcoRignanese[2], SageBauers[7], AndriyZakutayev[7], IsmailaDabo[6], DavidP. With the rapid rising of halide perovskites for photovoltaic applications, defect tolerance has emerged as a critical factor in assessing the efficiency potential of photovoltaic materials. Indeed, one of the most detrimental processes in solar cells is the recombination of photogenerated carriers mediated by deep defect levels. The question remains how to discover defect-tolerant materials? Here, we present a high-throughput computational workflow to search for new solar absorbers taking into account defect tolerance as a screening parameter. We apply this high-throughput workflow to a very large data set of materials in the Materials Project across various chemistries. We identify a few interesting candidates and especially a new family of ternary phosphides with extremely promising properties. We show that these phosphides show very attractive defect tolerance highlighted by extensive defect computations including nonradiative recombination. We will discuss the origin of these favorable defects and report on promising experimental results on the synthesis and characterization of this new family of solar absorbers.

4:15 PM DS03.04.08

A Universal Language for Experimental Protocol Reporting and Community Driven Platform for Enforcement of Field Standards RobertW. Epps[1], RobertR. White[1] and JosephJ. Berry[1,2,2]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

Many scientific disciplines are undergoing a crisis of reproducibility, and chemistry and materials science are no exception. Despite widespread adoption of the FAIR (Findable, Accessible, Interoperable, Reusable) guidelines in 2016, there is no indication of the issue lessening, and countless hours and resources continue to be wasted on failed protocol replication. Research communication is simply not being carried out in a way that facilitates complete knowledge transfer. With the rapid growth of new and innovative automated experimental platforms, the scientific community is under the threat of even more diverse and incompatible data reporting formats that conflict with FAIR principles and are neither machine-to-machine nor machine-to-human readable. With no clear system for the communication of research procedures between and among machines and researchers, there is a critical need for a robust and flexible universal protocol standard.

In this work, we present the Universal Workflow Language (UWL). UWL is a directed graph-based data entry language that enables the reporting of any arbitrary procedure in a machine-readable format. The system replicates the sequence of physical actions taken in a protocol and translates them into a data rich workflow architecture. Counter to the more traditional tabular data entry format, UWL enables flexibility to match the diverse and unique methods in which protocols are carried out in the real world. Instead of attempting to compress a full complex protocol into a series of tabulated parameters, UWL retains the initial complexity of a process.

Complementary to UWL, we have developed a user interface for management and recording of protocols in the UWL format with an emphasis on minimal user inputs and maximum data density. The entry management tool allows users to create and edit UWL entries with a drag and drop block-based interface. The software allows users to import, visualize, and modify shared workflows in a more accessible format. It also includes automated error checking and validation, and it enables experimentalists to create a framework for data entry through automated/robotic experiment conduction. Additionally, the tool transcribes the workflows into both plain text and interactive tabulated formats. The plain text system reads the UWL protocol and transcribes it into a natural language protocol with corresponding material and tool details and specifications. Through the language feature, users may validate their modifications to workflows in real-time and display protocols in a variety of spoken languages.

Finally, the user interface is linked to a field reporting standards system, driven by the research community. The standard system enables researchers to create and implement clear guidelines on protocol reporting standards so that procedures meet minimum detail requirements and adhere to FAIR principles. Standard creators can specify a library of workflow segments and designate error messages for missing or incomplete parameter reporting for their field of research. Every submitted standard undergoes a forum-based peer-reviewed certification process, where it is given a rating to designate comprehensiveness and field approval. This system allows researchers and manuscript reviewers to quickly evaluate whether a protocol is reported with sufficient detail without setting arbitrary constraints on the type of protocols that can be reported.

UWL and the accompanying software offers comprehensive, standardized, and machine-readable data entry for both human and robotic researchers, enabling greater detail and precision in communal database generation efforts. Application of these tools would likely reduce the impact of reproducibility challenges in human led research, improve universal communication of protocols, and facilitate more effective autonomous materials research.

4:30 PM DS03.04.09

Chemistry-Informed Machine Learning for Predictive Design of Fluorescent DNA-Stabilized Silver Nanoclusters PeterM. Mastracco[1], AnnaGonzalez Rosell[1], JoshEvans[1], CrystalMurillo[1], CarlosMelchor[1], StacyCopp[1] and PetkoBogdanov[2]; [1]University of California, Irvine, United States; [2]University at Albany, State University of New York, United States

DNA-stabilized silver nanoclusters (Ag_N-DNAs) are promising emissive nanomaterials for applications in biosensing, bioimaging, and nanophononics. These nanoclusters of just 10-30 Ag atoms are stabilized by DNA oligomers whose sequence selects the size, shape, and photophysical properties of the nanocluster[1]. DNA ligand sequence provides a unique way to select Ag_N-DNA emission wavelengths from 400 nm to 1,200 nm and achieve favorable properties such as high quantum yields and controlled chiralities. However, it is a major challenge to predictively design DNA ligand sequence for Ag_N-DNAs because there is a large sequence space of possible DNA oligomers and limited understanding of how DNA stabilizes Ag_N. Moreover, the nascency of first-principles models for Ag_N-DNAs currently prohibits their use in Ag_N-DNA design.

Here, we present a novel approach for machine learning-guided discovery of Ag_N-DNAs. A large data set of ~3,000 10-base DNA sequences and the emission spectra of the Ag_N-DNAs they stabilize was generated by high-throughput experiments. A machine learning classifier ensemble was then trained to classify DNA sequences by emission spectral ranges defined based on their known magic number properties. The model was designed to perform well for the scarce, imbalanced experimental training data set. Model performance was enabled by chemistry-inspired feature representation, informed by the first crystal structures of Ag_N-DNAs[2], to accurately capture how DNA sequence selects for Ag_N-DNA structure and emission spectrum. Moreover, feature analysis enabled model interpretability, providing insights into the sequence-to-color relationships of Ag_N-DNAs learned by the model. Sequences were designed by the model to select for green, far red, and near-infrared Ag_N-DNA emission were successfully designed, increasing prevalence of the target color range by 536%, 390%, and 1230%, respectively[3]. Our current work is focused on expanding the predictive power of these models for NIR-emissive Ag_N-DNAs for specific applications in deep tissue bioimaging. We are employing active learning methods to efficiently train models for prediction of DNA sequences that select NIR emission, which are more scarce in the training data, using a best vs second best approach. We are also expanding our models to design Ag_N-DNAs that are stable in biologically relevant solutions and have suitable photostabilities. This work demonstrates the power of machine learning for nanomaterials discovery and applications design, particularly for systems that cannot currently be modeled by traditional computational methods.

4:45 PM DS03.04.10

KAMEL-LOBE—A Tool for Data Standardization of Radial Distribution FunctionsS. ArmanGhaffarizadeh and GeraldJ. Wang; Carnegie Mellon University, United States

Radial distribution functions (RDFs) are widely used in materials simulation. Most approaches to computing RDFs require assembling a histogram over inter-particle separation distances, which in turn depends upon an arbitrary choice of discretization for bins. In this talk, we show that this arbitrary choice can lead to spurious phenomena in several commonplace computational materials science techniques that make use of RDFs. We demonstrate a data-standardization strategy ("KAMEL-LOBE"), which eliminates these issues. This approach is based on systematic and mass-conserving mollification of RDFs using a Gaussian kernel. We discuss several advantages of this technique, including in scenarios where original simulation data are unavailable and the only available data are the RDFs themselves. We present results from several molecular-simulation analyses, including detection of phase boundaries and prediction of transport properties, which benefit significantly from the use of KAMEL-LOBE.

8:30 AM *DS03.05.01
Self Supervised Learning and Language Models for Material Property Prediction AmirBarati Farimani; Carnegie Mellon University, United States

Machine learning (ML) models have been widely successful in the prediction of material properties. However, large labeled datasets required for training accurate ML models are elusive and computationally expensive to generate. Recent advances in Self-Supervised Learning (SSL) frameworks capable of training ML models on unlabeled data mitigate this problem and demonstrate superior performance in computer vision and natural language processing. Drawing inspiration from the developments in SSL, we introduce multiple recent models that incorporate language models, SSL, and multimodal training to enhance the performance of material property prediction tasks. For example, we will sow that by sharing the pre-trained weights when fine-tuning the GNN for downstream tasks, we can significantly improve the performance of GNN on 14 challenging material property prediction benchmarks.

9:00 AM DS03.05.02
Data-Driven, Physics-Informed Descriptors of Cation Ordering in Multicomponent Perovskite Oxides JiayuPeng, JamesK. Damewood and RafaelGómez-Bombarelli; Massachusetts Institute of Technology, United States

The chemical flexibility and versatility of multicomponent perovskite oxides have enabled their various key properties, including ion conductivity for batteries and surface reactivity for heterogeneous catalysis and electrocatalysis. Notably, the ordering and distribution of different cations in multicomponent perovskite oxides have a profound influence on their optical absorption, magnetic behaviors, ion mobility, catalytic activity, and electromechanical properties for diverse applications.

Unfortunately, the design and optimization of multicomponent perovskite oxides have been severely hampered by the lack of physical rules that universally rationalize and accurately predict their cation ordering. Essentially, experimentalists have only established empirical principles correlating the cation ordering in such oxides with the atomic parameters of their constituent ions, which often fail at accurately classifying perovskite oxides into cation-ordered and disordered structures.

High-throughput first-principles calculations could provide new, accurate design principles of cation ordering, but this exploration is constrained by the lack of a systematic benchmark between ab initio calculations and experimentally quantified ordering across a broad oxide space. This lack of co-validation between simulations and experiments can further impede the data-driven discovery of multicomponent perovskite oxides by high-throughput virtual screening, machine learning, and experimental validation.

To address these knowledge gaps, we established new data-driven, physically interpretable descriptors that can accurately classify ~90% multicomponent perovskite oxides as cation-ordered or disordered for an experimental dataset of 190 multicomponent perovskites (https://arxiv.org/abs/2305.01806). Notably, these descriptors can be obtained from the low-cost density functional theory (DFT) calculations of a few simple prototype structures and rationalized as physics-informed material parameters, such as thermodynamic probability and configurational entropy. Such new cation-ordering design principles outperform their conventional counterparts, accelerating high-throughput virtual screening by balancing the breadth and cost in the DFT sampling of multicomponent oxides with different cation configurations. Overall, this work offers a rigorous benchmark between theory and experiments and demonstrates an effective paradigm for understanding and predicting chemical ordering in multicomponent materials across a vast chemical space.

9:15 AM DS03.05.03
Interpretable Machine Learning-Aided Discovery of Multicomponent Catalysts for Propane Dehydrogenation JisuPark[1], JungmokOh[1], Jin-sooKim[2], JunghoShin[2], NamgiJeon[1], HyunjuChang[2] and YongjuYun[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Propylene serves as a crucial primary feedstock in the production of a wide range of chemical derivatives, including polypropylene, propylene oxide, and acrylonitrile. With the increasing demand for propylene, there is a growing interest in propane dehydrogenation (PDH), a selective reaction that produces propylene. In this study, we trained sure independence screening and sparsifying operator (SISSO) regression models to discover new catalysts exhibiting high performance for the PDH reaction. A database was established by compiling the performance of alumina-supported catalysts in PDH, obtained from our own experimental investigations. The SISSO model was trained using input variables that included the type, loading, and elemental properties of up to four active components, as well as reaction conditions, to predict propylene yield. The performance of the trained SISSO models was evaluated in order to select the optimal model, by comparing the predictive accuracy and simplicity of the resulting formulas. The formula derived from the optimal model was employed to predict the propylene yields of a total of 4,080 candidate catalysts, each consisting of three active components. Based on the predicted PDH performance, the catalysts were classified into categories of high-, moderate-, and low-performance. To experimentally validate these predictions, the actual performance of carefully chosen representative catalysts from each category was measured and compared with the predicted propylene yield. The superior performance of the catalysts categorized in the high-performance group, compared to those in the other groups, demonstrated the reliability of the developed SISSO model. Most importantly, the model identified highly efficient PDH catalysts that outperformed the catalysts tested during the construction of the database. The successful discovery of new and high-performing catalysts demonstrates the benefits of utilizing interpretable machine learning models in the development of multicomponent catalysts for heterogeneous catalysis.

9:30 AM *DS03.05.04
Scaling Up Materials Discovery using Deep Learning Ekin DogusCubuk; Google, United States

Materials science data and computational resources are growing rapidly. While machine learning offers a promising set of tools for learning models for large volumes of data (IID), these tools are not inherently good at generalizing to new (OOD) data. For this reason, the impact of deep learning on the computational discovery of stable inorganic materials has been limited. There are two observations from deep learning that encourage optimism: 1) scaling up neural networks with more data and compute can monotonically improve their IID generalization and 2) while OOD performance is almost always worse than IID performance, better IID performance is correlated with better OOD performance.

We explored these two directions to investigate if stable material discovery can be made more efficient via deep learning. I will introduce our pipelines for scaling up DFT calculations and graph neural networks, which allow us to discover a large number of inorganic crystals that are stable. Due to the diversity of candidate generation algorithms that has been employed, we discovered thousands of novel crystal prototypes. By screening these crystals for electronic and energy applications, we find that our dataset improves the number of promising candidates for certain applications by more than an order of magnitude. Finally, I will present the scaling behavior of our networks for robustness and zero-shot predictions on tasks they were not trained on.

Design and Understanding of Photovoltaic and Battery Materials MariaK. Chan; Argonne National Laboratory, United States

We will discuss the use of high throughput computation combined with AI/ML to understand and design battery and photovoltaic materials. For example, we will discuss the understanding of materials nanoscale structure and local environments in NMC battery materials and CdTe solar cell materials through ML-guided microscopy/spectroscopy.

11:00 AM DS03.05.06
Computational Approach for Structure Generation of Anisotropic Particles (CASGAP) for Data Driven Methods to Establish Structure-Property Relationships NitantGupta and ArthiJayaraman; University of Delaware, United States

The presence of anisotropic building blocks in synthetic or biological soft materials can have a direct influence on their physical properties. Characterization of structural anisotropy is critical in understanding their impact on structure-property relationships and for designing materials with target properties. Computational generation of three-dimensional real space structures with desired structural features will aid in the analysis of experimental characterization results like small angle scattering (SAS) profiles and will also serve to model initial configurations for

physics-based simulation techniques that relate structure to properties (e.g., structural color [2], mechanical properties). Moreover, generation of structures with anisotropic particles/domains presents unique challenges as compared to their spherical counterpart and in this talk, we will highlight these challenges and as a solution present the Computational Approach for Structure Generation of Anisotropic Particles (CASGAP) method [1]. This method generates structures with anisotropic particles/domains that have a target distribution of shapes, sizes, and orientational order. We will demonstrate the use of structures generated by CASGAP in preparing large datasets that connect a structure to their scattering profile and to their calculated property such as color. Such datasets can be used to train machine learning models linking design of materials, the 3D structure, and properties, enabling forward and inverse design.
[1] Nitant Gupta, Arthi Jayaraman, "Computational Approach for Structure Generation of Anisotropic Particles (CASGAP) with Targeted Distributions of Particle Design and Orientational Order" *submitted for peer review in May 2023*

11:15 AM DS03.05.07
Closed-Loop Multi-Property Materials Discovery, Progress and Opportunities ChristopherStiles[1,2], ElizabethPogue[1], AlexanderNew[1], NamQ. Le[1], BrandonWilfong[2], GregoryBassen[2], IzzeHendrick[2], EddieGienger[1], ChristinePiatko[1], JannaDomenico[1], KyleMcElroy[1], MichaelPekala[1], VictorLeon[1], ChristopherRatto[1], AndrewLennon[1] and TyrelM. McQueen[2]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

Machine learning (ML) techniques present tremendous opportunities to accelerate materials design and discovery, but significant developments are required to build on approaches from other domains. For example, ML models for materials must generally contend with sparser and more inhomogeneous data, these challenges compound in practical tasks that require simultaneous optimization of multiple properties. We present results from a "closed-loop" approach that integrates ML model predictions with experimental synthesis and characterization to provide new data and update the models. We first demonstrated success in the discovery of superconducting compounds by utilizing information from several public databases with in-house synthesis and characterization of crystal structure and critical temperature to train our ML models. Building on that framework, we expanded the task to include prediction of mechanical properties, as characterized experimentally using high-throughput nanoindentation. Finally, we explore the promise of ML techniques applied toward practical materials discovery; targeting multiple properties simultaneously, and outlining some of the near term opportunities.

11:30 AM *DS03.05.08
Machine Learning for Electron Microscopy—Large Scale Imaging Studies for Nanomaterial Synthesis KatherineSytwu[1], Min GeeCho[2], LuisRangel DaCosta[1,2] and MaryScott[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Electron microscopy (EM) is the characterization method of choice to observe the atomic-scale and microstructural local features within materials that play a critical role in material performance. Current TEM capabilities include a wide variety of imaging modalities to probe a material's local structure and composition. With resolution that can be deeply sub-Angstrom, a single image from a high-resolution electron microscope can measure atomic positions, defects, and strain. Coupled with advances in detector speed, automated imaging, and robotic sample preparation, EM imaging is becoming increasingly high throughput. Directly incorporating these EM methods for structural validation into high throughput materials prediction, design and synthesis routines would profoundly speed up the materials discovery process. However, image analysis and interpretation remains a bottleneck.

Machine learning offers an attractive solution to this problem. Recent advances in machine learning tools for computer vision, specifically convolutional neural nets (CNNs), make them promising options for high throughput analysis of EM data. However, CNNs are often designed for application to natural images, and optimizing performance and reducing bias when they are applied to scientific imaging data requires careful consideration. For example, data curation, CNN architecture, and performance metric choice can all play a role in the accuracy and usefulness of CNN predictions on EM data. Customizing CNNs for scientific data can therefore be challenging, especially when dataset sizes are small.

Here, we present a systematic study of application of CNNs to EM data. We consider how architecture influences image classification and segmentation, and illustrate the role that data curation can play in the tradeoff between flexibility and accuracy of CNNs. We then show application of these methods to a large-scale synthesis study of Cobalt oxide nanoparticles. By varying experimental parameters during synthesis, we produce cubic-shaped metal oxide nanoparticles with varying sizes, degrees of corner truncation, and face convexity. We illustrate successful strategies for application of CNNs to the hundreds of thousands of nanoparticles imaged in this study, and discuss error metrics and interpretation of the CNN results. The resulting statistical distributions of the nanoparticle enable us to understand the role of synthetic parameters on nanoparticle structure and shape, which ultimately will influence the catalytic behavior of these particles. These results provide intuition as to how neural network workflow design choices affect TEM image analysis, and provide guidance for researchers using CNNs for analysis of scientific images. Ultimately, this work is an example of large-scale EM analysis of hundreds of thousands or nanoparticles synthesized under a variety of conditions enabled by machine learning, and represents an important step towards incorporating high throughput EM analysis into automated and autonomous nanomaterial synthesis workflows.

SESSION DS03.06: Machine Learning and Experiment II

Informatics-Driven Design and Optimization of Materials for Industrial Applications GhanshyamPilania; GE Research, United States

After providing a bird's-eye view of probabilistic design and materials informatics capabilities at GE Global Research, this talk will focus on specific examples where machine learning is synergistically combined with simulations, experimental synthesis, characterization, testing and domain knowledge to expedite materials screening and development for certain applications of industrial relevance. I will conclude with a brief discussion of challenges and opportunities that lie ahead in this exciting field.

2:00 PM DS03.06.02
Voxelized Atomic Structure Framework for Atomistic Modeling of Multifunctional Materials MatthewC. Barry[1], MichaelChandross[2], SuryaR. Kalidindi[1] and SatishKumar[1]; [1]Georgia Institute of Technology, United States; [2]Sandia National Laboratories, United States

The behavior of material systems is governed by complex physical phenomena taking place over a hierarchy of length scales, making it computationally infeasible to model the full material response with physics-driven simulation methods alone. Machine learning (ML) approaches offer new opportunities to efficiently learn the multiscale, multiphysics process-structure-property relationships necessary to design, discover, develop, and understand the physics of complex material systems. However, the development of a single integrated, comprehensive ML framework that is capable of both bridging multiple length scales and accurately extrapolating over arbitrarily large material design spaces remains a significant challenge. The recently developed Voxelized Atomic Structure (VASt) framework establishes a protocol for developing structure-property relationships with atomic systems that can also serve as the foundation of a fully integrated hierarchical multiscale materials modeling framework. In this talk, we demonstrate that the VASt framework can be utilized to efficiently and accurately model complex material properties over a large material design space. We develop a VASt structure-property relationship to predict thermo-mechanical properties of a 7-component high entropy alloy as a function of chemical composition and show that high accuracy can be achieved over the complete chemical composition space with a limited set of training samples. The results of this study are then used to demonstrate the practical usefulness of the VASt framework for inverse design of materials by showing how it can directly correlate one or more properties of interest with controllable design parameters.

2:15 PM DS03.06.03
Introduction and Operation of Specialized Machine Learning Web Applications for Material Design in a Chemical Corporation YoshishigeOkuno and ShimpeiTakemoto; Resonac Corporation, Japan

Utilizing past experimental data is advantageous in material design. Recently, many scientists have applied machine learning methods to predict material properties. However, for successful machine learning, choosing an appropriate method, selecting attributes, and adjusting various hyperparameters are crucial. These settings can cause differences in machine learning results. Although constructing machine learning models has become easier with the advent of valuable libraries or software packages, it remains a challenge for materials scientists unfamiliar with machine learning. While materials scientists are exceptionally skilled at setting up the materials design space considering various constraints, coding for machine learning is difficult. Although data scientists can build appropriate machine learning models with their expertise in statistics, machine learning, and computer science, many need more domain knowledge, especially tacit expertise in materials design. As a result, data scientists' machine learning model predictions may seem unnatural to materials scientists.
To overcome the difficulties arising from the difference in expertise between materials scientists and data scientists, we have developed web applications with a user-friendly Graphical User

Interface for materials scientists. Data scientists specialize in building machine learning models and deploying them on cloud-based web applications. Even if some of the recommendations proposed by machine learning models are not reasonable to materials scientists, they can choose their favorites based on their experience and domain knowledge. This approach also helps reduce communication costs between materials and data scientists.
A large chemical corporation must deal with over a hundred types of chemical products. In most cases, we must prepare a separate machine learning model for each chemical, which requires us to handle and maintain numerous machine learning models deployed on web applications. This situation has motivated us to introduce Machine Learning Operations (MLOps) to manage both the machine learning models and the web applications. MLOps is a set of methods and philosophies for integrating the development and operation of machine learning models. MLOps include tools and operations for continuous training of machine learning models, continuous integration, continuous delivery, managing the lifecycle of machine learning models, and collaborative development between data scientists and web application developers.
We have already deployed over 100 machine learning web applications to business units within our corporation, and many materials scientists have used them. This deployment demonstrates our successful digital transformation in the field of materials.

Prospects for Autonomous Materials Discovery Guided by *In Situ* DiffractionSimonJ. Billinge; Columbia University, United States

Although theory has been quite successful at using AI and machine learning for predicting stable materials with potentially interesting properties, experimental science is playing catch-up. In this talk I will discuss some of the challenges and emerging opportunities for using AI and machine learning to guide experiments. I will focus on the use of advanced scattering sources coupled with in situ experiments that can be used together for materials discovery. I will discuss the challenges of extracting quantitative information from the data in real-time but the opportunities that emerge when this is possible, including the ability to carry out adaptive, no human in the loop, autonomous experiments. I will discuss challenges of data reduction in the presence of uncertainty, real time analysis approaches, and the development of autonomous in situ and operando experiments at synchrotrons and neutron sources. The talk will introduce the concepts and present preliminary results to illustrate them, with a goal of guiding the audience to think about how they might use these approaches in their own work.

4:00 PM DS03.06.05
Spectroscopy-To-Structure Prediction via Conditional Diffusion Model and its Application to Disordered Materials Yu-TingHsu, HyunaKwon, WenyuSun and Tuan AnhPham; Lawrence Livermore National Laboratory, United States

We approach the problem of property-to-structure inverse prediction for disordered materials by combining forward prediction and generative diffusion models. Such a combination is naturally implemented as the conditional score function in the theory of diffusion models. As a case study, we apply this conditional generation framework to sample the spatial coordinates of amorphous carbons conditioned on given or desirable spectroscopic signatures. Several important aspects of this framework will be highlighted and discussed: (1) the generation is not limited to the scale of the training sets (e.g., <1000s of atoms) and can be easily scaled up to any arbitrary size (e.g., 100,000 atoms); (2) the generative model (the prior) and the forward model (the likelihood) are completely decoupled and can be trained separately, thereby allowing a plug-and-play flexibility where the generative prior can work with different forward models for inverse prediction with respect to various output properties; (3) the generation outcome can be fine-tuned to better adhere to the generative prior or the specified output property. Finally, besides inverse prediction, we summarize the potential impact of our work in the broader context, such as out-of-distribution sampling for active learning.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. Funding was provided by LLNL Laboratory Directed Research and Development (LDRD) Program Tracking No. 22-ERD-014.

4:15 PM DS03.06.06
Digital Materials Discovery in Organic Electronics AlessandroTroisi; University of Liverpool, United Kingdom

We describe a general high-throughput virtual screening procedure to discover new molecular materials for organic electronics. The procedure is employed for a range of distinct application (i) low energy emitters (ii) dual emitters (iii) singlet fission molecules (iv) non-fullerene acceptors and (v) molecules with inverted single-triplet gap. Experimental verification is presented for some of the examples shown. The approach led to the construction of a software platform for the discovery of new organic electronics materials (DIADEM) where the search and refinement of computed property is linked with the chemical supply chain and predictions can be immediately verified experimentally.

Automated Classification of Big X-Ray Diffraction Data Using Deep Learning Models JerardoSalgado, ZhaotongDu, SamuelLerman, AyoubShahnazari, ZeliangZhang, ChenliangXu and NiazAbdolrahim; University of Rochester, United States

The development of new technologies such as superconductors, fusion energy, and superfast quantum computers heavily relies on a deep understanding of material properties. X-ray diffraction (XRD) is a powerful technique used for material characterization, providing valuable information about the atomic symmetry of materials. However, despite recent advancements in dynamic in-situ XRD experiments, fully characterizing these materials remains challenging due to the large amounts of data generated. This data contains crucial insights into material structure, behavior, and transformation pathways that could otherwise be overlooked.
To address this challenge, we have developed deep learning models integrated with physics-based reasoning, enabling automatic classification of the crystal system and space group of 1D XRD data. Our models were trained using a comprehensive dataset consisting of hundreds of thousands of diffraction images. These images were generated using our Python-based pipeline, which incorporates fundamental principles such as Bragg's Law and atomic scattering factors.
By leveraging high-quality training and evaluation data, we achieved accurate classification based on Bragg's Law and improved performance when applied to experimental data. Our models provide instantaneous feedback and can classify data without requiring human intervention, making them highly efficient for extracting valuable material insights from large XRD datasets. Moreover, the versatility of our models extends beyond XRD data. They can be applied to other spectral data, such as Raman spectroscopy or nuclear magnetic resonance spectroscopy, broadening their applicability to diverse material characterization techniques.
By combining the power of deep learning with physics-based justification, our approach enables efficient and accurate analysis of material properties, paving the way for accelerated advancements in various technological fields that rely on a deep understanding of materials.

Tuning Elinvar Effect in Severely Distorted Single Phase High Entropy Alloys HangWang; City University of Hong Kong, China

Elinvar alloys are well known for their elastic moduli being almost a constant over a certain temperature range, which can find many useful engineering applications, such as high precision mechanical equipment (e.g., reeds, reed relays, delay lines and chronometers). Fundamentally, the Elinvar effect in conventional ferromagnetic Fe-Ni and Fe-Co-based alloys originates from the loss of magnetic ordering with increasing temperature, which leads to elastic stiffening and counterbalances thermal softening over a temperature range of ~300 K. However, this

magnetism induced Elinvar effect has its limitation, which cannot function properly in a magnetic environment if there is a residual magnetic field.
In this work, we fabricated a series of severely distorted high-entropy Elinvar alloys through micro-alloying of $(CoNi)_{50-x}(TiZrHf)_{50}Fe_x$ (in atomic percentage). Through carefully designed experiments, we demonstrate a tunable Elinvar effect that is positively correlated with the overall lattice distortion in the single phase B2 high entropy alloys. Finally, we propose a simple physical model that captures the general trend of our experimental findings.

8:00 PM DS03.07.02
The Interplay of Quantum Capacitance with Van Der Waals Forces, Intercalation, Co-Intercalation and the Number of MoS2 Layers NagehK. Allam; American University in Cairo, Egypt

Polymorph MoS_2 attracts great attention for supercapacitor and Li-ion battery applications. Although the capacitance origin is usually attributed to the intercalation process, MoS_2 exhibits a well-defined electrical double layer (EDL) behavior. Nonetheless, the nature of the EDL behavior of MoS_2 is yet to be revealed. Herein, we investigate the quantum capacitance (C_Q) of the three main phases of MoS_2 (the semiconductor 2H and 3R phases and the metallic 1T phase). Interestingly, the number of MoS_2 layers greatly affects the C_Q of the material. In addition, the absence of Van der Waals (*VdW*) interactions overestimates the bandgap and C_Q, emphasizing the importance of the VdW correction in the C_Q calculations. As MoS_2 usually stores charges *via* the intercalation of cations, the effect of H^+, Na^+, Li^+, and K^+ intercalation on the C_Q of the three phases of MoS_2 is thoroughly investigated. The intercalation of all studied alkali metal cations leads to the transformation of the 2H and 3R phases into the metallic 1T phase and increases its stability. Importantly, the K^+ and Na^+ intercalations show the greatest impact in enhancing the C_Q of the studied phases. However, the charging process of K^+ and Na^+ ions is not as reversible as that of Li^+ as revealed from the estimated binding energies. To this end, herein, we demonstrate the co-intercalation of Li^+/Na^+ ions as a strategy to enhance the overall capacitance performance. The Li^+/Na^+ co-intercalation shows a C_Q of 3163 F/g with a more thermodynamically stable adsorption process. Finally, the study recommends the use of 2H–MoS_2 only as a positive electrode and 1T-MoS_2 as a negative and/or positive electrode in energy storage devices. Also, K^+ intercalation is recommended to achieve the highest C_Q and the Li^+/Na^+ co-intercalation for the best overall performance.

8:00 PM DS03.07.03
TADF-Based X-Ray Screens with Simultaneously Efficient Singlet and Triplet Energy Transfer for High Spatial Imaging Resolution ShoroogA. Alomar; Kaust, Saudi Arabia

In recent years, X-ray imaging scintillators have garnered significant attention for their potential in real-world applications such as medical radiography, food industry, and security inspection. However, high-performance scintillators have been limited to inorganic ceramic and perovskite materials, which are known to require harsh preparation conditions, high environmental toxicity, low stability, and very high fabrication costs. Alternatively, organic scintillators, particularly thermally-activated delayed fluorescent (TADF) systems, offer efficient utilization (nearly 100%) of both singlet and triplet excitons, making them a strong contender in the scintillation market. Their stability, low toxicity, scalability, and diverse radioluminescence mechanisms also make them an excellent alternative choice to compete, even not replace ceramic and perovskite scintillators.

In this contribution, we successfully introduce, for the first time, a novel approach for X-ray imaging scintillators that utilizes very efficient and ultrafast energy transfer at the interface of TADF chromophores for X-ray imaging scintillators with exceptional spatial resolution. More specifically, our study showcases the successful use of efficient singlet-singlet (S-S) and triplet-triplet (T-T) energy transfer mechanisms between the TADF donor (sensitizer) and the TADF acceptor (scintillator) to achieve high-resolution imaging of up to 20 lp/mm, representing the highest resolution reported thus far for organic scintillators, and is at least two times higher than that achieved by commonly used commercial inorganic scintillators. Our results highlight a new path to improve the resolution and sensitivity of imaging by leveraging the advantages of simultaneous S-S and T-T energy transfer mechanisms that nearly completely use the absorbed X-ray energy. Our experimental findings also demonstrated the enormous potential of this energy transfer strategy in yielding high-performance organic X-ray imaging scintillators, providing a robust and cost-effective alternative for X-ray imaging applications that are free from harsh preparation conditions and significant fabrication costs.

We believe that these innovative TADF-based X-ray screens, with their efficient interfacial energy transfer, will not only serve as a benchmark for the fabrication of efficient organic scintillators with a simple molecular engineering strategy, but also garner significant interest from the scientific community and expand the current understanding of X-ray imaging scintillators.

Abstract

Terahertz time-domain transmission spectroscopy (THz-TDS), is an effective method for characterizing materials and monitoring processes. Metals, semiconductors, 2D materials, and superconductors have all been tested with this technique, which does not require physical touch to obtain accurate results. Terahertz (THz) spectroscopy has developed as a method for investigating dielectric and transient photoconductive characteristics of materials over the past few decades. Since it can measure electrical resistance without touching the sample and has a temporal precision of a few picoseconds. Due to the low energy of THz radiation and the narrow pulse width, THz-TDS technology is non-destructive when used for extracting visual data from materials (picosecond range). This paper reveals optical parameters extraction methods by using THz transmission spectroscopy technology. In summation, materials with a low absorption of terahertz radiation can benefit from the adaptability of transmission methods, while materials with a high absorption capacity can take advantage of the advantages of reflection methods. To measure the magnetic material's optical properties like refractive index and absorption coefficient, we employ a transmission-type terahertz time domain spectroscopic instrument. The observations and analysis are performed in both the time domain and frequency domain, and we examine the transmission of terahertz radiation through magnetic nanoparticles at frequencies from 0.1 to 3 terahertz (THz). In the past few years, magnetic materials based on frequency selective surfaces (FSS) have become indispensable in the design of gigahertz (GHz) and terahertz (THz) millimeter-wave filters, polarizers, absorbers, EMI shielding, antenna reflectors, and radar applications.Here we also propose frequency selctive surface structure theoretically by using CST-MW studio software.

Optimizing 2.8 Micron Emission in Er:YLF Q-Switched Lasers RyanBulharowski[1], CarlosGutierrez[1], WesleyKinney[1] and MakhinThitsa[1,2]; [1]Mercer University, United States; [2]Laboratory of Information and Decision Systems, MIT, United States

We aim to develop advanced control strategies to be utilized in modulating and stabilizing the laser output characteristics in optical and photonic devices which face increasingly high demands on precision and level of performance. Especially, when these devices are used in medical applications or when high-energy ultra short pulses are involved, there is virtually no room for error. Open loop control is inept to handle issues arising from unexpected disturbances or when these devices need to perform well in harsh environment, which is the case for many defense applications. Built-in feedback control capabilities in these devices will regulate the desired output characteristics rendering the device reliable and robust. Pulsed 3-micron diode-pumped lasers find vast applications in a variety of fields ranging from medical instrumentation, environmental applications, and material processing to spectroscopy. For 2.6-3-micron emissions, Er: YLF has generated a lot of research interest recently as a laser gain medium due to its adequate radiation life time at key energy levels to support Q-switching. We studied the laser dynamics of Q-switching at 2.8 micron in Er: YLF laser with cascade lasing at 1.6 and 1.7 micron by control theoretic approach. We investigate the effect of pump power on population density at key energy levels as well as the average output power and various parameters of the laser dynamics such as heat generated in the material. We also propose pumping schemes which produce desired output pulse characteristics. Both mathematical analysis of the feedback control strategy and the numerical simulation results will be presented.

8:00 PM DS03.07.06
Sulfur-Containing High Refractive Index, Low Birefringence Thermoplastic Polymers SoohyePark and JeewooLim; Kyung Hee University, Korea (the Republic of)

High refractive index polymers (HRIPs) play a crucial role in various optoelectronic devices, such as display substrates, microlenses for image sensors, and optical adhesives. The conventional method for producing HRIPs involves incorporating aromatic units into polymer structures. However, this approach can result in excessively high glass transition temperatures and, more importantly, increased chromatic aberration and birefringence. To address these issues, we have introduced a sulfur-containing functional groups with high molar refraction into fluorene-based cardo monomer structure. The placement of high molar refraction, sulfur-containing aromatic functional groups at the 9-position of fluorene allowed for the preparation of a new class of functional monomers which was used as monomers for thermoplastic polyesters, poly(aryl ether)s, and poly(aryl thioether)s with refractive indexes exceeding 1.65. These polymers exhibit birefringence below 0.003, achieving a desirable combination of high refractive index and low birefringence. Furthermore, by varying the nature of the linking groups between monomers, the glass transition temperatures of the high refractive index thermoplastic polymers could be varied over a wide range of 90°C to 250°C.

8:00 PM DS03.07.07
Molecular Design of Hydroquinone-Based Compounds for High Energy Proton Batteries BiaoLiu; University of Puerto Rico at Río Piedras, Puerto Rico

Proton batteries offer higher energy storage capacity, enhanced safety, and a better environmental profile than traditional lithium-ion batteries. However, developing electrode materials remains a critical challenge for their widespread adoption as a viable energy storage solution. In this study, we used density functional theory computations to investigate the impact of hydroquinone-based compounds on the electrochemical performance of organic electrode materials in proton batteries. Our findings indicate that hydroquinone-based compounds hold significant potential as high-energy organic electrode materials for proton batteries, and we established a quantitative relationship between their structural properties and electrochemical performance. This research provides a valuable guideline for designing more efficient and sustainable proton batteries in the future, and contributes to the ongoing effort to develop better energy storage solutions to meet the growing demand for renewable energy sources.

8:00 PM DS03.07.08
Hybridization of Magnetic Fe_3O_4 with Mn-MOFs for High Performance Supercapacitor SaumayaKirti, ShobhaShukla and SumitSaxena; Indian Institute of Technology Bombay, India

Encapsulating guest compounds in metal–organic frameworks (MOFs) architectures is one of the most promising paths to achieve properties beyond those of the pristine MOFs and/or guest species. Contrary to the conventional host/guest composites encapsulating guest species inside MOF cavities, core–shell architectures exhibit a better accessibility to the pores ensuring an optimal diffusion of the substrate while presenting a unique structure that prevents the aggregation and the runoff of the active guests and ensures a tight interaction between core and shell, leading to synergistic effects. Herein, the integration of Fe3O4 with manganese-based MOF i.e., Fe_3O_4@Mn-MOF-NH_2 with varying shell thickness and hierarchical pore structure is synthesized. As a proof of concept, the obtained Fe_3O_4@Mn-MOF-NH_2 composite is used as an active material for supercapacitor applications which showed an enhancement of ~ 80% in specific capacitance with respect to pristine compounds.

8:00 PM DS03.07.09
A Paramagnetic NMR Cluster Expansion Toolkit for Spectral Assignment EuanBassey[1], AntonVan der Ven[2] and RaphaëleClement[1,2]; [1]Materials Science Laboratory, United States; [2]University of California, Santa Barbara, United States

Solid-state nuclear magnetic resonance (NMR) spectroscopy is an invaluable characterisation method for investigating local structural phenomena. Recently, NMR has been increasingly applied to paramagnetic systems, most notably in the field of Li- and Na-ion battery cathode materials, where unpaired electrons on redox-active transition metal (*TM*) ions result in severely broadened lines and large-magnitude shifts.[1–5] Invariably, these materials contain many different paramagnetic *TM* species, each contributing differently to the observed shift. These shifts can be computed using high-cost hybrid DFT methods and qualitatively rationalised using the Anderson-Goodenough-Kanamori rules.[6,7] Applying these methods to all local environments, however, becomes impractical and computationally demanding when the *TM* sublattice comprises more than one species—*e.g.*, Ni^{2+} and Mn^{4+}, as in $Li[Ni_xMn_yCo_{1-x-y}]O_2$ cathodes used in electric vehicles. Here, we perform a cluster expansion of the NMR chemical shift of Li^+ and O^{2-} ions in the family of layered cathode materials $Li_{1+x}[Ni_{1/2-3x/2}Mn_{1/2-x/2}]O_2$ in terms of both local composition (i.e., coordination environments of Li^+ and O^{2-}) and magnetic configurations. We compare our results against experimental ^{7}Li NMR spectra and extend the theory to perform Monte Carlo simulations at variable field strengths and temperatures. This new methodology will have benefits not only in battery fields, but for a large range of materials science problems.

8:00 PM DS03.07.10
Self-Assembly of Atomically Aligned Nanoparticle Superlattices from Pt–Fe3O4Heterodimer Nanoparticles ShengsongYang[1], R.A. LaCour[2], Yi-YuCai[1], YugangZhang[3], CherieR. Kagan[1], SharonGlotzer[2] and Christopher B.Murray[1]; [1]University of Pennsylvania, United States; [2]University of Michigan–Ann Arbor, United States; [3]Brookhaven National Laboratory, United States

Multicomponent nanoparticle superlattices (SLs) promise the integration of nanoparticles (NPs) with remarkable electronic, magnetic, and optical properties into a single structure. Here, we demonstrate that heterodimers consisting of two conjoined NPs can self-assemble into novel multicomponent SLs with a high degree of alignment between the atomic lattices of individual NPs, which has been theorized to lead to a wide variety of remarkable properties. Specifically, by using simulations and experiments, we show that heterodimers composed of larger Fe3O4 domains decorated with a Pt domain at one vertex can self-assemble into an SL with long-range atomic alignment between the Fe3O4 domains of different NPs across the SL. The SLs show an unanticipated decreased coercivity relative to nonassembled NPs. In situ scattering of the self-assembly reveals a two-stage mechanism of self-assembly: translational ordering between NPs develops before atomic alignment. Our experiments and simulation indicate that atomic alignment requires selective epitaxial growth of the smaller domain during heterodimer synthesis and specific size ratios of the heterodimer domains as opposed to specific chemical composition. This composition independence makes the self-assembly principles elucidated here applicable to the future preparation of multicomponent materials with fine structural control.

8:00 PM DS03.07.11
Composition Search in Multi-Component Alloys through Difussion Generative Models AmirhosseinNaghdi Dorabati[1,2], GrzegorzKaszuba[2], StefanosPapanikolaou[1] and PiotrSankowski[2]; [1]Nomaten CoE, Poland; [2]Ideas NCBR, Poland

Exploring the vast composition space of multi-component alloys present a challenging task for both ab initio (first principles) and experimental methods due to the multitude of possible compositions and the time-consuming procedures involved. These limitations ultimately impede the discovery of new stable materials with exceptional properties. Here, we utilize the Crystal Diffusion Variational Autoencoder (CDVAE) to characterize the stable compositions of NiFeCr alloys, including well-established compositions such as NiFe and CrNi2 from binaries, and then optimize the bulk elastic modulus across the entire compositional space. To this end, a computationally efficient framework is proposed which employs Molecular Dynamics (MD) simulations, equipped with high-quality interatomic potentials for inverse design of multi-component alloys in general. We also propose modifications to CDVAE that enhance its robustness when dealing with data characterized by large supercells and low variety of elements as well different material phases. The resulting workflow is valuable for the inverse design of other systems of interest involving various element types and varieties.

8:00 PM DS03.07.12
Advancing 2D Materials Research: A Unified Platform for Data Management, Visualization and Machine Learning Jin HoonYang[1], Yea-LeeLee[1], JonghwanKim[2,3], Young JunChang[4,4] and HyunjuChang[1]; [1]Korea Research Institute of Chemical Technology, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of); [3]Institute for Basic Science, Korea (the Republic of); [4]University of Seoul, Korea (the Republic of)

We present a comprehensive and user-friendly data platform tailored for 2D materials research, 2DMat.chemDX.org. This platform integrates efficient data management, specialized visualization, and machine learning toolkits, significantly enhancing research productivity. At this point, the platform supports primary research data obtained from Reflection High Energy Electron Diffraction (RHEED), Photoluminescence (PL), and Raman measurements, providing a robust foundation for uploading, managing, and sharing research data through a web-based platform. Data templates and parsing systems specialized for handling these data aid researchers in managing large datasets, reducing manual efforts, and enhancing data consistency. The platform features powerful visualization and analysis tools for RHEED, PL, and Raman spectra, facilitating easy data comprehension and enabling valuable insights with just a few clicks. Additionally, the platform incorporates machine learning toolkits for investigating 2D film growth mechanisms and super-resolution techniques for analyzing PL/Raman mapping data, promising a significant increase in efficiency. Our platform's modular design allows for seamless expansion and adaptation, ensuring it remains a valuable resource for the evolving field of 2D materials.

8:00 PM DS03.07.13
Using Text Descriptions to Predict Physical and Electronic Properties of Crystalline Solids AndreNiyongabo Rubungo, CraigArnold, BarryP. Rand and Adji BoussoDieng; Princeton University, United States

Developing methods capable of crystal property prediction is an important task that plays a crucial role in material design for advanced applications. Surprisingly, predicting crystal properties from its text description is understudied, despite the rich information and expressiveness that textual data have. In this work, we leverage the general-purpose learning capabilities of large language models (LLMs) to predict the crystal discrete and continuous properties from text descriptions. We propose an efficiently fine-tuned LLM on crystal text descriptions to predict physical and electronic properties such as band gap, direct vs indirect band gaps, and volume. The proposed approach outperforms three previously reported structure-based baselines, offering improvements of approximately 4%, 3%, and 66% with respect to predictions of band gap, direct vs indirect band gaps, and volume, respectively.

8:00 PM DS03.07.15
Application-Driven Design of Materials: Advancements in Composite Materials and Coatings Abul FazalM. Arif, Syed SohailAkhtar, KhaledAl-Athel and AbbaAbubakar; King Fahd University of Petroleum and Minerals, Saudi Arabia

In recent years, materials science and engineering have evolved significantly, emphasizing application-driven design—a strategy that customizes materials to meet precise performance criteria, resulting in notable innovations in composite materials and coatings. Composite materials, exemplified by carbon-fiber-reinforced composites in aerospace, have revolutionized aircraft design, offering outstanding strength-to-weight ratios and enhanced fuel efficiency. The automotive industry has similarly shifted towards high-strength, lightweight composites, as seen in Tesla's use of carbon fiber composites, improving structural integrity and reducing fuel consumption and emissions. Coatings have gained pivotal importance, adapting materials to specific environmental demands, with anti-corrosion coatings extending the service life of steel structures and smart coatings with embedded sensors monitoring structural health in real-time. Aerospace employs thermal barrier coatings to protect components from extreme temperatures, extending operational lifespan and enabling high-performance aviation and space exploration. These achievements highlight the transformative potential of application-driven design in materials development, offering tailored solutions to complex challenges across industries. As technology advances, application-driven design will play an increasingly vital role in creating innovative materials that meet modern demands.
Our presentation will highlight extensive research conducted at KFUPM in the field of computational materials design, spanning various applications. Over the years, our dedicated team has developed advanced computational methods for precise heterogeneous materials design, incorporating homogenization techniques that consider crucial material design parameters, including phase volume fractions, material properties, inclusion characteristics, dispersion, and interface conditions. This comprehensive approach enables highly accurate predictions of thermo-mechanical responses in complex materials. Furthermore, we've introduced an innovative multi-scale modeling methodology capable of simulating the thermo-mechanical behavior of heterogeneous materials across various length scales. These computational tools have practical applications in diverse fields, from composite materials to membranes and coatings. Additionally, we've introduced the concept of functionally graded (FG) materials to create SiAlON-based ceramic composites optimized for cutting tool applications, incorporating hybrid reinforcements like TiCN, Co, and hBN. To validate our predictions and optimize these composites, we've diligently applied effective medium theories and mean-field homogenization schemes, considering variables such as volume fractions, interfacial thermal resistance, reinforcement particle sizes, and porosity. This rigorous approach extends to the comprehensive characterization and analysis of fabricated ceramic samples, aligning computational predictions with real-world measurements. Additionally, we've explored the cold spray deposition process for tailored composite coatings, utilizing a physics-based hybrid computational approach that models the deposition of Ni-Ti/Al2O3 composite coatings for wear applications. This approach efficiently simulates critical aspects, including particle impact, deformation, and temperature variations, by combining point cloud and finite element techniques, providing valuable insights for optimizing wear-resistant coatings. Our presentation will comprehensively showcase the groundbreaking progress achieved in the field of application-driven materials design. The group is currently working on the application of machine learning methods and the development of digital twins for the design and development of coatings and composites. We look forward to sharing these insights and contributing to the exciting possibilities in this ever-evolving domain.

8:00 PM DS03.07.16
Computational Investigation of Ordered Framework Materials for Photocatalysis BeatrizMourino[1,2], KevinJablonka[1], SauradeepMajumdar[1], AndresOrtega-Guerrero[1], JeffreyB. Neaton[2] and BerendSmit[1]; [1]EPFL, Switzerland; [2]Lawrence Berkeley National Laboratory, United States

Metal (MOFs) and covalent (COFs) organic frameworks comprise a class of countless porous crystalline materials with building block construction[1]. In particular, the interest in investigating this class of materials for photocatalytic applications lies in the tunability of their optoelectronic properties with different building blocks, which ideally could be assessed computationally in an efficient way to redirect experimental efforts. However, the computational exploration of MOFs and COFs for photocatalysis can be challenging due to their large unit cells that can have hundreds of atoms. Therefore, investigating the optoelectronic properties of those materials with first principles requires cost-effective alternatives. To tackle this challenge, we have adopted strategies at different levels of theory to first explore large datasets, and then focus on investigating a few materials in depth. The first approach leverages cost-effective alternatives to compute DFT-based photocatalytic descriptors at a low level of theory to assess the fundamental steps of photocatalysis, that is, light absorption, thermodynamic feasibility of the photoredox reactions, charge carrier mobility and charge separation[2]. Such an approach allowed us to shortlist promising materials, and gain insights into structure-property relationship such as the use of β-ketoenamine linkages in COFs for right band edge alignment to the hydrogen evolution reaction and enhanced charge-carrier mobility[2]. Going further, ongoing work aims to investigate the electronic band gap and related properties of our best candidates with a higher level of theory. For that purpose, we make use of non-empirical screened range separated hybrids (SRSH) in density functional theory as it enables electronic band gap calculations in close agreement with more expensive state of the art GW methods[3]. The so far promising results of using wannier localization-based optimally tuned SRSH for MOFs suggest a potential cost-effective pathway to more accurately evaluate complex physical phenomena encompassing the electronic band gap.

Addressing Challenges of Multi-Property Optimization and Synthesizability in Inverse Design EvanAntoniuk, BhavyaKailkhura, NathanKeilbart, StephenWeitzner and AnnaM. Hiszpanski; Lawrence Livermore National Laboratory, United States

Inverse or generative models that can suggest novel molecules with optimized properties have promise to decrease materials discovery timelines for pharmaceutics, energetics, organic semiconductors, and polymers. However, the utility and promised time-savings of these models have yet to be fully realized due to challenges associated with co-optimizing multiple material properties, reducing model uncertainty when extrapolating beyond a known and trained chemical space to identify new molecules with extreme desired properties, and accounting for molecular synthesizability in a robust manner for suggested molecules. In our work, we have evaluated two state-of-the-art generative models – JTVAE and JANUS – for multi-property optimization of small molecules and have developed strategies for addressing the extrapolation and synthesizability challenges. We specifically focus on identifying novel and synthesizable molecules that have high density and high solid heat of formation – two important qualities for energetic molecules. Between the two models considered, we found that JANUS generally yielded more molecules with both higher density and heat of formation. To address the first challenge of accurately extrapolating to a chemical space beyond the known chemical space used for training, we employ two strategies. First, we created a high-throughput density functional theory pipeline capable of computing the density and heat of formation of ~1,000 molecules/day. We utilize the results from this pipeline to iteratively retrain our model, thereby increasing the data we have available in the chemical space we are extrapolating to and the accuracy of our predictions in this space. Second, we found that incorporating uncertainty quantification (where the uncertainty is the variance from an ensemble of models) in our property predictions also aided in filtering for suggested molecules that are more likely to have the predicted targeted properties. To address the second challenge of synthesizability, we found that the inclusion of a synthesizability score in our objective function is necessary for steering the generative model away from a completely unrealistic chemical space. However, the synthesizability score by itself does not directly correlate to true synthesizability. Thus, we utilize SciFinder's retrosynthesis planning tool to specifically screen for likely synthesis routes of the top candidate molecules. Using these tools in aggregate, we are identifying novel molecules that are most likely to have the desired properties we aim for and also a means of synthesizing them. Now, synthesizing our best candidates and experimentally validating their properties is the final necessary step towards realizing generative models' full utility.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

9:00 AM DS03.08.02
AI-Enabled Active Exploration of Small Molecules for n-Charge Generation Layer in Tandem Organic Light-Emitting Diodes JisuKim[1], JaesunKim[1], JinmuYou[1] and SeungwuHan[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute for Advanced Study, Korea (the Republic of)

The rapid evolution of organic light-emitting diodes (OLEDs) has profoundly transformed display technology, facilitating the development of flexible and thin solid-state lightning devices. Tandem OLEDs, composed of multiple stacked electroluminescent units connected by a charge generation unit, have emerged as an innovative solution for achieving high current efficiency and intense luminance. However, they confront the challenge of increased operational voltages due to the additional layers within the device structure. Hence, the development of an intermediate charge generation unit with efficient charge generation and transportation properties is crucial to mitigate the voltage drop.
In this study, we propose a two-step process involving unsupervised and supervised learning to investigate small molecule organic semiconductors suitable for the n-charge generation layer (n-CGL), a key component of the charge generation unit. Specifically, we focus on Li-doped phenanthroline derivatives, which have been extensively studied as n-CGL. Initially, we utilize unsupervised learning, demonstrated by k-means clustering, to generate a set of molecules that can represent the vast chemical space of phenanthroline derivatives. This condensed set of molecules serves as a manageable starting point for further exploration of the broader n-CGL chemical space.
Subsequently, we employ a relational graph neural network as a means of supervised learning, in conjunction with the Monte Carlo dropout method to quantify prediction uncertainty. We calculate multiple molecular properties including reorganization energy and electron affinity by density functional theory (DFT) calculation to formulate a scoring function for evaluating the suitability of molecular properties as n-CGL. We then design a novel active exploration algorithm by integrating query strategy and data augmentation. This algorithm not only enhances the prediction accuracy but also generates new promising molecules that were not initially sampled by unsupervised learning.
Our approach led to the discovery of molecules that surpass known phenanthroline derivatives, such as bathophenanthroline (BPhen), according to our scoring system. Furthermore, we gain insights into the common characteristics of promising molecules, including the substituted carbon position in the phenanthroline. This comprehensive approach presents a systematic and efficient strategy for exploring the vast and challenging chemical space of n-CGL.

9:15 AM DS03.08.03
Data-Driven Electrospinning Process Surrogate Modeling with Guided Experiments ChandrachurBhattacharya, JungkukLee, JoshuaChristopher, AshleySimmons, BethanyLusch, YuepengZhang and DebolinaDasgupta; Argonne National Laboratory, United States

Electrospinning is a manufacturing process used to fabricate fibers of various chemical composition with fiber diameters in the nanometer range. These fibers find a variety of applications including fuel cells, batteries, and medical membranes such as masks. The manufacturing process itself is governed by highly non-linear physics. The working material is fed as a solution into the electrospinning system through a needle. An applied electric field attracts the material from the needle tip to a depositor drum. This draws out the fibers and if the conditions are amenable, leads the formation of uniform fibers. Conversely, certain combinations of input parameters may cause unwanted phenomenon such as bead formation in the fibers, webbing, or even wet deposition and dripping from the needle tip with no fiber formation at all. The electric field, governed by the voltage difference and distance across which it is applied, i.e., between the needle and the drum, plays an important role in controlling the outcome. Additionally, the concentration of the solution and the flowrate of the solution into the system are the two other principal governing parameters. Thus, it is important to know which operating conditions can produce good fibers. A step further is being able to select operating conditions required to produce fibers of a desired morphology. In this research, the goal is to develop a surrogate model of an electrospinning process using polyethylene oxide (PEO) material. To learn good models using limited experiments, advanced machine learning based surrogate modeling methods are leveraged from the very onset of this study. A few initial experiments are used to develop a preliminary surrogate which invokes active learning to select conditions for subsequent experimentation. This allows developing good models using limited data, saving on experimental costs by making informed decisions. During the experiments, near-needle videos are taken to capture the flow features of the jet formed between the needle and drum via image processing. The experiments that successfully produce fibers then have Scanning Electron Microscope (SEM) imaging done on the samples produced. Fiber morphology information is extracted by another image processing algorithm along with an outcome label as specified by the user requirement. A custom-designed multi-modal machine learning framework combines findings from the various observations into a singular model that can now predict the experimental outcome given the operating conditions. The experimental data was collected in phases, with the machine learning model informing the choices of subsequent experiments by choosing informative samples. This research also demonstrates how the machine learning models are flexible and can be adapted in various phases of such studies to accommodate for additional experimental considerations learnt along the way to make the surrogate model more robust. In this research, the surrogate model framework is built using GPU-accelerated open-source libraries.

Data-Driven Chemical Understanding with Bonding Analysis JanineGeorge[1,2]; [1]Federal Institute for Materials Research and Testing (BAM), Germany; [2]Friedrich-Schiller-Universität Jena, Germany

Bonds and local atomic environments are crucial descriptors of material properties. They have been used to create design rules and heuristics for materials.[1] More and more frequently, they are used as features in machine learning.[2,3] Implementations and algorithms (e.g., *ChemEnv* and *LobsterEnv*) for identifying these local atomic environments based on geometrical characteristics and quantum-chemical bonding analysis are nowadays available.[4,5] Fully automatic workflows and analysis tools have been developed to use quantum-chemical bonding analysis on a large scale and for machine-learning approaches.[5,6] The latter relates to a general trend toward automation in density functional-based materials science.[7] The lecture will demonstrate how our tools, that assess local atomic environments, helped to test and develop heuristics and design rules and an intuitive understanding of materials. [5,8–11]

Machine Learning Enabled Inorganic Synthesis Planning and Materials Design ElsaOlivetti, EltonPan and ChristopherKarpovich; Massachusetts Institute of Technology, United States

Data-driven synthesis planning with machine learning is a key step in the design of novel inorganic compounds with desirable properties. Inorganic materials synthesis is often guided by heuristics and chemists' prior knowledge and experience, built upon experimental trial-and-error that can be both time and resource consuming. Recent developments in natural language processing (NLP) have enabled large-scale text mining of scientific literature, providing open source databases of synthesis information of realized compounds, material precursors, and reaction conditions (temperatures, times). An obstacle to the realization of novel inorganic materials with desirable properties is efficient optimization over both the materials property and synthesis spaces. We will present two novel reinforcement learning (RL) approaches to inverse inorganic materials design which can efficiently identify promising compounds with specified properties and synthesizability constraints. These approaches learn chemical guidelines such as thermodynamic stability, charge neutrality, and electronegativity neutrality while maintaining high chemical diversity and uniqueness. We demonstrate a multi-objective reinforcement learning approach which can generate novel compounds with both desirable materials properties (formation energy, bulk modulus, shear modulus) and synthesis objectives (low sintering temperatures). Using this approach, the model can predict promising compounds of interest, while suggesting an optimized chemical design space for inorganic materials discovery.

11:00 AM DS03.08.06
ZeoSyn: A Comprehensive Zeolite Synthesis Dataset Enabling Machine-Learning Rationalization of Hydrothermal Parameters EltonPan, SoonhyoungKwon, ZacharyJensen, YuriyRoman and ElsaOlivetti; Massachusetts Institute of Technology, United States

Zeolites, crystalline aluminosilicate materials with well-defined porous structures, have emerged as versatile materials with applications in various fields, including catalysis, gas separation, and ion exchange. Hydrothermal synthesis is the most widely used method for zeolite production, offering control over composition, crystallinity, and pore size. However, the intricate interplay of synthesis parameters and their impact on zeolite properties necessitates a comprehensive understanding to optimize the synthesis process. Hitherto, publicly available zeolite synthesis databases only contain a subset of key parameters. Furthermore, they are small in scale, with the largest consisting of only a few thousand unique synthesis routes. In this paper, we present ZeoSyn, a
comprehensive dataset of 23,925 unique zeolite hydrothermal synthesis routes, encompassing over 200 zeolite topologies and 900 organic structure-directing agents (OSDAs). Each unique synthesis route consists of a comprehensive set of key synthesis variables: 1) gel compositions (molar ratios between heteroatoms, mineralizing agents, and water) 2) reaction conditions (crystallization/aging temperature and time), 3) OSDA, and 4) resultant zeolite product. Extracted from over 50 years of zeolite scientific literature using a semi-automatic approach leveraging a natural language processing pipeline, the dataset enables a holistic analysis of zeolite synthesis parameters and their influence on the final zeolite product. Analysis of the dataset reveals clear, physical relationships between synthesis parameters and the resultant frameworks. To showcase the utility
of this dataset, we train a supervised classification machine learning model on ZeoSyn to predict the zeolite framework product given a synthesis route. The model exhibits strong performance on the challenging 220-way classification task with an overall accuracy of >70% and macro-averaged F1 of >0.6. In addition, we show that Shapley Additive Explanations (SHAP) can serve as a powerful tool to reveal the most important synthesis parameters driving the formation of over 200 known zeolite frameworks. Furthermore, we introduce an aggregation approach to extend SHAP analysis for explaining the formation of all known composite building units reported. Lastly, we show potential applications of such analysis on the rational design of parameters for phase-
selective and intergrowth synthesis. Analysis at this unprecedented scale sheds light on key synthesis parameters driving zeolite crystallization and has the potential to guide zeolite synthesis.

Extracting Information from TEM—Battling Noise with Machine Learning Matthew HelmiLeth Larsen, WilliamB. Lomholdt, CuauhtémocN. Valencia, ThomasW. Hansen and JakobSchiotz; Technical University of Denmark, Denmark

High-Resolution Transmission Electron Microscopy (HRTEM) will always be a compromise between signal-to-noise ratio (S/N) and beam damage, as the energetic electrons passing through the sample inevitably heats and damages the sample on their way to the detector. In conventional HRTEM, the entire sample is illuminated simultaneously by the electron beam, and while this lowers the electron dose rate (and often also the total dose), it comes at the price of the image being phase contrast, and thus not always easy to interpret.

Machine learning has been shown to be a powerful way to interpret HRTEM images [1-3]. We here investigate the minimal required frame dose (in electrons per area) for object detection and segmentation with neural networks. We show that the Multi-Scale Dense (MSD) network architecture proposed by Pelt et al. [4] is particularly promising in the low S/N regime, where it outperforms the industry standard U-Net architecture both for simulated and experimental images. The MSD-net displays mild visibility of an Au nanoparticle at 20-30 $e^-/Å^2$ and converges at 200 $e^-/Å^2$ where a full segmentation of the nanoparticle is achieved. Between 30 and 200 $e^-/Å^2$ object detection applications are still possible.

We also highlight the importance of modelling the modulation transfer function (MTF) of the detector when training with simulated images for applications on images acquired with scintillator-based detectors such as the Gatan OneView camera.

For further information, see also Leth Larsen et al. [5].

The Vendi Score: A Diversity Metric For Science And Machine Learning Adji BoussoDieng; Princeton University, United States

Measuring diversity correctly is important for science and machine learning. In this talk, I'll describe the Vendi Score, a diversity metric that connects and extends ideas from ecology and quantum mechanics. The Vendi Score is applicable in any domain where similarity can be defined. I'll showcase the usefulness of the Vendi Score in efficiently exploring molecular conformation spaces and in enabling the discovery of novel MOFs and organic photoredox catalysts.

Entropic Sampling and its use in Automatic Materials Design KojiTsuda; The University of Tokyo, Japan

In automatic materials design, samples obtained from black-box optimization offer an attractive opportunity for scientists to gain new knowledge. Statistical analyses of the samples are often conducted, e.g., to discover key descriptors. Since most black-box optimization algorithms are biased samplers, post hoc analyses may result in misleading conclusions. To cope with the problem, we propose a new method called self-learning entropic population annealing (SLEPA) that combines entropic sampling and a surrogate machine learning model. Samples of SLEPA come with weights to estimate the joint distribution of the target property and a descriptor of interest correctly. In short peptide design, SLEPA was compared with pure black-box optimization in estimating the residue distributions at multiple thresholds of the target property. While black-box optimization was better at the tail of the target property, SLEPA was better for a wide range of thresholds. Our result shows how to reconcile statistical consistency with efficient optimization in materials discovery. We also present an application of entropic sampling to chemical processes.

Bayesian Active Machine Learning for Cluster Expansion Construction HantongChen[1], SayanSamantha[1], SiyaZhu[1], JanSchroers[2], StefanoCurtarolo[3] and Axelvan de Walle[1]; [1]Brown University, United States; [2]Yale University, United States; [3]Duke University, United States

The Cluster expansion (CE) is a powerful method for representing the energetics of alloys from a fit to first principles energies. However, many common fitting methods are computationally demanding and do not provide the guarantee that the system's ground states are preserved. Thus, we have developed an efficient implementation of a Bayesian algorithm for cluster expansion built upon the method proposed by Cockayne and van de Walle (2010), which ensures all the input structural energies are fitted perfectly while reducing computational cost. This method also enjoys favorable convergence properties as it allows user to incorporate physics-based priors on the magnitude of the interactions. We have also made multiple improvements over this approach. First, we propose a procedure based on optimizing the hyper-parameters of the prior to improve the predictive power of the CE. Secondly, we devise an efficient algorithm to calculate the cross-validation (CV) score in linear time. Third, we use an active machine learning scheme that autonomously searches for new ground state structures to incorporate in the CE training set. Finally, all mechanisms described above have been integrated into the Alloy Theoretic Automated Toolkit (ATAT), thus allowing users to seamlessly adopt the new method. As performance tests, we calculate the phase diagram of the Fe-Ir system and study the short range order (SRO) in an equimolar MoNbTaVW system. We find that we typically need about 1/5 of the structures to reach the same precision of the CE constructed via traditional methods.

2:15 PM *DS03.09.03
Overcoming Challenges in Real-World Materials Science Optimization—A "Choose Your Own Adventure" Approach with Ax TaylorD. Sparks[1,2], SterlingBaird[1], JasonHall[1,3] and RamseyIssa[1]; [1]University of Utah, United States; [2]University of Liverpool, United Kingdom; [3]Northrop Grumman Corporation, United States

Real-world materials science optimization tasks are often noisy, heteroskedastic, multi-fidelity, multi-objective, high-dimensional, constrained, and mixed numerical/categorical optimization problems. While each of these have state-of-the-art implementations in computer science, the application of these to materials science tasks have been limited. One of the few optimization platforms that can support all of the use-cases mentioned above without oversimplification and therefore poor efficiency is Meta's Adaptive Experimentation (Ax) platform. While Ax and its backbone, BoTorch, have seen increasing usage in chemistry and materials science, project-specific implementations and adaptations of advanced Bayesian optimization topics are non-trivial, even for veteran materials informatics practitioners. Inspired by the PyTorch installation docs (https://pytorch.org/get-started/locally/), we implement a "choose your own adventure" template generator for Ax scripts tailored towards materials science applications. We demonstrate its usage and performance in three case studies: composition-based optimization, physics-based simulations, and a self-driving lab demo. We envision that this tool will dramatically reduce the barrier-to-entry for utilizing advanced Bayesian optimization for real-world materials science tasks.

Decreasing the Environmental Impact of Cement with Data-Driven Design KristenSeverson; Microsoft, United States

Concrete is the most widely used building material in the world with an estimated global annual production of 30 billion metric tons. Largely because of this scale, the concrete industry is estimated to produce approximately 8% of all global CO2 emissions, therefore decreasing the carbon footprint of the concrete industry is an important consideration for the global decarbonization effort. In this talk, I will present a method to design concretes with decreased global warming potential using an optimization framework which relies upon quality attributes estimated from an amortized Gaussian process model. Using industrial data, our approach proposed novel concrete formulations with 60% reductions in climate impact. I will also demonstrate how the model can be used to accelerate experimentation.

3:45 PM DS03.09.05
Computational Prediction of Stacking Mode in Conductive Two-Dimensional Metal-Organic Frameworks—An Exploration of Chemical and Electrical Property Changes MingyuJeon and JihanKim; KAIST, Korea (the Republic of)

Conductive two-dimensional metal-organic frameworks (2D MOFs) have attracted interest as they induce strong charge delocalization and improve charge carrier mobility and concentration. However, characterizing their stacking mode depends on expensive and time-consuming experimental measurements. Here, we construct a potential energy surface (PES) map database for 36 2D MOFs using density functional theory (DFT) for the experimentally synthesized and non-synthesized 2D MOFs to predict their stacking mode. The DFT PES results successfully predict the experimentally synthesized stacking mode with an accuracy of 92.9% and explain the coexistence mechanism of dual stacking modes in a single compound. Furthermore, we analyze the chemical (i.e. host-guest interaction) and electrical (i.e. electronic structure) property changes affected by stacking mode. The DFT results show that the host-guest interaction can be enhanced by the transition from AA to AB stacking, taking H_2S gas as a case study. The electronic band structure calculation confirms that as AB stacking displacement increases, in-plane charge transport pathway is reduced while the out-of-plane charge transport pathway is maintained or even increased. These results indicate that there is a trade-off between chemical and electrical properties in accordance with the stacking mode.

Towards Oxygen Ion Conductor Designs Based on Lattice Dynamics DanieleVivona[1], KiarashGordiz[1], LambertHu[1], SumathyRaman[2], RandallMeyer[2] and YangShao-Horn[1]; [1]Massachusetts Institute of Technology, United States; [2]ExxonMobil Research and Engineering, United States

The existing oxygen ion conductors exhibit insufficient conductivity for practical applications in solid oxide electrochemical cells. To design oxygen ion conductors with higher conductivities at lower temperatures, a deeper understanding of the processes governing ionic conductivity is needed. This understanding is crucial to identify new chemistries with superior conductivities. In pursuit of this goal, the Arrhenius law emphasizes the importance of decreasing activation energy and increasing the pre-exponential factor for enhancing oxygen ion conductivity. However, a major obstacle lies in the lack of understanding surrounding the compensation law, where reducing activation energy is typically associated with decreasing the pre-exponential factor. This limitation hampers progress in designing improved oxygen ion conductors.
In this presentation, we discuss designs of oxygen ion conductors with low activation energies and high pre-exponential factors. Specifically, we establish a correlation between pre-exponential factors and changes in lattice dynamics that occur during oxygen migration from equilibrium to the transition state. Variations in the order of magnitude of pre-exponential factor values across oxides with the perovskite and fluorite structures are attributed to changes in vibrational properties, such as the vibrational entropy of migration. By utilizing density functional theory simulations, we gain atomic-scale insights into these vibrational property changes and investigate their coupling with the electronic structure and activation energy. Our new findings and proposed descriptors hold great potential for accelerating the discovery of new oxygen ion conductors through machine learning and high-throughput virtual screening (HTVS). By leveraging the growing approaches of computation-aided designs, the next generation of oxygen ion conductors can be developed to catalyze the clean energy transition.

4:15 PM *DS03.09.07
Traversing Scales for the Design of Catalyst Materials for Energy Conversion SnehaA. Akhade; Lawrence Livermore National Laboratory, United States

With growing emphasis on decarbonization and increasing energy demand, materials that can efficiently capture, store, and utilize energy can potentially pave the path for sustainable decentralized energy networks that are powered using renewable electricity while simultaneously abating carbon emissions. Inherent in the future energy system will be greater operational uncertainty, regional and temporal variability, and larger price fluctuations in the renewable electricity available for the energy infrastructure. Material design for the infrastructure elements that can catalytically move, store, and use carbon and hydrogen needs to consider the variability and dynamics of the larger system into which it is integrated. Consequently, the optimal catalyst material may differ greatly depending on its mode of usage and what sector it supports. While existing material design efforts place significant emphasis on improving the activity and selectivity of catalysts for energy conversion, they often fail to address the critical durability of the material under real-time operating conditions. The structure, composition, and electronic properties of the material are all key factors that impact the performance and extent of degradation. Moreover, material evolution often is a multiscale problem; necessitating the need to develop multi-physics modeling frameworks for realistic operational understanding of materials for energy conversion and eventual design of more durable systems. In this talk, I will provide an overview of some of our multi-scale and cross-scale efforts to examine various factors contributing to selection, performance, and process integration of catalyst materials. I will discuss how atomistic, mesoscale, continuum and system level modeling can be leveraged towards realizing the complexities of catalyst material design for energy conversion. To this end, our efforts at LLNL in traversing multiple length and time scales in developing these models for sustainable carbon and hydrogen energy conversion will be showcased. This work was performed under the auspices of the U.S. DOE by Lawrence Livermore National Laboratory under contract DE-AC52-07NA27344.

The Structure Dynamics Dyad in Concentrated Aqueous Electrolytes AuroraE. Clark; University of Utah, United States

Concentrated aqueous electrolytes, so called water-in-salt solutions, are emerging new materials for high-voltage batteries. Although long-studied, concentrated electrolytes exhibit multiple lengthscale organizational behavior in their neutron and X-ray scattering pair distribution functions, the origin of which can be challenging to interpret. At the same time, recent work studying the dynamic behavior of ions and water (using quasi elastic neutron scattering, NMR, and optical Kerr effect spectroscopy) are revealing distinctive multiscale dynamic behavior. The connection between solution structure and dynamics is essential toward the rational design of electrolyte compositions designed to optimize transport and energy density characteristics. This work will describe our combined efforts to understand this “structure dynamics dyad” using atomistic simulations, predictive characterization and applied mathematics.

9:15 AM DS03.10.02
Nature of the Superionic Transition of Lithium Nitride GabrielKrenzer[1], JohanKlarbring[1,2], KasperTolborg[1], Chang-EunKim[3], HugoRossignol[4], AndrewMcCluskey[5], BenjaminJ. Morgan[6] and AronWalsh[1,7]; [1]Imperial College London, United Kingdom; [2]Linköping University, Sweden; [3]Lawrence Livermore National Laboratory, United States; [4]Trinity College Dublin, The University of Dublin, Ireland; [5]European Spallation Source ERIC, Denmark; [6]University of Bath, United Kingdom; [7]Ewha Womans University, Korea (the Republic of)

Understanding ion transport in the superionic regime and the underlying physics of the superionic phase transition remains a long-standing challenge for computational chemistry and materials science. This presents a barrier to the development and optimisation of superionic solid electrolytes.
There has also been much attention given recently to material descriptors that explore the connection between lattice dynamics and ion diffusion. Moreover, in some materials the superionic transition is accompanied by significant changes in vibrational spectra.
We use *ab initio* lattice dynamics calculations to demonstrate that harmonic and quasi-harmonic descriptions of the phonons in lithium nitride show no change in features across the superionic transition. The anharmonic model, however, exhibits a breakdown for all modes. The implications for developing anharmonic lattice-dynamics-based descriptors to accelerate the discovery of superionic conductors are discussed.
To further explore the superionic phase transition of lithium nitride and accurately simulate diffusion above and below the superionic transition temperature, T_s, we take advantage of the recent developments in the field of Machine Learning Force Fields (MLFF). We train a Gaussian Approximation (GAP)-style MLFF using on-the-fly sampling of reference configurations. We demonstrate that our MLFF trained for lithium nitride (T_s=678K) offers near-*ab initio* accuracy at a significantly reduced computational cost compared to direct *ab initio* molecular dynamics simulations. Crucially, the MLFF allows us to accurately simulate the long-timescale diffusive behaviour of lithium nitride for temperatures as low as 400K, where ion transport is slow.
Using our trained MLFF, we characterise lithium nitride above and below the superionic transition temperature by calculating the heat capacity, Li^+ ion self-diffusion coefficient, and Li defect concentrations as functions of temperature. We show that both the Li^+ self-diffusion coefficient and Li vacancy concentration follow distinct Arrhenius relationships in the normal and superionic regimes. The activation energies for self-diffusion and Li vacancy formation decrease by a similar proportion across the superionic phase transition. This result suggests that the superionic transition may be driven by a change in defect formation behaviour, rather than changes in Li transport mechanism. This insight may hold implications for other superionic materials.
We address a question at the heart of materials chemistry for over a century –why do some materials exhibit a superionic phase transition? This is linked to the design of solid-state batteries to address some of society’s biggest problems around energy storage. The application of machine learning methods and the resulting novel understanding of the superionic phase transition in terms of both lattice dynamics descriptors and defect formation behaviour are of interest to experimental and theoretical researchers within materials chemistry, from both academic and industrial backgrounds. This research is deeply relevant to the wide audience of the symposium on emerging challenges and opportunities in materials by design.

9:30 AM DS03.10.03
Directing Assembly Through Variation of the Inter-Particle Attractive Interactions JessicaNiblo, JacobSwartley, ZhongminZhang and KateriH. DuBay; University of Virginia, United States

The self-assembly of complex structures typically occurs within a narrow window of interaction strength due to large kinetic barriers that emerge as attractive interactions become too strong. At moderate interaction strengths, thermodynamic products form as the system relaxes to thermodynamic equilibrium. However, as interaction strength increases, there is a switch from thermodynamic to kinetic products, which emerge as high energetic barriers develop. By dynamically changing the free energy landscape through modification of the inter-particle interactions, certain kinetic traps may be overcome or the system may assemble into novel non-equilibrium structures. In this work, we model the assembly of rigid, 2D triangular particles into capsid-like hexamers to investigate the relationship between assembly and dynamic changes in the inter-particle potential. Specifically, we examine how oscillations of the attractive interactions in time and spatially variant attractions can allow for differences within the assembly process. Variation of the attractive interactions enables particles to diffuse out of original configurations and readily reorganize. We find that oscillation periods that are equivalent to the timescales needed for particles to diffuse from one another shifts the window of capsid formation. The distance particles diffuse from one another to shift the window of assembly is comparable to the lengthscales of the inter-particle interactions and particle size. Our results provide insights on how dynamic inter-particle interactions can alter self-assembly, and predicts how different systems can respond to attractive interaction variation.

9:45 AM DS03.10.04
Adaptive Kinetic Monte Carlo Simulation on Platinum Oxidation at Electrochemical Conditions using Machine-Learned Potentials JisuJung[1], HyungminAn[1], DeokgiHong[1] and SeungwuHan[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute for Advanced Study, Korea (the Republic of)

Platinum is the most commonly used electrochemical catalyst. However, platinum suffers from oxidation in the operation conditions, which gradually degrades activity and lifetime of catalysts in applications like fuel cells and CO oxidation. Although many experiments have investigated oxidation kinetics of Pt, a comprehensive understanding has not yet been achieved. For instance, it is known that platinum oxidation occurs through a place-exchange mechanism, but the detailed atomic pathway remains elusive. While computational study could supplement the experiment, the spatial and temporal scales of platinum oxidation reactions are beyond the capabilities of computational approaches such as density functional theory (DFT) and classical molecular dynamics (MD) simulations. Kinetic Monte Carlo (kMC) simulations, which use an event table to transition between local minima, can investigate long-term evolution but require an efficient algorithm for identifying saddle points on-the-fly, in the open-ended style.
In this presentation, we will discuss our adaptive kMC simulation for platinum oxidation behavior on a 2 nm × 2 nm Pt(111) surface. This is achieved by combining two computational advancements. Firstly, we employ Behler-Parinello type machine-learned potentials (MLPs) as surrogate models of DFT for increased computational speed. The present MLP achieved energy and force root-mean-square errors of 7 meV/atom and 0.22 eV/Å, respectively, on the DFT validation set consisting of platinum oxide crystal and platinum surface with randomly distributed oxygen atoms at various coverages. Secondly, we found that the state-of-the-art algorithm for identifying saddle points, such as ARTn, is inefficient in the presence of soft modes prevalent on the surface. To address this, we developed the SHERPA (Saddle point Hunting based on Energy surface for Reaction PAthways) package, incorporating two key features: constrained-orthogonal relaxation within ARTn and dynamic-active volume. These improvements resulted in a 50% higher success ratio and halved computational time compared to the conventional

ARTn approach.
To emulate oxygen flux from the electrolytes, we combine kMC simulation with a grand-canonical Monte Carlo (GCMC) simulation, controlling the oxygen chemical potential based on voltage and pH. Our simulation provides detailed pathways for the platinum surface oxidation via a place exchange mechanism, with oxygen atoms penetrating the platinum subsurface and displacing platinum atoms. For comparison, we also perform a hybrid GCMC-MD simulation at elevated temperatures. We believe this study deepens the understanding of platinum oxidation and paves the way to long-term atomistic simulation.

10:00 AMBREAK

10:30 AM DS03.10.05
Computational Studies to Understand the Effect of Polysulfamide Designs on Structure and Properties JayA. Shah, ZijieWu and ArthiJayaraman; University of Delaware, United States

Plastic waste is currently generated at a rate of 400 million tons per year. The amount of plastics accumulating in the environment is growing rapidly since the degradation time for the plastics on the surface is in order of micrometres per year. Due to rising environmental concerns, there is a need for environmentally friendly and sustainable alternatives to these common commodity plastics. One such commonly used commodity plastic is polyurea which is used in many applications such as concrete coating, waterproofing and anti-corrosion on ships and a protective material. The wide range of applications for polyurea is due to the flexibility of changing the backbone chemistries. This leads to the formation of different morphologies, which are driven by the hydrogen bonding between the urea groups. However, polyurea takes a long time to degrade. Thus, there is a quest for alternate polymers that have similar structural features as polyurea but can be degraded easily, making them sustainable and environmentally more friendly. Michaudel and coworkers have recently introduced one such alternate for polyurea called polysulfamide, where the carbonyl group in polyurea is replaced with a sulfamide group in polysulfamide. They have shown that polysulfamides exhibit high thermal stability, tunable glass transition temperature and are degradable in green aqueous conditions. These attractive properties and sulfamide's chemical structure being analogous to urea, make polysulfamides a potential replacement for polyurea. To facilitate such replacement, we need a fundamental understanding of how varying polysulfamide design impacts its structure (chain-level and self-assembled domains) and physical properties, which require synergistic molecular modeling, simulations, and experiments are needed. To complement experiments from Michaudel and coworkers, we have developed a coarse-grained (CG) model for polysulfamide to use in molecular dynamics simulations to investigate how polysulfamide design impacts the hydrogen bonding induced self-assembly of polysulfamides. This computational approach is validated by comparing simulated structures' positional and orientational order for varying polysulfamide designs to that observed in experiments using X-ray diffraction (XRD) and infrared (IR) spectroscopy. Ongoing work is focused on extending this computational approach to a larger set of design parameters, including polydispersity in molar masses. Using the simulated and experimental data, we will train machine learning models to establish a design-structure-property relationship and accelerate the understanding of polysulfamides.

10:45 AM DS03.10.06
Unified Design Flow for Facilitating Fast Li-Kinetics in Layered Oxide Cathodes JuncheolHwang[1] and DuhoKim[1,2]; [1]Kyunghee University, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of)

Non-parallel flow of electric vehicles (EVs) and the rechargeable battery market motivates energy materials researchers to study advanced batteries. Although, it is possible to produce a 90 kWh battery pack with a 300-mile cruise range, unfortunately, their charging rate still lags significantly behind that of internal combustion engine vehicles (ICEVs). This shortfall in power density causes a 'range anxiety' for existing EV owners and poses a barrier for potential owners. Li-layered oxides (LLOs), typically with an O3-type stacking sequence, have been the most mainstream cathode material since their commercialization by Sony in 1991. For O3-type LLOs, Li-ion occupies thermodynamic stable octahedral sites, which are the phases that have edge sharing with neighboring transition metals at the initial state of the hopping mechanism. And the environment at the intermediate tetrahedral site significantly influences the Li-kinetics, affecting the power density of a battery. And the activation barrier for Li-kinetics is determined by the size of the intermediate site, and the valence state of the transition metal surrounding the Li-ion at the tetrahedral site. Despite attempts to induce fast mass transport using traces of various dopants, the fundamental limitations of the O3-type stacking sequence have prevented breakthroughs. Therefore, a study aiming to break the originated limitations of the O3-type LLOs and uncover novel Li-ion transport mechanisms is indispensable. By performing computational calculations, we propose a two-design perspective to enhance the rate of (de)lithiation by intentionally arranging Li-ion sites for O3-type LiCoO2 (O3-LCO), the most conventional cathode material. For the first step, we introduce a new framework to overcome the fundamental limitations of the existing O3-type LLOs. We manipulated the stacking sequence of O3-LCO from O3- to O2-type, which induces a stable intermediate tetrahedral site. The O2-type LCO has edge-sharing relationships between the LiO_4 tetrahedral site, serving as an intermediate step in the hopping mechanism, and the adjacent MO_6 (M refers to transition metal) octahedron in the transition metal layer. This configuration makes the intermediate site energetically more stable than the O3-type and allows for fast Li hopping from the relatively unstable intermediate site to the final site in the O2-type framework due to the lower activation barrier than the O3-type. Additionally, the anionic electrostatic repulsion between facing O-O in the LiO_2 layer results in a larger Li slab thickness, creating wider pathways for Li-ion movement. The second step involves screening the optimal material candidates for fast Li-kinetics by inducing even more stable intermediate sites through a change in material content by trace amounts of substitutional dopants. We design a strategy to lower the activation barrier by substituting contents (y) in O2-type $Li_{1-x}(Co_{1-y}M_y)O_2$ with 3d transition metals that have a large ionic radius, aiming for volumetric expansion of the tetrahedral site through in-plane direction broadening. While the nine candidates showed similar values of Li-slab thickness, the ionic radius, and ab-plane area showed overwhelmingly high values when Ti was substituted. The larger ionic radius causes a wider ab-plane and thus increases the volume of the LiO_4 tetrahedral site. We demonstrated through density functional theory (DFT) calculations that an expansion in the volume of the tetrahedral site lowers the activation barrier for Li-ion, resulting in high-rate performance that can be implemented. Furthermore, we figure out that materials designed according to our proposed concept induce fast Li-kinetics. Our unified design flow for facilitating fast Li-kinetics can serve as a cornerstone for the design of fast-charging LLOs cathode materials.

11:00 AM DS03.10.07
Shape Dependence of Two-Body Interatomic Potential Functions on Phase Stability of Close-Packed Polytype Structures ShinyaOgane[1], KojiMoriguchi[1] and KazumasaTsutsui[2]; [1]Tohoku University, Japan; [2]Nippon Steel, Japan

Many crystalline compounds are composed of one or more structural units. When these units can be "stacked" in various ways to form stable or metastable phases, the resulting phases are known as polytypes [1]. Among these polytypes, the crystal systems composed of close-packed (CP) layers have received particular attention over the years due to their fundamental and technological significance. While the demand for material engineering in controlling polytype structures is spanning across various fields such as wide-gap semiconductors [2], catalytic science [3], lightweight structural materials [4], and more, the scientific control of the polytype phase is still incomplete in the realm of industrial practical materials. Despite the fact that there are mathematically countless stacking arrangements with equal packing densities, most observed CP crystal structures exhibit short repeating sequences such as face-centered cubic (fcc) or hexagonal CP (hcp). There is, however, currently no general theory explaining why these structures can take the robust ground state.
Since the descriptors for the energetics of crystal structures are typically discrete physical quantities such as atomic configurations, we are forced to search their energetic stability in a discontinuous descriptor space, which makes it challenging to completely predict the most stable structure. For polytype structures, the convergent series lattice theories, such as the axial next-nearest neighbor Ising (ANNNI) model [5] and the model recently submitted by Loach and Ackland [6], are useful for representing the infinite continuous energetic space spanned by the expansion parameters. The computational analyses based on these models have suggest that it is necessary to consider at least the interactions involving the third-nearest-neighbor distance or longer-range interlayer interactions to accurately estimate the total energetics of metallic CP polytypes [6, 7]. Furthermore, molecular dynamics (MD) simulations have shown that the ground state structures based on the finite-range Lennard-Jonesium can encompass not only fcc and hcp arrangements, but also a wide range of more complex stacking sequences, depending on the interatomic interaction distance and cutoff function [8].
In the previous work, in order to investigate the bifurcation of polytype energetics as a function of interaction distance, we have presented the interlayer partial energy model where the total energy constructed from the two-body interactions is projected onto the interlayer interactions in CP polytype structures [9]. While the polytype structural energies tend to be degenerate with respect to hexagonality in the systems with the short interaction distance, the energetic degeneracy manifested by the short-range interactions has been found to split in the systems with the third neighbor interlayer interactions based on this analytical model [9]. To confirm the theoretical results, this work has systematically investigated the shape dependence of the interatomic potentials on the phase stability of the CP polytype structures by constructing specific two-body potential functions, referring to [10]. In the presentation on the day, we will discuss the variations in the phase diagram of the polytype ground state in the space defined by the potential variables associated.

Particle Self-Organization Under Oscillatory Interaction Potentials KateriH. DuBay and JessicaNiblo; University of Virginia, United States

Multiple simulations on colloidal self-assembly have demonstrated that an oscillatory inter-particle potential can alter the self-assembly process, potentially expanding the interaction space that leads to orderly assembly or establishing non-equilibrium steady-state structures that may be inaccessible to equilibrium assembly processes. Previous theoretical work in this area has shown that the assembly dynamics at the limit of fast inter-particle potential oscillations should proceed in the same way as those under the constant interaction potential that is equal to the interaction potential averaged over a single oscillation. In this work, we first use a 2D model of the assembly of a viral-capsid-like structure to confirm this result in our model system. We then work through the implications of that earlier finding for designing novel self-organizing materials via physically realizable interaction potentials.

11:30 AM DS03.10.09
Harnessing Structural Stochasticity in Designing Architectured Materials: Deep Generative Design and Curvature Functional-Based Design HongyiXu, LeidongXu and KiarashNaghavi Khanghah; University of Connecticut, United States

Bridging the gaps among various categories of microstructures, which include the periodic microstructures and various types of stochastic microstructure, remains a challenge in architectured material design. Traditionally, different microstructure categories require significantly different mathematical methods to define the design space. The purpose of this work is to establish a computational framework that provides a unified design space that embodies various categories of structural patterns for the design automation of mixed-category microstructures. The structural patterns include various stochastic patterns such as random particles, random fibers, random cells, spinodal structures, random amorphous structures, etc., as well as periodic structural patterns collected from metamaterial research works.
First, we established a property-aware Variational Autoencoder-based deep generative design framework that embodies both stochastic and periodic 2D microstructure patterns. The proposed framework is demonstrated on two sets of design case studies: (i) searching a periodic metamaterial pattern with desired properties with a stochastic pattern as the starting point, and (ii) searching a stochastic microstructure with desired properties with a periodic pattern as the starting point.
Second, we present an in-depth investigation on designing 3D mixed-category stochastic microstructures for desired properties. We establish and compare two methods, a data-driven method based on deep generative models and a mathematical method based on curvature functionals. The metrics of comparison include design performance, computational cost, scalability, interpretability of the statistical equivalency, and convenience of generating functional graded structure designs. This work is concluded with a summary of the pros and cons of each method.

11:45 AM DS03.10.10
Inverse Design of Low-Carbon Concrete Materials by Machine Learning MathieuBauchy; University of California, Los Angeles, United States

Concrete—which is by far the most manufactured material in the world—is responsible for 5-to-10% of human CO_2 emissions. Here, we present an uncertainty-aware, machine-learning-enabled optimization scheme that aims to accelerate the discovery of new optimized concrete mixes featuring minimum embodied CO_2 while meeting target performance and manufacturing constraints. We curate an unprecedented dataset comprising more than 1 million concrete mixtures with varying mixture proportions, together with their measured properties (compressive strength, slump, shrinkage, setting time, etc.). The dataset is used to train a series of Gaussian Process regression (GPR) forward models that accurately map concretes' mixture proportions to their properties, and uncertainty thereof. We then introduce a new inverse design approach that simultaneously leverages (i) multi-property predictions from the GPR model, (ii) uncertainty thereof, and (iii) physical knowledge to guide the discovery of new concrete mixtures featuring minimum embodied CO_2 while presenting required performance metrics (e.g., with a strength meeting or exceeding a given target) and obeying manufacturing constraints (e.g., with compliant slump, pumpability, finishability, etc.). This pipeline leads to the discovery of several new concrete mixtures presenting a >50% decrease in embodied CO_2, with no cost increase.

An Inverse Design Scheme of Creation of Crystal Structure Reproducing X-Ray Diffraction Pattern Without Relying on Database JoohwiLee, JunpeiOba, NobukoOhba and SeijiKajita; Toyota Central R&D Lab. Inc., Japan

An X-ray Diffraction (XRD) analysis is widely used for determination of crystal structure. A measured XRD of the synthesized sample is identified by comparing it with the XRD patterns of the candidate crystal structures searched in database (DB). In addition, a Rietveld refinement is used to slightly modify the structure to reduce the gap the XRD patterns of the measured sample and the candidate structure. However, such a method strongly depends on the DB. If the measured XRD pattern is from an unknown structure, it is difficult to identify the correct crystal structure of the measured sample. Therefore, it is needed to develop an inverse design method to automatically create a crystal structure which reproduces the given XRD pattern.

In this study, we propose an inverse design scheme, named Evolv&Morph, to generate a crystal structure reproducing the target XRD pattern. It consists of Evolutionary algorithm [1] and crystal morphing [2]. This scheme tries to create enormous crystal structures with maximizing the similarity score between the XRD pattern of the created structure and the target. Evolutionary algorithm is an optimization method with generating various structures based on genetic operators such as random selection, crossover, and mutation. Crystal morphing is an interpolation method to generate intermediate structures between the input structures. It can also optimize the similarity score of XRD pattern with the support of Bayesian optimization. For sixteen different material systems, Evolv&Morph successfully created crystal structures with the XRD pattern almost the same as the given target XRD pattern.

This scheme is an automated crystal structure creation scheme, not relying on a database. Therefore, the suggested algorithm is applicapable to other material design application for specific properties. More detailed descriptions for Evolv&Morph can be found in Ref. [3].

Macromechanical Modeling of hBN Aided by Molecular Dynamics Simulations Provides Key Insights on Novel Toughening and Strengthening Mechanism SimantaLahkar; Indian Institute of Technology Gandhinagar, India

The practical exploitation of novel properties of the diverse range of 2D materials known today relies crucially on the availability of effective computational techniques for their efficient design and modeling in emerging material applications like nanodevices and nanocomposites. Hexagonal boron nitride is one such promising 2D material whose unique and significantly-anisotropic failure behavior makes its comprehensive mechanical characterization particularly challenging. The issues of reliably predicting material failure under varied stresses also extend to other 2D materials and macro-scale anisotropic layered structures, such as layered composites, further restricting their computational as well as experimental design applications. While macro-mechanical strength theories and failure criteria, which can potentially help determine a material's maximum stress tolerance in a structure, have been typically employed with variations depending on the unique failure characteristics of a given class of materials, there remains a significant gap in adapting them for layered materials with one of the key challenges being to assess the accuracy of the failure as they require the operation in full 6D tensor stress space. In this study, we carried out comprehensive MD failure simulations of hBN and obtained a methodology for optimization of the general Tsai-Wu strength criterion by proposing an equivalent-stress-based quantification technique that can be used to determine the error between the failure surface prediction and the simulation data objectively. The final optimized criterion was tested with over 99% accuracy against multiaxial stress simulations in two arbitrary orientations, which also indicated significant strengthening behavior in hBN on ripple formation in the layers. Detailed analysis of crack nucleation toughness and bond strength revealed an intrinsic distortion-mediated mechanism of simultaneous toughening and strengthening in hBN, which is also expected in other asymmetric 2D materials. Furthermore, our study can act as an important reference for future work on multiscale failure modeling of highly anisotropic materials.

8:30 AM DS02/DS03/DS05.03
Effect of Naturally Generated Mictostructure of a Ceramic on Ion Transport—Lithiation of Titania SergeiManzhos[1], TakumaOkamoto[1], AnastasiaSorkin[2], KeisukeKameda[1], ManabuIhara[1] and HaoWang[2]; [1]Tokyo Institute of Technology, Japan; [2]National University of Singapore, Singapore

Microstructural features of ceramics can have a significant effect on ion transport in different renewable energy generation and storage technologies, most notably fuel cells and metal-ion batteries. Mictostructural features such as grain boundaries also affect electronic properties relevant for optoelectronic application (e.g. creating band gap states). Experimental insight is difficult into bulk (as opposed to surface) structure. Atomistic modeling is usually done on *postulated* grain boundaries, while real microstructures have distributions of different grain boundaries.
Microstructural features can be generated 'naturally' with molecular dynamics (MD) by simulating a heat treatment. While this has been successfully done for several monoatomic systems (e.g. Fe, Si), achieving microstructure of ceramics by MD is more difficult. We show the generation of titania grains with MD which required a finer control of the computational heat treatment than in monoelemental systems. We demonstrate that a distribition of grain sizes and grain boundaries obtains, and is dependent on the heat treatment. We compute the lithiation of the obtained structures and compare them to ideal crystal titania, and also compare mechanical properties inclduding plasticity and fracture.

8:45 AM DS02/DS03/DS05.04
Comprehensive Multimodal Deep Learning for Designing Materials with Diverse Properties ShunMuroga, YasuakiMiki and KenjiHata; National Institute of Advanced Industrial Science and Technology, Japan

In response to the increasing need for rapid advances in materials and manufacturing processes, the field of computational materials science, particularly data-centric methodology, has gained significant traction. Traditional data-centric methods have primarily focused on molecular descriptors such as elemental composition, chemical bond types, neighborhood associations, and electronic interactions to facilitate the discovery of molecules, inorganic compounds, and crystals. However, these techniques fall short when applied to complex materials with indeterminate structures, as molecular descriptors require accurate elemental coordinate information. As a result, a variety of everyday materials, such as plastics, metal alloys, rubber, and wood, with indeterminate structures face significant challenges in the context of a data-centric approach.
This study introduces an innovative technique for materials design, called multimodal deep learning, to overcome the limitations of traditional methods. This approach mimics human cognition by integrating information from multiple sensory modalities (e.g., vision, hearing) to achieve a holistic understanding. Due to its superior performance, multimodal deep learning has attracted considerable interest, especially in the field of human activities, such as emotion analysis and psychological testing. Despite these advances and growing interest, the application of this methodology to materials design has remained largely unexplored.
Our primary strategy in applying multimodal deep learning is to incorporate rich information about the physical and chemical structures of materials. The proposed advanced multimodal deep learning methodology consists of several modules: (1) multiple generative deep learning models that represent physical or chemical structure characterization data, (2) an integrated deep learning model that fuses a wide range of information from different sources to predict various properties of materials. The effectiveness of the proposed multimodal deep learning method was clearly demonstrated on polymer composites consisting of ten compositions (matrices, additives, fillers) and encompassing eight mechanical, thermal, and electrical properties. By merging optical microscope images, infrared spectra, Raman spectra, and compositional data, the trained multimodal deep learning model successfully predicts the eight physical properties. This trained multimodal deep learning model was then used to virtually screen materials over 114,210 compositional conditions. Pareto frontiers under conflicting multiple physical properties and optimal compositional changes in materials were clearly identified from the predictions of the trained multimodal deep learning model. We are confident that the proposed multimodal deep learning has the flexibility and adaptability required for a wide range of materials, paving the way for profound insights into materials and inspiring future research in advanced materials design.

The BIGMAP Approach Towards Holistic Battery Characterization SandrineLyonnard[1] and CinthyaK. Trujillo Herrera[2]; [1]University of Grenoble Alpes, France; [2]Insitute Laue Langevin, France

Energy storage devices such as Li-ion batteries are key towards a fossil-fuel free society. The characterization of material evolutions during battery cycling is critical in understanding the reaction mechanisms and finding the origin of capacity fading, which limits the cycle life of the system. Operando techniques are widely used to probe the structural and chemical changes that occur in the bulk and at interfaces in electrodes and electrolytes while the battery is charged and discharged. In this quest to visualize and quantify the various processes in real-time and at all relevant scales, neutron and synchrotron techniques are instrumental thanks to their capacity to deeply penetrate dense systems, therefore enabling to probe battery cells working in close-to-real or real conditions. Moreover, unprecedented time and space resolutions are achievable in some cases, leading to ultimate views of particle evolutions and electrode-scale heterogeneities. In this talk, we will present examples of correlative experiments performed using 2D scanning techniques and 3D imaging techniques. We will focus on the benefits of multimodal approaches [1] where isotopic-contrasted neutron experiments are combined, for instance, to high resolution scanning microXRD experiments. We will also present the complex experimental workflow developed in the frame of the BIGMAP project, where a central AI orchestrates advanced characterization, multiscale modelling, machine learning methods, high throughput synthesis and robotics to accelerate materials discovery. Taking the graphite/LNO battery as a use case, we will show how we combine a variety of experiments ranging from spectroscopies to advanced tomography and 2D/3D mapping techniques in order to gain a more holistic understanding of the ageing mechanisms in the electrodes, as well as to evaluate the impact of electrolyte additives onto the Solid Electrolyte Interphase (SEI) formation and growth.

9:30 AM DS02/DS03/DS05.06
Deep Learning for Improving Piezoresponse Force Microscopy Sensitivity for Weak Ferroelectrics PanithanSriboriboon[1], HuiminQiao[1,2], OwoongKwon[1,2], RamaK. Vasudevan[3], StephenJesse[3] and YunseokKim[1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sungkyunkwan University (SKKU), Korea (the Republic of); [3]Oak Ridge National Laboratory, United States

Hafnium oxide-based ferroelectrics have been extensively studied because of their existence of ferroelectricity, even in ultra-thin film form. However, studying the weak response of the ultra-thin film requires high-sensitivity piezoresponse measurements. In general, resonance-enhanced piezoresponse force microscopy (PFM) has been used to characterize ferroelectricity by fitting between the acquired piezoresponse spectrum and a simple harmonic oscillation model. However, an iterative approach, such as traditional least square (LS) fitting, is highly sensitive to noise and can result in the misinterpretation of weak responses. In this study, we introduce a deep denoising autoencoder (DDA) and principal component analysis (PCA) to hybridize with a deep neural network (DNN) for the extraction of piezoresponse information. The DDA/PCA-DNN improves the PFM sensitivity down to 0.3 pm, allowing measurement of weak piezoresponse with low excitation voltage in 10-nm-thick $Hf_{0.5}Zr_{0.5}O_2$ thin films. Our hybrid approaches could provide more chances to explore the low piezoresponse of the ultra-thin ferroelectrics and could be applied to other resonance-based microscopic techniques.

9:45 AM DS02/DS03/DS05.07
Simplifying the Identification of Differential Scanning Calorimetry (DSC) Curves YanxiZhang; Netzsch Instruments North America, United States

Currently DSC is a very common instrument in material characterization lab. Interpretation of DSC curve requires a lot of experience and time by looking up in application note and literature or consulting with experts. Thanks to “Identify” software, interpretation of DSC curve is not a tough job anymore, can with a single mouse click.

“Identify” is a unique database system in thermal analysis for the recognition and comparison of measurement curves of DSC, TGA, DIL/TMA as well as data on the specific heat capacity, Cp. “Identify” is the first database search software in thermal analysis. The database includes more than 2000 entries from the fields of ceramics and inorganics, metals and alloys, polymers, organics, food and pharmaceuticals, as well as chemical elements. “Identify” software offers an automatic DSC curve recognition of unknown measurements and thus interpretation via

database search, which is in general be very helpful for material identification, failure analysis and quality control. “Identify” serves as archiving system, too, for data mining since evaluated curves can restore in database easily. The database can expand by users’ own libraries shared with several users in the computer network.

Limitation of database search is that curve recognition is not automatically material recognition. Sometimes multiple interpretation is possible. “Identify” software develops to use with combined TGA and DSC, TGA-c-DTA® and STA measurements. Not only the best hit with one signal considers, but also several signals (DSC, TGA etc), which allows for material identification with greater certainty.

ARES™ Autonomous Experimentation Systems for Clean Energy Materials BenjiMaruyama[1], RahulRao[1] and RobertWaelder[2,1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

The current materials research process is so slow and expensive, taking decades from invention to commercialization, that it may not impact 2050 CO_2 emission goals to mitigate disastrous impacts from human-driven climate change. The Air Force Research Laboratory pioneered ARES™, the first autonomous research system for materials development. A rapidly growing number of researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of doing iterative experimentation orders of magnitude faster than today. We will discuss concepts and advances in autonomous experimentation in general, and associated hardware, software and autonomous decision methods.

We will focus on the simultaneous generation of clean hydrogen plus sequestered carbon to lightweight transportation and construction materials through natural gas pyrolysis to hydrogen plus carbon nanotubes. For Carbon Nanotubes (CNTs), we show progress in autonomous and data science methods to understand and control the fundamental mechanisms that drive CNT synthesis via CVD.

In the future, we expect autonomous research to revolutionize the research process, and propose a “Moore’s Law for the Speed of Research,” where the rate of advancement increases exponentially, and the cost of research drops exponentially. We also consider a renaissance in “Citizen Science” where access to online research robots makes science widely available.

11:00 AM DS04.01.02
Direct Materials Printing Makes Autonomous Energy-Materials Research Accessible for Smaller Labs EuniceAissi, AlexanderE. Siemenn, JamesSerdy, FangSheng, BasitaDas, HamideKavak and TonioBuonassisi; Massachusetts Institute of Technology, United States

While autonomous research presents a promising approach to accelerate the development of new energy materials, acquiring the human and capital resources to establish and maintain these advanced tools can be daunting. For smaller labs investigating a wide range of energy materials, there is demand for flexible, high-throughput, and high-quality materials synthesis and characterization tools. For such an approach, an additional constraint is demonstrating equivalence with, and translatability to, standard synthesis techniques — a task complicated by the fact that optoelectronic properties of energy materials are often sensitive to dilute concentrations of defects.

We address the material synthesis and characterization bottleneck by presenting a framework that we believe is suitable for smaller labs: Self-built, low-cost automation for energy applications. The design philosophy is to de-risk the lab automation process by keeping costs low, failing fast, and leveraging common resources in electronic systems and additive manufacturing. We present the example of a home-built Direct Multi-Material Printer (DMMP) adapted to operation in the glovebox, hood, and benchtop environments. The DMMP takes two or more fluid precursors and prints a materials gradient within a set of droplets, line segments, or another user-specified shape. The tool is self-built, leveraging a low-cost 3D printer chassis, and is affordable at about $500. Our build cycle takes one day and utilizes open-source platforms for its firmware. The DMMP can deposit up to 1,000 different energy material compositions from liquid precursors in under one minute, requiring only three steps: creating a print pattern, loading the precursors, and printing the materials. We evaluate the fluid mixing dynamics of the system through imaging.

We validate the material synthesis capacity of the DMMP on a perovskite alloy series of interest to photovoltaic engineers, from methylammonium lead iodide (MAPbI3) to formamidinium lead iodide (FAPbI3), by showing equivalence to traditional spin-coated samples through X-ray diffraction measurements and other microstructural, compositional, and optoelectronic characterization methods. To screen for materials durability (an early step toward long-lasting perovskite-based solar PV modules), we demonstrate high-throughput characterization of the perovskite materials through an automated image segmentation algorithm that quantifies color changes in each material as a proxy for material degradation. To close the loop in a data-driven fashion (toward autonomy), we can use "stability" as a response variable for an active learning loop.

In summary, we present and validate a framework of customized automation for energy materials, focused on improving reproducibility, speed, adaptivity, and accessibility for smaller labs.

11:15 AM DS04.01.03
An Automated Multi-Scale NMR Framework Helps Understand Solvent Exchange Dynamics in Multivalent Batteries RashaAtwi[1], YingChen[2], Dan ThienNguyen[2], Kee SungHan[2], KarlMueller[2], VijayakumarMurugesan[2] and Nav NidhiRajput[1]; [1]Stony Brook University, The State University of New York, United States; [2]Joint Center for Energy Storage Research (JCESR), Pacific Northwest National Laboratory, United States

Liquid electrolytes are integral parts of numerous materials science applications, including energy storage devices and solar panels. Optimizing these technologies requires designing optimal electrolytes, which calls for an exhaustive, unbiased exploration of wide chemical and parameter spaces. This process involves detailed investigations of the structural, dynamical, and thermodynamical properties of the chemical species that comprise complex, multi-component liquid electrolytes. To accelerate these investigations, we developed a fully automated, high-throughput multi-scale computational framework[1,2] that predicts solvation structures. The framework automatically processes hundreds of thousands of atomic clusters from MD simulations, identifies stable species, and performs their NMR chemical shift calculations via DFT. The output is an extensive database of chemical shifts from a broad range of electrolyte solutions, generated with minimal user intervention and free from any trial-and-error process. By coupling the framework with experimental NMR measurements, we investigate solvation structure and solvent exchange rates of magnesium electrolytes in a wide range of solvent classes. We uncovered a correlation between solvent exchange dynamics and charge transfer efficiency at the electrolyte/electrode interface, suggesting the desolvation process as the rate-determining step.

Automated Computation and Machine Learning of Electron Scattering and Charge Transport of Semiconductors TianqiDeng[1], MichaelB. Sullivan[2], GangWu[2], Shuo-WangYang[2] and KedarHippalgaonkar[3,4]; [1]Zhejiang University, China; [2]Institute of High Performance and Computing, Singapore; [3]Nanyang Technological University, Singapore; [4]Institute of Materials Research and Engineering, Singapore

Charge carrier scattering and transport processes are fundamental to semiconductors for electronics, thermoelectrics, and many other applications. However, detailed scattering and transport characterizations are limited to a small number of materials. In this work, we profile the charge transport properties of about 1800 experimentally known semiconductors by incorporating electron-phonon and electron-impurity scatterings from density functional theory calculations. We demonstrate that electron-optical-phonon interaction is unambiguously the dominant scattering mechanism for the majority of these semiconductors, while many of them exhibited trend which was conventionally associated with acoustic phonon scatterings. Combining the knowledge with machine learning models, we further predicted the carrier mobilities of over 19000 semiconductors with substantially reduced cost. High-performance semiconductors and their key structural and electronic features are also identified to assist materials discovery and optimization.

SESSION DS04.02: Autonomous Experimental Methods II
Session Chairs: Yangang Liang and Shijing Sun
Monday Afternoon, November27, 2023

1:30 PM *DS04.02.01
How AI and Automation Can Help in Experimental Materials Research ShijingSun[1,2]; [1]Toyota Research Institute, United States; [2]University of Washington, United States

Innovation in energy storage and conversion is essential for addressing global challenges such as climate change. Artificial intelligence (AI) has emerged as a powerful tool to accelerate materials discovery, but there are still challenges in realizing the potential of computational designs in the laboratory. One question increasingly get asked on self-driving labs is that 'will robots replace scientists?' In this talk, I will discuss, rather than replacing researchers, how emerging technologies can augment and amplify human expertise, leading to unprecedented breakthroughs in energy materials, device and systems. I will present examples of data-driven approaches that can address atomic-to-device level challenges in materials science. I will focus on how to predict experimental outcomes, explain results with interpretable machine learning, and design new experiments that incorporate physical knowledge into an automated framework, thereby guiding the discovery of new materials.

2:00 PM DS04.02.02
Materials Acceleration Platforms—Toward the Laboratory of the Future for Perovskite and Organic PV Research TobiasStubhan[1], AndrejClassen[1], MoritzScholl[1], PeterFendt[1], MatthiasKoegl[1], JerritWagner[2,3], ChristianBerger[2,3], JensHauch[2,3] and ChristophJ. Brabec[2,3]; [1]SCIPRIOS GmbH, Germany; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [3]Helmholtz Institute Erlangen-Nuremberg, Germany

The development of complex functional materials poses a multi-objective optimization problem in a large multi-dimensional parameter space. Solving it requires reproducible, user-independent laboratory work and intelligent preselection of experiments. However, experimental materials science is a field where manual routines are still predominant, although other domains like medicine, biotechnology or pharmacy have long used robotics and automation. As the number of publications on Materials Acceleration Platforms (MAPs) increases steadily, we review selected systems [1,2] and fit them into the stages of a general material development process to examine the evolution of MAPs up to the AMANDA (Autonomous Materials and Device Application) platform [3]. Subsequently, we present our newest approach to lab automation for perovksite and organic PV research with the example of precise time-controlled quenching processes for perovskite film formation with solvent, gas and vacuum and autonomous perovskite film deposition optimization using automated optical characterization (Abs, photoluminescence) and machine learning for planning of the next generation of experiments.

Automated Phase Identification in Large Material Spaces Using Neural Networks NamQ. Le[1], MichaelPekala[1], AlexanderNew[1], EddieGienger[1], JannaDomenico[1], ChristinePiatko[1], ElizabethPogue[1], TyrelM. McQueen[2] and ChristopherStiles[1,2]; [1]Johns Hopkins University Applied Physics Laboratory, United States; [2]Johns Hopkins University, United States

High-throughput materials discovery systems require the ability to rapidly screen promising candidates. X-ray diffraction (XRD) provides a useful modality in settings where properties are strongly tied to particular crystalline phases. For example, many A15 phases are Type-II superconductors at relatively high temperatures among metallic alloys; identifying novel A15 phases could therefore lead to a high proportion of novel superconductors. Machine learning (ML) models have been shown effective for automating similar phase identification tasks from XRD patterns. However, previous work has generally been limited to material systems of up to five elements. We report the results of convolutional neural networks trained to classify A15-like phases from XRD patterns from a broad space of binary and ternary material systems spanning 23 elements. High performance can be achieved whether using crystal structures measured experimentally (Inorganic Crystal Structure Database, ICSD) or computed theoretically using density functional theory (Materials Project, MP). Performance decreased significantly when trained and tested on different sources, but can be recovered by augmenting datasets with both experimentally- and theoretically-derived structures. High classification performance can even be maintained on held-out XRD patterns measured experimentally in-house. This work suggests that ML models for XRD screening can be effective for phase identification not only within

material systems with already experimentally-measured patterns, but also in novel material systems through careful augmentation with theoretically-computed structures.

2:30 PM *DS04.02.04
Rules and Goals to Replace Clockwork Automation JasonHein; University of British Columbia, Canada

Automation and real-time reaction monitoring have revolutionized synthetic chemistry by enabling data-rich experimentation, leading to a comprehensive understanding of chemical processes. This talk emphasizes the significance of data-rich experimentation (DRE) in reaction process optimization and discovery and explores the potential of artificial intelligence (AI) and machine learning (ML) tools in enhancing automated real-time reaction monitoring.

DRE focuses on extracting real-time reaction progress data to gain insights into reaction kinetics, intermediates, rate constants, and by-product reaction pathways. Automation plays a crucial role in enabling DRE by accurately capturing and analyzing reaction aliquots, processing complex analytical data, and executing precise reaction manipulations. This approach enhances decision-making capabilities, reduces optimization time and resource requirements, and facilitates the exploration of reaction mechanisms and dynamics.

This presentation highlights the current paradigm of data-driven reaction investigation, which often relies on human interpretation. However, the integration of real-time monitoring data with AI and ML tools presents an opportunity to accelerate process optimization and reaction discovery. Real-time monitoring telemetry allows automated systems to receive critical feedback and adapt to variable circumstances, enabling error-free autonomous synthesis. ML-based predictive models and autonomous optimization platforms reduce the number of experiments needed and consider a broader range of reaction parameters beyond simple yield measurements.

Real-time reaction monitoring provides comprehensive kinetic data that addresses issues of data integrity, bias, and oversimplification. It captures variations in reaction performance, identifies intermediates and by-products, and facilitates the classification of underlying reaction mechanisms. By combining automated data-gathering methods with AI and ML tools, synthetic chemistry can predict optimal conditions and discover new synthetic routes more efficiently.

Mastering Compositional Complexity in High Entropy Materials for Energy Applications - Towards Accelerated Materials Discovery by Integration of High-Throughput Experimentation, Simulation, and Materials Informatics AlfredLudwig; Ruhr University Bochum, Germany

Discovery of new materials is a key challenge in materials science. New materials for sustainable production/storage/conversion of energy carriers are necessary to improve existing and to enable future energy systems. Compositionally complex materials, frequently called high entropy materials, offer a vast multidimensional search space, which provides opportunities for discovering new materials. However, efficient methods for the exploration and exploitation of this search space are necessary. Here, the integration of high-throughput thin-film combinatorial materials science methods with simulation and materials informatics (1) is presented as an effective means to produce large datasets on new materials, which enables mastering of the search space. The approach combines theoretical predictions from high-throughput computations with production of large, consistent and complete experimental datasets, which are used for materials informatics. Thin-film materials libraries are fabricated by combinatorial sputter deposition and optional post-deposition treatments, followed by high-throughput characterization, and finally the organization of the acquired multi-dimensional data in adequate databases as well their effective computational analysis and visualization, e.g., of quinary systems in the form of composition-processing-structure-function diagrams, interlinking compositional data with structural and functional properties. The talk will discuss examples of combinatorial discoveries (2, 3) and the targeted development of new compositionally complex materials for electrocatalysis (4) where compositional complexity offers a new design principle (5). Furthermore, a new approach (6) to accelerate atomic-scale measurements for complex alloys is presented as well as applications of materials informatics to accelerate and improve the materials discovery process (7, 8).

High-Throughput Mechanical and Elastic Properties of Two-Dimensional Materials from First Principles ChangpengLin[1], SamuelPoncé[2], FrancescoMacheda[3], DavideCampi[4], FrancescoMauri[5] and NicolaMarzari[1,6]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Université Catholique de Louvain, Belgium; [3]Istituto Italiano di Tecnologia, Italy; [4]Università degli Studi di Milano-Bicocca, Italy; [5]Università di Roma La Sapienza, Italy; [6]Paul Scherrer Institute, Switzerland

Mechanical and elastic properties of materials are among the most fundamental quantities for many engineering and industrial applications. Here, we present an efficient and accurate approach for calculating the elastic and bending rigidity tensor of crystalline solids based on interatomic force constants and Born perturbation theory, valid equivalently for any dimension. We implement the theory in the first-principles Quantum ESPRESSO software suite, and perform an extensive validation against conventional finite-difference calculations and experimental measurements for Si, NaCl, graphene and monolayer MoS_2. The developed computational approach is then applied to the high-throughput screening of around one-thousand two-dimensional materials from the MC2D database, where we identify various candidates with outstanding or unique mechanical properties. The methodology developed and elastic database of two-dimensional materials produced in this work will benefit the discovery and design of novel functional materials.

4:15 PM DS04.03.03
A Comprehensive Inert-Gas Workflow for High-Throughput Combinatorial Aging Studies of Vapor-Deposited Metal Halide Perovskite Thin-Films AlexanderWieczorek[1], AustinG. Kuba[2], JanSommerhäuser[1], LuisCaceres[1], SiarheiZhuk[1], ChristianWolff[2] and SebastianSiol[1]; [1]Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]EPFL – École Polytechnique Fédérale de Lausanne, Switzerland

High-throughput experimentation (HTE) is increasingly being employed to accelerate metal halide perovskite (MHP) thin-film development.[1] As of now, most approaches focus on solution-based deposition methods.[2–4] To address the need for scalable fabrication approaches, vapor-based deposition methods are gaining popularity. However, durability concerns remain a major obstacle for large-scale deployment.[5] This motivates high-throughput stability studies of vapor-deposited MHP thin films.

Combinatorial materials science is perfectly suited to address this challenge, specifically for time-consuming degradation studies where parallelization of experiments is key.[6] Using vapor deposition techniques, large parameter spaces can be covered on single substrates, whereas automated characterization and data analysis facilitate rapid properties screening.[7]

In this work, we present a comprehensive workflow for the aging behavior of thin-film MHPs which includes structural, optical and chemical characterization. To mitigate ambient degradation of pristine thin films during characterization or transfers, we employ a complete inert-gas workflow. Furthermore, we perform a rapid *in situ* screening of the transmission and reflectance in a broad wavelength range under accelerated aging conditions. Specifically, the samples are exposed to 85 °C and 1 kW m^{-2} white light bias, probing intrinsic material degradation in an accelerated fashion. With a temperature variation of ±1 °C and light intensity variation of <2% across combinatorial libraries, meaningful combinatorial stability screening is enabled. Automated characterizations of the structural properties as well as optoelectronic properties relevant to device applications yield deep insights into the aging process, extending and validating insights from changes in the optical transmission. Furthermore, the workflow can be combined with high-throughput surface characterization techniques that our group previously demonstrated as a novel tool for accelerated materials discovery.[8–10] Consequently, the investigation of surfaces and interfaces relevant for device applications is enabled.

We investigate the effect of residual precursors on the stability of two-step deposited MHP thin films grown on vapor-deposited templates for multiple chemical spaces. As a result, we discuss strategies to derive guidelines for the two-step synthesis of stable MHP thin films.

MISPR: A High-Throughput Multi-Scale Infrastructure for Automating Materials Science Computations Nav NidhiRajput, RashaAtwi and MatthewBliss; Stony Brook University, United States

Developing the capability to accurately predict the macroscopic properties of complex multicomponent solutions from microscopic features of molecular species is a grand challenge spanning chemistry, materials science, and engineering. Despite significant efforts undertaken in the past, the existing studies fall short of predicting the properties of multicomponent solutions due to multiple length and time scales of functional properties and a vast chemical and parameter space, which cannot be efficiently explored using trial and error based experimental approaches, brute-force computational approaches, and/or high-throughput computational approach that typically focus on just a single scale.

Driven by these needs, we developed a high-throughput computational framework coined **MISPR (Materials Informatics for Structure-Property Relationships - https://github.com/molmd/mispr)** that seamlessly integrates density functional theory (DFT) calculations with classical molecular dynamics (MD) simulations to robustly predict molecular and ensemble properties in complex multi-component liquid solutions. Functionalities of MISPR include *(i)* full automation of DFT and MD simulations, *(ii)* creation of computational databases for establishing structure-property relationships and maintaining data provenance and reproducibility, *(iii)* automatic error detection and handling, *(iv)* support for flexible and well-tested DFT workflows for computing properties such as bond dissociation energy, binding energy, and redox potentials, and *(v)* derivation of ensemble properties such radial distribution functions, ionic conductivity, and residence time. The infrastructure allows running 100-1000s of calculations in parallel by minimizing manual interference and generates high-fidelity databases of computational properties and force field parameters.

In this talk, I will demonstrate the unique features of MISPR by highlighting its different automated workflows and their application in designing optimal electrolytes for next-generation energy storage devices.[1] I will then show (1) a novel ***"DFT-CMD-DFT"*** approach to accurately predict various stable species present in a multi-component solution by analyzing experimental nuclear magnetic resonance (NMR) spectra[3] and (2) how MISPR can help screen thousands of potential solvents and salts to identify optimal electrolyte systems.

Investigating Combinatorial Thin Films and Scanning Electrochemical Techniques for High Throughput Data Generation NataliePage[1], NaohiroFujinuma[2], JeffreyHettinger[1] and SamuelE. Lofland[1]; [1]Rowan University, United States; [2]Sekisui Cemical Co., Ltd, Japan

Heterogenous catalysts demonstrate promise for generating sustainable carbon neutral fuels and recycling carbon resources, but high cost has made implementation economically unfeasible, and a lack of understanding of catalytic reaction mechanisms has hampered new developments needed for scalability and production. High throughput experimentation (HTE) has had success in novel material discovery, but there are limited HTE techniques for electrochemical catalysts. Here we discuss HTE on precious metal quaternary alloys for electrocatalysis. Combinatorial thin films synthesized via magnetron sputtering were investigated with a custom scanning electrochemical cell made by additive manufacturing. The scanning system allows for a variety of measurements including cyclic voltammetry, chronoamperometry, electrochemical impedance spectroscopy, and electrolyte analysis. Using robust machine learning algorithms, we correlate these results with the physical properties investigated by traditional techniques such as scanning electron microscopy, energy dispersive spectroscopy, x-ray diffraction, and atomic force microscopy in order to identify candidate alloys that satisfy key metrics such as selectivity, productivity, durability, and efficiency.

SESSION DS04.04: High-Throughput Experimentation and Data-Driven Methods II

8:30 AM *DS04.04.01

Designing High Throughput Workflows: From Experiment Automation to Data Management JohnM. Gregoire[1], JoelA. Haber[1], DanGuevarra[1], LanZhou[1], KevinKan[1], RyanJones[1], YungchiehLai[1], Ja'NyaBreeden[1], MichaelStatt[2], BrianRohr[2] and SantoshSuram[3]; [1]California Institute of Technology, United States; [2]Modelyst LLC, United States; [3]Toyota Research Institute, United States

In the quest to accelerate materials discovery via experiment automation and artificial intelligence, we recognize the challenges in emulating human capabilities with respect to contextualizing data and rapidly adapting experiments based on real-time data streams. In the development of infrastructure for next-generation workflows, these aspects of traditional research are most tightly connected to instrument control software and the management of experimental data. We will describe the evolution of these capabilities at Caltech, from automated workflows focused on throughput and consistency to workflows that embrace modularity and responsiveness to new knowledge, where techniques for this latter approach are being developed collaboratively with Modelyst, Inc. and Toyota Research Institute. The lessons learned with respect to data management may be the most generalizable to the materials chemistry community, especially our development of Event-Sourced Architecture for Materials Provenance Management (ESAMP) and the Materials Experiment Knowledge Graph (MekG), which addresses the hierarchical nature of materials data. Regarding representation of materials data, high-level descriptors can be provided by the chemical elements, crystal structure motifs, and types of materials properties,

and ultimately a given piece of data must be considered in the context of its acquisition. Detailed descriptors of a piece of experimental data include not only the metadata for the experiment that generated it, but also the prior history of synthesis and metrology experiments. Graph databases offer an opportunity to represent such hierarchical relationships among data, organizing semantic relationships into a knowledge graph. Initial reports of knowledge graphs in materials science highlight the breadth of approaches for their development. We describe a knowledge graph of materials experiments whose construction encodes the complete provenance of each material sample and its associated experimental data and metadata. Additional relationships among materials and experiments further encode knowledge and facilitate data exploration. MekG is sufficiently large and complex to demonstrate a path toward a global materials knowledge graph. We characterize the scalability of this approach, especially with respect to executing queries, illustrating the value that modern graph databases can provide to the enterprise of data-driven materials science.

9:00 AM DS04.04.02
Predicting Synthesizability using Positive-Unlabeled Learning Geun HoGu; Korea Institute of Energy Technology, Korea (the Republic of)

The high-throughput screening of the crystal databases has accelerated the discovery of new materials. To expand the screening scope, density functional theory (DFT) optimization is combined with generative models, evolutionary algorithms, and element substitution to create “virtual” crystals that have not been synthesized previously but are predicted to be stable in silico. However, the synthesizability of the virtual candidates remains a critical concern as their actual synthesis methods are unknown. To address the synthesizability of virtual candidates, DFT calculated energy such as formation energy, and energy above the hull is often used as intuitive screening criteria. While some of the thermodynamically stable virtual crystals are indeed synthesizable and functional, many virtual candidates are unsynthesizable, deeming the virtual crystal search impractical. These results are, however, not unexpected as the density functional theory-based energy metrics do not account for chemical potentials at the synthesis condition, as well as the kinetics of the complex synthesis. Quantifying the synthesizability is crucial to improving the reliability and practicality of virtual crystal exploration and advancing materials discovery.
Here, we present a probabilistic approach called positive-unlabeled learning to predict the synthesizability of the virtual crystals to improve the quality of the virtual crystal screening. The model framework implicitly considers the structural similarities between the virtual candidates and the previously synthesized candidates by training an ensemble of binary classification models with previously synthesized data as positive and randomly selected unlabeled data as negative. The average of the ensemble of the model predicts the synthesizability score that we call the crystal-likeness score. We train our model with Materials Project data, demonstrating the 87.4% true positive rate (TPR) for the test set of experimentally reported cases (9356 materials). We further validate the model by predicting the synthesizability of newly reported experimental materials in the last 5 years (2015–2019) with an 86.2% true positive rate using the model trained with the database as of the end of the year 2014. Our analysis shows that our model captures the structural motif for synthesizability beyond what is possible by Ehull. We find that 71 materials among the top 100 high-scoring virtual materials have indeed been previously synthesized in the literature.
We further explore the applications by performing transfer learning to inorganic perovskite crystals. We find that the model shows a 95.7% TPR. Further validation is established by demonstrating that 179 virtual crystals that are predicted to be synthesizable have already been synthesized in literature, and those with the lowest synthesizability scores have not been reported. These numbers are comparable to 943 perovskite crystals in OQMD, MP, and AFLOW that are registered as previously synthesized. While previous methods focused on metal oxides, our model applies to other classes of perovskites, including chalcogenide, halide, and hydride perovskites, as well as anti-perovskites. For comparison, Goldschmidt factor-based screening is applied which was only applicable to 388 perovskites out of 943 registered perovskites, and a TPR of 0.863 was obtained for the 388 crystals. We apply the method to identify synthesizable perovskite candidates for metal halide optical materials. With the proposed data-driven metric of the crystal-likeness score, high-throughput virtual screenings can benefit significantly by reducing and prioritizing the candidate for experimental testing.

9:15 AM DS04.04.03
Predict Thermodynamic, Thermal and Mechanical Properties of High Entropy Alloys using Physics-Informed Machine Learning MichaelGao, WilliamTrehern, YiWang and SaroSan; National Energy Technology Laboratory, United States

High entropy alloys represent a new paradigm shift in materials design. The main challenges in high entropy alloys development are the lack of efficient and reliable tools to predict the composition-processing-microstructure-properties relationships of vastly unexplored compositional space as well as their dependence on temperature, pressure, and other environmental/operating conditions. In this talk we will present our ongoing research effort in predicting thermodynamic, thermal and mechanical properties of HEAs by integrating multi-scale computational modeling with machine learning. Modeling techniques include high throughput CALPHAD calculations, density functional theory methods (DFT), and continuum models. CALPHAD method allows us to predict phase diagram information including phases and their mole fractions and phase transformations. Single crystal elastic constants and average elastic properties, defect energetics (such as surface energy and stable and unstable stacking fault energies), and intrinsic ductility are predicted using DFT methods. To predict coefficient of thermal expansion (CTE) and temperature-dependent elastic constants, we adopt an optimized Debye model by calibrating the Debye temperature and its volume dependence of pure elements by comparing the predicted heat capacity and CTE to the experimental results. Based on these predicted properties from physics-based models and reported experimental results, machine learning modeling are performed to predict thermal and mechanical properties of HEAs. The integration of high-fidelity multiscale modeling with machine learning not only helps decipher complex materials challenges such as high temperature strength and creep behavior but also accelerates the design of cost-competitive high-performance alloys for extreme environment applications.

9:30 AM DS04.04.04
Convex Hull Aware Active Search for Phase Stability in High-Dimensional Composition Spaces AndrewNovick[1], DianaCai[2], QuanNguyen[3], VladanStevanovic[1], RomanGarnett[3], RyanAdams[2] and EricS. Toberer[1]; [1]Colorado School of Mines, United States; [2]Princeton University, United States; [3]Washington University in St. Louis, United States

High-entropy ceramics have a variety of clean-energy applications including catalysis, thermoelectrics, and batteries. Building a library of stable, high-entropy ceramics is a critical first step for eventually discovering exceptional compositions. As such, considerable efforts have been made in producing high-throughput screening methods for identifying single-phase compositions. A convex hull is required for assessing the stability of a composition; despite ongoing efforts, it remains incredibly costly—and often infeasible—to produce an accurate free energy convex hull in many dimensions.

For this purpose, we have devloped convex-hull aware active search to efficiently produce the free energy convex hull. In each iteration of the active search algorithm, we choose the composition that is expected to give the most information about the hull. As such, we do not waste calculations trying to accurately model irrelevant compositions that are clearly above the hull. Often, large swaths of composition space are far above the hull, and by ignoring them, our algorithm allows for efficient exploration. Since Bayesian methods are employed, the uncertainty in the hull is naturally resolved as a function of composition, allowing for intelligent decisions based on the produced predictions. We offer this method as a tool for effectively building a library of stable, high-entropy ceramics. As a proof of concept, we calculate the free energy convex hull for the senary (Pb,Sn,Ge)(S,Se,Te), a relevant composition space for thermoelectrics.

9:45 AM DS04.04.05
Data-Driven Bayesian Optimization of P-Type Polymer Dopant Complexes for Next-Generation Thermoelectrics ConnorGanley[1], TushitaMukhopadhyaya[1,2], HowardE. Katz[1] and PauletteClancy[1]; [1]Johns Hopkins University, United States; [2]Georgia Institute of Technology, United States

Semiconducting polymers have shown remarkable performance in applications such as organic light-emitting diodes (OLEDs), organic solar cells (OSCs), and thermoelectric materials, establishing their status as formidable candidates for “greener” next-generation materials. These materials are solution-processable, hence their manufacture is low-cost and highly scalable. Doping suitable polymers with small molecules has a demonstrably positive impact on the electronic properties of the final polymeric thin film by increasing the charge carrier concentration and electrical conductivity. We have previously published several studies exploring different *p*- and *n*-type polymers, dopants, and their respective properties, showing, in some select cases, record-breaking thermoelectric performance. Unfortunately, the search for optimal polymer-dopant pairs thus far has been largely Edisonian and based on ill-quantified means like expert knowledge and chemical intuition. This work seeks to leverage the power of *ab initio* electronic structure calculations in conjunction with a machine-learning-based optimization for high-performing *p*-type doped semiconducting polymers.
The goal of this work is to identify a novel high-performing *p*-type polymer-dopant combination from a combinatorically expansive pool of candidates, which will consequently demonstrate the utility of a data-based approach toward polymer engineering. Such an identification will be conducted using the Physical Analytics pipeLine (PAL), a Bayesian Optimization (BO) code written in Python and developed by the Clancy group. PAL has been shown previously to incorporate physical domain knowledge (*e.g.* DFT results) into an efficient optimization over a large compositional space. The input data will consist of electronic properties obtained from density functional theory (DFT) calculations, such as sigma profiles, HOMO-LUMO gaps, and ionization potentials/electron affinities. For reference, sigma profiles are unnormalized histograms of the screened surface charge of a molecule that provide important information about charge distribution in a molecule. This important information provides information on the degree of localization of charges, which impacts electron transfer. A large amount of model training data already exists from our previous papers about doped *p*-type polymers. The BO algorithm will attempt to maximize electron transport properties such as the Seebeck coefficient, power factor, and conductivity, in separate single-objective experiments. These properties will be calculated for candidate complexes using BoltzTraP2, a Python code that quantifies electron transport behavior.

High-Throughput Automation and AI Accelerate New Material Development GrantGavranovic, RickSidler and DelJackson; Unchained Labs, United States

High-throughput lab automation systems are well established for dramatically accelerating the development of novel pharmaceutical treatments and other functional chemicals. More recently, this technology has been directed to energy storage applications, including synthesis and characterization of electrode materials, electrolytes, catalyst inks, and more. These advances have involved the evolution of existing technologies and creation of new capabilities specific to material development applications.

By combining the inherent characteristics of lab automation, including high accuracy and precision, and capture of structured data with advances in software interoperability, such as open APIs and widespread use of Python, researchers are now able to develop and train ML/AI models more easily for their specific research goals. These models have also been used to direct automated systems to perform the desired experiments, including in fully autonomous systems.

This presentation will include examples of key hardware and software capabilities that have been applied to high-throughput material development workflows. It will also address challenges and important factors to consider when implementing new automated systems, such as self-driving labs.

11:00 AM DS04.04.07
Pre-Treatment Methods for Machine Learning in Finer UV Spectrum Inference HajimeShinohara, IndraPriyadarsini S, DaijuNakano, AkihiroKishimoto and SeijiTakeda; IBM Research - Tokyo, Japan

Spectroscopy is a crucial modality for evaluating the properties of materials. In particular, UltraViolet (UV) spectra enable the measurement of important energy gap structures that provide information about the electronic structure. Spectral features encompass not only direct properties such as peak positions and bandwidths but also quantitative evaluations of features like graph curvature, which can be challenging. This highlights the potential effectiveness of spectroscopy as a modality for machine learning.
Previous studies utilizing Long Short-Term Memory (LSTM) have achieved partial success in predicting the shape of spectra for certain substances, while struggling with others. Meanwhile, Transformers have gained significant attention in machine learning in recent years due to their ability to combine structures and exhibit various variations.
In this study, we constructed a Transformer architecture to train on UV spectra. The input consisted of Simplified Molecular Input Line Entry System (SMILES) representations tokenized using a tokenizer, allowing us to infer spectra from chemical structures. The training data included both existing data from prior studies. Furthermore, several techniques were implemented to enhance the model's performance, and the results were compared and examined. Additionally, a comparison was made with other models such as LSTM and Gated Recurrent Unit (GRU) to further assess the model's performance.
In this presentation, we will provide an explanation of the results, discussions, and considerations derived from this comparative analysis.

11:15 AM DS04.04.08
High-Throughput Calculation Workflows for Solid State Systems AlpE. Samli[1], RachelN. Kerber[2], MisbahSarwar[2] and DavidO. Scanlon[1,3]; [1]University College London, United Kingdom; [2]Johnson Matthey Technology Centre, United Kingdom; [3]University of Birmingham, United Kingdom

The automation of calculations is key for high-throughput computational screening which can accelerate materials discovery and characterisation for a myriad of applications. These include Johnson Matthey's areas of expertise such as the catalysis of green hydrogen production via electrolysis and NO_x reduction for clean air using rutile oxides (e.g. IrO_2 and RuO_2). AiiDA[1,2] is one of several platforms that can be used to automate calculations with a focus on preserving data provenance using a database backend.

In this work, we have used AiiDA[1,2] to create material-agnostic workflows for high-throughput CASTEP[3] density functional theory calculations of materials' properties. These workflows can automate various calculations including convergence testing, density of states, band structure, phonon, and core electron loss calculations. In addition to running these calculations, our workflows use several packages such as Sumo[4] and Galore[5] to produce publication ready plots of the density of states, band structure, phonon dispersion, and simulated spectra of materials. The simulated spectra cover both electronic (UPS, XPS, HAXPES, EELS) and vibrational (IR, Raman) spectroscopy techniques, and can be compared to experimental spectra to aid the characterisation of new materials. We have tested these workflows with rutile TiO_2, a widely studied photocatalyst, and found that our results are in good agreement with the literature. We will now extend our workflows for cluster expansion and surface slab calculations in order to study rutile oxides and their alloys for green hydrogen catalysis.

Functional High Entropy Alloys Discovered by Active Learning DierkR. Raabe and ZiyuanRao; Max Planck Institute for Iron Research, Germany

High-entropy alloys are solid solutions of multiple principal elements, capable of reaching composition and feature regimes inaccessible for dilute materials. Discovering those with valuable properties, however, often relies on serendipity, as thermodynamic alloy design rules alone often fail in high-dimensional composition spaces. In this talk we present an active-learning strategy to accelerate the design of novel high-entropy Invar alloys in a practically infinite compositional space, based on very sparse data. Our approach works as a closed-loop, integrating machine learning with density-functional theory, thermodynamic calculations, and experiments. After processing and characterizing 17 new alloys (out of millions of possible compositions), we identified 2 high-entropy Invar alloys with extremely low thermal expansion coefficients around $2x10^{-6}$ K^{-1} at 300 K. Our study thus opens a new pathway for the fast and automated discovery of high-entropy alloys with optimal thermal, magnetic and electrical properties [1].

Automated Phase Mapping of High Throughput X-Ray Diffraction Data Encoded with Domain-Specific Knowledge YizhouZhu; Westlake University, China

Combinatorial synthesis and high-throughput characterization have emerged as powerful tools for expediting the discovery and design of novel materials. A crucial step in establishing the structure-properties relationship is the accurate extraction of constituent phase information and gaining insights from high-throughput X-ray diffraction data obtained from combinatorial libraries. Essential information includes the identification, abundance, and distribution of phases across all samples, while advanced details encompass lattice changes, texture information, defects, and solid solutions. Integrating domain-specific knowledge, such as crystallography, X-ray diffraction, thermodynamics, kinetics, and solid-state chemistry, into automated algorithms is imperative for the development of automatic phase mapping algorithms. In this presentation, we show that how we combine first-principles calculations, machine learning techniques, and physics-encoded constraints within an automated workflow to solve multiple combinatorial library datasets. We show that by implementing domain-specific-knowledge-based constrains, our model successfully solved these datasets and gain important materials insights. Furthermore, we explore future directions, offering recommendations and ideas for data-driven combinatorial approaches in dataset generation and collection.

2:00 PM DS04.05.02
Machine Learning of Magnetoelectric Multipoles AriaMansouri Tehrani and TessSmidt; Massachusetts Institute of Technology, United States

In this work, we have developed and implemented equivariant neural networks to help understand and discover new magnetoelectric multiferroics, a class of energy materials with application in energy-efficient memory devices. Magnetoelectric multiferroics are materials exhibiting simultaneous spontaneous switchable electric polarization (ferroelectricity) and magnetization (ferromagnetism or other types of magnetic ordering). A bottleneck in the design of these materials is evaluating their linear magnetoelectricity, which we addressed by using the irreducible representations of their magnetoelectric multipole tensor. We achieved this by constructing efficient symmetry-preserving neural networks (leveraging the e3nn library) that can learn scalar, vector, and tensorial quantities. Next, we employed our methodology to predict new crystal structures and magnetic orientations that maximize linear magnetoelectricity in the BiFeO$_3$ phase space. Not only our work provide a framework to discover new multiferroics, but it will also provide new data-driven frameworks for materials design by enabling the efficient prediction of materials properties with complex forms.

The Era of Data-Driven Innovation and Design of Energy Materials KristinA. Persson[1,2]; [1]UC Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Entering the era of the fourth paradigm of materials science, we recognize that highly curated, tested, and provenanced data is the fuel for machine learning. As part of the Materials Genome Initiative, the Materials Project (www.materialsproject.org) was founded in 2010 at Lawrence Berkeley National Laboratory to accelerate materials design using supercomputing and software infrastructure together with state-of-the-art quantum mechanical theory. Today, the Project has over 400,000 registered users and supplies millions of data records every day to an increasingly data-hungry community. As one example, early attention to the importance of data, the Project saved and curated millions of relaxation trajectories, which since 2017 has provided the basis of training highly accurate interatomic machine learning potentials. In this talk we will give an update on recent work in the realm of data-driven materials design for energy applications, showcase successes and comment on remaining bottlenecks in accelerating materials innovation.

AI Guided Workflows for Efficiently Screening the Materials Space: Examples for Thermal Insulators and Heterogeneous Catalysis MatthiasScheffler, ThomasA. Purcell and LucasFoppa; The NOMAD Laboratory at the FHI of the Max Planck Gesellschaft, Germany

Reliable artificial-intelligence models are key to accelerate the discovery of new functional materials with optimal properties for the applications of interest. In this talk, we present a general, data-driven framework for steering data creation via a combination of symbolic regression, compressed sensing, and sensitivity analysis. Our SISSO approach (sure-independence screening and sparsifying operator) provides ***quantitative rules*** in terms of ***analytical functions*** that depend on the governing materials-characteristics parameters (also called "***materials genes***" for the function of interest).[1, 2]
We demonstrate the power of the framework for the lattice thermal conductivity using only 75 experimentally measured values. By extracting the most influential material properties from this model, we are then able to hierarchically screen 732 materials and find 20 materials with an ultra-low thermal conductivity of < 1 W/mK.[3] Further examples include the performance of heterogeneous catalysts.[4]

Unraveling the Catalytic Effect of Hydrogen Adsorption on Pt Nanoparticle Shape-Change CameronJ. Owen[1], NicholasMarcella[2], YuXie[1], JonathanVandermause[1], AnatolyFrenkel[3,4], RalphNuzzo[2] and BorisKozinsky[1,5]; [1]Harvard University, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Stony Brook University, The State University of New York, United States; [4]Brookhaven National Laboratory, United States; [5]Robert Bosch LLC Research and Technology Center, United States

Understanding atomic-level processes in surface science and heterogeneous catalysis is complicated by the wide range of time- and length-scales needed for realistic simulations for comparison to experiments. To accelerate molecular dynamics simulations, we rely on machine-learning methods to capture interatomic interactions with quantum-mechanical accuracy. Our method (FLARE) enables autonomous selection of training sets for reactive systems, based on an adaptive closed-loop algorithm that constructs accurate and uncertainty-aware Bayesian force fields on-the-fly from molecular dynamics simulations. From this accelerated sampling routine, a machine-learned force field (MLFF) is built that can access long time- and length-scale simulations of catalytic reaction dynamics. We use ML-accelerated MD simulations to study heterogeneous reactions and nanoparticle shape-changes that are catalyzed under exposure to reactive atmospheres. These observations allow for improved opportunities in material design, where material exposure to temperature or adsorbates can yield shape-changes or reconstruction, and consequently different catalytic behavior under operating conditions.

To illustrate these phenomena, we present the catalytic effect of hydrogen adsorption on small Pt nanoparticle shape-change [1]. The MLFF provides an accurate description of these systems under the effects of temperature and reactive adsorbates, which are corroborated by experimental observations, establishing confidence in the ability of the MLFF to provide atomic resolution regarding the underlying mechanisms driving these processes.

4:00 PM DS04.06.03
Exploring Optimal Candidates for Water-Splitting Reactions in ZnTe-Based Alloys: A Machine Learning Approach using Small Dataset SeunghyunV. Oh[1], Su-HyunYoo[2] and AloysiusSoon[1]; [1]Yonsei University, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Aiming towards a sustainable-and-clean-energy era, designing efficient photocatalysts for water splitting has been an active area of research, especially pertaining to deliberate band engineering and its related properties. To discover potential candidate materials, synthesizing solid-solutions and alloys are some of the promising approaches to meet the criteria. However, the enormous possible configurations of solid-solutions and alloys hinder the experimental screening within this multidimensional materials space, and thus machine-learning (ML) approaches may accelerate the discovery of new and novel mixed material systems. A conventional prerequisite for ML approaches is a large database containing accurate properties/data of materials that will essentially require a huge amount of computing resources. In this work, we demonstrate that the screening of mixed binary alloys (up to hexanary systems) can be performed accurately and successfully by utilizing a small database. This approach allows us to minimize the number of high-level theoretical calculations with ZnTe-based alloys as a prototypical example, based on the Sure Independent Screening and Sparsifing Operator (SISSO) and the *agreement* method (-method) [1]. With this, we propose ML-designed ZnTe-based alloys as optimal candidates for water-splitting reactions.

4:15 PM *DS04.06.04

Automated Catalyst Layer Fabrication and Characterization for Faster Electrocatalyst Screening DominikDworschak[1], ThomasAckstaller[1,2], GünD. Akkoç[1,2], SimonThiele[1,2] and KarlJ. Mayrhofer[1,2]; [1]Forschungszentrum Juelich, Helmholtz Institute Erlangen-Nuremberg, Germany; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Facing the consequences of climate change, the demand for highly efficient energy solutions is increasing rapidly. Still, before large-scale use of the existing technical devices like fuel cells and electrolyzers, they still require the implementation of new materials and components making them more efficient and less expensive. However, the pace of the innovation chain is a huge technical barrier for the commercial implementation of innovative materials and components in technical devices. While related research fields as batteries[1] and printable photovoltaics[2] are already using fully automated laboratories for accelerated materials screening, a comprehensive infrastructure for electrocatalysis is still missing.
Here we show how we apply the concept of an automated research platform on electrocatalysis research. In a high-throughput manner we can fabricate and characterize catalyst layers. Starting with catalyst powder, solvents and ionomers, the setup is capable to produce and characterize catalyst inks and subsequently fabricate catalyst layers on substrates. Those get electrochemically characterized with a robot-mounted flow cell. Besides activity from electrochemistry we as well track stability by downstream degradation analysis with ICP-MS. Application of robots not only increases the amount of tested samples but also repeatability. A structured data aquisition along the workflow further enables the later use of machine learning algorithms.
Showcased on acidic oxygen evolution reaction (OER) the system can be widely applied for other ink-based electrocatalytic reactions. Our automated, high-throughput approach is an important step towards self-driving laboratories for accelerated electrocatalysis research.

The "Materials Genes" of Catalysis Identified via AI LucasFoppa[1,2] and MatthiasScheffler[1,2]; [1]Fritz-Haber-Institut der Max-Planck-Gesellschaft, Germany; [2]Humboldt-Universität zu Berlin, Germany

The performance in heterogeneous catalysis is an example of a materials function governed by an intricate interplay of multiple underlying processes, such as the surface reaction networks, the material restructuring under the reaction, and the transport of reactants and products. In this talk, the combination of experimental and theoretical data with artificial intelligence (AI) is presented as an approach to model catalysis and determine the key physicochemical descriptive parameters ("materials genes") reflecting the processes that trigger, facilitate, or hinder the materials performance.[1] The symbolic regression and subgroup discovery AI approaches leverage the small number of materials that can be accessed experimentally and identify nonlinear correlations that can be exploited for the design of materials with statistically exceptional performance.

Unraveling the Mechanisms of Stability in $Co_xMo_{70-x}Fe_{10}Ni_{10}Cu_{10}$ High Entropy Alloys via Physically Interpretable Graph Neural Networks MiguelTenorio and JamesChapman; Boston University, United States

In recent years high entropy alloys (HEA) have become a topic of significant interest due to their combinatorial nature, showing promise for hypersonics and catalysts. In particular, the HEA system $Co_xMo_{70-x}Fe_{10}Ni_{10}Cu_{10}$ has been studied experimentally and computationally due to its reported superiority as a catalyst for ammonia decomposition. However, such catalytic reactions take place at elevated temperatures, leading to potential HEA instability and eventual phase separation at catalytically active temperatures. To this end, we combine density functional theory (DFT) calculations of mixing free energies, that include mixing and vibrational entropy terms, with physics-inspired graph neural networks (GNN) and consider binary ($A \leftrightarrow B + C$), ternary and quaternary decomposition routes. We show that by learning the mixing free energy with our GNN framework we can rank geometric and chemical HEA features to better understand which features are more important than others at stabilizing HEA stability at catalytically active temperatures.

8:00 PM DS04.07.02
Autoencoder Based on Graph and Recurrent Neural Networks and Application to Property Prediction AkihiroKishimoto, HiroshiKajino, IndraPriyadarsini S, HajimeShinohara, DaijuNakano and SeijiTakeda; IBM Research - Tokyo, Japan

Machine learning has been applied to various subjects in material science, including property prediction and molecular structure generation. Successful machine learning models can lead to discovering promising materials more quickly. However, a challenge remains on automatically acquiring features that can effectively represent materials.

An autoencoder attempts to learn an effective representation in a so-called latent space and has been applied to learn for molecular structures. Given a molecular structure as input, the encoder of the autoencoder encodes its input into a vector in the latent space called a latent vector. The decoder of the autoencoder decodes that latent vector back to the original molecular structure. The autoencoder has a potential to be able to learn features as latent vectors even without labeled training data.

Molecular Hypergraph Grammar Variational Auto-Encoder (MHG-VAE) consists of an encoder and a decoder based on recurrent neural networks combined with molecular hypergraph grammar. While MHG-VAE can additionally ensure structural validity of decoded molecules, it suffers from a drawback that new molecular structures cannot always be encoded. MHG-VAE, therefore, has a limited applicability to address downstream tasks on new molecules, when their features need to be represented as the latent vectors of MHG-VAE.

We introduce a new autoencoder that can always encode any molecular structure. Our autoencoder achieves this advantage by replacing the encoder of MHG-VAE with a graph neural network. Our autoencoder inherits all the other advantages of MHG-VAE including the structural validity of the decoder.

We have trained an autoencoder model with a large set of molecules available at the PubChem database. We have also trained a prediction model that receives the latent space of the autoencoder model as input to perform a prediction of a material property. We show that such a downstream task can have molecules that cannot be encoded by MHG-VAE. Additionally, our prediction model outperforms MHG-VAE even if the training and test datasets are restricted to the molecules encoded by MHG-VAE.

8:00 PM DS04.07.03
Chemical State Analysis Assisted Combinatorial Exploration of New Phase Spaces: Application to Ternary Zn-M-N Nitrides and Synthesis of Wurtzite Zn_2TaN_3. SiarheiZhuk[1], AlexanderWieczorek[1], AmitSharma[2], JyotishPatidar[1], KerstinThorwarth[1], JohannMichler[2] and SebastianSiol[1]; [1]Empa-Swiss Federal Institute of Materials Science and Technology, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The experimental realization of predicted functional materials is a key challenges in the development of new technologies.[1] Combinatorial high-throughput approaches using reactive sputtering and automated analysis are commonly employed to screen unexplored phase spaces.[1,2] Especially, when synthesizing new materials in complex phase spaces results from a conventional structural phase screening can be ambiguous.

In this presentation, we show how chemical state analysis based on X-ray photoelectron spectroscopy can complement conventional high-throughput workflows. Specifically, we highlight how studies based on the Auger parameter are ideally suited to probe the local chemical state and coordination in insulating or semiconducting materials. Firstly, the Auger parameter is insensitive to charging and erroneous calibration of the instrument.[3,4] Secondly, the analysis typically does not require multi-component peak fitting, which facilitates high-throughput

workflows.[4]

As a proof of concept, we perform a combinatorial screening of the Zn-Ta-N phase space with the aim to synthesize the novel semiconductor Zn_2TaN_3. While the results of the XRD phase screening are inconclusive, including chemical state analysis mapping in our workflow allows us to see a very clear discontinuity in the evolution of the Ta Auger parameter. This is indicative of a change in the Ta oxidation state and coordination and consequently confirms the formation of the phase of interest. In additional experiments, we then isolate the material and perform a detailed characterization confirming the formation of single phase WZ-Zn_2TaN_3.[5] Besides the formation of the new ternary nitride, we map the functional properties of $Zn_xTa_{1-x}N$ and report previously unreported clean chemical state analysis for Zn_3N_2, TaN and Zn_2TaN_3.

Overall, the results of this study showcase common challenges in high-throughput materials screening and highlight the merit of employing characterization techniques sensitive towards changes in the materials' short-range order and chemical state. The workflows and concepts described in this presentation are applicable to many different energy materials and can be applied using standard XPS equipment.

8:00 PM DS04.07.04
Data-Driven Doping for Semiconductors: Identifying Top Dopant Candidates for Complex Crystals JiwooLee[1], AnthonyOnwuli[2], KeithT. Butler[2] and AronWalsh[2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

Stoichiometric crystals, while often insulators, pose a challenge for technological applications that require excess electrons (n-type) or holes (p-type) through p-n junctions. Complex crystals, such as ternary and quaternary systems, offer numerous dopant possibilities, making it difficult to determine the optimal substituting element. This research utilizes a data-driven approach to identify the top 10 potential dopants for multicomponent materials.

Our "doper" code utilizes chemical similarity metrics based on structure analysis and machine-learned representations. It generates n-type p-type cation and anion potential dopants based on the input species of multicomponent materials. We validate our approach using density functional theory (DFT) calculations, considering solubility energy and defect levels. Our methodology is implemented within the Semiconducting Materials from Analogy and Chemical Theory (SMACT) framework, which offers rapid screening tools based on chemical element data.

Our results demonstrate a strong correlation between the data-driven top dopant candidates generated by "doper" and DFT calculations. This validates the efficacy of our approach in identifying promising dopant elements for semiconductors. By leveraging machine learning and structure analysis, our data-driven technique accelerates materials discovery and optimization, significantly reducing time and cost in dopant selection.

8:00 PM DS04.07.05
Optimizing Active Learning in Materials Discovery Through a Holistic Pruning Strategy for NN-based Agents WeikeYe, XiangyunLei and AmalieTrewartha; Toyota Research Insitute, United States

During a closed-loop materials discovery process, a surrogate model is often used to form hypotheses about which new regions of parameter space to explore, and then more expensive experiments or higher-fidelity computations are performed to confirm or deny these hypotheses. The relatively high cost of re-training/fine-tuning surrogate models as high-fidelity data is acquired leads to a trade-off between accuracy and computational cost, which can in practice limit the ability to deploy state-of-the-art neural networks as surrogate models. In this work, we first propose a holistic pruning technique based on the Lottery Ticket Hypothesis that allows for structure optimization of neural networks (NN). We demonstrate that, for both fully connected NNs and graph-based convolutional NNs, we can find sparse sub-nets of the original models that can be trained faster to achieve commensurate or better accuracy and better generalizability with ~ 70 % or fewer weights. Subsequently, we combine the pruning technique with active learning frameworks for materials discovery to show that the additional pruning step reduces the total iterations required to locate all desired samples by up to 20% and decreases the retraining time of the NN-based agent by up to 40% in each iteration. We believe this acceleration allows for more rapid exploration of the parameter space, leading to faster identification and validation of new materials.

8:00 PM DS04.07.06
Hydrogen Absorption and Diffusion in High Entropy Alloys: Insights from DFT and Machine Learning VladislavKorostelev and KonstantinKlyukin; Auburn University, United States

The emergence of hydrogen as a promising clean energy source has underscored the critical need for the development of advanced alloys that can efficiently store this valuable resource. However, the presence of hydrogen also poses challenges, particularly in the form of hydrogen embrittlement, which can compromise the structural integrity of alloys. As a result, there is a pressing demand for the exploration and design of new alloys that not only enable efficient hydrogen storage but also exhibit enhanced resistance to the detrimental effects of hydrogen. In order to simultaneously address the challenges of efficient hydrogen storage and resistance to hydrogen embrittlement, we have embarked on the development of a comprehensive model with the capability to predict hydrogen solubility and diffusivity.
The focus of our research lies in unraveling the atomistic factors that dictate hydrogen's interactions in high entropy alloys (HEAs) and investigating the underlying descriptors that influence its absorption and diffusion processes. Our ultimate objective is to construct an interpretable machine learning model that can accurately predict hydrogen absorption energy and diffusion rates, utilizing local physical descriptors associated with each interstitial site.
To achieve this, we used Density Functional Theory (DFT) to calculate hydrogen absorption energies for over 1000 unique octahedral, tetrahedral and triangular interstitial sites within 12 HEAs. Subsequently, we performed calculations to determine the relevant local environment descriptors, which encompassed a comprehensive analysis of electronic structure features such as the d-band center. Additionally, we investigated structural descriptors, including interstitial pore volume, and examined the dynamical structure of the lattice atoms through an analysis of the phonon structure.
To build an actual model, we used the sure-independence-screening-and-sparsifying-operator (SISSO) machine learning algorithm. This allowed us to develop physics-based model that accurately predict hydrogen absorption energy across various metallic systems. By identifying the key descriptors governing hydrogen absorption in HEAs, our models enable accelerated screening of potential compositions with optimal hydrogen solubility and diffusivity properties.
During the presentation, we will discuss the key descriptors, which have a profound impact on hydrogen absorption and diffusion. Additionally, we will present the performance of our model on previously unseen HEAs and other metallic systems, including intermetallic compounds.

8:00 PM DS04.07.07
A Convergence of Fast Sintering, Grain Growth Analysis, High Throughput Measurements, and Data Driven Computer Models to Develop New Solid-State Sodium-Ion Battery Materials MichaelThuis[1], SeyedArefpour[2], BrysonClifford[2], SufendLiu[2], RamanujaSaravanan[2], ShuoWang[2], AliciaKoenig[3], ChrisMarvel[3], MartinHarmer[3], LiangbingHu[2], YifeiMo[2] and SossinaM. Haile[1]; [1]Northwestern University, United States; [2]University of Maryland, United States; [3]Lehigh University, United States

Rapidly increasing demand for electric vehicles is straining the supply of battery materials. This need could be met with improved batteries using solid-state electrolytes and alternative battery chemistries. The ADDD-Ions collaborative project is working to combine high throughput electrochemical measurements and data analysis with computational models to predict and develop new sodium-ion solid-state battery materials, in particular electrolytes. These methods are paired with an ultra-fast high-temperature synthesis (UHS) method allowing access to previously theoretical structures with simplified manufacturing steps. Scanning transmission electron microscopy (STEM) analysis is used to understand the unique grain growth and microstructure of these materials under fast sintering conditions. Bulk pellets are made using traditional and UHS methods to compare processing effects on the properties of solid-state electrolytes. Thin film samples are used to probe the chemical compositional and structure effects on the ionic conductivity of these materials.

8:00 PM DS04.07.08
A Unified Theory Quantifying How Lattice Dynamics Facilitate Proton Transport in Various Ternary-Oxide Phases HeejungW. Chung, PjotrsZguns, JuLi and BilgeYildiz; Massachusetts Institute of Technology, United States

Understanding the lattice dynamics of proton-conducting metal oxides is important for many applications, from optimizing hydrogen production to designing low-power neuromorphic-computing devices. Transport mechanisms in metal oxides are well-studied [1], so we know that protons stay localized to oxygens and hop between neighboring O…O pairs; the energy barrier of hopping is lower for pairs separated by shorter distances.

However, studies considering lattice dynamics are usually limited to simple perovskites, and phonons are only used to estimate attempt frequencies [2]. Others only treat phonons implicitly by correlating energy barrier with coarse quantities like unit-cell volume [3]. Recent work from our research groups has found phonon-based descriptors for proton-conduction in solid acids, which contain hydrogen in their nominal structures [4]. However, studying metal oxides requires a different approach, since the conduction pathways and proton sites within the lattice differ from those in solid acids.

Here, we developed a more general theory describing how lattice dynamics affect proton-transport energy-barriers in a variety of ternary oxides. In particular, we focused on phonon modes which bring neighboring O…O pairs closer together, thereby lowering the associated energy barrier. Lower-frequency modes, which are more accessible at lower temperatures, are more suitable for assisting proton transport. Following this principle, we formulated descriptors like thermal relative displacement between O…O pairs. We interpreted these descriptors by extracting the dominant phonon modes, and we found that they align well with the literature for systems like the perovskite, $BaZrO_3$. In order to validate this principle more broadly, we aim to correlate phonon-based descriptors with calculated energy barriers for emerging phases like brownmillerite and Ruddlesden-Popper. Although energy barriers are most commonly estimated using nudged-elastic-band, we are evaluating whether these static calculations sufficiently capture lattice flexibility, or whether dynamic simulations are required.

Developing these descriptors and analyzing the dominant modes will enhance our understanding of proton transport. This will enable various downstream applications, such as physically interpretable, high-throughput virtual screening and data generation. Building on prior high-throughput studies [4, 5], we can first pull oxides from a database, then expand the pool of candidates using elemental substitution and doping. Phonon-based descriptors can then be included in a suite of filters which help identify the most promising proton conductors. Given a large enough design space, active learning can also be employed to intelligently select candidates for more thorough calculations.

Machine Learning Prediction of Heat Capacity for Solid Mixtures of Pseudo-Binary Oxides JuliánBarra[1], SimoneAudesse[1], RajniChahal[2] and StephenLam[1]; [1]University of Massachusetts Lowell, United States; [2]Oak Ridge National Laboratory, United States

Direct resistance-heated thermal energy storage in firebricks has been proposed as a low-cost energy storage alternative that could improve the economics of carbon-free electricity generation through both renewable and nuclear energy sources. The bricks used in these energy storage systems must be composed of oxide mixtures with specific material properties, amongst them a high heat capacity. While there are many methods available for the prediction of heat capacity in oxide mixtures, they all face different problems, with the Neumann-Kopp rule underperforming at higher temperatures and computational methods such as CALPHAD and Density Functional Theory being computationally expensive. Machine Learning algorithms have already shown promise in applications to predict the heat capacity of pure solid inorganics and could be used as a less computationally-demanding tool for the prediction of this property in pseudo-binary oxide mixtures, with the main impediment to its use being the unavailability of a heat capacity database for oxide mixtures. For this work, we use the CALPHAD software Thermo-Calc and its TCOX11 database of oxide Gibbs Free Energy functions obtained by approximation of empirical data in order to to generate a molar heat capacity dataset for pseudo-binary oxide mixtures at different temperatures and percentage compositions, and then use this dataset to train and test Machine Learning algorithms to predict molar heat capacity, using descriptors obtained from publically available DFT result repositories. By this process, we obtain algorithms capable of predicting heat capacity, some of them with an r^2 over 0.98, a MAE under 0.2 J/(molK) and a MAPE under 0.7%.

8:00 PM DS04.07.10
An Artificial Intelligence's Interpretation of Complex High-Resolution *In Situ* Transmission Electron Microscopy DataXingzhiWang[1,2], ChangYan[1,2,3], JustinOndry[1,4,5], PeterErcius[2] and PaulAlivisatos[1,2,5]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Shanghai Jiao Tong University, China; [4]Kavli Energy NanoScience Institute, United States; [5]The University of Chicago, United States

In situ transmission electron microscopy (TEM) has enabled researchers to visualize complicated nano- and atomic-scale processes with sub-Angstrom spatial resolution and millisecond time resolution. These processes are often highly dynamical and can be time-consuming to analyze and interpret. Here, we report how variational autoencoders (VAEs), a deep learning algorithm, can provide an artificial intelligences interpretation of high-resolution *in situ* TEM data by condensing and deconvoluting complicated atomic-scale dynamics into a latent space with reduced dimensionality. In this work, we designed a VAEs model with high latent dimensions capable of deconvoluting information from complex high-resolution TEM data. We demonstrate how this model with high latent dimensions trained on atomically resolved TEM images of lead sulfide (PbS) nanocrystals is able to capture movements and perturbations of periodic lattices in both simulated and real *in situ* TEM data. The VAEs model shows capability of detecting and deconvoluting dynamical nanoscale physical processes, such as the rotation of crystal lattices and intraparticle ripening during the annealing of semiconductor nanocrystals. With the help of the VAEs model, we can identify an *in situ* observation that can serve as a direct experimental evidence of the existence of intraparticle ripening. The VAEs model provides a potent tool for facilitating the analysis and interpretation of complex *in situ* TEM data as a part of an autonomous experimental workflow.

8:00 PM DS04.07.11
A Transformer Based Large-Scale Molecular Representation Model IndraPriyadarsini S, SeijiTakeda, AkihiroKishimoto, HajimeShinohara and DaijuNakano; IBM Research - Tokyo, Japan

Large scale molecular representation methods have shown to be useful in several applications and areas of material science including virtual screening, drug discovery, chemical modeling, material design and molecular dynamics simulation. These representations prove to provide both effective and efficient analysis of molecular data. With the advancements in deep learning, several models have been developed to learn the representations directly from the molecular structures. Recently, transformer based molecular representations have gained significant importance in the field of material informatics. The importance of transformer-based molecular representation continues to grow as researchers explore their potential in advancing drug discovery, materials science, and other areas of molecular research.

In this study, we develop one such transformer-based model that is capable of capturing complex relationships and interactions within molecules. While most of the existing works focus on only capturing the representations through encoder-only models, we present an encoder-decoder model based on BART (Bidirectional and Auto-Regressive Transformers) that is not only capable of efficiently learning the molecular representations but also auto-regressively generate molecules from the representations. This can prove to be highly impactful especially in cases of new molecule design and generation, enabling efficient and effective analysis and manipulation of the molecular data.

The model is trained on a dataset of 10 billion molecules from the publicly available ZINC-22 database, rendering it the most extensive training dataset employed to date. The dataset is encoded to SELFIES (SELF-referencing Embedded Strings) representation as SELFIES provides a more concise and interpretable representation, making it suitable for machine learning applications where compactness and generalization are important. The encoded SELFIES are then tokenized using an efficient tokenization scheme with masking in order to improve generalizability. We show that the learned molecular representation outperforms existing baselines on downstream tasks, thus validating the efficacy of the large pre-trained model.

8:00 PM DS04.07.12
Statistical and Machine-Learning-Based Durability-Testing Strategies for Energy Storage MaherAlghalayini, MarcusM. Noack and StephenJ. Harris; Lawrence Berkeley National Lab, United States

As the global climate is heating up at accelerated rates, human civilization is turning away from fossil fuels to renewable energy sources. While abundant, wind, solar, and water power are intermittent, motivating investment in long-duration energy storage technology research. The grand vision is to predict circa 20 years of energy-storage cycling behavior with less than one year of new testing data. On the other hand, machine learning and artificial intelligence are revolutionizing most aspects of science and engineering, but adopting those advancements has been slow in the energy-storage community. The reasons are the expense of battery testing and the associated sparsity of datasets, the need to extrapolate instead of interpolating, the inherent stochasticity of the problem, and the deep connection between failure mechanisms and physical and chemical processes. All of this causes a purely data-driven approach to be suboptimal. Herein we propose a new customization of a Gaussian Process for stochastic, domain-knowledge-informed energy storage-failure-distribution prediction. For that, we equip the Gaussian

Process with tailored prior mean and kernel functions to give it the ability to use experts' domain knowledge of candidate failure mechanisms to extrapolate into the future while minimizing the amount of required data. Our results show that our method can, in fact, approximate failure distributions early in the testing process. In short, this work provides the basis for revolutionizing energy storage testing and discovering new technologies for energy storage systems.

8:00 PM DS04.07.13
Achieving Low-Thermal Conductivity with Inverse-Designed Nanostructures GiuseppeRomano; Massachusetts Institute of Technology, United States

Tuning thermal transport in nanostructures is currently done with try-and-error; while established concepts, such as phonon bottlenecks [1], may help identify promising structures, the majority of the configuration space is often left unexplored. To fill this gap, we recently introduced a framework [2] based on the adjoint gray phonon Boltzmann transport equation (BTE) to perform systematic topology optimization for nanoscale heat transport applications. In this talk, we will describe our recent efforts in extending our framework to the mode-resolved BTE, enabling a direct comparison with experiments. Our approach is based on the adjoint method and differentiable programming, which enables a fast experimentation with various objective functions. The code is implemented in the open-source code OpenBTE [3]. Length scale constraints are also included in the optimization framework, thus the optimized structures adhere to the specification of a given foundry. Several examples will be showcased, including tuning the anisotropic thermal conductivity tensor and maximizing phonon size effects. The talk will conclude with current efforts in fabricating the optimized structures.

Self-Driving Laboratories for Organic Flow Batteries AlanAspuru-Guzik[1,2]; [1]University of Toronto, Canada; [2]Vector Institute, Canada

In this talk, I will discuss the progress of my research group at the University of Toronto in developing technology for the accelerated discovery of molecules for organic flow batteries. This work includes efforts towards automating the synthesis and characterization of these compounds, as well as AI-driven molecular design.

9:00 AM DS04.08.02
An Integrated High-Throughput Robotic Platform and Active Learning Approach to Accelerate Electrolytes Discovery YangangLiang[1], JuranNoh[1], HieuA. Doan[2], HeatherJob[1], LilyA. Robertson[2], LuZhang[2], RajeevSurendran Assary[2], KarlMueller[1] and VijayakumarMurugesan[1]; [1]Pacific Northwest National Laboratory, United States; [2]Argonne National Laboratory, United States

Solubility is an essential physiochemical property of redox-active molecules and closely associated with the energy density of redox flow batteries. However, the lack of large-scale and high-fidelity experimental solubility databases limits the potential application of data-driven approaches to accelerate electrolyte materials discovery. Here, we describe a highly efficient and robust automated workflow that combines a high-throughput experimentation platform with active learning to optimize the solubility of redox active molecules in organic solvent systems. We successfully demonstrate this platform by identifying several solvents that yield high solubility (> 6 M) of a model redox active molecule, 2,1,3-benzothiadiazole, among 2,101 solvent candidates. More significantly, our combined approach only requires solubility measurement of less than 10% (~200) of the solvent candidates. Our findings indicate that binary solvent mixtures based on 1,4-dioxane significantly enhance the solubility of 2,1,3-benzothiadiazole, providing promising prospects for high-energy density redox flow battery applications. While this work focuses on flow battery solvent formulation, our AI-guided high-throughput robotic platform can be used as a versatile tool for discovering energy materials with desired properties in a cost-effective and efficient manner.

Predictive Supremacy of Chemical Foundational Model for Battery Electrolytes VidushiSharma, EduardoA. Soares, EmilioV. Brazil, YoungH. Na and RenatoCerqueira; IBM, United States

Electrolytes are a critical design black-box for batteries that aspects all major performance metrices. Electrolyte discovery and optimization can accelerate decarbonization and has drawn major focus from across all economic sectors. Consequently, electrolyte formulations are now guarded trade secrets of battery companies that are rarely shared publicly, making electrolyte data landscape scarce for AI-driven discovery. The most challenging aspect of development of battery electrolytes is their non-generalizability. There exist several major battery chemistries in research stages that require unique concoction of solvent-salt systems with special attention to underlying phenomenons such as lithium solvation, surface reactions and self-discharge. These challenges of limited data and non-generalizability can be overcome with large transformers-based foundation models that have mastered extraction of molecular information in a self-supervised manner of learning from extensive unlabeled corpora. MoLFormer, a chemical large language model, has learned chemical and physical panorama of over 1 billion molecules from simple extractable chemical representations such as SMILES strings. As the result, MoLFormer's reliance on labeled data for downstream task is significantly reduced. In present work, we demonstrate the predictive capabilities of a customized MolFormer model for battery electrolytes with a mere 140 electrolyte formulations datapoints. Gathering electrolyte formulations vs battery performance data from experimental process is a challenging endeavor. The proposed model predicts battery performance metrices such as coulombic efficiency and specific capacity based on 2 separate electrolyte formulation datasets with best accuracies among all the known machine learning models that simultaneously map structure and composition of formulation constituents. The potential of foundation models in designing mixed material systems such as liquid battery electrolytes present a groundbreaking opportunity to accelerate the discovery and optimization of new formulations across various industries.

9:30 AM DS04.08.04
Accelerating Battery Organic Materials Discovery Dong YoungKim, SeulwooKim, Seung BumSuh, SoojinKim, JitenSingh, SunminLee, Dong-HeeYeon, Seok JoonYoon and Gi-HeonKim; Samsung SDI, Korea (the Republic of)

The increasing energy storage capacity of next-generation materials for Li-ion batteries underscores the crucial role of organic electrolyte materials in suppressing degradation and enhancing performance of the systems, highlighting the criticality of electrolyte materiel development. Recently, the material development paradigm has been changing into employing automation, data, and deep learning. However, in the case of organic electrolyte materials, it is arduous to define and model multifaceted behaviors, let alone computational automation to extract features, due to complex interplay of various physicochemical properties of electrolyte materials such as ion transport in a solvation state, interaction between electrode and electrolyte components, and formation and evolution of interfaces. Organic molecules have inherently enormous chemical diversity, making it more difficult to develop hypotheses related to the function of electrolyte materials. While there have been attempts to apply data-driven methodologies for developing organic electrolyte materials in batteries, most previous studies have described models for the complex behavior of electrolytes with simple chemical properties in a single molecular state, and there have been no reports of building intermolecular relational databases.
This presentation provides a pioneering framework for accelerating the discovery of battery organic materials by establishing the first-ever intermolecular relational database. For organic electrolyte materials that are difficult to understand due to their multifaceted behavior, more than 10 material design factors based on systematic operating mechanisms were quantified using density functional theory (DFT) modeling. These design factors define crucial functions of electrolyte materials such as behavior at the interface and electrolyte stabilization, and were verified using representative electrolyte materials with known functionalities, including commercially used electrolyte materials. We have developed python-based automation program AUTOMOL that encompasses the entire process from SMILES (Simplified Molecular Input Line Entry System) input to database construction, including molecular modeling of intermolecular interactions. The AUTOMOL-DB of thousands of organic material has been established by high-performance computing whereby conducting practical material development. This study is worthwhile due to the scarcity of automated modeling processes for intermolecular interactions, and thus, the exclusive database that includes molecular interactions with hydrogen, proton, cation, anion, radical, and small molecule, is invaluable as a source that can be extended to applications in chemical, biological, medical, functional molecular and nanomaterial research. It also developed a web-based system that integrates all design factors of the database so that material data can be searched, selected, and analyzed. The AUTOMOL-DB web system provides all researchers at our R&D center with a new approach to enhancing research horizons with insight into development while understanding the location of electrolyte materials in the big data space of organic matter. This system serves as a navigator for electrolyte material excavation as well as accelerate material discovery. In addition, in order to overcome the inherent disadvantage in computational cost and minimize the intervention of human intuition, state-of-the-art machine learning technology that predicts design factors and generates target materials in

real time is being applied to our workflow.

9:45 AM DS04.08.05
Beyond Words and Numbers: Pioneering Sodium-Ion Battery Advancements with NLP and Cost Modeling Synergy MrigiMunjal[1], ThorbenPrein[2], MahmoudRamadan[1], HughSmith[1], VineethVenugopal[1], JenniferL. Rupp[2], IwnetimI. Abate[1], KevinHuang[1] and ElsaOlivetti[1]; [1]Massachusetts Institute of Technology, United States; [2]Technische Universität München, Germany

Sodium-ion batteries (SIBs) have been increasingly gaining attention for applications like grid-scale energy storage, largely owing to the abundance of sodium and an expected favorable $/kWh figure. Consequently, the published literature in this field has been increasing exponentially, making it difficult for researchers to keep up with the latest developments and challenges. Improving the performance of SIB electrode materials will enable these batteries to compete with mature technologies like lithium-ion batteries (LIBs) at scale. SIBs can leverage the well-established manufacturing infrastructure knowledge of LIBs, but several materials and synthesis-based challenges for electrode materials need to be addressed for SIBs to mature from lab to market scale. This work aims to extract challenges in the performance and synthesis of SIB Cathode Active Materials (CAMs) and systematically review corresponding mitigation strategies from a combination of SIB and related LIB literature employing custom Natural Language Processing (NLP) tools. Finally, selected mitigation strategies are evaluated using a process-based cost model. This approach facilitates the generation of quantitative insights and enables a unique comparison among a broad set of existing lab-proposed mitigation strategies. These derived insights enable researchers and industry to navigate a large number of proposed strategies and focus on impactful mitigation strategies to accelerate the transition between laboratory-scale research and market-scale implementation.

Data-Driven Research for Aqueous Organic Redox Flow Batteries WeiWang, YangangLiang, EmilySaldanha, VijayakumarMurugesan, AaronHollas, HeatherJob and WillDean; Pacific Northwest National Laboratory, United States

Aqueous organic redox active materials have recently shown great promise as alternatives to transition metal ions as energy-bearing active materials in redox flow batteries for large-scale energy storage due to their structural tunability, cost-effectiveness, availability, and safety features. However, development to date has been limited to a small palette of aqueous soluble organics. This presentation will provide an overview of a data-driven approach to accelerate the discovery and development of aqueous organic redox-active molecules for flow batteries, including database curation, structure-property correlation, and automated property characterization and performance testing.

Data-Driven Understanding of Battery Formation and Lifetime Prediction XiaoCui[1], ShijingSun[2] and William C.Chueh[1]; [1]Stanford University, United States; [2]Toyota Research Institute, United States

Formation plays a critical role in battery manufacturing as it significantly impacts the quality of the solid electrolyte interface (SEI) formed, which in turn affects battery performance. However, formation can be time-consuming, costly, and difficult to optimize. In this study, a dataset comprising 150 cells, 50 different formation protocols, and 6 formation parameters was generated. The results reveal a wide range of battery lifetime based on different formation conditions. Interpretable machine learning is used to systematically study the contribution of formation parameters to battery performance. Furthermore, since cycling aging is kept the same for all the cells, the value of using this dataset for feature testing is discussed, along with an investigation into the predictive origin of the dominant features. We highlight the multi-purpose of this dataset for both Bayesian optimization and feature testing.

11:15 AM DS04.08.08
Battery Lifetime Predictions: Information Leakage from Biased Training AlexisGeslin[1,2], Bruisvan Vlijmen[1,2], XiaoCui[1,2], ArjunBhargava[3], PatrickAsinger[4], RichardBraatz[4] and William C.Chueh[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Toyota Research Institute, United States; [4]Massachusetts Institute of Technology, United States

Data-driven models are being developed to predict battery lifetime because of their ability to capture complex aging phenomena. In this work, we demonstrate that it is critical to consider the use cases when developing prediction models. Specifically, model features need to be classified to differentiate whether or not they encode cycling conditions, which are sometimes used to artificially increase the diversity in battery lifetime. Many use cases require the prediction of cell-to-cell variability between identically cycled cells, such as production quality control. Developing models for such prediction tasks thus requires features that are blind to cycling conditions. Using the dataset published by Severson et al. in 2019 as an example, we show that features encoding cycling conditions boost model accuracy because they predict the protocol-to-protocol variability. However, models based on these features are less transferable when deployed on identically cycled cells. Our analysis underscores the concept of using the right features for the right prediction task. We encourage researchers to consider the usage scenarios they are developing models for, and whether or not to include features encoding cycling conditions in order to avoid data leakage. Equally important, benchmarking model performance should be carried out between models developed for the same use case

11:30 AM DS04.08.09
Data-Driven Optimization of Polymer Electrolytes for High-Performance Solid-State Li-Ion Batteries ChuhongWang, SiwenWang and LingChen; Toyota Research Institute of North America, United States

High-performance polymer electrolytes are of paramount importance for advancing solid-state batteries due to the advantages such as high chemical stability and enhanced safety. In addition, the desirable flexural strength of polymer electrolyte offers the effective strategy to mitigate the effect of vast volume variation of Si anodes during electrochemical operations. However, the ionic conductivity of most polymer electrolytes is at the level of 10^{-4} S/cm, about one to two orders magnitudes lower than that of typical liquid electrolytes and even ceramic solid electrolytes. The discovery of novel polymer electrolytes with improved conductivities is crucial for their implementation in battery applications. In this talk, we present a data-driven optimization approach to enable the fast screening and identification of polymer electrolytes with desirable electrochemical properties. Our method combines the molecular dynamics (MD) workflow and multi-objective Bayesian optimization to streamline the candidate selection and property evaluation process. Through the screening in the vastly large chemical space of potential polymer electrolytes, the data-driven approach discovers a series of promising candidates with the ionic conductivity reaching to the level of 10^{-3} S/cm and above. The discovery of novel polymer electrolytes through data-driven optimization paves the road for enabling the realization of high-performance solid-state Li-ion batteries and propelling the clean energy revolution forward.

11:45 AM DS04.08.10
Machine Learning Aided Screening of MXenes as Sulfur Host Cathodes for Al-S Batteries SouvikManna and BiswarupPathak; Indian Institute of Technology Indore, India

The dissolution of polysulfide intermediates into electrolytes has been a major bottleneck in the development of Al-Sulfur battery. To address this, the introduction of promising anchoring materials is highly necessary. The anchoring agents must be able to adsorb the polysulfides optimally as strong adsorption can lead to irreversible electron flow process whereas weak adsorption will result in the dissolution of polysulfides into the electrolyte. MXenes have garnered considerable interest as electrode materials in energy storage devices for their exceptional metal-like conductivity, rapid charge transfer capabilities, and remarkable surface charge accumulation. These unique properties make MXenes highly promising for applications in metal−sulfur batteries, where they can facilitate rapid charge transfer and ensure excellent electrode conductivity. Notably, properties of MXenes can be tuned according to requirements by varying the terminal groups which is quite easy during the synthesis process. In this regard, MXenes are expected to show good anchoring effect for Al-S batteries. However, identifying potential sulfur host cathode material from a large space of MXenes materials through traditional experiments or density functional theory (DFT) methods will be a very tedious job. Machine Learning (ML) tools have emerged as an efficient tool known for their ultra-fast high throughput screening potential in recent years. In this regard we propose a novel approach combining DFT and ML to monitor the anchoring capability of a large number of MXenes for possible Al-S polysulfide intermediates. Accurate DFT generated data can be utilized for the training and testing purpose of various ML models to acquire knowledge regarding the adsorption phenomena of possible polysulfides. Suitable and easily available descriptors are chosen to accurately distinguish each of the systems to ensure efficient training of ML models. An optimized ML model along with a set of suitable descriptors will enable us to explore unknown material space to identify novel and potential MXene materials for the enhancement of Al-S battery performance. Further the suitable MXenes showing optimum anchoring will be analyzed in detail to identify the role played by various components of the MXenes and factors influencing the adsorption processes. Thus, the present work paves the way forward for accelerated screening of MXenes as host cathodes for Al-S batteries as well as providing crucial insights for rational designing of materials for next-generation energy storage technologies.

Leaning Governing Relations in Battery Electrodes: Hybridizing Physics- and Data-Driven Approaches William C.Chueh; Stanford University, United States

The vast design space and long lifetime of batteries have limited the speed of innovations at the materials, cell, and systems level. In this talk, I will overview efforts at Stanford to dramatically accelerate the pace of research and development for lithium-ion batteries by hybridizing physics-based and data-driven approaches. Specifically, I will present our recent work on predicting not only battery lifetime but also aging mechanisms, which lays the foundation for transferable learnings between multiple battery chemistries. I will also showcase new methods for learning heterogeneities at the particle and electrode levels by combining multi-fidelity characterizations, physics-based modeling, and machine learning.

2:00 PM DS04.09.02
Discharge Capacity Prediction from Unstructured Cathode Material Data in Li-Ion Batteries ChangyoungPark, JaewanLee, HongjunYang, SehuiHan and WoohyungLim; LG AI Research, Korea (the Republic of)

In the process of material development such as battery materials, structured tabular data such as Excel is widely utilized to integrate data such as material information, process information, and analysis information. Recently, various machine learning techniques have been applied to analyze such structured data.1) In particular, tree-based machine learning models and deep learning models are mainly used to analyze structured data.2) Among the models, deep learning models can (1) directly process unstructured data such as cathode materials and (2) consider the relationships between interrelated features such as composition and crystal information - LiNi0.6Mn0.2Co0.2O2 and lattice constants from X-ray diffraction. In this study, we developed a deep learning model to predict the discharge capacity from data collected during the development of cathode materials, which is originally unstructured data. The features were grouped by name to consider the relationship between the features. Each groups, for example composition, were embedded into a representation, and used to predict the discharge capacity.

Reaction and Ionic Migration at the Electrode-Electrolyte Interface in Solid State Batteries from Machine Learning Molecular Dynamics JingxuanDing, YuXie, AlbertMusaelian, MenghangWang, AndersJohansson, SimonBatzner and BorisKozinsky; Harvard University, United States

Atomistic-level understanding of the chemical reactions forming the solid-electrolyte interphase (SEI) in solid-state lithium batteries has remained challenging, primarily due to the limited resolution in experimental techniques and the insufficient accuracy in large-scale simulations. In this work, we combine on-the-fly active learning based on Gaussian Process regression (FLARE) with local equivariant neural network interatomic potentials (Allegro) to construct a machine-learning force field (MLFF) to perform large-scale long-time explicit reactive simulation of a complete symmetric battery with ab initio accuracy. The MLFF is validated with experimental values of mechanical properties of bulk lithium and diffusion coefficient of solid electrolyte. For the symmetric battery, atomic descriptors are used to identify the reaction products and estimate the evolution of the SEI. We observe prominent fast reactions at the interface and characterize the dominant reaction products along with their evolution time scales. The methods in this study exhibit great potential in revealing atomistic mechanisms in complicated systems and provide insights for the development of solid-state lithium batteries.

3:30 PM DS04.09.04
Artificial Intelligence Aided In-Silico-Design of Organic Cathode Materials for Li-Ion Battery Devices RodrigoCarvalho[1], CleberMarchiori[2], DanielBrandell[1] and MoysesAraujo[2,1]; [1]Uppsala University, Sweden; [2]Karlstad University, Sweden

The organic electrode materials (OEM) are emerging as a promising alternative to develop greener and sustainable battery technologies. However, significant improvements are still required in their cycling stability, rate capability and energy density. This can only be achieved through a fundamental understanding of the electrochemistry at molecular level establishing the structure-properties relationships. To contribute to this end, we are developing methodologies based on evolutionary algorithms (EA) and artificial neural networks (ANN) at interplay with density functional theory (DFT) based calculations. The EA has initially been employed to predict the structure and electrochemistry of a set of dicarboxylates. In a second stage, we have developed a wider database of organic materials for energy applications that contains information about molecular geometries and high-level features extracted from DFT calculations. Based on this database, we have developed a machine learning approach to predict the redox potentials by giving only chemical species and molecular structures, completely by-passing the computer-demanding DFT calculations. A number of learning algorithms based on ANN have been investigated along with different molecular representations. Here we have also included a layer to predict redox-stable compounds. This machinery has been employed to screen a large organic materials library (45 million molecules) leading to the discovery of novel cathode materials[1], which is actually one of the bottlenecks on the development of organic batteries. The computational materials design platform developed here has the potential of significantly contribute to accelerate the discovery of organic electrode materials with superior properties.

[1] Rodrigo P. Carvalho, Cleber F. N. Marchiori, Daniel Brandell and C. Moyses Araujo “Artificial intelligence driven in-silico discovery of novel organic lithium-ion battery cathodes” *Energy Storage Materials* **44**, 313-325 (2022).

3:45 PM DS04.09.05
Investigation of Li-Ion Diffusion in Argyrodite Solid-State Electrolytes using Machine-Learned Potentials SuyeonJu[1], JihoLee[1], JinmuYou[1], JisuJung[1] and SeungwuHan[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute for Advanced Study, Korea (the Republic of)

Solid-state batteries incorporating solid Li-ion conductors have gained significant attention due to their advantages in safety and higher energy density compared to conventional liquid electrolyte batteries. However, these solid-state conductors inherently suffer from low ionic conductivities at room temperature, spurring investigation into diverse materials. Among them, argyrodite sulfide systems such as Li_6PS_5Cl have shown promising outcomes, achieving ionic conductivity higher than 10 mS/cm at room temperature. The high conductivities in argyrodites have been attributed to the presence of substitutional anion disorders. Yet, the precise mechanisms governing Li-ion diffusion remain unclear due to limitations in experimental analysis resolution. Theoretical investigations based on density functional theory (DFT) calculations are illuminating in this regard. However, recent DFT studies have encountered challenges in accurately quantifying diffusivities or ionic conductivities across various disorder levels, leading to substantial discrepancies with experimental results. These discrepancies mainly stem from two factors: i) the selection of semilocal exchange-correlation functionals based on the generalized-gradient approximation, which tends to overestimate lattice parameters and consequently increase conductivity, and ii) small simulation cells, which are susceptible to correlated Li-ion diffusions between periodic images and do not adequately account for the disorder of S/Cl ions. Furthermore, Li-ion jumps are rare at room temperatures, requiring simulations over an extended timescale, which is beyond the scope of current DFT calculations.
In this presentation, to overcome the aforementioned computational issues, we employ Behler-Parrinello type neural network potentials (NNPs) to obtain Li-ion conductivities in argyrodite Li_6PS_5Cl with 0−100% Cl disorder at 4c sites. Leveraging the speed and accuracy of NNPs, we estimate the Li-ion conductivity directly at room temperatures, fully considering the S/Cl disorder and ergodicity of Li distributions. Using the SIMPLE-NN package, we train the NNP with strained bulk crystals and *ab initio* MD data at 600 and 1200 K. For the exchange-correlation energy among electrons, we select the SCAN functional, which reproduces the lattice parameter within 0.2% from the experimental value. We carry out NNP MD simulations with 4×4×4 supercells, encompassing more than 3,000 atoms, up to 15 ns simulation time at 300 K. Through parameter tests on the simulation timescale and ensemble averages of initial Li distributions, we were able to minimize the statistical fluctuations in the conductivity within 0.5 mS/cm. The estimated activation energies and ionic conductivities in the presence of disorders align well with experimental data. Interestingly, Li-ion conductivity peaks at 25% Cl at 4c sites. Free energy analysis confirms that these structures are thermodynamically accessible, suggesting a method to enhance the intrinsic Li-ion conductivity in Li_6PS_5Cl by tuning the site disorder. Furthermore, we analyze the diffusion mechanisms of ordered and disordered structures, focusing on the jumps between Li-ion cages. This work paves the way for predicting and analyzing properties of disordered complex solid-state electrolyte materials using accurate and cost-effective NNPs.

Extracting Physics from Database with Systematic DFT Calculations: Intercalation Energies of Layered Intercalation Compounds with Various Ions NaotoKawaguchi,

KiyouShibata and TeruyasuMizoguchi; The University of Tokyo, Japan

Layered intercalation compounds, which have a structure in which atoms or molecules (intercalants) are inserted into the interlayer of a layered compound (host), have been extensively studied due to their characteristic physical properties and the variety of synthetic methods[1]. Their applications in energy storage have been investigated due to their ability to intercalate/de-intercalate ions, and various properties resulting from their two-dimensional nature, such as superconductivity and topological electronic states, have also been studied. In this context, we have recently reported the possibility of new graphite intercalation compounds with superconductivity and charge density states.[2] There are various combinations of intercalants and hosts in layered intercalation compounds, and it is important to control the combinations to achieve some functional development. However, a comprehensive understanding of which combinations of hosts and intercalants are stable has not been achieved.
To achieve this, we performed systematic DFT calculations for 9,024 layered intercalation compounds with a structure in which a single atom is inserted into the host changing the intercalant atom, and constructed database of their optimized crystal structures, electronic states, and intercalation energies, which is the reaction energy between the host and the intercalant.
Consequently, we revealed that the intercalation energy can be linearly regressed, using only two experimental value. The obtained equation was found to be similar to reported ones in crystalline solids with divalent metal ion[3] and metal-ligand complex.[4]
This result develops material design criteria for layered intercalation compounds and has the potential to be applied to other inorganic compounds with different structures. The details will be shown in my presentation.
This study was supported by the Ministry of Education, Culture, Sports, Science and Technology (MEXT) (Grant no. 19H00818 and 19H05787), and the special fund (Tenkai) by the Institute of Industrial Science, the University of Tokyo.

Characterizing Grain Boundary Effects on Mg^{2+} Conduction in Metal–Organic Frameworks TongtongLuo, YangWang, DunweiWang, UdayanMohanty and JunweiL. Bao; Boston College, United States

Next generation solid-state materials for fast ion conduction have the potential to revolutionize battery technology. Metal-organic frameworks (MOF) are a promising material for achieving this goal. Given their structural diversity and complexity, design of efficient MOF-based ion conductors can be accelerated by detailed understanding and quantitative prediction of ion conductivity. To this end, the chemical behavior and transport properties of an $Mg(TFSI)_2$/DME electrolyte system inside Mg-MOF-74 were studied by a combination of computational and experimental methods.The dominant minimum energy pathway (MEP) for Mg^{2+} conduction inside Mg-MOF-74 was found to be “solvent hopping” mechanism, with an energy barrier of 4.4 kcal/mol.
However, due to the polycrystalline nature of solid-state materials, specifically MOF-74 in our case, grain boundary effects need to be taken into consideration, which is complicated by challenges in grain boundary characterization, as well as modeling of ensemble transport properties. To address these issues, we developed an approach for modeling ion transport at grain boundaries and predicting their contribution to conductivity. In particular, Mg^{2+} conduction in Mg-MOF-74 thin film was studied as a representative system. Using computational techniques and guided by experimental data, we investigated the structural details of MOF grain boundary interfaces to determine accessible Mg^{2+} transport pathways. Computed transport kinetics were input into a simplified model of the MOF nanocrystal, which combined ion transport in bulk structure and at grain boundaries. The model was able to predict Mg^{2+} conductivity in MOF-74 thin film within chemical accuracy (<1 kcal/mol difference for apparent activation energy), validating our approach. The results indicate that Mg^{2+} conduction in MOF-74 is inhibited due to strong Mg^{2+} binding at grain boundaries. Only favorable alignments of the grain boundary interface allow for fast Mg^{2+} transport through MOF and contribute notably to ion conductivity. The relative scarcity (~0.1% frequency) of these favorable alignments results in a reduction of conductivity by 2-3 orders of magnitude, illustrating the large impact of the grain boundary contribution. Grain boundary structure and its interaction with ions are critical for a molecular-level understanding of solid-state ion transport and quantitative prediction of conductivity.
Our work provides a computation-aided synergistic platform for quantifying the role of grain boundaries in mediating ion transport, which can serve as a complementary characterization tool for the solid-state ion conductor community and providing insights for MOFs’ application in Mg battery area.

Leveraging Community Knowledge in Machine Learning Models to Accelerate the Discovery of New MOF Catalysts and Materials HeatherJ. Kulik; Massachusetts Institute of Technology, United States

I will discuss our efforts to use machine learning (ML) to accelerate the computational tailoring and design of metal-organic framework (MOF) materials for catalysis as well as gas separations and storage. One limitation in a challenging materials space such as open shell transition metal chemistry present in the open metal sites of most catalytically active MOFs is that ML models and ML-accelerated high-throughput screening traditionally rely on density functional theory (DFT) for data generation, but DFT is both computationally demanding and prone to errors that limit its accuracy in predicting new MOFs. I will describe how we have curated a dataset of thousands of MOFs that have been experimentally synthesized and used this data to train ML models to predict experimentally reported measures of stability. These models are able to predict experimental thermal stability and activation stability, which would be extremely difficult to predict using computational modeling. I will describe how we have leveraged these models to then screen for mechanically stable materials as well as stable catalysts in the direct conversion of methane to methanol. I will also describe how we have used these models to accelerate the discovery of novel stable MOFs, creating a dataset of transition metal complexes enriched with stability and diversity 1-2 orders of magnitude beyond what is typically included in most hypothetical MOF datasets.

Machine-Learning-Based Solvent-Antisolvent Screening for Tin-Based Perovskite Solar Cells Noor Titan PutriHartono, MahmoudHussein, ShengnanZuo, ChiaraFrasca, GuixiangLi, ZafarIqbal and AntonioAbate; Helmholtz-Zentrum Berlin, Germany

All perovskite solar cells (PSCs) with an efficiency beyond 20% contain lead, which is bioavailable and toxic, posing a high risk for health and safety and becoming a highly-debatable issue within PSCs research field, industry, and regulator. The alternative to lead-based PSCs, tin-based PSCs, have several advantages: (1) they are less bioavailable, which lower the risk for environment in the case of leakage, and (2) they have a more optimum bandgap, which increase the theoretical maximum power conversion efficiency. However, the progress of tin-based PSCs efficiency is still lagging behind lead-based PSCs, mainly because it is challenging to minimize Sn^{2+} oxidation and control the crystallization dynamics during fabrication. On top of that, DMSO, the commonly used solvent for tin-based PSC precursors is known to oxidize the Sn^{2+}, causing defects, which hamper performance (https://doi.org/10.1002/chem.202103919). Finding an alternative solvent-antisolvent pair to improve crystallization dynamics and reduce Sn^{2+} oxidation is important but challenging because of the large number of possible solvents, and understanding which properties of solvent-antisolvent pairs lead to formation of thin film is not straightforward. In this study, we screen 14 solvents and 73 antisolvents, totaling to 1,022 pairs of solvent-antisolvent in the vials screening of formamdinium tin iodide perovskite solution, and select 6 solvents and 73 antisolvents for the thin-films screening. We automate the data processing using the solution and thin film color, and develop a machine learning algorithm for the thin-film color prediction. We also use feature importance rank, namely Shapley value (https://doi.org/10.1038/s42256-019-0138-9), to find solvent-antisolvent properties which affect dark film formation the most. We discover several alternatives for solvent-antisolvent pairs which can replace DMSO as a solvent and hence, reduce the risk of Sn^{2+} oxidation and improve the efficiency of tin-based PSCs.

8:00 PM DS04.10.02
Optimization of Silver Nanowire Spin Coating for Flexible Transparent Conducting Electrodes Guided by Machine Learning JuliaW. Hsu, MarkLee, RobertPiper and BishalBhandari; The University of Texas at Dallas, United States

Transparent conducting electrodes (TCEs) play a crucial role in various energy applications, including light-emitting diodes (LEDs), photovoltaics, and thin-film transistors. Achieving both

high transparency and high conductivity in TCEs poses a significant challenge. When using metal grids, a higher filling factor produces a layer with a higher conductivity but lower transmittance. Similarly, indium tin oxide (ITO), the most commonly used transparent conducting oxide, exhibits reduced transmittance with increasing film thickness, even though its conductivity improves. To fabricate TCEs on polyethylene terephthalate (PET) substrates, we combine silver nanowires (AgNWs) with sol-gel indium zinc oxide (IZO). Doing so can enhance the conductivity of solution-processed IZO films to meet the sheet resistance requirements for TCEs used in LEDs and photovoltaics. [1]

Our study primarily focuses on optimizing the spin-coating process of AgNWs, as they significantly influence the transmittance and sheet resistance of TCEs. Our goal is to achieve high transmittance and low sheet resistance simultaneously. The optimization problem involves mapping a three-dimensional input (AgNW solution concentration, spin speed, and dispense volume) to a two-objective output (transmittance and sheet resistance). Using data obtained by Latin hypercube sampling (LHS) of the input space, we construct two independent Gaussian process (GP) regression models: one for transmittance and one for sheet resistance, using cross-validation to tune their hyperparameters. These models have distinct kernel parameters due to the differing nature of the objectives. Having two models also enables us to conduct multi-objective analysis. We analyze the data and GP models in two ways. Firstly, we utilize a well-established criterion [2] to define a scalar figure-of-merit (FOM) and utilize the GP models to predict the maximum FOM and associated uncertainty. Secondly, we construct a Pareto frontier based on the GP models, which helps identify processing conditions that strike the best trade-off between higher transmittance and lower sheet resistance. It is important to note the difference between the two approaches. Using FOM cannot individually specify the objective values, so it proves useful when separate requirements for transmittance and sheet resistance are desired when optimizing FOM. Finally, we compare the predictions of models with tuned hyperparameters using different cross-validation methods. Subsequently, we conduct experiments using the identified input parameters, from both the predicted maximum FOM and the Pareto frontier, and compare the results with the model predictions.

This work is supported by NSF CMMI-2109554.

8:00 PM DS04.10.03
A Statistical Understanding of the Growth and Etching of Anisotropic Colloidal Gold Nanoparticles Assisted by Machine Learning XingzhiWang[1,2] and PaulAlivisatos[1,2,3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The University of Chicago, United States

Colloidal gold nanoparticles (AuNPs) have been widely studied due to their various chemical and biomedical applications. Recently, anisotropic AuNPs, such as Au nanorods, nanodisks, and triangular nanoprisms, have received much attention, due to their shape-specific, tunable plasmonic properties ideal for a variety of potential applications. While reliable colloidal pathways to the synthesis of many anisotropic AuNPs have been developed, the mechanisms leading to the formation of these shapes remain a matter of debate. To better elucidate the mechanism of the formation of anisotropic Au nanoparticles, statistical level information on the evolution of the shapes of AuNPs during their growth is necessary. Previously, shapes of AuNPs and their evolution during colloidal growth and etching have been studied by transmission electron microscopy (TEM). However, few previous studies were able to analyze the shapes of AuNPs at a population level (>1000 nanoparticles), due to the inefficiency of manual analysis of TEM data. We have previously developed AutoDetect-mNP, an algorithm that can automatically extract and classify the shapes of nanoparticles from TEM data with minimum human intervention, enabling the analysis of the shapes of thousands of nanoparticles in a matter of minutes. In this work, applying AutoDetect-mNP, we will demonstrate the mechanism and thermodynamics governing the formation of anisotropic Au NPs based on statistical analysis, using Au triangular nanoprisms as a model system. By analyzing the shapes of Au triangular nanoprisms at different stages of their growth and etching, on a statistically significant level, we will attempt to elucidate the formation of anisotropic AuNPs as a function of the relative reactivities and stability of different crystal facets. In this way, we hope to provide a systematic and quantitative understanding of how anisotropic shapes form during the growth of AuNPs. Further, we believe that this method of statistical analysis of nanoparticles shapes can be generalized to nanoparticle systems beyond AuNPs, including, for example, semiconductor quantum dots, and hence provides a potential solution to a range of fundamental questions in nanosciences.

8:00 PM DS04.10.04
Confocal Raman Microscopy and Machine Learning Analysis for Spatiochemical Characterization of Battery Electrodes StevenT. King[1], LeiWang[2,1], EstherS. Takeuchi[1,2], DavidBock[2,1], ShanYan[2,1], AmyMarschilok[1,2] and KennethJ. Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Battery electrodes are extremely complex and dynamic chemical environments, typically comprised of a broad range of different materials, often representing more than one chemical or physical phase, in a heterogeneous spatial configuration. Comprehensive study of such devices necessitates the use of a probe which can capture and resolve information arising from each of these physiochemical components in a way which permits consideration of the electrode as being greater than the sum of its parts. Confocal Raman microscopy provides just such a probe; it is chemically sensitive to nearly all materials regardless of their phase or crystallinity, permits spatially-constrained measurements with 3-dimensional resolution on the order of single microns, and is intrinsically capable of measuring all chemical components present in a sample in a single measurement. Moreover, the large datasets which result from such analyses are well-suited for processing using SVD-like machine learning techniques, especially non-negative matrix factorization, for rapid signal deconvolution and accurate measurement and mapping of individual chemical components. In this presentation, studies will be presented which highlight the capabilities and utility of confocal Raman microscopy combined with machine learning-assisted analysis for the study of electrodes for electrochemical energy storage devices.

Revisit Bi_2Te_3 Thermoelectric Material: From Existing Literature to Machine Learning Model SarthakRoy and SukantiBehera; Maulana Azad National Institute of Technology Bhopal, India

Thermoelectric materials are hot topic in materials research, mainly due to renewed focus to tackle climate change and global warming from renewable sources of energy. Bismuth Telluride (Bi_2Te_3) based materials are one of the most researched materials with regards to their thermoelectric properties primarily, their relative ease of preparation and impressive thermoelectric properties at room temperature. Recently, there are methods/tools in addition to experiments by which the properties of a material can be known or predicted accurately to a certain degree. Here, in this project, we intend to utilize machine learning principles on literature, databases and other information sources containing thermoelectric data to find the optimum doped stoichiometry required for the bismuth telluride-based materials under different conditions which yield the maximum figure of merit. This is utilized by the proper use of material informatics to gather data, data science to curate and clean the data, and finally machine learning to create models via different regression algorithms such as Decision Tree, Random Forest and SVM, etc. Such models will yield information that can then be investigated by the use of DFT studies with different exchange correlations and further experimental work, thus trying to bridge the gap between computational studies and experiments. By doing so, we reach a synergy that is established between ML-aided materials informatics, computational materials science through DFT, and experimental work.

8:00 PM DS04.10.06
***Doped*: A Python Package for Solid-State Defect and Dopant Calculations**SeánR. Kavanagh[1,2], AronWalsh[1] and DavidO. Scanlon[3]; [1]Imperial College London, United Kingdom; [2]University College London, United Kingdom; [3]University of Birmingham, United Kingdom

Point defects are a universal feature of crystalline materials, dictating the functionality of most semiconductor materials, such as microelectronics, solar cells and batteries.[1] The major impact, despite minute concentrations, of defects in solids, renders their identification and characterisation by experiment extremely challenging. Thus, computational methods (typically Density Functional Theory (DFT) but also quantum embedding, *GW* and empirical potentials approaches) are widely used to predict defect behavior in solids, before combining and comparing theoretical predictions with experimental measurements. However, there are many critical stages in the computational workflow for defects in solids, which, when performed manually, not only leave room for human error but also consume significant time and effort of the researcher.

Here we report *doped*, our python package for the full generation, calculation setup, post-processing and analysis of defect supercell calculations.[2–5] The generation and thermodynamic analysis (i.e. defect formation energy diagrams, chemical potentials & stability region, doping analysis etc.) are agnostic to the underlying first-principles software, while input file generation is supported for several of the most widely-used DFT codes, including VASP, FHI-aims, CP2k, Quantum Espresso and CASTEP. Moreover, *doped* is built to be compatible with other computational toolkits for advanced defect characterisation, including *ShakeNBreak*[6] for defect structure-searching, *py-sc-fermi*[7] for in-depth concentration and Fermi level analysis, and *CarrierCapture.jl*[8]/*nonrad*[9] for non-radiative recombination calculations. Its object-oriented python framework make it readily-usable in high-throughput architectures such as *atomate(2)* or *AiiDA*, with examples included in the documentation.

We will discuss the key features of *doped* for computational defect workflows, exemplified with relevant systems (CdTe, *t*-Se, $Y_2Ti_2O_5S_2$). We anticipate that *doped* will serve as a highly useful tool for computational defect researchers, being an efficient platform for conducting reproducible calculations of solid-state defect properties.

8:00 PM DS04.10.07
Machine Learning-Assisted Design of Vapor-Deposited Perovskite Solar Cells RuilongWang, HaofengZheng and ShaocongHou; Wuhan Univerisity, China

In recent years, the power conversion efficiency (PCE) of perovskite solar cells (PCEs) has been significantly improved by the lab-scale solution fabrication process. Compared with solution method, the vapor deposition method is beneficial for the large-scale preparation of PSCs, however, its development lags behind that of the solution method.
Here, we used machine learning to analyze the device compositions and the preparation conditions of more than 200 PSCs data collected from the literature. Combining random forest and genetic algorithm, we constructed a prediction model of PCE with a Pearson coefficient of 0.67. Furthermore, we applied SHAP analysis to the model, the ratio of cations to anions in the perovskite layer and the annealing temperature are the two factors that most influence PCE. After thoroughly examining the available variable spaces, we proposed an ideal device architecture and its manufacturing parameters, predicting the greatest PCE of 26.1%, which surpasses the previous record for the most advanced efficiency. Our work advances the industrial production of vapor-deposited PSCs and speeds up their development.

8:00 PM DS04.10.08
Discovery of Stable Surfaces with Extreme Work Functions by Machine Learning PeterSchindler; Northeastern University, United States

The discovery of thermally stable materials with surfaces that exhibit an ultra-low work function would allow thermionic energy conversion of heat directly to electricity with high efficiencies and enable next-generation electron emission devices such as THz sources and fluorescent light bulbs. In contrast, surfaces with ultra-high work functions are crucial for devices where large contact barriers are required to suppress electron leakage such as in dynamic RAM and modern transistor architectures. Further, the work function is crucial for band alignment in heterostructures and interfaces. Recently, data-driven approaches based on high-throughput first principles computation have emerged as a new paradigm to facilitate the search through vast chemical spaces for new materials with tuned properties. Most material databases largely lack to report surface properties like the work function and surface energy, as each bulk material typically has dozens of distinct low-index crystalline surfaces and terminations.
Here, we report on recent progress in our high-throughput workflow using density functional theory (DFT) to calculate both the work functions and the cleavage energies of over 55,000 surfaces that we created from ~3,700 bulk materials (with a zero bandgap and including up to ternary compounds). Moreover, we developed a physics-based approach to design surface descriptors and established a surrogate machine learning model to predict the work function. Our machine learning model achieves a mean absolute test error 4 times lower than the baseline, comparable to the accuracy of DFT. This surrogate model enables rapid predictions of the work function (~10^5 faster than DFT) across a vast chemical space. This facilitates the discovery of metallic surfaces that have an extreme work function but also a low surface energy paving the way for new materials solutions in thermionic energy conversion, electron emission devices, and contact electronics.

8:00 PM DS04.10.09
Informing Precursor Choices for Sol-Gel Synthesis of BiFeO3 Thin Films using Text-Mining and Chemical Reaction Networks ViktoriiaBaibakova[1], KevinCruse[1], CarolinM. Sutter-Fella[2], AnubhavJain[2] and SamuelM. Blau[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

This research proposes a novel approach to streamline the choice of precursors for the sol-gel synthesis of BiFeO3 (BFO) thin films [1], leveraging text-mining and chemical reaction networks. An initial dataset of 340 recipes from 178 scientific papers was manually compiled, providing insight into typical experiment steps. However, the reasonings behind material choices and their interplay remain largely obscure [2]. To clarify these aspects, the study categorizes precursor materials by roles (e.g., metal source, solvent, chelating agent) and analyzes their interactions and influence on the synthesis process. A major challenge is the gelation step, influenced by material selection, which can introduce impurities in the final film [2]. We also highlight the crucial roles of solvent in forming a dense, stable precursor molecule and the chelating agent in enhancing the film's homogeneity. We propose to integrate chemical reaction networks [3] representing all plausible reactions within the materials system, allowing for a more profound understanding of the processes in the precursor. In our study, we employed an integrated automated computational pipeline including a semi-empirical xTB package [4] for high-throughput calculations. This setup facilitated ab-initio calculations revealing that Bi prefers a coordination number of 8 and stabilizes when bidentately coordinated with solvent ligands. To generate a comprehensive chemical reaction network, we utilized Molecular Graphs to represent molecules, creating an exhaustive set of intermediate species for each reaction step. For the reaction between Bi nitrite and 2-methoxyethanol solvent, we identified 634 unique molecular graphs, and fed their 3D representations into the chemical reaction network pipeline. Recovering reactions with chemical reaction networks for various systems (e.g., metal source + solvent, metal source + solvent + chelating agent) is an effective strategy to track final film formation and study the role of chelating agent. This method enhances our understanding of sol-gel precursor processes and promises to facilitate the design and optimization of synthesis methods for high-quality BFO thin films.

8:00 PM DS04.10.10
High-Throughput Identification of Materials for Silicon Tandem Solar Cells YanzhenZhao[1], ZhikunYao[1], ChangLiu[1], WeiRen[1] and LeeA. Burton[2]; [1]Shanghai University, China; [2]Tel Aviv University, Israel

Today, more than 90% of the market share of solar energy uses silicon (Si) as an absorber material. However, it is well established that Si is not an optimal light absorber because it has a band gap that is both indirect and lower than ideal according to the Shockley–Queisser efficiency limit. While some researchers seek alternate technologies to supplant silicon solar cells, building on the existing success of Si is the most efficient way to increase PV deployment. Therefore, a dual-junction device is desirable, which uses two materials to absorb different portions of the

solar spectrum in the same cell rather than one in so-called “tandem” cells.
High-throughput calculations are employed to identify the most promising materials for silicon tandem solar cells. Starting with the Materials Project database of more than 131 000 materials, we evaluate the relevant properties of thermodynamic stability, lattice mismatch with silicon, band gap, effective mass, optical absorption coefficient and dynamic stability. The identified 11 optimal candidates represent a variety of material chemistries with oxides, pnictogenides, and chalcogenides included. Among them, perhaps the most promising is Cu2ZnSiSe4, which has almost ideal properties for all physical criteria and is composed of relatively earth-abundant constituents.

8:00 PM DS04.10.11
High-Throughput Synthesis and Screening of Mn^{2+} Doped Perovskite Nanoparticle Megalibraries for Customized Single-Component White Light Emitters TongCai and ChadA. Mirkin; Northwestern University, United States

Materials that efficiently convert energy into white light would mitigate the consumption of energy in optoelectronic applications, such as lighting and displays. Yet commercial white light generation currently relies on devices that incorporate multiple materials, including color conversion layers, which suffer from issues like long-term instability. One solution to this challenge is to explore materials capable of single-component white light emission while simultaneously accommodating different emission channels to achieve polychromatic light. In this pursuit, here we explore metal halide perovskite materials using high throughput synthesis of Mn^{2+} doped PEA_2PbX_4 (PEA: Phenethylammonium, X: halide anions) nanoparticle (NP) megalibraries. Megalibraries are centimeter scale chips that contain millions to billions of individually addressable NPs prepared by scanning probe lithography techniques. In this work, we combine evaporation-crystallization polymer pen lithography, thermal annealing assisted doping and solvent vapor assisted recrystallization processes to yield Mn^{2+} doped NP megalibraries. Single particle optical studies revealed that dual-wavelength photoluminescence (PL) profiles of the obtained Mn^{2+} doped perovskite NPs originated from both exciton recombination and energy transfer processes. Combinatorial synthesis and high throughput PL screening of NP megalibraries were also pursued and analysis of the composition-PL-chromaticity coordinate relationships resulted in a “chromaticity triangle” tuning diagram. The ideal perovskite composition for white light emission was identified within a megalibrary containing a compositional gradient (i.e., $PEA_2Pb_{1-x}Mn_xBr_{4-4y}I_y$ ($0\leq x\leq 1$, $0\leq y\leq 1$)). This study advances our understanding of composition-structure-function relationships of doped perovskite NPs and exemplifies how NP megalibraries can be used to accelerate materials discovery for next-generation optoelectronic materials for solar energy conversion applications.

8:00 PM DS04.10.12
Modeling Complex Materials with Chemical Accuracy using the Constrained and Smoothed Empirical (CASE) Framework for Next-Generation Density Functionals ZacharyM. Sparrow, BrianErnst, TrineQuady and RobertA. DiStasio Jr; Cornell University, United States

Density functional theory (DFT) has become the *de facto* standard when performing electronic structure calculations—a critical need in both simulation-based and data-driven thrusts in materials screening and discovery. While DFT is an exact theory, its accuracy depends on the underlying density functional approximation (DFA) used to describe the non-trivial and many-body exchange-correlation interactions between electrons in molecules and complex materials. To date, DFAs have been primarily designed using either non-empirical strategies (*via* satisfaction of physical constraints and appropriate norms) or empirical strategies (*via* data-driven optimization). In this work, we present a general framework that unites these two seemingly contrasting strategies. The proposed method employs B-splines, bell-shaped spline functions with compact support, to construct the inhomogeneity correction factors (ICF) in a given DFA. This choice offers several distinct advantages over traditional polynomial expansions, including: (1) the ability to explicitly enforce both linear and non-linear constraints as well as ICF smoothness using Tikhonov and penalized B-splines (P-splines) regularization, and (2) the flexibility to leverage high-quality quantum-mechanical and/or experimental data during the optimization process. As proof-of-concept, we use the resulting Constrained and Smoothed Empirical (CASE) framework to construct a constraint-satisfying and data-driven global hybrid DFA that exhibits enhanced performance across a wide and diverse set of chemical properties. By maintaining the physical rigor and transferability of non-empirical DFAs and simultaneouslty leveraging high-quality quantum-mechanical and/or experimental data to remove the arbitrariness of ansatz selection and improve performance, we argue that the CASE approach can be used to develop next-generation DFAs able to model complex materials with chemical accuracy.

Quantum Chemistry-Enabled Machine Learning for Designing Improved Molecular Materials for Energy and Conversion. RajeevSurendran Assary; Argonne National Laboratory, United States

A priori and reliable simulations can enable timely and cost-efficient design and discovery of materials for energy. Therefore, ‘*Let’s Start from Computing*’ is an optimal approach to initialize modern day R&D processes. In energy storage, *beyond lithium-ion (BLI) research* has the potential to revolutionize consumer electronics including portable and stationary power, transportation, and grid energy storage sectors. Multi-valent (Mg, Ca, Zn) energy storage or economically viable monovalent (Na, K) batteries, high-density metal-air, metal-sulfur batteries, or grid-storage systems are considered in the beyond lithium-ion research and development. *All these R&D efforts require significant fundamental knowledge via a priori computations for materials discovery, property prediction, and optimization*. Atomistic modeling when coupled with reliable Artificial Intelligence (AI) approaches can provide *accurate* insights to *accelerate* discovery of *optimal*electrolytes, electrodes, and membranes for BLI systems to *reduce the cost*. Thus, coupled with AI and multi-scale simulations techniques, atomistic modeling can address prediction of molecular level properties of materials (redox potentials, solvation, spectroscopic, and reactivity) to down-select *optimal materials or material combinations*. In this presentation, I will describe some of our recent efforts (2018-2022) in active learning coupled with large scale first principles simulations to down select/optimize desired molecules for *flow battery* technology. This concept can be utilized for design of experiments using autonomous experimentation. Additionally, I will describe some of our quantum chemistry-informed molecular property predictions redoxmers and liquid organic hydrogen carriers. In addition to molecules, I will present. A data driven approach to study longer time scale diffusion of ions for multivalent battery concepts. Finally, I will describe our computational catalysis program development timeline with details of a recent data-driven approach for catalytic property prediction using high performance periodic density functional computing and deep learning .

9:00 AM DS04.11.02
Coupling Reinforcement Learning Approaches with Efficient Quantum Chemical Models for Organic Electronic Materials Discovery and Design DanielTabor; Texas A&M University, United States

In this talk, we will focus on two angles for accelerating organic materials design, with our application spaces focusing on optoelectronic and redox-active organic materials. The first angle focuses on developing discriminative machine learning models that can predict non-extensive organic material properties (e.g., redox potential, reorganization energy) from a low number of training points. In this area, our main areas of focus are on developing appropriate features for the model, quantifying uncertainty in prediction, and developing active learning strategies for developing robust models with as few training points as possible. The second angle focuses on developing methods that pick the right materials to simulate and ensuring that algorithms avoid the numerous local minima that exist in chemical space. We will discuss our work on leveraging reinforcement learning schemes for the inverse design of conjugated and non-conjugated materials and if time permits, our work on integrating these reinforcement learning methods with other representations for molecular materials.

9:15 AM DS04.11.03
Rotation Assisted Proton Conduction Mechanism in Solid Acid Compounds using Machine Learning Molecular Dynamics MenghangWang[1], CameronJ. Owen[1], GraceXiong[2], JingxuanDing[1], YuXie[1], SimonBatzner[3], AlbertMusaelian[1], AndersJohansson[1], NicolaMolinari[1], NiZhan[4], SossinaM. Haile[2] and BorisKozinsky[1]; [1]Harvard University, United States; [2]Northwestern University, United States; [3]Google DeepMind, United States; [4]Princeton Unversity, United States

Rotation-assisted diffusion has emerged as a prevalent mechanism in various superionic conductors, offering wide-ranging applications from highly efficient solid-state electrolytes to hydrogen electrooxidation catalysts. However, a comprehensive understanding of the specific contribution of anion dynamics to the superionic behavior across different compound types has remained elusive. In the superprotonic phase, solid acid proton conductors exhibit intriguing behaviors characterized by local proton hop within the O-H···O bond and anion reorientation, both of which presumably contribute to long-range proton motion. Therefore, gaining insight into the intricate interplay between protons and anions in the superprotonic phase is essential for further advancing our understanding of the mechanisms underlying superprotonic behavior.

Previous experimental endeavors have successfully characterized the timescales of proton oscillation and anion rotation using techniques such as NMR. However, to fully interpret these

timescales, computational studies are necessary to provide atomistic level mechanistic insight into the transport process. Existing computational studies, while shedding light on some aspects of the transport, are constrained by their limited scale, typically involving simulations with a few hundred atoms over a timescale of a few hundred picoseconds.

In this study, we employ machine learning molecular dynamics (MLMD) to investigate the dynamics of anion reorientation and its interaction with proton motion in solid acid proton conductors, specifically focusing on CsH_2PO_4 and $CsHSO_4$. Our approach leverages machine learning interatomic force fields (MLFFs) developed through uncertainty-aware active learning and equivariant neural networks. By combining the accuracy of ab-initio methods with the scale required to simulate thousands of atoms over nanosecond timescales, our MLFFs enable us to explore the correlation between anion dynamics and proton transfer with more sufficient statistics. Using this approach, we find that polyanion group reorientation can occur without contributing to long-range proton motion, a feature not observed in prior simulations.

9:30 AM DS04.11.04
***De Novo* Design of Molecules with Low Viscosity (1): MD Calculations and the Design by Applying the REINVENT Method**NobuyukiN. Matsuzawa[1], HiroyukiMaeshima[1], TatsuhitoAndo[1], AtifAfzal[2], KyleMarshall[2], BenjaminCoscia[2], AndreaBrowning[2], AlexGoldberg[2], MathewD. Halls[2], KarlLeswing[2], MayankMisra[2], FarhadRamezanghorbani[2] and TsuguoMorisato[3]; [1]Panasonic Industry Co., Ltd., Japan; [2]Schrödinger Inc., United States; [3]Schrödinger K.K., Japan

Molecules exhibiting lower viscosities than conventional organic solvents are in high demand for applications of electrochemical devices such as lithium-ion batteries and various capacitors, as such molecules improves the electric resistance of the devices, thus improve the efficiency of the devices, especially at low temperatures. In order to find such molecules, intensive molecular dynamics (MD) calculations were performed to predict viscosities of 10,000 molecules that were randomly selected from the GDB-17 [1] chemical structural database with a restriction of the selection to be the number of heavy atoms being less than 11. The prediction of viscosities was done based on the Nernst-Einstein and Green-Kubo equations. In addition to the MD calculations for the viscosities, DFT calculations were also performed to predict energies of highest occupied molecular orbital (HOMO) of the 10,000 molecules. By using the 10,000 values each of the viscosity and HOMO level as training datasets, machine-learned models were built to predict the two quantities. With the models built, de novo design of molecules was subsequently performed by applying the REINVENT method [2], which is a method based on reinforcement learning of SMILES strings. The method explored molecules that minimize viscosity while having a sufficiently low HOMO level to ensure the stability of the designed molecules, and succeeded in obtaining chemical structures whose viscosity is lower than 2 mPa s while exhibiting a sufficiently low HOMO energy level. Further details will be presented on the de novo design of molecules with low viscosity for electrochemical applications.

9:45 AM DS04.11.05
***De Novo* Design of Molecules with Low Viscosity (2): Multi-Property Optimization using the REINVENT Method**AtifAfzal[1], BenjaminCoscia[1], AndreaBrowning[1], AlexGoldberg[1], KarlLeswing[1], MathewD. Halls[1], TsuguoMorisato[1], NobuyukiN. Matsuzawa[2], HiroyukiMaeshima[2] and TatsuhitoAndo[2]; [1]Schrödinger Inc., United States; [2]Panasonic Industry Co., Ltd., Japan

Molecular modeling and machine learning are becoming essential tools in designing new materials. However, optimizing for a specific property often results in a compromise on other critical properties. Thus, it is crucial to develop a method that considers multiple targeted properties for efficient material design in specific applications. For instance, electrochemical devices such as liquid electrolyte lithium-ion batteries and various capacitors require molecules with lower viscosities, specific electronic properties, and boiling points above the maximum operating temperature. This study demonstrates the use of physics-based modeling and advanced machine learning techniques to design molecules with such target properties. We use molecular dynamics (MD) to compute the viscosity and boiling point; and density functional theory (DFT) to compute the HOMO energy of molecules. We validate the results by comparing them with experimental values. We generate ML models for all these properties and subsequently use the models for the de novo design of molecules. For the de novo design, we implement the REINVENT method [1], based on reinforcement learning of SMILES strings. We create targeted molecules based on two criteria: minimizing viscosity while keeping the boiling point above 82OC and minimizing viscosity while attempting to minimize HOMO under a constraint of the boiling point being higher than 82OC. Based on these criteria, we selected the best 200 candidates from the REINVENT method and validated the molecules using MD and DFT characterization. We demonstrate that de novo design approaches are effective in designing molecules with various desired characteristics.

10:30 AM *DS04.11.06
Improving Crystal Structure Prediction: Accelerating Flexible Unit Structure Engine (FUSE) with Machine Learning Predictions TaylorD. Sparks[1,2], HasanSayeed[1], ChristopherCollins[2] and MatthewRosseinsky[2]; [1]University of Utah, United States; [2]University of Liverpool, United Kingdom

To enable efficient exploration of vast composition spaces and enhance crystal structure prediction, we have extended the capabilities of the Flexible Unit Structure Engine (FUSE) by integrating machine learning (ML) techniques. FUSE is a widely used computational tool for materials discovery across diverse compositions. Our approach consists of two key components. Firstly, we employ classical ML models to accurately predict volume/atom ratios, facilitating the estimation of unit cell sizes for various compositions. Secondly, we integrate a well-established ML-driven crystal structure prediction technique, utilizing advanced methods such as graph networks to establish correlations between crystal structures and formation enthalpies. To expedite the search for crystal structures with the lowest formation enthalpy, this technique incorporates an optimization algorithm. Through the integration of ML-based volume/atom prediction and crystal structure prediction within FUSE, our approach significantly accelerates the discovery of experimentally realizable compounds. This integration offers a promising pathway for efficient materials discovery, pushing the boundaries of knowledge in complex composition spaces.

11:00 AM DS04.11.07
Proton Transfer in Nanoporous TiO_2 Films: Insights from Deep Potential Molecular Dynamics Simulations HyunaKwon, MarcosCalegari, TadashiOgitsu and Tuan AnhPham; Lawrence Livermore National Laboratory, United States

Understanding proton transfer and water splitting reactions in nano-porous materials is critical for a wide range of emerging technologies, including hydrogen production through photoelectrochemical water splitting. However, elucidating mechanism and energetics of these processes remains a significant challenge for experimental probes. In this work, we combine large-scale molecular dynamics simulations with machine learning potential derived from first-principles calculations to investigate kinetics of proton transfer in nano-porous TiO_2 as a representative photocatalyst material. We developed and applied a deep neural network potential to reconstruct the free energy surface of water dissociation and proton transport for a wide range of pore sizes to elucidate confinement effects. We show that reactivity of porous TiO_2 with water recovers its behavior at the interface with the bulk liquid for a pore diameter larger than 10 Å. On the other hand, confinement below 5 Å diameter significantly affects the water reactivity and proton transport near the interface with the pores. Specifically, we show that a limited hydrogen bond network in these narrow pores facilitates redox reactions and enhances proton transfer. Our study highlights the critical competition between kinetic and thermodynamic factors introduced by nano-confinement, suggesting potential strategies for optimization of photocatalytic systems for efficient water splitting reactions.

This work was supported as part of the Center for Enhanced Nanofluidic Transport (CENT), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under award DE-SC0019112. T.O. acknowledges support from Ensembles of Photosynthetic Nanoreactors (EPN) funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences. The work at the Lawrence Livermore National Laboratory was performed under the auspices of the U.S. Department of Energy under contract DE-AC52-07NA27344.

11:15 AM DS04.11.08
Multi-Modal Foundation Model for Material Discovery with Conversational User Interface SeijiTakeda, AkihiroKishimoto, IndraPriyadarsini S, HajimeShinohara and DaijuNakano; IBM Research Tokyo, Japan

Background
The advent of AI-driven models has revolutionized material discovery process through predictive as well as generative modeling. However, a majority of these models remain constrained in their utility due to their isolation in three aspects: (i) data modality used for training, (ii) specificity to certain material domains, and (iii) focus on independent application tasks. This approach curtails the sharing of knowledge across models, restricts access to diverse datasets, and fosters redundancy through the parallel development of analogous models globally. These constraints delineate the inefficiencies in recent AI development within the materials and chemistry sector.

Objective
We introduce Foundation Model (FM) tailored for material discovery, seeking to surmount the aforementioned limitations. This FM employs a pre-training phase leveraging massive datasets

across multiple modalities such as SMILES, property tables, and spectra, spanning diverse material domains (e.g., electronics, polymers, pharmaceuticals). By encoding generalized knowledge and representations onto its latent space, the FM serves as a versatile foundation for numerous downstream applications including predictive analysis and material generation.

Methodology

To adeptly capture multi-modal representations, our FM utilizes a late-fusion scheme, which aligns representation vectors from distinct modalities into a shared latent space. This is achieved by pre-training modality-specific autoencoders (e.g., for SMILES) and subsequently aligning each modality's individual latent spaces through contrastive learning on the shared latent space. We constructed three modality-specific models trained with SELFIES, DFT properties tables, and UV/Vis optical absorption spectra using self-supervised learning. Data was curated from public database such as PubChem and ZINC, in conjunction with DFT-simulated datasets, over 10 billion samples in total. The models were then integrated into a fusion model that projects the representations into a shared latent space.

Results and Demonstration

Our FM exhibited exceeding performance across diverse downstream tasks, including material property predictions and generative applications utilizing pre-trained datasets. We will also showcase the FM's efficacy in predicting properties on distinct datasets through fine-tuning external predictive models connected to the FM's shared latent space. Additionally, we will unveil an multi-modal conversational Graphical User Interface (GUI) for human interaction. The GUI integrates text-based interaction with a multi-modal input panel featuring a molecular editor, property table editor, and spectrum drawer. This innovative interface heralds new possibilities for human-model synergy within materials science and chemistry.

Conclusion

This research introduces a transformative Foundation Model for material discovery, bridging modalities and domains. Through its versatile architecture and intuitive human-interface, it paves the way for more efficient and interactive material and chemistry research.

11:30 AM DS04.11.09

Methods for Feature and Image Selection for Machine Learning Potentials: A Comparative Study ChengZeng, ZacheryHindley, NathanPost and JackLesko; Roux Institute at Northeastern University, United States

Machine learning interatomic potentials (MLIPs) have revolutionized atomistic simulations, enabling predictions of materials properties with first-principles precision while only taking a small fraction of DFT time cost. The reliability and transferability of MLIPs strongly depend on the quality of features and structures used to represent the underlying *ab initio* potential energy surfaces. To reduce the computational overload of expensive first-principles calculations, there is an urgent need to select informative image and features, in particular for complex materials such as high-entropy materials. Current methods for image and feature selection use linear correlations in the feature space (and output space) spanned by the training data. However, the relationship between features and properties can be highly non-linear, rendering it questionable for linear methods. Here, we propose an alternative method for image and feature selections. This approach uses auto-encoder to perform non-linear dimensional reduction. Images selection will then be conducted in the low-dimensional latent space, and the following feature selection will be realized through sensitivity analysis. We benchmark the method on first-principles data of AlCrFeNiCo high-entropy alloys. This class of high-entropy alloys is crucial in many applications as it is an emerging material with superior mechanical properties and corrosion resistance. We compare the new feature and image selection method with existing ones using atom-centered neural network potentials as models and Gaussian symmetry functions as local chemical environment descriptors.

Data-Driven Microstructure-Property Mapping: The Importance of Microstructure Representation, Size of Data and Implications for Model Generalization OlgaWodo; State University of New York at Buffalo, United States

Mapping microstructure-sensitive properties with microstructure representation is invariably challenging due to the mismatch between the high dimensionality of microstructural information (e.g., via microscopy or simulations) and the principal degrees of freedom (or salient features) governing the properties. This is because microstructural imaging aims to provide detailed, high-resolution maps. Hence, imaging techniques inevitably produce high-dimensional representations of microstructure, while the goal of establishing practically useful structure-property models is to identify the smallest set of features that can successfully predict the effective properties exhibited by the material. Often, this set is not known a priori, especially for complex multi-physics phenomena governing the material properties.

Data-driven approaches become the integral approach to establishing reliable microstructure-property mappings. However, materials science datasets are typically small, or the property evaluations are computationally or experimentally demanding, and this requires approaches that integrate the small datasets or seek smart sampling strategies. One critical aspect of data-driven approaches is the ability to represent materials microstructure in machine-friendly formats. This talk presents three methods: statistical descriptors (e.g., 2-point correlations), vector of physically meaningful descriptors, and latent space learned using autoencoder. Using the combination of different representations, we explore three questions: Given a few datasets with distinct microstructure annotated with the property of interest: 1) Can a small subset of features be selected to train a robust microstructure-property predictive model? And is this subset agnostic to the choice of feature selection algorithm? 2) Can the addition of expert-identified features improve model performance? 3) Can the generalizable model be trained for independent microstructure datasets (different microstructure types)? The questions are essential for any microstructure-sensitive properties. Still, in this talk, we will utilize the problem of constructing structure-property models for organic photovoltaics applications (OPV) to understand data-driven SP models.

2:00 PM DS04.12.02

Understanding Green Solvents for Metals Recycling using Machine-Learned Molecular Dynamics JuliaYang[1], Amanda Whai ShinOoi[2], Ah-Hyung AlissaPark[2,2] and BorisKozinsky[1,1]; [1]Harvard University, United States; [2]Columbia University, United States

A projected two million tons of lithium-ion battery waste in the next decade requires development of novel, low-energy, minimally wasteful metals recycling processes to enable a sustainable and environmentally just energy transition. Recently, type III deep eutectic solvents have been gaining great interest as they can supposedly address all of these practical constraints. In particular, ethaline, a 2:1 molar ratio of ethylene glycol and choline chloride, leaches and electrodeposits critical minerals efficiently [1], albeit at the cost of thermal decomposition into toxic products [2]. Computationally-driven efforts to assess neat solvent and its phase stability over temperature cannot be achieved using refined classical molecular dynamics which do not include bond breaking, nor with accurate ab initio simulations due to prohibitive costs. However, machine-learning assisted molecular simulations can bridge the gap between accurate simulations and thermodynamic sampling of these fully explicit models.

Herein, we systematically benchmark density functional and quantum chemistry calculations and use them to construct a machine-learned force field (MLFF) for ethaline. We verify the fidelity of the MLFF against its existing thermodynamic properties and use large-scale molecular dynamics simulations to evaluate the onset of thermal decomposition, after which, at higher temperatures, we find that toxic byproducts such as chloromethane and dimethylaminoethanol are formed irreversibly. Our molecular-level assessment suggests a temperature upper operating limit of ethaline, and is the first to computationally examine the utility and stability of ethaline as a stable solvent for metals recovery applications. The results of our analysis can rationalize the selection of other solvents which span a vast underexplored, combinatorial design space.

2:15 PM DS04.12.03

Accelerating the Construction of ANN Interatomic Potentials using Surrogate Models In WonYeu[1], AnnikaStuke[1], JonLópez-Zorrilla[2], JamesStevenson[3], DavidR. Reichman[1], RichardA. Friesner[1,3], AlexanderUrban[1] and NongnuchArtrith[4]; [1]Columbia University, United States; [2]University of the Basque Country, Spain; [3]Schrödinger, Inc., United States; [4]Utrecht University, Netherlands

Artificial neural network (ANN) potentials trained on data from first-principles calculations enable large-scale atomistic simulations with thousands to millions of atoms with an accuracy comparable to the reference method used to train them. However, applying ANN potentials to complex materials may require huge first-principles energy databases to sample the potential

energy surface (PES) with sufficient precision. Including atomic force information in ANN potential training greatly reduces the data requirements, improves PES prediction accuracy, and increases transferability, but it is computationally demanding. We previously showed that force training can be accelerated through energy extrapolation via Taylor expansion [1] or parallelization on graphics processing units (GPUs) [2]. Here, we discuss an extension of the extrapolation methodology that allows us to further improve ANN potentials without increasing the training databases. We demonstrate how a surrogate model based on Gaussian process regression (GPR) can be used to translate atomic forces into approximate energies, augmenting ANN training data with more accurate and robust energy information than the Taylor expansion method. We benchmarked this synthetic data approach for diverse and complex materials, including ethylene carbonate (EC) molecules and Li metal-EC interfaces which are technologically relevant for solid-electrolyte interphases in Li metal batteries. We also thoroughly compared ANN potentials trained with the GPR-augmented data set against conventionally trained ANN potentials regarding accuracy and training cost.

An Intrusive, Bayesian Paradigm for Scientific Machine Learning Outperforms Neural Networks in Typical Scientific Modeling Contexts DavidS. Mebane[1,2]; [1]West Virginia University, United States; [2]KBR Wyle Services, United States

Neural networks (NNs) are powerful tools for machine learning, with stunning results in computer vision and large language models dominating the news. However NNs are often misapplied in scientific modeling contexts, in which the input-output space dimensionalities are small to moderate. There are numerous examples of other methods such as decision trees and Gaussian processes (GPs) outperforming NNs in both accuracy and inference speed for tabular estimation. A shift away from NNs in scientific modeling contexts promises faster and more accurate performance. A framework for scientific machine learning in which fast, decomposed GPs represent well-defined scientific functions has shown considerable promise, outperforming recurrent neural networks (such as LSTM) on multiple benchmark dynamic modeling tasks. These well-defined functions also present opportunities for multi-scale modeling, linking electronic and atomistic scales to device scales. Multiple applications in materials modeling for energy applications -- including in solid-state batteries and high-temperature CO2 electrolyzers -- will be presented.

2:45 PM DS04.12.05
Alternative Machine-Readable Representation of Molecules for More Efficient Use of Computational Resources in Machine Learning Applications Emilio Alexis de la CruzNuñez Andrade[1], IsaacVidal-Daza[2,1], RafaelGómez-Bombarelli[3] and FranciscoMartin-Martinez[1]; [1]Swansea University, United Kingdom; [2]Universidad de Granada, Spain; [3]Massachusetts Institute of Technology, United States

The rapid increase in computational resources demand is unprecedented because of the surge in artificial intelligence (AI), big data, and high-throughput computing. In chemistry, machine learning (ML) is revolutionizing molecular discovery, materials design, and property predictions in areas ranging from biomedicine to energy harvesting and storage, among many others. In practice, the implementation of ML methods relies on the codification of chemical structures into a suitable format for practical implementation in computational tools. To this end, the chemistry community adopted the Simplified Molecular Input Line Entry System (SMILES)[1] for initial structure codification, and the subsequent DeepSMILES[2] and SELFIES[3] (SELF-referencing Embedded Strings) as more sophisticated approaches. These representations are further encoded into a machine-readable format that captures the structural and chemical characteristics of molecules, such as One Hot Encoding (OHE), Molecular Graphs (MG) or Descriptors (Molecular Fingerprints), whose selection depends on the application, the data set, and the ML model to train. In this study, we propose an alternative representation to traditional OHE of SMILES, DeepSMILES and SELFIES, which allows for comparable results in model accuracy and robustness but improves the efficiency in the use of computational resources compared with the traditional alternatives. To evaluate the effectiveness of this alternative representation, we conducted a set of benchmarks and comparative analysis with a Variational Autoencoder and a Recurrent Neural Network. We also explored the impact of this alternative representation in the required size of the training dataset, the molecular diversity, novelty, and validity, as well as in the model complexity for different number of hyperparameters. This alternative representation provides a new avenue for more efficient computing with less use of computational resources and faster performance, which impacts ML methods for chemistry, but also for any other fields that uses OHE as data representation.

Applications of Large Language Models in Materials Discovery and Design AnubhavJain; Lawrence Berkeley National Laboratory, United States

In the past year, natural language processing has quickly evolved from a relatively niche field used by a small community of materials researchers to a commonplace and wide-ranging tool used worldwide. In particular, large language models such as GPT-3, ChatGPT, and GPT-4 have demonstrated that many natural language processing tasks that have conventionally been challenging are now within reach - but with important limitations. In this presentation, I will review our group's recent work in using large language models to extract structured data sets from the literature, including techniques to make such extractions effective. Applications include parsing nanoparticle and solid state synthesis recipes, creating data sets of doping data for subsequent machine learning, and understanding known materials and their properties. I will also demonstrate how we are deploying this information through platforms such as the Materials Project to make the results from these models publicly accessible and usable in real-world materials design applications. Finally, I will conclude with an outlook on future use cases and potential pitfalls of using large language models in the materials domain.

4:15 PM DS04.12.08
Robustness of Local Predictions in Machine Learning Models for Materials SanggyuChong[1], FedericoGrasselli[1], ChihebBen Mahmoud[1], JoeD. Morrow[2], VolkerL. Deringer[2] and MicheleCeriotti[1]; [1]EPFL, Switzerland; [2]University of Oxford, United Kingdom

Many machine learning (ML) models for the prediction of material properties rely on a decomposition of the global target quantity (e.g. total energy, magnetic dipole, electronic density of states, etc.) into local contributions associated with individual atoms, or clusters of atoms. By interpreting and learning the global quantities as a sum of local contributions, the models are essentially trained to make predictions on the locally decomposed environments of a given structure. This approach is computationally convenient, significantly improves the transferability and scalability of the resulting ML models, and allows one to discover useful structure–property relationships as they associate simple atomic motifs with complicated macroscopic properties. While the practical benefits of the local decomposition is clear, one must recognize that only the global quantity is rigorously defined, and the decomposition can arbitrarily take place in numerous different ways. It hence remains largely unclear to what extent the local predictions of the ML model can be trusted.

In this contribution, we introduce the local prediction rigidity (LPR),[1] a generally applicable metric that quantifies how “rigid”, or robust, the ML model is in the local predictions that it makes. Through our investigation on a range of models and materials datasets, we reveal that the LPR can vary drastically between different local predictions, and it largely depends on the degeneracies associated with locally decomposing the global target quantity. We then investigate strategies to systematically increase the LPR by the careful curation of the training dataset, and demonstrate these strategies in linear, kernel, and neural network models for silicon, carbon and GaAs. The LPR has great potential for proposing effective active learning schemes, where the assessment and improvement of the ML model performance can all take place at the local level. We also note that, as the derivation of LPR is not limited to an atomic decomposition, it can be extended to other decomposition schemes: multiple body-order decomposition, short-range vs. long-range decomposition, etc. This allows one to scrutinize the model and precisely identify where it lacks robustness, and propose effective ways to improve the ML model.

Uncertainty Quantification in the Atomistic Modelling of Grain Boundaries AnqiQiu[1] and ElizabethHolm[2]; [1]Carnegie Mellon University, United States; [2]University of Michigan–Ann Arbor, United States

Atomistic simulations have been successful in the prediction of materials properties in many applications. Commonly used atomistic simulation methods such as density functional theory (DFT) and molecular dynamics (MD) possess inherent uncertainties that may greatly impact simulation results. However, the uncertainties are rarely quantified, mostly due to the limitations in computational resources and the complexity of the methods for uncertainty quantification.

Grain boundaries are interfaces between grains in polycrystalline materials, being in an intermediate state in between crystalline and amorphous materials, has many unique properties, such as the ability to provide fast transport paths for atoms and ions. Grain boundary motion is a key process that governs the microstructural evolution in materials. In energy materials such as batteries, grain boundaries are crucial to ionic transport. Due to the limitations of current experimental methods in understanding the mechanisms of grain boundary motion at the atomic level, atomistic simulations have become an essential tool for mechanistic studies.

In our study, we adopt elemental metallic materials as model materials, and investigate the migration and diffusion of grain boundaries using MD simulations. We demonstrate that some sources of uncertainty can significantly impact simulation results, but were usually ignored in prior works. In the simulations, atomic velocities are randomly assigned according to the Maxwell-Boltzmann distribution. The different assignments of initial velocities can significantly impact the simulation results of grain boundary migration rate and diffusion coefficient, but the effects are rarely quantified. This work highlights the impact of different assignments of initial velocities and the quantification of the uncertainty in the measurement of grain boundary migration rate and diffusion. We also show that the simulation box sizes at which similar types of simulations are usually performed may cause unphysical artifacts that can be resolved by using larger simulation box sizes.

SESSION DS04.13: Accelerated Catalysis Discovery II

Extracting Catalytic Reaction Mechanisms from Large-Scale Simulations Accelerated by Machine Learning Interatomic Potentials AndersJohansson, YuXie, CameronJ. Owen, Jin SooLim, LixinSun, JonathanVandermause and BorisKozinsky; Harvard University, United States

Machine learning interatomic potentials (MLIPs) have become a prevalent approach to bridging the gap between slow-but-accurate ab initio calculations and fast-but-inaccurate empirical potentials for molecular dynamics. Among MLIPs, there is a pareto front of models with different tradeoffs between accuracy and speed. The FLARE interatomic potential aims to push the boundary of scalability and performance, while maintaining sufficient accuracy to study complex, reactive systems.

In our recent work [1], we demonstrated the ability of FLARE to simulate catalytic systems of up to 0.5 trillion atoms using 27336 GPUs, with an accurate MLIP efficiently trained using active learning. With the exceptional speed of FLARE on modern HPC architectures, we can combine the atomistic resolution of molecular dynamics simulations with the large length and time scales required for realistic simulations and sufficient sampling of rare catalytic events, while providing the near-quantum level of accuracy provided by the MLIP. In this talk, we will showcase how this combination of scales and accuracy enables new insights into chemically complex processes such as heterogeneous catalysis.

Multi-Code Benchmark on Simulated Ti K-Edge X-Ray Absorption Spectra of Ti-O Compounds FanchenMeng[1], BenediktMaurer[2], FabianPeschel[2], SencerSelcuk[1], MarkHybertsen[1], XiaohuiQu[1], ChristianVorwerk[3], ClaudiaDraxl[2], JohnVinson[4] and DeyuLu[1]; [1]Brookhaven National Laboratory, United States; [2]Humboldt University of Berlin, Germany; [3]The University of Chicago, United States; [4]National Institute of Standards and Technology, United States

X-ray absorption spectroscopy (XAS) is an element-specific materials characterization technique that is sensitive to structural and electronic properties. First-principles simulated XAS has been widely used as a powerful tool to interpret experimental spectra and draw physical insights. Recently, there has also been growing interest in building computational XAS databases to enable data analytics and machine learning applications. However, there are non-trivial differences among commonly used XAS simulation codes, both in underlying theoretical formalism and in technical implementation. Reliable and reproducible computational XAS databases require systematic benchmark studies. In this work, we benchmarked Ti K-edge XAS simulations of ten representative Ti-O binary compounds, which we refer to as the Ti-O-10 dataset, using three state-of-the-art codes: XSPECTRA, OCEAN and exciting. We systematically studied the convergence behavior with respect to the input parameters and developed a workflow to automate and standardize the calculations to ensure converged spectra. Our benchmark comparison shows: (1) the two Bethe-Salpeter equation (BSE) codes (OCEAN and exciting) have excellent agreement in the energy range studied (up to 35 eV above the onset) with an average Spearman's rank correlation score of 0.998; (2) good agreement is obtained between the core-hole potential code (XSPECTRA) and BSE codes (OCEAN and exciting) with an average Spearman's rank correlation score of 0.990. Our benchmark study provides important standards for first-principles XAS simulations with broad impact in data-driven XAS analysis.

9:00 AM DS04.13.03
Exploring the Family of AM_2Pn_2 Materials and Their Alloys for Use as Solar Absorbers AndrewPike[1], ZhenkunYuan[1], MuhammadR. Hasan[2], GideonKassa[1], KirillKovnir[2], JifengLiu[1] and GeoffroyHautier[1]; [1]Dartmouth College, United States; [2]Iowa State University of Science and Technology, United States

Some compositions of the formula AM_2Pn_2 have recently been observed as promising solar absorbers through high-throughput computing. In this talk, I will explore how isovalent substitutions on this crystal structure can tune the band structure and defects (A= Ba, Sr, Ca, Yb, Eu, Mg, M=Mn, Mg, Cd, Zn, Pn= Bi, Sb, As, P). In order to increase the design space for an optimal material, the alloys between the endmember AM_2Pn_2 compounds will be considered for their effect on stability and optical properties. Our results show that many members of this class of materials are stable and have a range of bandgaps from metallic behavior to well above what is optimal for solar applications.

9:15 AM DS04.13.04
Unbiased Graph Embedding Prediction of Graphene Nanoflake Properties AmandaJ. Parker; The Australian National University, Australia

In order to apply machine learning to the study of structure-property relationships domain knowledge is typically required for feature extraction. However, this process may introduce bias if there is a focus on known aspects of structure, thereby impeding the discovery of new science. Here, we develop an approach that uses only atomic Cartesian coordinates to predict the electronic properties of simulated graphene nanoflakes (from a publically available data set). Our approach addresses the limits of currents methods by greatly extending the degree of material complexity, assymetry, surface details and size differences that can be encoded by a graph embedding.

The workflow developed decribes graphene nanoflakes with graphs that are more representative than the ball-stick atom-bond representation that is intuitive to reserachers. We generate fixed-size embeddings of these graphs using a neural embedding framework. Pairing the graph embeddings with a convolutional neural network produces a highly accurate predictive model for electron affinities, band gap energies, Fermi energies and ionization potentials. The hold out test set model performance fit has R^2 from $0.9-0.96$ for nanoflakes with a very challenging variation in size from tens to thousands of atoms. These predictions were benchmarked against results for optimized predictive models with geometric domain-driven features and exceeded their model accuracy for predictions of Fermi energy, electron affinity and ionisation potential and met their model accuracy for band gap energy. We also introduce and optimize a model hyperparameter that gives insight into the relevant lengthscales of interactions for the material modelled.
\end{abstract}

From Cells to Batteries: Semantic Segmentation's Evolution in Quality Control DanielaUschizima[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

In an unexpected leap forward for the world of battery technology, an investigation that was first introduced at the Materials Research Society (MRS) conference in 2019 has evolved into a cutting-edge computational tool with potential application to the quality and reliability of batteries. This remarkable innovation leverages the power of semantic segmentation, a sophisticated image analysis technique, to detect and monitor crucial morphological structures such as dendrites during the cycling of batteries.

The journey of semantic segmentation in the realm of science and technology has been nothing short of remarkable. It all began with pioneering efforts to apply this technique to understanding and detecting abnormal cells in the early 2000s [1]. Researchers ventured into the intricate world of "hairy cells" in leukemia, demonstrating the potential of semantic segmentation to dissect and analyze complex biological structures with unprecedented precision.

For over a decade, scientists delved into the mysteries of brain cells, harnessing semantic segmentation to unravel the intricate shapes of brain cells and neuroproteins that power our minds. Their tireless efforts culminated in a groundbreaking paper published in the esteemed Neuroimage journal, earning them the prestigious Precision Medicine World Conference Pioneer Award in 2023 [2]. This recognition marked a turning point in the field, solidifying the importance of semantic segmentation in advancing our understanding of radioactive tags to be used in the human brain.

Now, this transformative technology has taken another leap into the world of energy storage. Researchers have successfully adapted semantic segmentation to scrutinize the inner workings of batteries, specifically targeting dendrites, which have long been a challenge in the realm of battery research. The results of this innovative work were published in the prestigious Nature Partner Journal Computational Materials journal in 2023 [3]*, showcasing the immense potential of semantic segmentation to revolutionize battery quality control.
The implications of this breakthrough are immense. Imagine batteries that are not only more powerful but also safer, thanks to the ability to detect and mitigate dendrite-related issues before they become problematic. This advancement promises to usher in a new era of protocols for testing energy storage devices.

As the research community eagerly awaits further details on the practical applications of this technology, one thing is clear: the future of batteries is brighter than ever, thanks to the extraordinary journey of semantic segmentation from leukemia cells to brain cells and now to the heart of our energy solutions. Stay tuned for more updates on this development that promises to reshape how we understand morphologies within batteries.

Creating Materials Databases Autonomously using Open Large Language Models VineethVenugopal and ElsaOlivetti; Massachusetts Institute of Technology, United States

It is estimated that there are around 150 million scientific papers altogether, of which at least 10 million deal with materials and their structure-property-processing relationships exclusively. Despite this enormous abundance of scientific information, there are very few machine readable databases of materials and their experimentally determined processing, property relations. This has in turn severely limited our ability to extend artificial intelligence models to materials discovery and development which have proved revolutionary in some tasks such as image and text recognition and generation. Efforts to develop databases autonomously have usually relied on rule based string extraction from text, training of BERT based models using manually annotated data or recently through large GPT based models. The last one in particular has attracted the attention of the wider community given the success that ChatGPT has enjoyed. However, GPT 3.5 and 4 are unsuitable for large scale text mining given the proprietary API restrictions placed by the developers.

We show that open large language models such as Llama 1 and 2, Flan T-5, Alpaca, Dolly etc can perform on par with much larger GPT models when fine tuned on specific tasks. This is demonstrated on a range of entity recognition, relationship extraction, text classification, and text generation tasks. By combining large language models with large embedding vector stores, we show that a single prompt or extraction task can lead to the generation of a complete database of materials and their required property fields. Strategies are discussed to mitigate and remove factually incorrect data points that arise as a natural consequence of language model generations. The fine points of training models using bit quantization approaches, and the challenges in model performance are discussed.

In addition to the significant strides made in harnessing open large language models for materials science tasks, it's important to highlight the broader implications of this breakthrough. The ability to effectively extract, process, and organize information from scientific literature using these models extends beyond materials science alone. This approach has the potential to revolutionize the way we access and utilize scientific knowledge across various domains. The success in entity recognition, relationship extraction, text classification, and text generation tasks not only paves the way for comprehensive materials databases but also opens doors to more efficient knowledge discovery and innovation in fields ranging from medicine to environmental science. As we continue to refine and expand these methods, the impact on scientific research and technological advancement is poised to be profound.

High-Throughput Screening and Experimental Validation of Aqueous Organic Redox Flow Battery Electrolytes AyushNarsaria[1], MuratC. Sorkun[2], KaustubhKaluskar[1], XuanZhou[2], NicolaMenegazzo[1], PeterKlusener[1], SharanShetty[1] and SüleymanEr[2]; [1]Shell, India; [2]Dutch Institute for Fundamental Energy Research, Netherlands

Increasing renewables share in power mix has necessitated improvement and further research on various battery technologies. Aqueous organic redox flow batteries (AORFBs) exhibit many advantages, such as high ionic conductivity, safety, cost-effectiveness, and well-developed technology to compensate for the narrow voltage window that is limited by the electrolysis of water. For this purpose, discovery of novel organic electroactive molecules is highly warranted. Herein, we have developed a computational workflow that can screen millions of organic molecules in a modular fashion using similarity metrics with known electroactive molecules, machine learning based prediction of redox potential and solubility, and finally on the ease of availability and cost. Through this workflow we were able to narrow down to almost 60 molecules, among which some are already reported to have high performance in AORFBs, while some are completely new molecules for the redox flow battery application that are also experimentally validated through cyclic voltammetry experiments.

10:45 AM DS04.14.02
Systematic Modification of Functionality in Disordered Elastic Networks Through Free Energy Surface Tailoring DanMendels[1], FabianBylehn[2], TimSirk[3] and JuanJ. de Pablo[2]; [1]Technion–Israel Institute of Technology, Israel; [2]The University of Chicago, United States; [3]U.S. Army Research Laboratory, United States

Advances in manufacturing and characterization of complex molecular systems have created a need for new methods for design at molecular length scales. Emerging approaches are increasingly relying on the use of Artificial Intelligence (AI), and the training of AI models on large data libraries. This paradigm shift has led to successful applications, but shortcomings related to interpretability and generalizability continue to pose challenges. Here, we explore an alternative paradigm in which AI is combined with physics-based considerations for molecular and materials engineering. Specifically, collective variables, akin to those used in enhanced sampled simulations, are constructed using a machine learning (ML) model trained on data gathered from a single system. Through the ML-constructed collective variables, it becomes possible to identify critical interactions in the system of interest, the modulation of which enables a systematic tailoring of the system's free energy landscape [1]. To explore the efficacy of the proposed approach we have applied it to numerous case studies, a few of which will be discussed

and illustrated within this talk.

Autonomous Discovery of Triple-Conducting high-Entropy Oxides for Protonic Ceramic Fuel Cells Ivano EligioCastelli and Benjamin H.Sjølin; Technical University of Denmark, Denmark

We develop and implement an autonomous multi-fidelity computational workflow to explore the chemical space of high-entropy perovskite oxide materials with general formula ABO_3, screening for stable, high-performance cathodes for low-temperature protonic ceramic fuel cells. The workflow, implemented in the framework of Density Functional Theory (DFT), is based on the calculation of thermodynamic, electric and kinetic properties, which include phase and electrochemical stability, electronic conductivity, and ionic diffusivity. To accelerate the calculation of the kinetic properties, we employ accelerated methods that leverage recent advances in machine learning for materials science to predict transition barriers for ionic diffusion. The computational cost of the workflow is additionally decreased while retaining the quality of results through a thorough examination of the required level of theory for all descriptive properties. Moreover, the aim is a general and chemistry-neutral approach that can be applied to other crystal prototypes and materials screenings.

11:15 AM DS04.14.04
Deep Reinforcement Learning for Dopants Design in Crystalline Materials XiangyuYin[1], XiangyunLei[2], WeikeYe[2] and JosephMontoya[2]; [1]Carnegie Mellon University, United States; [2]Toyota Research Institute, United States

Deciphering the atomic or crystal structure of doped materials is a crucial endeavor in materials science, serving the dual purpose of controlling material properties and enhancing device performance. However, this task is compounded by the minuscule scale of the materials, complexity from dopant disruption, and intricate dopant-host material interactions, along with other quantum mechanical effects. Given the intricate nature of this task, it is often compared to solving a perpetually evolving puzzle, situating it at the heart of materials science and condensed matter physics research. Despite the importance of this task, existing computational dopant design methods grapple with challenges such as imbalanced exploration-exploitation, scalability limitations, and a lack of generalizability. To address these persistent issues, we propose a novel use of reinforcement learning (RL) to manage the complexity of dopant design. This approach encompasses a framework that effectively casts generic dopant design problems as RL games, facilitating an interactive and iterative design process. Concurrently, we construct an invariant, explainable policy network employing a policy gradient method, allowing us to derive an optimal doping strategy that is both effective and interpretable. To illustrate the practicality and unique advantages of our RL-based design approach, we applied the method to an oxygen storage material (CeZrO4) and a garnet phosphor host material (Y3Al5O12). These applications highlight the impressive search efficiency of this approach, its potential to generalize to larger systems, and its robustness in handling systems with varied dopant concentrations. Overall, this research provides a promising, efficient, and adaptable pathway for designing doped materials.

Designing Formulations of Bio-Based, Multi-Component Epoxy Resin Systems via Machine Learning RodrigoAlbuquerque, FlorianRothenhäusler and HolgerRuckdäschel; University of Bayreuth, Germany

Petroleum-based epoxy resins are commonly used as matrix in fiber reinforced polymer composites. Bio-based epoxy resin systems might be a more environmentally friendly alternative to conventional epoxy resins. In this work, novel formulations of multi-component, amino acid-based resin systems exhibiting high or low glass transition temperatures (Tg) were designed via Bayesian optimization and active learning techniques. After only five high-Tg experiments, thermosets with Tg already higher than those of the individual components were obtained, suggesting the existence of synergistic effects among the amino acids used and confirming the efficiency of the theoretical design. Linear and non-linear Machine Learning (ML) models successfully predicted Tg with a mean absolute error of 3.98 oC and R2 score of 0.91. A price reduction of up to 13.7 % was achieved while maintaining the Tg of 130 oC by using an optimized formulation. The LASSO model provided information about the dependence of Tg on the number of active hydrogen atoms and aromaticity. This study highlights the importance of

Bayesian optimization and ML to achieve a more sustainable development of epoxy resin materials.

11:00 AM DS05.01.02
Machine Learning Strategies for Improved Polyolefin Sorting Based on Near-Infrared Spectroscopy BradleyP. Sutliff, ShailjaGoyal, TylerMartin, PeterBeaucage, DebraAudus and SaraOrski; National Institute of Standards & Technology, United States

Polyolefins are cost-effective and exhibit a myriad of desirable characteristics such as chemical, shock, and impact resistance. While practical for consumer and industrial applications, the stability of polyolefins enables long-term environmental persistence. Recycling and reuse of waste materials would mitigate their long-term environmental impact, but incompatible molecular architectures often result in downgraded material properties for the recyclates. To prevent degradation of the polymers during recycling, the various subclasses of low-density (LD-), high-density (HD-), and linear low-density (LLD-) polyethylene (PE) must be separated from one another as well as from polypropylenes (PP) and other polymers. Unfortunately, the chemical similarities between these polyolefins present a large hurdle to facile separation using common high throughput techniques such as near-visible infrared spectroscopy (NIR). In this work, we explore using machine learning (ML) techniques, coupled with NIR measurements, to enable enhanced sorting of polyolefin species beyond what is possible using current NIR databases. NIR spectra of polyolefins were collected for polyolefins spanning a range of branch content, processing conditions, and additives. Common scattering corrections and preprocessing steps such as multiplicative scatter correction, linear detrending, and Savitzky-Golay filtering were evaluated for their effects on classifier outcomes. Data reduction techniques such as functional principal component analysis (fPCA) and uniform manifold approximation and projection (UMAP) were also investigated for data visualization and classification enhancements. This survey of preprocessing steps and ML algorithm combinations identified multiple data pipelines capable of successfully sorting polyolefin materials. Multiple combinations properly distinguished PP from PE, and separated subclasses of these polyolefins. This work discusses the effects of each data analysis step on the final classification results.

11:15 AM DS05.01.03
Unbiased In-Silico Design of pH-Sensitive Tetrapeptides. YueHu[1], FedericaRigoldi[1], AlfonsoGautieri[2] and BenedettoMarelli[1]; [1]MIT, United States; [2]Politecnico di Milano, Italy

Oligopeptides are short peptides consisting of two to twenty amino acids (AA) that can spontaneously fold and assemble through a combination of hydrogen bonds and π-π interactions to form functional nanostructures. From an engineering perspective, oligopeptides folding and assembly can be designed to fabricate fibers, tubes, nanosheets, pallets, gels, vesicles, and nanoparticles, with applications in biomedicine, food science, regenerative medicine, and biosensing. Peptide-based biomaterials offer in fact the opportunity to combine the simplicity of small biomolecules with the functionality of proteins. The design of oligopeptides that assemble in nanostructured materials often follows principles of bioinspiration and rational design. Most of the short (i.e. <5AA) oligopeptides-based biomaterials found in literature are directly derived from AA *motifs* with biological relevance (e.g. DFNKF, KLVFF) and, are composed of hydrophobic AA (e.g. FFF, VYV) to drive self-assembly in water. The combination of bioinspiration with rational design, despite successful, has limited the design of oligopeptides to few sequences tested experimentally, when compared to the x^n (where x=20 AA and n=number of AA in the oligopeptide) theoretical possibilities, and biased the AA choice to impart low solubility. Such restrictions have strongly limited the discovery of new AA sequences.
As an alternative route, in silico tools can be used to predict oligopeptides' properties, accelerating their design into biomaterials. Machine learning (ML) algorithms such as TorchMD, Convolutional neural networks, and Deep neural networks have been successfully used to quickly model and predict peptides' folding, energies, and reaction pathways, but the limited accuracy and completeness of high-quality training data still limit the resolution of predictive results of ML when compared to molecular dynamics (MD) simulations, which in turn are extremely intensive. To combine the benefits and limit the individual weaknesses of MD and ML, hybrid ML-MD approaches are now pursued to accelerate simulations and improve the understanding of complex biomolecular systems (e.g. flexible molecular force fields, where ML tools are used to accelerate the simulation process). However, these tools are still in their infancy and their applications to decrease the intensity of MD simulations have to be fully explored.
Here, we developed a new computational design protocol to discover oligopeptides that self-assemble in nanostructured biomaterials by combining an unbiased AA selection (i.e. agnostic to chemical features) with coarse grain (CG) MARTINI forcefield (highly parameterized for natural amino acids), which yields a speed-up of 2–3 orders of magnitude compared to atomistic forcefield. We focused on tetrapeptides as n=4 represents a wide but approachable sequences space (20^4 possible unique sequences) to screen and test computational unbiased methods while possessing an amphiphilic form and the proven ability to self-assemble into nanofibrillar structures. This method allowed us to simulate the assembly of all the possible tetrapeptides without bias, resulting in the screening of appropriate side chain combinations to embed responsiveness to environmental stimuli, such as pH. This pH-triggered assembly of tetrapeptides can be used to engineer new biomaterials for drug delivery that assemble/disassemble in response to pH changes, nanofibrillar matrices for separation of large biomolecules like proteins, antimicrobial surfaces, and scaffolds to support for cell growth.

Virtual Forward Synthesis: Designing Novel Polymers from Commercially Available Chemistries JosephD. Kern, ShivankS. Shukla, MadhubantiMukherjee and RampiRamprasad; Georgia Intitute of Technology, United States

Every year, humanity churns out a staggering 380 million tons of plastic, with millions of these tons escaping into the environment. The modern plastics we rely on possess such remarkable thermodynamic stability that recycling them remains a daunting task, with only a meager 9% successfully recycled, while they persist for decades, if not centuries, in our ecosystems. This dire situation has ignited an ecological crisis as these plastics seep into the environment, fragment into minuscule particles, and accumulate within the bodies of humans, plants, and animals.

In response to this critical issue, we've developed a computational method known as 'Virtual Forward Synthesis' (VFS) to explore the creation of hypothetical polymers using readily available chemicals. This approach involves the automated retrieval of chemical data and pricing from vendors, followed by systematic cataloging of the substructures of these chemicals. Viable chemicals are then subjected to virtual reaction templates, yielding hypothetical polymers, with machine learning being used to predict the polymers' properties.

The most promising polymers, along with comprehensive information on their chemical composition, pricing, vendors, and the reaction procedure used to create them, are then shared with our collaborating chemists who attempt to synthesize these novel polymers. We evaluate a polymer's potential by assessing how well it matches the required properties for common plastic applications like packaging. We assign scores based on how closely its predicted properties align with the desired values. Additionally, this presentation provides an overview of our carefully designed, performance-optimized relational database schema.

Playing with Entanglements to Structure Polymer Materials KurtKremer; Max Planck Institute for Polymer Research, Germany

Entanglements are known to dominate the rheological properties of long chain polymer melts and dense solutions. Their properties and consequences lead to the generally accepted and well established reptation/tube model, which is at the basis of our understanding of many properties and processes. However, beyond analysing their effects and understanding the very nature of entanglements, one also can take the approach to use them to manipulate and structure materials. The talk will give a few such examples ranging from melts of non-entangled to very long, highly entangled polymer systems. By appropriately mapping chemical chain lengths onto idealized bead spring models one can (semi-) quantitatively compare simulation and experiment and predict new materials. Based on predictions from simulations we recently prepared stable nanoporous polymer films just by mechanical deformation. Furthermore, we applied a new data driven approach to determine the glass transition temperature of polymer melts and (ultra) thin films.

2:00 PM DS05.02.02
Morphology, Structure and Dynamics of Ionic Polydimethylsiloxane-Silica Nanocomposites ArgyriosKaratrantos[1], ClementMugemana[1], AhmadMoghimikheirabadi[2] and MartinKroger[2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]ETH Zürich, Switzerland

We designed ionic polydimethylsiloxane (PDMS)-silica nanocomposites from (cationic) ammonium-functionalized PDMS and (anionic) sulfonate-functionalized nanosilicas, with the aim of influencing the distribution and dispersion of the nanoparticles. The impact of the PDMS molecular weight, charge density and charge location on the distribution, dispersion of ionic nanosilicas and on the mechanical reinforcement of the nanocomposites is explored. Self-healing property arises from reversible ionic interactions located at the interface between PDMS matrix and nanosilicas. We use coarse grained equilibrium molecular dynamics to model ionic nanocomposites and to investigate their behavior, in particular, polymer conformations, entanglements and dynamics for different loadings, for two types of charge-sequenced polymers at two different Bjerrum lengths. We calculate the lifetimes of temporary ionic crosslinks that are created between ionic nanoparticles and polymers. Non equilibrium molecular dynamics is used to investigate the stress - stress behavior, ionic crosslinks and entanglements under deformation.

Breaking Down the Building Blocks: Multi-Scale Model of Diels-Alder Reactions for Future Self-Healing and Recyclable Polymer Networks LiseVermeersch[1], FreijaDe Vleeschouwer[1], AdriVan Duin[2] and NikoVan Den Brande[1]; [1]Vrije Universiteit Brussel, Belgium; [2]The Pennsylvania State University, United States

Self-healing network materials (SHNs) have the potential to entirely change the way we view and use materials. By using SHNs, damage prevention will no longer be the key factor dictating the properties of a material, which makes that overdesigning will no longer be the strategy at hand to increase the lifetime of a material. SHNs based on Diels-Alder reversible crosslinks are a proven technology - furan-maleimide systems, for example, have been used to create self-healing soft robotic grippers. These materials have yet to be valorised, as the current materials still face some issues. Synthesis and healing times are too long, which pose a barrier for application in industry. Besides this, the large number of diene-dienophile combinations allow for a range of material properties, which can open doors towards other applications in construction materials, coatings and renewable energy. Exploring this chemical space using experiments, however, would be a tedious process. By creating a multi-scale model, ranging from the quantum-chemical level to molecular dynamics, we can predict suitable candidates depending on the desired material properties. In this study, density functional theory (DFT) is used to relate the structure of the diene and dienophile to the resulting kinetics and thermodynamics of 100 Diels-Alder reactions, for which both *endo* and *exo* cycloaddition have been considered. For seemingly interesting combinations, this data will be used to train a force field in the ReaxFF molecular dynamics software, which will in turn allow to predict macroscopic material properties, such as the glass transition temperature and Young's modulus of the resulting polymer. Each step in the multi-scale model will be benchmarked to available experimental data.

2:30 PM DS05.02.04
Predicting Polymer Properties via Quantitative Disorder Metrics RobertMakin[1], SteveDurbin[1], Samerender NagamHanumantharao[2] and SmithaRao[2]; [1]Western Michigan University, United States; [2]Michigan Technological University, United States

The Bragg-Williams approach to quantifying disorder through x-ray diffraction measurements is routinely applied to a range of crystalline materials including metallic alloys. In this formulation, which dates to the early 1930s, a numeric value (represented by S) is assigned to represent the degree of ordering, where S = 1 corresponds to fully ordered and S = 0 corresponds to fully randomized. Recently, the methodology has been extended to enable the use of additional measurement techniques, including Raman spectroscopy and scanning electron microscopy, both of which are straightforward to apply to organic polymer materials; typically, two decimal place agreement or better is obtained from any of these methods, as validated by measuring samples with multiple techniques. Whereas S in the context of metallic alloys represents the number and type of antisite defects within the atomic lattice, for polymers the value of S is associated with tacticity (S = 0 correponds to atactic whereas S = 1 corresponds to syndiotactic).

We have shown that certain electronic as well as mechanical properties exhibit a linear dependence on the squared value of S, specifically that $P(x, S) = [P(x = 0.5, S = 1) – P(x, S = 0)]S^2 – P(x, S = 0)$, where P is the property dominated by pair-wise interaction between methyl groups, and x relates to the ratio of methyl groups on either side of the polymer chain. Example properties which exhibit this dependence include bandgap, specific capacitance, and Young's modulus, and creating an experimental plot of the property under consideration as a function of S^2 enables a determination of the full accessible range of values for that property. Further, identifying the relationship between S and synthesis parameters provides a direct pathway to achieving the full range of property values, which is valuable given that a typical process may naturally confine itself to a narrow range of S in the absence of explicit modification. For example, we have shown that when electrospinning PANI-PCL increasing the applied voltage from 20 kV to 23kV can cause the S value the PANI-PCL to double from 0.31 to 0.63.

Here, we present results of our disorder based predictive property analysis--specifically highlighting the potential for accessing property values outside the ranges commonly reported in the literature -- for four types of polymers: polyvinyl fluoride (PVDF), polycaprolactone (PCL), polyaniline (PANI) and polyaniline-polycaprolactone (PANI-PCL) fibers. For PANI, our experimetnally derived results predict an S=1 band gap of 0.7 eV and specific capacitance of 643 F/g. Similarly, for the Young's modulus of PVDF, PCL, and PANI-PCL our analysis predicts values for the S=1 value of: 33 MPa, -1.25 MPa and -1.13 MPa, respectively. We will also examine how, in some instances, certain macroscopic sample properties can also exhibit a linear dependence on S^2, which provides an alternative route to engineering final properties for specific applications from the synthesis stage.

2:45 PM DS05.02.05
A Computational Approach to Insights into Aggregate Formation between Cellulose Acetate and Xylan Acetate Md Imrul RezaShishir, MelissaPasquinelli and SunkyuPark; North Carolina State University, United States

The production of insoluble gel particles (IGP) during cellulose acetylation is a persistent issue in the industry, adversely affecting both processability and final product quality. The formation of IGP has been attributed to factors such as uneven cellulose acetylation and the presence of hemicellulose acetates, yet there is still debate surrounding the underlying mechanisms. Cellulose acetate (CA) and xylan acetate (XA), both derived from cellulose, exhibit intricate aggregation phenomena, further complicating the understanding of IGP formation. These cellulose-derived polymers possess unique structural and chemical characteristics, which influence their aggregation behavior. The interplay between molecular interactions, such as hydrogen bonding and hydrophobic interactions, plays a crucial role in the formation and stability of aggregates in CA and XA systems. This study adopts a comprehensive computational approach to unravel the complex processes underlying aggregate formation and stability in cellulose acetate and xylan acetate systems. In this comprehensive study, we adopt a synergistic approach by combining molecular dynamics (MD), dissipative particle dynamics (DPD), and density functional theory (DFT) to gain a multifaceted understanding of the systems under investigation. Our primary focus is on the behavior of XA and CA in various solvents, which we explore through MD simulations. By closely examining their interactions and dynamics, we obtain valuable insights into these cellulose-derived polymers' solubility characteristics and behavior. Additionally, DPD simulations are employed to investigate the formation of aggregates, allowing us to explore the dynamic behavior, intermolecular interactions, and aggregation kinetics. Our investigation extends to the formation of aggregates, a phenomenon of great significance in the field. Through these simulations, we delve into the driving forces and underlying mechanisms that govern the formation of IGP, a common challenge encountered during cellulose acetylation processes. This integrated computational framework offers valuable information on the underlying driving forces and mechanisms that govern the formation of IGP.

Sequence Dependent Phase Separation and Aggregation of Macromolecules: What Can We Learn from Simulations and Machine Learning?AntoniaStatt[1], DebjyotiBhattacharya[2], HelenaCasademunt[3], DevonKleeblatt[2] and WesleyReinhart[2]; [1]University of Illinois, United States; [2]The Pennsylvania State University, United States; [3]Harvard University, United States

In this talk, I will present the phase separation behavior of different sequences of a coarse-grained model for intrinsically disordered proteins or sequence defined block copolymers. They exhibit a surprisingly rich phase behavior, and not only conventional liquid-liquid phase separation is observed, but also reentrant phase behavior, in which the liquid phase density decreases at lower temperatures. Most sequences form open phases consisting of aggregates, rather than a normal liquid. These aggregates had overall lower densities than the conventional liquid phases and complex geometries with large interconnected string-like or membrane-like clusters. Minor alterations in the sequence may lead to large changes in the overall phase behavior, a fact of significant potential relevance for biology and for designing self-assembled structures using block copolymers. I will also discuss recent results from unsupervised manifold learning (UMAP) to classify the different aggregate types and what we can learn from machine learning. Using a bidirectional-gated recurrent units-based Neural Network (RNN), we can now predict which sequence will self-assemble into what aggregate structure.

4:00 PM DS05.02.07
Machine Learning to Bridge Scales in the Multiscale Modeling of Radical-Containing Polymers RiccardoAlessandri and JuanJ. de Pablo; The University of Chicago, United States

Polymers with electronic properties offer unique solutions for stretchable electronics, biomedical sensors, and all-organic batteries. Due to their multiscale nature, the rational design of polymers with tailored electronic properties is obscured by the interplay of electronic and structural degrees of freedoms over a wide range of spatiotemporal scales. This interplay renders quantum mechanical descriptions at mesoscopic spatiotemporal scales critical to accurately predict electronic functionalities in these polymers. Hence, efficient computational approaches incorporating both mesoscale morphological features and electronic properties are required.

We present an efficient computational approach, combining physics-based and machine learning techniques, to incorporate electronic structure information at coarse-grained scales. As an example, we focus on radical-containing, redox-active polymers, an emerging class of materials for all-organic energy storage. Coarse-grained modeling allows to probe relevant polymeric material length- and timescales. At the same time, electronic structure information is retained, enabling trained machine learning models to rapidly predict electronic properties from coarse-grained polymer morphologies. In this way, the approach allows to obtain relationships between electronic properties and the material morphology and processing conditions. We compare our results to the standard methodology which involves backmapping the coarse-grained morphology to atomistic resolution followed by quantum chemical calculations, and find that our approach retains good accuracy while achieving orders of magnitude speedups. As such, the proposed approach holds promise in greatly expediting multiscale computational workflows aimed at bridging the quantum and mesoscopic scales in polymer modeling.

4:15 PM DS05.02.08
AI-Assisted Discovery of High-Temperature Record-Breaker Dielectrics for Energy Storage RishiGurnani[1], StutiShukla[2], DeepakKamal[1], ChaoWu[2], JingHao[2], ChristopherKuenneth[1], YangCao[2], GregorySotzing[2] and RampiRamprasad[1]; [1]Georgia Institute of Technology, United States; [2]University of Connecticut, United States

Electrostatic capacitors serve as critical energy storage units in advanced electrical and electronic systems used in the energy, defense, aerospace, and transportation sectors. Energy density, the figure of merit for electrostatic capacitors, is primarily determined by the choice of dielectric material. Most industry-grade polymer dielectrics are flexible polyolefins or rigid aromatics. These polymers possess high energy density or high thermal stability, but not both. Here, we use advanced artificial intelligence (AI) techniques, established polymer chemistry, and molecular engineering to discover a handful of dielectrics in the polynorbornene and polyimide families. One exhibits a record-setting energy density of 8.3 J/cc at 200 °C, 11× that of any commercially available polymer dielectric. We find that each of the discovered dielectrics has high thermal stability but varying energy density. By incorporating oxygen into the polymer backbone, we observed the greatest impact on energy density, with an increase of over 5.5 J/cc at °C. Additionally, position and identity of the phenyl substituents modulate the energy density by nearly 1 J/cc. Our findings broaden the range of potential applications for electrostatic capacitors within the 85–200 °C range, such as wind pitch control, hybrid vehicles, and pulsed power systems. We also evaluate available pathways to further enhance the polynorbornene and polyimide families so that these capacitors may perform in even more demanding applications (e.g., aerospace) while being environmentally sustainable. More broadly, this research demonstrates the impact of AI on chemical structure generation and property prediction, highlighting the potential for materials design advancement beyond electrostatic capacitors.

4:30 PM DS05.02.09
High-Throughout Exploration of Amorphous Multicomponent Phase Diagram Space for the Accelerated Design of Organic Thin Films HaoLiu and OlgaWodo; State University of New York at Buffalo, United States

During solvent-based fabrication of organic blends, the blend composition changes significantly as solvent is removed from the blend triggering phase transformations and structure formation. The choice of the solvent in conjunction with the processing pathways (i.e. quench profile) affects this process. Using a combination of solvents as well as solvent additives has produced favorable structures for organic electronic applications. For example, in the context of organic solar cells, changing solvents, utilizing solvent blends, including solvent additives, and adding thermal annealing as a post-processing step, have all produced significant jumps in photovoltaic efficiency. With the number of possible solvents potentially in the hundreds, choosing solvent blends, solvent additives and similar strategies represent a combinatorically large set of possibilities. Most processing variants reported have invariably been chosen through a trial-and-error approach, suggesting that only a small subset of the selection set has been explored. The selection of solvents has a rich history of empirical and theoretical design rules. The solubility sphere (HSP sphere) technique is an often used approach that allows the down selection of solvents when dealing with blends of materials. However, this becomes impractical with an increasing number of components and has no straightforward way to consider quench depths, crystalline phases or processing pathways as no additional thermodynamics (let alone kinetics) is considered. Consequently, it has remained challenging to establish reliable design rules that can be used for solvent blend selection, as well as selecting (and expanding) the processing space. In this work, we consider using the full phase diagram as a signature for solvent selection. The phase diagram is a comprehensive representation of the thermodynamic characteristics of the multi-component material system. Using high throughput exploration and clustering method, we learn simple and interpretable rules of phase diagram type and its sensitivity to the changes in the interaction parameter. This work has implications for the solvent selection but also solvent replacement for the efficient devices.

4:45 PM DS05.02.10
Forming Long-Range Order in Solution-Processed Semiconducting Polymers Minh NhatPham[1], Yu-ChingHuang[2], Chun-JenSu[3], Yu-YingLai[1], Ting-HanLin[1], Yong-KangLiaw[1], Kun-TaLin[1], Ting YuHuang[1], Yun ShuanChu[1], U-SerJeng[3], Jr-jengRuan[1] and BenB. Hsu[1]; [1]National Cheng Kung University, Taiwan; [2]Ming Chi University of Technology, Taiwan; [3]National Synchrotron Radiation Research Center, Taiwan

Intermolecular interactions control molecular dissolving and stacking through directional solution processes, which determine the thin-film morphologies. While directional solution processes have been widely used, their resulting morphologies are often disordered or ordered in small scale, making their electronic characterizations unreliable. To overcome this issue, ordered structures created by regulating complex intermolecular interactions is required. This study aims to quantitatively identify and control the intermolecular interactions between semiconducting polymers and self-assembled monolayers (SAMs) in solutions to achieve long-range order. The proposed methodology of intermolecular guidance involves optimizing the processing temperature for dissolving aggregates into shorter bundles, finding their guidable intermolecular scale, and then guiding them along 1D nano-templated SAMs to form unidirectional fibers. The validity of this methodology is confirmed by various spectroscopic and morphologic techniques, demonstrating highly-ordered molecular stacking in unidirectional fabric structures. Based on Flory-Huggins theory and our experiments, the critical intermolecular scale and energy of the guidance and ordering are confirmed to be about 3 Å and 40 meV. In this range, small and random aggregates can be aligned to form macroscopically-ordered fibers, showing an increase in anisotropic Raman scattering intensity from around 1 to 10. Overall, this work provides a quantitative guideline to control complex intermolecular interactions of dissolving, stacking, and ordering between semiconducting polymers and self-assembled monolayers, showing the angstrom-scale controllability in molecular assembly.

Templating Effects by Pre-Formed Seed Oligomers in Irreversible Step-Growth Copolymerization WenxinXu, NhuQ. Nguyen and KateriH. DuBay; University of Virginia, United States

The synthesis of sequence-controlled polymers is believed to be an effective way to produce materials with desirable properties. However, the complexity of polymerization processes makes precise control of sequences difficult to achieve for synthetic polymers. In previous studies from our group, unexpected kinetics and self-assembly have been observed to arise from relatively weak non-bonded interactions between like monomers and be controlled by solvent selectivity, chain geometry, and activation energy. This influence is attributed to the phase separation of growing oligomers following Flory-Huggins Theory. Additionally, the appearance of non-monotonic growth of dispersity and a characteristic block length at sufficient stiffness and non-bonded interactions suggests the presence of self-templating effects. Self-templating effects are common in the synthesis of biopolymers and may provide an interesting opportunity to control the sequence of synthetic copolymers and supramolecules. Therefore, in this work, we seek to investigate templating effects for reaction kinetics and polymer sequences arising from the addition of seed oligomers to an irreversible step-growth copolymerization through coarse-grained simulations. We found that the rate of polymerization and resultant chain sequences depend on the sequence and length of seed chains. Moreover, the addition of seeds can yield combined effects with other reaction conditions, such as the viscosity and non-bonded attraction, on the block-length distribution and the characteristic block length.

8:00 PM DS05.03.02
Investigating Pathways to Solid-State Refrigeration: Simulating the Barocaloric Effect in Polymers SaabirPetker, ClaireHobday and AntoniaMey; The University of Edinburgh, United Kingdom

New refrigeration technologies are in demand with global targets to reduce the use of hydrofluorocarbons in refrigeration due to their environmental harm.[1] Materials that exhibit a barocaloric effect (BCE) are solid state alternatives, changing temperature as a hydrostatic force is applied.[2] We focus on BCE exhibiting polymers (BCEPs), specifically vulcanised natural rubber (VNR). A complete theoretical framework of the mechanism behind the BCE in BCEPs is yet to be produced, with hypotheses the BCE arises from either reversible re-aligning of polymer chains or stress induced crystallisation.[3, 4]
In this work, we will show that by using molecular dynamics simulations, we can generate a pressure-temperature phase diagram of VNR. These simulations uncover atomistic information about the BCE in VNR, e.g. we will demonstrate where the colossal entropy changes (137 J kg^{-1} kg^{-1}) originate on an atomistic level, as well as determine the barocaloric coefficient of VNR to be ~60 K GPa^{-1}.

Conformation Transition of Polyelectrolytes Induced by Temperatures, Salt Concentrations and Electric Fields via Atomistic Molecular Dynamics Simulations TianyiWang and YaxinAn; Louisiana State University, United States

Polyelectrolytes are a class of polymers that contain repeated units with electrolyte groups categorized roughly as polycations, polyanions, and polyampholytes. They exhibit strong interaction with ionic solutes, polar solvents and surface and electrons under electric fields, making them crucial to energy storage, drug delivery, adhesives, and other applications. However, the atomistic understanding of the interplay between polyelectrolytes and ions/solvents/electrons is still limited, impeding the precise control of their conformation and properties. To gain atomistic insights into the local ion/solvent structure and its impact on the conformation of polyelectrolytes, we performed atomistic simulations of two representative polyelectrolytes, poly(vinylbenzyl trimethylammonium chloride) (PVBTAC) and polystyrene sulfonate (PSS) at varying salt concentrations. The behaviors of PVBTAC and PSS differed as the salt concentration increases. Specifically, the radius of gyration of PVBTAC increased while that of PSS decreased at 310 K. As the temperature increased to 350 K, the PVBTAC chain exhibited slight changes, whereas the PSS chain became significantly stretched. Furthermore, we investigated the effects of the electric field on the conformations of PVBTAC and PSS. To elucidate the mechanism driving the=conformation changes induced by salt concentrations, temperatures, and electric fields, we analyzed the local solvent and ion structures, as well as hydrogen bonds. This study provides atomistic insight into the interplay between polyelectrolytes and ions/solvents, offering guidelines for precise control over the conformation and properties of polyelectrolytes by adjusting salt concentrations, temperatures, and electric fields.

8:00 PM DS05.03.05
Enhanced Thermal Performance Properties of EPDM Carbon Black Composites via Crossover Curing Agents Arshad RahmanParathodika and KinsukNaskar; Indian Institute of Technology Kharagpur, India

Elastomeric products in the automotive and industrial sectors often have to meet conflicting performance requirements, such as both high flexibility and higher thermal resistance. However the feasibility of using ultra-high-performance elastomers like FKM is often restricted by financial constraints. The practical solution involves modifying the crosslinking system and developing a synergistic hybrid system to achieve contradictory properties. This work discusses the possibility of developing a hybrid crosslinking system in the ethylene propylene rubber (EPDM) matrix. Sulfur-cured EPDM is more flexible due to its carbon sulfur and sulfur sulfur crosslinks, while peroxide-cured EPDM has carbon-carbon crosslinking and higher thermal stability, making it less flexible. This study focuses on the development of systems creates co-existence of both forms of crosslinks, in order to meet the conflicting property requirements. EPDM is chosen for this study due to its viability and established industrial applications with both curing systems. This study also examines the multifunctional role of 1,3-bis(citraconimidomethyl)benzene (BCIMB) in two different curing systems, acting as a reversion-resistant agent in sulfur curing and as a coagent in peroxide curing. The study investigates the potential of a hybrid curing system that containing BCIMB to maintain the stability of networks and temperature-stable compounds while preserving their flexibility. The results of the study indicate that optimized hybrid systems containing BCIMB can retain performance properties after 504 hours of thermal aging at 125° C with only a 13% change in initial values.

8:00 PM DS05.03.06
Designing High Glass Transition Temperature Fluoropolymers using Transfer Learning Jin HoonYang, Ji YoungLee, Eun HoSohn, HyunjuChang and SeunghunJang; Korea Research Institute of Chemical Technology, Korea (the Republic of)

In this study, we propose a novel machine learning approach to accurately predict fluoropolymers' glass transition temperature (T_g) and demonstrate its potential in guiding the design of high T_g copolymers. Firstly, we utilize the QM9 dataset for model pre-training, providing robust molecular representations for subsequent transfer learning on a specialized copolymer dataset. Our pre-trained model expertly encodes complicated molecular structures and general molecular properties using atom-level (graph) and global molecular-level (global state) features. This extensive feature set is processed via a dual network system, with the outputs merged to form a comprehensive molecular descriptor. Dealing with a small copolymer dataset, we encounter significant discrepancies between individual models, a common issue in limited data. We address this problem by adopting an ensemble approach and providing more reliable and robust predictions. Finally, we can navigate a vast chemical space comprising 61 monomers and identify promising candidates for developing high T_g fluoropolymers. Our work shows the potential of machine learning in materials design and discovery and the effectiveness of ensemble models in addressing the challenges associated with small datasets.

8:00 PM DS05.03.07
Accelerating Discovery of Liquid Crystal Polymeric Materials with Extreme Properties using Machine Learning HaichaoWu; Harvard University, United States

Liquid crystal polymeric materials are polymers combining the ordering properties of liquid crystals and rubbery elasticity from the polymer network. Liquid crystal polymers have demonstrated great potential as implants and medical devices due to the versatile stimuli responsiveness and programmable actuation. Here, we are interested in identifying new liquid crystal polymeric materials with extreme properties, such as body-temperature phase transition temperature, high fatigue resistance, and high actuation strain. The traditional way to identify materials with desired properties is intuition-driven, based on trial-and-test strategies, which is not only time-consuming but highly likely to miss the optimal candidates, especially under the scenarios that multiple “conflicting” properties need to meet at the same time. To address this issue, we inverse design of polymer with desired properties using machine learning methods. In particular, we use generative models to explore potential chemical space and use transfer learning to find the quantitative structure-property relationship (QSPR) based on a limited dataset. The methods developed here are highly generalizable to solve other polymer design problems from the molecular scale.

SESSION DS05.04: Polymer Informatics III

Sheraton, Third Floor, Gardner

10:00 AM *DS05.04.01
Polymer Informatics—Algorithmic Advances for Materials Design RampiRamprasad; Georgia Institute of Technology, United States

Polymers display extraordinary diversity in their chemistry, structure, and applications. However, finding the ideal polymer possessing the right combination of properties for a given application is non-trivial as the chemical space of polymers is practically infinite. This daunting search problem can be mitigated by surrogate models, trained using machine learning algorithms on available property data, that can make instantaneous predictions of polymer properties. I will present a versatile, interpretable, and scalable scheme to build such predictive models. Our ‘‘multi-task learning’’ approach is used for the first time within materials informatics and efficiently, effectively, and simultaneously learns and predicts multiple polymer properties. It is thus a powerful tool to solve “forward materials problems”, i.e., property predictions. I will also discuss new approaches to solve “inverse materials problems”, i.e., identifying materials that satisfy target property criteria. These forward and inverse method developments are expected to have a significant impact on data-driven materials discovery.

Extensive Evaluation and Advancement of Extrapolation Performance in Polymer Property Prediction HajimeShimakawa, AkikoKumada and MasahiroSato; The University of Tokyo, Japan

Polymer Informatics (PI), an emerging field which integrates computational science and data science, has gained significant attention as a powerful approach for accurately predicting intricate polymer properties. The prevalent approach in PI heavily depends on structure-based models, specifically deep learning and nonlinear regression models, which excel at capturing complex relationships within polymer molecular structures. However, these structure-based models face challenges when dealing with small data predictions, particularly in PI where the available database is still insufficient. Despite their effectiveness with interpolation of large datasets, the generalization performance of these models can be compromised in limited data [1]. Moreover, the highly expressive nature of these black-box models poses difficulties in interpreting and explaining their predictions, especially when extrapolating beyond the range of available data [2]. It is crucial to explore the potential of PI in identifying highly functional polymers that surpass the limits of existing data.
In this study, we evaluate the extrapolation performance of baseline ML models used in polymer property prediction. Our evaluation employs experimental and computational datasets encompassing a wide range of data scales, including mechanical, thermal, and electrical properties. Additionally, we propose a novel ML model that effectively extrapolates polymer properties by leveraging a framework previously demonstrated in extrapolating the properties of small organic molecules. In contrast to conventional approaches relying on black-box ML techniques, our constructed ML model incorporates microscopic physical features derived from molecular computations. This integration allows for the explicit extraction of correlations between microscopic physical quantities and macroscopic polymer properties, resulting in an explainable ML model with enhanced extrapolation capabilities. Through extensive evaluations of the extrapolation performance, we demonstrate the limitations of conventional models in extrapolation tasks while highlighting the effectiveness of our proposed approach.

Designing Novel Polymer Dielectrics using polyVERSE ShivankS. Shukla, MadhubantiMukherjee, RishiGurnani, Kuan-HsuanShen and RampiRamprasad; Georgia Institute of Technology, United States

As the demand for polymers with improved properties and performance in dielectric applications continues to grow, researchers are exploring alternative polymer chemistries that differ from the conventional polymers commonly used in the industry. The traditional polymer compositions present a compromise between high energy density and high thermal stability, preventing the simultaneous achievement of both attributes. To overcome this challenge, we employ a high-throughput virtual screening approach, exploring an extensive and diverse chemical space of monomers and polymerization templates that can lead to synthetically accessible high-performance polymers. We call this approach polyVERSE: polymers created using Virtually-Executed Rule-Based Synthesis Experiments. Subsequently, the limitless number of virtually produced polymers undergo screening using machine learning (ML) model predictions of the relevant properties, namely, dielectric constant, band gap and glass transition temperature. These ML models leverage advanced learning techniques, including multi-task learning, and incorporate Molecular Dynamics simulation-generated data specifically for the glass transition temperature, enabling precise property predictions for a broad range of polymer chemistries. Data generation respecting synthetic feasibility, physics-driven computations, measured property databases, multi-task machine learning algorithms, virtual screening, and synthetic validation are integrated. By leveraging this approach, we present novel dielectrics predicted to simultaneously achieve both high energy density and high thermal stability, thereby surpassing conventional polymers.

11:00 AM DS05.04.04
Improving the Performance of Polymer Property Predictions Through Polymer Graph Development and Literature Data Extraction EvanAntoniuk, PeggyLi, BhavyaKailkhura, DavidButtler and AnnaM. Hiszpanski; Lawrence Livermore National Laboratory, United States

Across the physical sciences, machine learning models have been demonstrated as powerful tools for capturing the complex relationships between chemical systems and their properties with remarkable accuracy. However, the pursuit of such structure-property relationships in the domain of polymer chemistry has been hindered by two significant challenges: i) the lack of representations that can capture the periodic, ensemble that comprise polymeric structure, and ii) the lack of sufficiently diverse polymer property datasets.

In this talk, we will show how we address this first challenge through the creation of a periodic polymer graph representation. This periodic polymer graph representation improves over fingerprint-based descriptors on monomers by directly accounting for the periodicity of the polymer, as well as utilizing learned atomic descriptors. We benchmark this periodic polymer graph representation across 10 unique homopolymer property datasets and find that our periodic polymer graph representation achieves state-of-the-art predictive performance on 8 of the 10 properties. Ablation studies on our graph representation highlight that this improvement in predictive performance is the direct result of the use of both learned descriptors as well as including periodicity. In this way, our results highlight how accurate polymer property predictions can be achieved through the development of representations that better account for the unique and complex chemical structure of polymers.

Beyond predicting the properties of only homopolymers, there is considerable interest in expanding the scope of polymer property prediction models to encompass a broad range of polymer types including copolymers, crosslinked-polymers or network polymers. However, the development of such generalizable models is currently hindered by the lack of polymer property datasets that are accessible and sufficiently descriptive of the polymer structure. To combat this challenge, we have developed an automated pipeline for extracting polymer property data from the scientific literature. With this pipeline, we extract polymer property data from a diverse range of polymer types to augment existing homopolymer property datasets. By retraining the above periodic polymer graph on this augmented polymer dataset, we show that this approach is an effective strategy towards enabling polymer machine learning models to generalize well across all types of polymers.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

11:15 AM DS05.04.05
Large Language Model-Based Pipeline for Extraction of Polymer Property Records PranavShetty, SonakshiGupta, AishatAdeboye and RampiRamprasad; Georgia Institute of Technology, United States

Polymer informatics has made great strides in recent years in predicting polymer properties and designing new materials. These data-driven models are powered by curated data and require painstaking manual curation often from the rapidly growing corpus of journal articles. Data curators and materials scientists who search for material property information from this growing body of literature face an uphill task.

In this work, we present a pipeline that leverages large language models to extract material property information from the text of journal articles. We frame the problem as a text-completion problem by inputting the text containing material property data and a prompt with the relevant instructions to the GPT3.5 model accessed through the OpenAI API. An example prompt looks like 'Extract all bandgap values from the following text in json format: ...'. The output produced by the language model for this prompt is the tuple of material and property value as a dictionary. We use the paradigm of few-shot prompting wherein a few representative examples are selected and input output pairs are provided as a prompt to the model. This specifies a format for the data to be extracted and increases extraction performance. We benchmarked our method on two datasets of abstracts containing polymer glass transition temperature and bandgap respectively and show that this method outperforms information extraction using fully supervised methods using named entity recognition and heuristic rules for relation extraction. The resulting method was then applied to a corpus of 2.6 million materials science articles to extract all polymer glass transition temperature and bandgap values recorded therein.

11:30 AM DS05.04.06
De Novo Design of Polymer Electrolyte with High Ionic Conductivity using GPT-Based and Diffusion-Based Generative Models ZhenzeYang[1,2], WeikeYe[1], XiangyunLei[1], DanielSchweigert[1], Ha-KyungKwon[1] and ArashKhajeh[1]; [1]Toyota Research Institute, United States; [2]Massachusetts Institute of Technology, United States

Solid polymer electrolytes hold significant promise as materials for next-generation batteries due to their superior safety performance, enhanced specific energy, and extended lifespans compared to liquid electrolytes. However, the vast polymer space poses considerable challenges to their screening and design. In this study, we harness the capabilities of generative AI for the de novo design of polymer electrolytes. This approach not only augments the existing polymer data but also facilitates the generation of polymers towards tailored, desirable properties. To optimize the generation, we compare different deep learning architectures, including both GPT-based and diffusion-based models. We further employ full-atom molecular dynamics

simulations to validate the top candidates produced by each model and discover one polymer with superior ionic conductivity compared to any other polymers in our database. In addition, by adopting a pretraining and fine-tuning methodology, we significantly improved the efficacy of our generative models, achieving quicker convergence, enhanced performance with limited data, and greater diversity. Using the proposed method, we can easily generate hundreds of thousands of novel, diverse, valid, and synthesizable polymers, enabling us to identify promising candidates with markedly improved efficiency.

11:45 AM DS05.04.07
Machine Learning Strategies for The Structure-Property Relationship of Copolymers YingLi; University of Wisconsin–Madison, United States

Establishing the structure-property relationship is extremely valuable for the molecular design of copolymers. However, machine learning (ML) models can incorporate both chemical composition and sequence distribution of monomers, and have the generalization ability to process various copolymer types (e.g., alternating, random, block, and gradient copolymers) with a unified approach are missing. To address this challenge, we formulate four different ML models for investigation, including a feedforward neural network (FFNN) model, a convolutional neural network (CNN) model, a recurrent neural network (RNN) model, and a combined FFNN/RNN (Fusion) model. We use various copolymer types to systematically validate the performance and generalizability of different models. We find that the RNN architecture that processes the monomer sequence information both forward and backward is a more suitable ML model for copolymers with better generalizability. As a supplement to polymer informatics, our proposed approach provides an efficient way for the evaluation of copolymers.

SESSION DS05.05: Polymer Informatics IV

1:30 PM *DS05.05.01
The NIST Autonomous Formulation Laboratory: Virtual Scattering Instruments for Active Learning Agent Development TylerMartin, DuncanSutherland and PeterBeaucage; National Institute of Standards and Technology, United States

Machine-learning (ML) is revolutionizing the way we do material science with ML models that are discovering new polymer chemistries, designing syntheses, guiding measurements, and analyzing data, all with unprecedented accuracy and speed. Despite these advances, many challenges remain in creating the next generation of polymer ML models. A key limitation for polymer science focused models is the lack of high-quality, well-tagged measurement data in sufficient amounts for supervised training. The generation of measurement data for soft materials is hampered by limited polymer availability, tedious sample preparation, slow instruments, and involved data processing. While synthetic data can help alleviate this data scarcity, it is challenging to produce data that correctly accounts for instrument artifacts and resolution effects. Beyond the instrumental effects, mimicking the behavior of real soft-material samples requires accounting for impurities, processing effects, and other non-idealities that go beyond simple analytical models. In this talk we will describe our attempts to overcome these challenges with the development of a virtual small-angle scattering (SAS) instrument. This goal of our framework is to produce high-quality SAS data as a function of input parameters (e.g., sample composition, processing parameters, instrument configuration) that can be used for model training or ML agent development. We will specifically highlight the design of the virtual instrument and how it can be used to tune active learning agents. Finally, we will demonstrate how these tuned agents are performant in guiding real small-angle scattering experiments.

2:00 PM DS05.05.02
Chemometrics Approach Based on Wavelet Transforms for the Estimation of Monomer Concentrations from FTIR Spectra Araki Wakiuchi[1,2], SwaritJasial[1,1], ShigehitoAsano[2], RyoHashizume[2], MihoHatanaka[3], Yu-yaOonishi[2], TakamitsuMatsubara[1,1], HiroharuAjiro[1,1], TetsunoriSugawara[2], MikiyaFujii[1,1] and TomoyukiMiyao[1,1]; [1]Nara Institute of Science and Technology, Japan; [2]JSR Corporation, Japan; [3]Keio University, Japan

Traditionally, monitoring of chemical reactions has been performed by calculation of reactant concentrations through spectroscopies like NMR, IR, NIR, and UV-vis. But these methods often require complex isolation techniques before analysis, making concentration identification a slow process. Fourier-transform infrared (FTIR) spectroscopy holds potential for quick estimation of concentration, as it uses Beer-Lambert law to acquire concentration information from specific absorbance of substance. However, practical applications such as copolymerization reactions have difficulty in obtaining concentration due to multiple overlapping peaks from different components.

To address this problem, we are proposing a chemometric method that uses wavelet transforms (WT) for decomposing overlapped peaks into features which are then input to a sparse linear regression model built by the elastic net (EN) for predicting concentration of reactant. This new method, validated through careful comparison with other methods, shows superior predictive performance and is interpretable by humans. Visualization of regression coefficients with Gaussian distributions help in understanding the model by showing how broad regions in spectra are related to the model prediction.

We have used our method for predicting monomer concentrations in copolymerization reactions involving methyl methacrylate and five different monomers; styrene, glycidyl methacrylate, cyclohexyl methacrylate, p-acetoxystyrene and tetrahydrofurfuryl methacrylate, showing its practical use for complex chemical analysis. In addition, we have made our method, data sets, and implementation available to public (https://github.com/Wa-Araki/WT-ENCV) for promoting future progress in the field of chemometrics.

Our study introduces a powerful, interpretable, and an efficient tool for quantitative analysis of copolymerization reactions using FTIR spectra. By avoiding the need for complicated isolation techniques and careful handling of overlapping peaks, our WT-based method holds significant potential for a wide application in monitoring of chemical reaction and beyond.

Mechano-Spectroscopy of Soft Materials with Nanometer Spatial Resolution: When Atomic Force Microscopy is Combined with Machine Learning MikhailPetrov[1], NikitaKulachenkov[1], DanielCanena[1], PierreNickmilder[2], PhilippeE. Leclere[2] and IgorSokolov[1]; [1]Tufts University, United States; [2]University of Mons, Belgium

Here we present a method to identify the material composition over a sample surface with the spatial resolution down to single nanometers. The method is based on the use of atomic force microscopy (AFM) working in imaging sub- resonance tapping Ringing mode, which allows collecting multiple physical/mechanical maps of the sample with subnanometer lateral resolution. Using a database of these properties collected on known materials, the presented method allows identification of the location of these materials on samples made of the known materials. The materials are identified at each pixel of the image with the help of machine learning algorithms, such as neural networks and decision trees. We demonstrate this approach on various blends made of three different polymers, namely polystyrene (PS), polyvinyl pyrolidone (PVP), and polyethylene oxide (PEO). The advantages and limitations of the presented method compared to other spectroscopy methods will be discussed.

Graph-Based Machine Learning to Predict Particle Dispersion Evolution from Training Image Sequences SameeraNalin Venkat[1], ThomasCiardi[1], MingjianLu[1], JubeAugustino[1], AdamGoodman[1], PrestonDeLeo[1], PawanK. Tripathi[1], AnirbanMondal[1], FrankErnst[1], ChristineA. Orme[2], YinghuiWu[1], RogerH. French[1] and LauraBruckman[1]; [1]Case Western Reserve University, United States; [2]Lawrence Livermore National Laboratory, United States

We develop a spatiotemporal particle-based graph neural network (st-PGNN), an image-based graph machine learning framework to predict the shape and size evolution of growing particles as part of particle ensembles. Using crystallization of amorphous fluoroelastomer layers as a model system from atomic force microscopy image sequences. The new method involves implementing a spatiotemporal particle graph neural network. This will enable us to study the impact of neighboring crystallites on the growth kinetics and to obtain quantitative spatiotemporal correlations. The insights from this approach will enable quantification of radial particle growth rates and improve nucleation density statistics. In the long term, our approach is expected to provide data for detailed comparisons to existing particle-growth theories.

Work performed by CO was under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52- 07NA27344.

Polymer Design Across Industries: Intersection of Physics-Based Simulation and Machine Learning AndreaBrowning, AtifAfzal, BenjaminCoscia, AnandChandrasekaran and MathewD. Halls; Schrodinger, INC, United States

Adoption of digital design in polymers has gained in both visibility and impact as more industries see the value in computer based analysis of materials. A key to continuing this adoption is to expand digital analysis capabilities to more and more complex systems to match the reality of polymer use in products from cosmetics to pharmaceuticals to aerospace composites. Understanding the role of the polymer chemistry and microstructure in these complex systems requires advances in physics-based calculations and the leveraging of machine learning techniques. In this presentation a series of three examples will be provided showing advancement of physics-based simulation for polymers in complex formulations, the application of physics-based calculations to the degradation of polymers, and the improvement of predictive capability of physics-based calculations through the combination of machine learning. The continued development of physics-based tools and leveraging of machine learning will be highlighted as critical to the successful digital design of polymers in important product applications.

3:45 PM DS05.05.06
AI-Driven Polymeric Membrane Design for Efficient Binary-Component Solvent Separation JanhaviNistane, LihuaChen, YoungjooLee, Kuan-HsuanShen, RyanLively and RampiRamprasad; Georgia Institute of Technology, United States

Manufacturing polymers, plastics, fibers, solvents, and fuel additives in numerous industries rely extensively on starting materials like benzene and its derivatives, including toluene, ethylbenzene, and the xylene isomers. To use petroleum-based products effectively, they often require separation into different components. This separation is achieved through energy-intensive thermal distillation processes, accounting for 10-15% of global energy usage. However, emerging membrane-based technologies have the potential to achieve these separations with about one-tenth of the current energy consumption[1]. A polymer membrane essentially acts as a selective filter for solvents based on their diffusion behavior. Solvents with low diffusivity are retained by the polymer membrane, while those with higher diffusivity permeate through. For a successful separation, observing a minimum two-order difference in diffusivity between the solvents as it diffuses through the polymer membrane is necessary. The main challenge associated with membrane-based separations is identifying a tailored membrane material suitable for a specific solvent-solvent separation. Given the unimaginably vast chemical polymer space, conventional experimental methods to design new polymers are slow. Hence, we employ AI-aided material design that can efficiently explore the vast chemical polymer space in a very time and cost-effective manner, as has been achieved in the design of dielectric polymers in the past. [2,3] Around 10,000 potential polymer membrane candidates will be generated using our virtual forwarded synthesis, as an initial step to AI-aided material design. These hypothetical candidates will be screened using our best-in-class ML polymer-solvent diffusivity predictor, which has been trained on available experimental data, and our computationally generated data via molecular dynamics simulations. The ML polymer-solvent diffusivity predictor is trained on around 1200 data points (experimental and simulated) for 91 polymers and 50 solvents. This scheme to generate computational data is highly scalable, and we continue to keep augmenting new data to explore more polymer chemistries. Upon identifying promising candidates that meet the proposed screening criteria, experimental validation will follow. This approach will provide insights into the power, as well as the limitations of AI-driven materials design.

Multi-Fidelity Machine Learning Predictors for Gas Permeability Through Polymers: An Example of Experimental and Simulation Data Fusion BrandonK. Phan, Kuan-HsuanShen, RishiGurnani and RampiRamprasad; Georgia Institute of Technology, United States

Polymer based gas separation membranes have a wide variety of applications ranging from carbon capture, drug delivery, and food packaging. Such technology, when extended to biodegradable or chemically recyclable polymers has the potential to advance green sustainable energy and applications. Polymer membrane discovery and design has been accelerated using machine learning (ML) prediction models trained on experimental gas transport property data. Predictions in the known scope of experimental chemical spaces are reputable; however, they are less reliable when extrapolating to new spaces. In this work, we use a high-throughput molecular dynamics (MD) simulation pipeline to explore new chemical spaces. This pipeline we built produces simulation data for gas diffusivity, solubility, and permeability. Subsequently, we create multi-task deep learning models trained on both “high-fidelity” experimental and “low-fidelity” simulation data. The new multi-task model shows a significantly improved performance over models trained with only experimental data, particularly in data-scarce situations. The algorithm ascertains the correlation between low- and high-fidelity data, and this basis allows for a more informed decision when making predictions in new chemical spaces. This approach demonstrates the benefit of high-throughput classical MD simulations with data fusion to produce best-in-class property predictors especially when experimental data is not as accessible for properties of interest.

4:15 PM DS05.05.08
In-Silico Polymer Generation using Fine-Tuned Regression Transformers with Open Reference Data RonaldoGiro[1], HsianghanHsu[2], MatteoManica[3] and MathiasB. Steiner[1]; [1]IBM Research - Brazil, Brazil; [2]IBM Research - Albany, United States; [3]IBM Research - Zurich, Switzerland

In-silico design for homopolymers accelerated by machine learning and high throughput screening has garnered widespread attention and recognition in recent years. However, applications to specific domains are still challenging because data scarcity (typically structure-property pairs) not only limits model generalization but increases uncertainty in model inference. QSPR (Quantitative Structure-Property Relationship), a method widely used to aid data augmentation, is suitable for exploring unaddressed feature spaces. The method performs satisfactorily for intrinsic materials properties such as density, molar weight, and cohesive energy. However, for properties reflecting a material’s interaction with the chemical environment, such as refractive index or gas permeability, the QSPR method it less suited. In this contribution, we start materials discovery from tabulated information available in open-access literature. Furthermore, instead of training models from scratch, we rely on publicly available regression transformer models pretrained on large chemical datasets that we fine-tune on a small number of data points we extracted from literature. The models are tailored for finding new polymer membrane candidates with expected CO_2 and N_2 permeability.

We have evaluated published reference data beyond their initial scope of application. To that end, we have focused on tabulated data with clear experimental condition stated. The semi-automated extraction processes include an OCR (Optical Character Recognition) step, the validation with ground truth, and the merge into a data table. Some of the documents include either rich tables [1] or XML raw format data [2] which greatly accelerates the process. To obtain pSMILES (SMILES for specified homopolymers), we have fetched information from online database and documents. In total, we have collected 160 pSMILES with CO_2 and N_2 permeability values under comparable experimental condition. The molecular weights of the collected species range from 40 to 1000 and the pSMILES string length ranges from 5 to 148.

A regression transformer (RT) handles regression as a generative task by modeling continuous properties with a group of tokens representing digits and their orders of magnitude [3]. The RT algorithm used here exploits a custom pSMILES tokenizer and is available through GT4SD (Generative Toolkit 4 Scientific Discovery) [4]. Before fine tuning the model, both permeability values are converted to log scale for stabilizing model variance and minimizing skewed data distribution. 25 % of the dataset is used for model testing. Training the RT yields a dichotomous model that seamlessly transits between property prediction and conditional molecule design. As an example, a structure-property pair has the input format “<pco2log>2.255|*C(Cl)=C(*)CCCC”. We have evaluated the pretrained models with both single and multiple properties. Some generated polymer candidates such as *C(F)SC(*)[Si](C)(C)C and *c1c(Cl)cc(c2cc(C)c(N3C(=O)c4cc5c(cc4C3=O)C3(C)CCC5(C)c4cc5c(cc43)C(=O)N(*)C5=O)c3ccccc23)c2ccccc12 show high permeability values for CO_2 and are currently under investigation in automated molecular dynamics simulation.

In this contribution, we have reported the generation of new homo-polymer candidates for gas separation applications which are currently being validated with gas filtration simulations. The advancement of natural language processing and machine learning has accelerated the automated scientific discovery process. The publicly available dataset and open-source algorithms will help researchers to reproduce our discovery results with minimum effort, and to expand the scope to other polymer applications.

4:30 PM DS05.05.09
Utilizing Machine Learning to Model and Predict Interdependency of Bulk Molecular Weight, Solute Concentration and Thickness of Spin Coated Polystyrene Thin Films AlexanderC. Wang[1], SamuelChen[2], EvanXie[3], MatthewChang[4], AnthonyZhu[5], AdamHansen[6], JohnJerome[7] and MiriamRafailovich[6]; [1]Sewickley Academy Senior School, United

States; [2]Ed W. Clark High School, United States; [3]The Pingry School, United States; [4]Woodbridge High School, United States; [5]Barrington High School, United States; [6]Stony Brook University, The State University of New York, United States; [7]Suffolk Community College, United States

Spin coating is a widely used, quick, and inexpensive method to deposit nanometer-thick thin films of various polymers on top of solid substrates through the centrifugal force produced by a rapidly spinning platform [1]. Polystyrene (PS) is an amorphous polymer that is often spin-coated to create thin films for a variety of industrial and research applications [2]. Since the thickness of a film affects a number of mechanical, optical, and degradation properties, it is essential to develop a simple method to predict thickness based on other manipulatable factors, such as bulk polymer molecular weight and initial solution concentration. Previous works have attempted to model these spin coating relationships through complex mathematical models informed by theoretical physics and limited experimental data [3]. Therefore, advancements can be made in predicting spin coated film thickness. In this study, we implement a machine learning model to learn the relationship between initial solution concentration, thin film coverage thickness, and monodisperse bulk molecular weight
To model this relationship, we collected data points by creating PS solutions of molecular weight 30,000 amu, 50,000 amu, 123,000 amu, 200,000 amu, 311,000 amu, 650,000 amu, 1,080,000 amu, and 2,000,000 amu at concentrations of 10 mg/mL, 15 mg/mL, 20 mg/mL, 25 mg/mL, and 30 mg/mL. After spin coating these PS solutions onto silicon wafers at 2500 rpm velocity and 1000 rpm/s acceleration for 30 seconds, we then measured the thickness of these films via light-refraction ellipsometry (Auto El II Ellipsometer).
With the aforementioned ellipsometry thickness data, we trained 42 machine learning models to relate the three spin coating parameters: concentration, thickness, and molecular weight. The models accept molecular weight and thickness as inputs and predict the critical concentration, the solution concentration required to spin coat a sample of a specific molecular weight into the desired thickness. Compared to the 41 other models, the curve-fit model exhibited the best performance. It achieved the second lowest root-mean-square error (RMSE) and mean average percent error metric (MAPE) scores for its predictions on the training data set, at 2.39 and 6.46%, respectively. At the same time, it correctly modeled a continuous and monotonically increasing relationship between thickness and both molecular weight and solution concentration, aligning with previously formulated spin coating theories. Thus, it outperformed the lowest RMSE and MAPE scoring model, XGBoost, which failed to learn these general trends and instead overfitted to the training data.
To confirm the accuracy of the machine learning model beyond the training data set, we subsequently spin coated PS samples of previously unused molecular weights at several random concentrations to act as test data for the model. When predicting the critical concentration of these new molecular weights and thicknesses, the model achieved an RMSE of 2.51 and MAPE of 10.54%, which indicates that the model accurately learns and generalizes the relationship between concentration, thickness, and molecular weight, rather than overfitting to the training samples and data points. Further work will be completed on how polydisperse bulk molecular weight polystyrene samples fit on this machine learning model.

The Materials Galaxy: A Social Network Analysis Approach to Uncovering Materials Properties MehrdadJalali, DingaWonanke and ChristofWöll; Karlsruhe Institute of Technology, Germany

This study explores the application of social network analysis SNA in the field of materials science specifically focusing on analyzing metalorganic frameworks MOFs SNA a graph theory approach is employed to create a galaxy of MOFs and conduct community detection to predict MOF properties more accurately than conventional machine learning methods The study highlights the utility of SNA in predicting gas storage properties a popular application of MOFs
In the field of materials science where researchers deal with vast amounts of data it is crucial to streamline experimental and computational processes and improve result quality Developing a materialsfocused social network provides a valuable approach to analyzing data anticipating material properties identifying novel materials and investigating the factors influencing material behavior Previous research has employed SNA methods to study the properties of MOFs and highentropy alloys HEAs This study focuses on enhancing the gas adsorption properties of MOFs a typical application of porous materials
SNA utilizes graph theory and methods to examine network social relationships and communication patterns In materials science SNA can be used to understand the structure of materials networks analyze social relationships between them and predict properties or behaviors based on their connections Machine learning in social networks involves learning from graph representations of data In this study MOFs are represented as nodes and their connections are represented as edges in the developed social network The MOF social network is akin to a galaxy of materials from which communities of MOFs are extracted and utilized to predict gas adsorption properties by considering the behavior of other MOFs within the community
The proposed research has the potential to lead to novel applications in various materials data problems and improve the prediction of material properties and materials discovery It can also extend the applicability of machine learning methods to materials that are currently not adequately addressed by conventional artificial intelligence techniques However the effectiveness of the proposed method should be validated through experimental evaluation in the laboratory
A subset of curated MOFs from the CSD dataset is used to construct the MOF social network The network is undirected and weighted resembling galaxies of MOFs Community detection algorithms such as GirvanNewman are employed to predict gas adsorption by iteratively removing edges with the highest number of shortest paths between nodes
The data preparation involves extracting and standardizing relevant features according to expert specifications Similarities between MOFs are calculated and the resulting adjacency matrix

represents the links between them The adjacency matrix is transformed into a graph to visualize the MOF galaxy SNA methods such as community detection are then applied to predict gas adsorption
Gas adsorption analysis using the MOF social network involves establishing the network identifying distinct communities and predicting gas adsorption levels for each community The mean absolute error MAE is used to evaluate the prediction performance of each community and the overall MAE results are compared to three established machine learning algorithms The results demonstrate that the constructed social network significantly improves prediction accuracy compared to traditional machine learning methods
This study showcases the suitability of SNA for analyzing MOF databases in materials science By leveraging SNA the research demonstrates the ability to predict MOF properties by training communities extracted from the MOF galaxy social network The method has the potential to uncover fundamental characteristics of materials and find applications in other areas of material science.

Large Language Models for Materials Science with Attribution and Physics-Based Simulations GowoonCheon, AmilMerchant, Ekin DogusCubuk, EmrahKostem, MuratahanAykol, SamuelYang, ShutongLi, SubhashiniVenugopalan and VaheTshitoyan; Google, United States

Recent advances in large language models(LLMs) have generated much excitement across our society, including applications for science. In materials science, LLMs are starting to perform complex scientific tasks such as synthesis planning. While LLMs show great promise for accelerating materials science research, concerns around hallucination and the reliability of LLM generated content persist. This is especially problematic for science, where factual accuracy is critical and literature training data for cutting-edge research is sparse. We build LLM-assisted workflows for materials science that is grounded in scientific knowledge and simulations, and demonstrate how LLMs can accelerate materials science research using examples from real world materials discovery problems.

11:15 AM DS06.01.03
Inverse Design of Next-Generation Superconductors using Data-Driven Deep Generative Models DanielWines[1], KevinF. Garrity[1], TianXie[2] and KamalChoudhary[1]; [1]National Institute of Standards and Technology, United States; [2]Microsoft Research, United Kingdom

Over the past few decades, finding new superconductors with a high critical temperature (T_c)has been a challenging task due to computational and experimental costs. In this work, we present a diffusion model inspired by the computer vision community to generate new superconductors with unique structures and chemical compositions. Specifically, we used a crystal diffusion variational autoencoder (CDVAE) along with atomistic line graph neural network (ALIGNN) pretrained models and the Joint Automated Repository for Various Integrated Simulations (JARVIS) superconducting database of density functional theory (DFT) calculations to generate new superconductors with a high success rate. We started with a DFT dataset of ~1000 superconducting materials to train the diffusion model. We used the model to generate 3000 new structures, which along with pre-trained ALIGNN screening results in 62 candidates. For the top candidate structures, we carried out further DFT calculations to validate our findings. We extended this approach to high-pressure hydride superconductors, utilizing our deep learning and DFT workflows to discover new high-T_c hydride-based structures outside of the initial training. Our approaches go beyond the typical funnel-like materials design approaches and allow for the inverse design of next-generation materials.

Large Language Models for Materials Science Education and Research MohdZaki, N M AnoopKrishnan and MausamMausam; Indian Institute of Technology Delhi, India

Scientific theories and facts are available in books, research papers, and websites. The advancement of computing power enabled researchers to train language models that can understand scientific text and explain it in natural language when prompted. These models have more than ~100 billion parameters and are trained on programming codes and text data. This training paradigm imparts these models the capability to solve mathematical equations, write computer programs, analyse a given text and answer the associated questions. Recently, these models became available for public use and can be equally used by students and teachers. In this work, we analyse the capability of two generative large language models, GPT-3.5 and GPT-4, to solve and understand undergraduate-level materials science questions. Specifically, we take questions which require reasoning, logical thinking, and numerical solving abilities. This analysis will help the teachers to engage with students to enable an in-depth understanding of materials science. We have also classified questions from a materials science perspective. The performance of both the LLMs from the domain point of view will enable the decision-making of researchers on how to use them for different materials science tasks.

11:45 AM DS06.01.05
Leveraging Large Language Models for Crystal Structure Prediction: Text2Struc ViktoriiaBaibakova[1,2], WeikeYe[2] and StevenTorrisi[2]; [1]University of California, Berkeley, United States; [2]Toyota Research Institute, United States

The process of experimental and theoretical materials discovery has witnessed remarkable acceleration through the integration of computational materials science workflows into the discovery process. However, recent advancements in Large Language Models (LLMs) (OpenAI, 2023) offer an alternative avenue for automation of key workflow steps. This study focuses on crystal structure prediction, the initial step in materials science, and explores the feasibility of employing LLMs for this task. Our contribution, Text2Struc, is a novel tool designed to transform natural language descriptions of crystals into valid crystal structures. The training protocol encompasses three key elements: the methodology, the training dataset, and the performance metrics. Inspired by Toolformer (Schick et al., 2023), our approach involves instructing LLMs to use an API interface through its calls which are then executed. We sourced structures from open-access databases and curated a dataset of question-answer pairs enriched with API calls. Text2Struc was also configured to execute the generated API calls. Fine-tuning of this model was shown to reduce test set prediction error, as measured by perplexity. To assess model performance, we compared sourced true crystal structures, structure predictions with post-text completion by LLMs, and structures generated after calling the API. Our primary findings demonstrate that API execution effectively mitigates hallucinations, as evidenced by a 10% reduction in invalid structure predictions. Furthermore, our metrics indicate that structure executions closely align with true structures compared to structure predictions. Additionally, we have developed and will demonstrate a graphical user interface (GUI) for Text2Struc, enhancing its accessibility and usability. This work demonstrates the potential of LLMs in automating crystal structure prediction, advancing materials discovery to be more efficient and user-friendly.

SESSION DS06.02: Machine Learning for Battery Materials

Development of Reactive Force Field (ReaxFF) for $BaTiO_3$ Electrode Interface YasuakiOkada, MizukiAnan, YayoiKatsu, NoriakiOzaki, HideyukiKamisaka, HiroyukiHarano and NobuhikoTanaka; Murata Manufacturing Co., Ltd., Japan

Barium titanate ($BaTiO_3$) based multi-layer ceramics capacitors (MLCCs) have been extensively used in various electrical devices such as home appliances, automotives, and smartphones. Among several factors that affects its performance and reliability against insulation resistance degradation under functioning applied voltage, oxygen vacancy concentration at the grain-boundary and the $BaTiO_3$-electrode boundary are considered the crucial factors for the reliability of MLCCs. Density functional theory (DFT) is often used to investigate electronic structures and thermodynamic stabilities of such interfaces. However, feasible number of atoms in DFT calculations is limited up to a few hundred due to its high computational cost, which hinders its application to realistic interfacial models consist of more than several thousand atoms. For this reason, we developed an accurate machine learning assisted interatomic potential for systems containing $BaTiO_3$ and a few electrode materials. The ReaxFF [1] was adapted for its applicability to complicated interfacial systems consist of different types of materials. The accuracy of ReaxFF molecular dynamics (MD) simulations strongly depends on the quality of parameterization for target systems. In this study, we employed our in-house code based on multi-objective genetic algorithm optimization methods, by extending functionality of EZFF code developed by A. Krishnamoorthy *et al.* [2]. In 2019, D. Akbarian *et al.* reported a ReaxFF parameter set for $BaTiO_3$ that reproduce the crystal structures of Ba-Ti-O compounds and phase transition between tetragonal and cubic phases of $BaTiO_3$ [3]. However, their predicted phase transition temperature does not coincide with experimental data and their study does not take into account of the orthorhombic phase, which dominates the low temperature dynamics of $BaTiO_3$ occurring in the operating temperature of MLCCs. Besides, to the best of our knowledge, there has been no ReaxFF parameter set published so far for the $BaTiO_3$-electrode interfacial

systems. Therefore, we developed new ReaxFF parameters that can describe the successive phase transition including orthorhombic phase, and the interfacial structures of $BaTiO_3$ with base (Ni) and noble (Pt) metals, respectively. First, we performed several hundred DFT calculations to prepare training data for compounds consist of Ba, Ti, O, Ni, and Pt atoms and developed new ReaxFF parameters using the in-house code. Second, we confirmed its reproducibility of the successive phase transition among orthorhombic-tetragonal-cubic phases by conducting heating/cooling ReaxFF-MD simulations with 6 × 6 × 6 periodic $BaTiO_3$ supercell. Finally, we performed ReaxFF-MD simulations for realistic interfacial structure models, involving S 3 type symmetrically-tilt grain boundaries of $BaTiO_3$ and interface against the electrode materials. NPT-MD simulations were performed as preparation to optimize the lattice constants along the gradually increasing temperatures from 300 K to 1500 K. Then, NVT-MD simulations are carried out at each temperature to investigate sintering behavior of MLCC devices. Our simulations successfully reproduced the thermal expansion of electrode materials and revealed the difference in interfacial atomic structures among the electrode materials. Namely, the Ni-electrode, the base metal, has higher affinity toward oxygen atoms in $BaTiO_3$, thus forming Ni-O atomic layer at the interface. On contrary, the noble metal (Pt) has much lower affinity to the oxygen and preferred to form Pt-Ti atomic layer at the interface. We anticipate these findings and further MD simulations using this newly developed ReaxFF may play a key role in elucidation of the degradation mechanisms of MLCCs in future.

Rate Determining Step of Anhydrous Proton Transport in Phosphonic Acid Electrolytes Revealed by Machine-Learned Potential SaoriMinami and RyosukeJinnouchi; Toyota Central R&D Labs., Inc., Japan

Phosphonic acid-based electrolyte is a key material for anhydrous proton transport in fuel cells that are operatable at medium temperature. These materials, however, suffer from a severe trade-off relation between proton conductivity and stability; immobilizing phosphonic anion groups prevents leaching out of anions while it suppresses proton transport [1]. To reveal the origin of the relation, we simulate proton transport in phosphoric and phosphonic acids with different alkyl chain length. MLFFs that precisely reproduce first principles interatomic potentials [2, 3] are generated by an efficient active learning scheme implemented in Vienna Ab initio Simulation Package (VASP) [4] on the fly during first-principles calculations. The generated MLFFs are used to simulate proton transports involving Grotthuss mechanism. The simulations indicate that proton diffusivity is strongly corrected with the reorientation speed of anions; as the alkyl chain length increases, both the proton diffusivity and reorientation frequency decrease. Detailed analyses show that in all materials, proton shuttles between a pair of anions with a high frequency of ~10 ps^{-1}. However, the proton transport is limited by 3 order of magnitude slower reorientations of anions, and only 0.1% of shuttling protons can transport to the adjacent anion. As the alkyl chain length increases, the reorientation frequency decreases, and the proton diffusivity decreases. These results indicate that retaining rotational freedoms of anions is essential to enhance the anhydrous proton conductivity. This work was partially supported by NEDO (New Energy and Industrial Technology Development Organization) financially.

Information Extraction from Materials Science Research Papers MohdZaki, KausikHira, DevanshiKhatsuriya, N M AnoopKrishnan and MausamMausam; Indian Institute of Technology Delhi, India

Predicting properties of materials for inverse design requires the development of suitable machine learning models. These models require a large dataset of materials compositions and their respective properties. The preparation of such datasets through manual compilation is a tedious task. The required information is reported in tables, text, and figures, of which the tables contain about 85 % of glass compositions. Further, a given glass composition can be found in different research papers discussing its various properties. In this work, we use DiSCoMaT, a pipeline solution for composition extraction of materials, based on graph neural networks, rule-based parsers, and a materials domain language model – MatSciBERT, materials domain language model to extract materials compositions and its modified version to extract material properties. We then extract the properties of these compositions from respective research papers using a modified version of DiSCoMaT architecture and compile them into machine-readable databases, which can be used for discovering glass compositions for tailored applications.

2:15 PM DS06.02.04
***De Novo* Design Methods Benchmark of GAN and Flow Models for Minimizing Hole Reorganization Energy**KarlLeswing[1], AndreaBrowning[1], AlexGoldberg[1], MathewD. Halls[1], TsuguoMorisato[1], NobuyukiN. Matsuzawa[2], HiroyukiMaeshima[2] and TatsuhitoAndo[2]; [1]Schrodinger, United States; [2]Panasonic Corporation, Japan

In recent years, generative design methods have gained significant attention in the field of molecular ideation, offering new possibilities for the discovery and optimization of novel molecules. These methods employ algorithms and machine learning techniques to explore vast chemical spaces, generating diverse molecular structures with desired properties. As these approaches rapidly evolve, it becomes crucial to benchmark and evaluate their performance to ensure their reliability and effectiveness in real-world applications.
In this work we study two classes of generative algorithms from literature, generative adversarial networks and normalizing flow models. Generative Adversarial Networks (GANs) have emerged as a powerful framework for generating ideas in various domains, offering unique advantages over traditional generative models. GANs offer remarkable capabilities for generating ideas by capturing complex data distributions, promoting creativity and exploration, facilitating the generation of diverse ideas, and adapting to specific requirements. For this study we benchmark MolGAN: An implicit generative model for small molecular graphs [1] and A de novo molecular generation method using latent vector based generative adversarial network [2]. The other architecture studied in this benchmark are normalizing flow algorithms, a family of algorithms which promise easy training and fast sampling. For normalizing flows we benchmark GraphAF: a Flow-based Autoregressive Model for Molecular Graph Generation [3], and GraphNVP: An Invertible Flow Model for Generating Molecular Graphs [4].
In this benchmark we build molecular distributions over 250,000 OLED like molecules using these four methods and attempt to minimize hole reorganization energy using three different quality machine learning models. We then analyze the performance characteristics of the methods, the ideas they create, the idea diversity, and the compute cost.

Multi-Physical Factor in Enabling Homogeneous Dendrite Growth for Alkali Metal Batteries GwanghyeonChoi[1], YoungohKim[2,3], JoonmyungChoi[2,3] and DuhoKim[1,1]; [1]Kyung Hee University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]BK21 Four ERICA-ACE Center, Hanyang University, Korea (the Republic of)

Homogeneous dendritic growth in lithium-metal anode has been acknowledged as of paramount importance in achieving safe high-energy-density performance for lithium-metal batteries. However, its intrinsic origin during electrochemical growth is unclear, and it still continues to pose a serious challenge to enabling homogeneity. Therefore, a thermodynamic factor in controlling (in)homogeneous electrochemical growth is suggested here based on an in-depth understanding of three alkali metal (AM: Li, Na, and K) models using unified-multiscale atomistic calculations. First, the importance of alkali metal disordered phases as a transition state is covered with thermodynamic energy big dataset using density functional theory (DFT) calculations, which provides the intriguing concept that disordered-phase energy level (DPEL) plays a decisive role in controlling the degree of (in)homogeneity during electrochemical deposition. Second, the two-type physical parameters are derived by the DFT-assisted machine learning method, and DPEL-related cohesive energy (E_c) is investigated. Third, reliable molecular dynamics simulations systematically compare (in)homogeneous alkali metal growths upon charging, and their results show severe fluctuating-morphology including sharp tips in Li metal and smooth surfaces in Na and K metals. Finally, correlating the transition-state thermodynamics and (in)homogeneous growth is understood by molecular dynamics cross-sectional models. The metallic Li prefers to be adsorbed on its crystalline phase rather than the disordered phase containing grain boundaries, which leads to severe dendritic Li growth. Whereas, these characteristics are rarely observed in K metal over the entire deposition process. From our comprehensive understanding of the growth mechanisms of three-type alkali metal models, DPEL is expected to be a universal design strategy for evaluating the alkali metal anode's homogeneous growth. Based on this thermodynamic understanding, this study additionally suggested a mechanical factor that enables controlling (in)homogeneous electrochemical growth. A large dataset of thermodynamic energies for Li disordered phase decoupled the dual-body effective cluster interactions (ECI) into three components: i) crystal-like, ii) long, and iii) short bonds of Li−Li based on machine learning assisted by DFT calculations. Their dual-body contributions provided a mechanical factor for regulating a disordered-ordered phase transition upon electrochemical deposition, and the compressive effect, which was proposed to enable the homogeneity, was confirmed. In addition, to determine the correlation between the mechanical and thermodynamic factors, DFT calculations were performed to generate a large formation energy data set based on two disordered models: i) compression and ii) over-compression. The thermodynamic energy level under the compression mode is lower than that under the unstrained condition but the over-compression mode demonstrates higher DPEL than both the reference and the compression values owing to the evolution of strong Li−Li repulsion. Interestingly, the ECI values in the crystal-like bond group are closer to 0.0 eV/bond than those under the compression-free dataset but the ECI values in the short bond group are higher relative to those with the compression-free mode,

and the variation is induced by the over-compression dataset. These re-calculated ECI values more concretely depict the mechanical factor for stabilizing the disordered phase for giving rise to homogeneous Li metal growth upon charging. Finally, the proposed multi-physical factors are expected to be a critical design factor for harnessing the full potential of alkali metal-based batteries and provide fundamental insights into enabling homogeneous lithium-metal dendrite growth.

Physics-Informed Neural Networks for Radiative Transfer and Boltzmann Transport Problems of Optoelectronic Device Modeling RobertoRiganti and LucaDal Negro; Boston University, United States

There is a growing interest in developing deep learning (DL) and artificial intelligence (AI) algorithms for electromagnetic wave engineering and materials design. Rapidly emerging approaches include training artificial neural networks (ANNs) to solve inverse problems and parameter estimation in complex photonic environments. Although successfully demonstrated at solving several inverse design problems, traditional DL methods are essentially data-driven techniques requiring time-consuming training steps that use massive datasets. Moreover, in order to improve on purely data-driven methods, it is important to constrain and regularize them by leveraging the underlying physics of the investigated problems. Here we discuss our advances in building a robust framework for the design of photonic materials and devices based on auxiliary physics-informed neural networks (APINNs) for the accurate solution of complex forward and inverse problems in electromagnetic scattering and radiative transfer theory. In particular, we introduce and discuss APINNs architectures for the inverse solution of high-dimensional integro-differential Boltzmann-type transport problems of relevance to optoelectronic devices and optical materials design and we demonstrate efficient parameter estimation in coupled conductive-radiative systems with applications to heat transfer in semiconductor devices. Specifically, we employ APINNs to solve the phonon Boltzmann transport equation (BTE) for AlGaN alloys in different geometries. Our work shows that APINNs possess the flexibility, accuracy, and noise robustness required to become a powerful design approach for inverse scattering and the non-local thermal modeling of optoelectronic devices beyond the Fourier thermal transport limit. The presented work expands upon the current capabilities and range of applications of physics-informed neural networks and paves the way to the study of complex transport problems and light-matter interactions in strongly scattering media with applications to nanophotonics, biomedical imaging, and semiconductor device modeling.

Study of The Boson Peak in Phase-Change Materials using Machine-Learning Potential Simulations PyungjinPark, SungminSong, JesunJang and Seung-HoonJhi; Pohang University of Science and Technology, Korea (the Republic of)

The boson peak is a peculiar feature in the vibrational density of states, mostly observed in disordered materials. Its origin has been attributed to various factors such as defects, atomic disorder, or mass density fluctuations [1,2], while a consensus is not reached yet. We investigate the boson peak in amorphous and metastable cubic Ge-Sb-Te phase-change materials to determine primary driving mechanism behind the boson peak. Utilizing the Gaussian approximation potentials [3] and a machine-learning scheme named the randomized atomic-system generator [4], we conduct large-scale simulations inaccessible from first-principles calculations to investigate this phenomenon. We employ an analytical approach involving the elastic theory, Voronoi cell analysis, atomic scale stress and strain to demonstrate the correlation between atomic disorder, density variation, shear elastic heterogeneity and the boson peak in the phase change materials.

Paddle-Wheel Effect Mediates Polymorph Transitions but not Li Transport in the Ionic Conductor Li_3PS_4. AndreyPoletayev[1], JamesA. Dawson[2], BenjaminJ. Morgan[3] and M. SaifulIslam[1]; [1]University of Oxford, United Kingdom; [2]Newcastle University, United Kingdom; [3]University of Bath, United Kingdom

Ionic transport is a key determinant of performance in energy technology devices, and simultaneously a convenient testing ground for machine-learned neural-network interatomic potentials. Of particular interest is the influence of slow degrees of freedom on ion conduction. Here we investigate the influence of large-amplitude polyhedral-anion flips on Li transport in the modern solid-state ion conductor Li_3PS_4, where a paddle-wheel effect has been proposed to benefit transport, using ensembles of local equivariant graph neural network potentials.
We find that at elevated temperature a large variety of models yield consistent predictions for the rate of polyhedral flips, approximately one per nanosecond at 800 K, and variance within a factor of 2 between models trained with distinct hyperparameters and across different sizes of training data (32-128 atom cells) despite the large increase in out-of-dataset testing errors versus larger-scale ab initio frames.
Importantly, we find that the large-amplitude paddlewheel flips are orders of magnitude too slow to facilitate Li transport. Further, using well-tempered metadynamics enhanced sampling, we estimate the free-energy kinetic barriers for the polyhedral flips to be $\geq$0.7 eV, which is approximately double the activation of ion conduction. Instead, the lowest-activation polyhedral-anion flip is collective and mediates the phase transition between room-temperature and elevated-temperature polymorphs in a one-dimensional mechanism.
Overall, our simulations are consistent with the orientational disorder observed experimentally, and suggest that such disorder rather than a purely dynamic paddle-wheel effect is beneficial to ion conduction. Owing to its rich dynamical landscape and polymorphism coupled to it, Li_3PS_4 can serve as a benchmarking material for testing machine-learning interatomic potentials and enhanced sampling methods.

4:00 PM DS06.02.09
Deep Operator Machine Learning Framework for Modeling All-Solid-State Batteries WeiLi and JunerZhu; Northeastern University, United States

All-solid-state batteries (ASSBs) have generated significant interest in recent years due to their high energy density and safety features, making them a promising candidate for next-generation storage systems that can support the societal goal of decarbonization. However, ASSBs continue to suffer from significant chemo-mechanical failures, such as lithium dendrite growth, penetration, various interfacial aging phenomena, and mechanical damage. As a result, most research efforts are currently focused on experimenting with materials and structures to overcome these challenges. Except for the experimental efforts, developing an accurate model that can reveal the underlying physics and predict the chemo-mechanical behaviors of ASSBs is also crucial. A model at the electrode level would be especially beneficial to practical implementations. However, traditional physics-based models often require relatively large computation costs, making them impractical for real-time applications.
To address this challenge, we propose a machine learning framework based on deep operator neural networks (DeepONets) to accurately and efficiently model ASSBs at the electrode level. The framework incorporates important physics, such as mass and charge conservation, as well as several mechanical and interfacial aging mechanisms. To successfully model the whole complex system, we first separately train the DeepONets for each governing equation or physics and then couple them together. For example, a DeepONet is trained to map the source term to the potential field for the charge conservation equation (Poisson's equation); and a separate DeepONet is trained to learn the mapping from the current concentration field to the next state for the diffusion equation. These two DeepONets are then coupled through the kinetics (Butler-Volmer) equation. The trained DeepONets can enable fast predictions for real-time control and optimization.

4:15 PM DS06.02.10
Predicting Kinetic Reactivity of Solid-State Battery Interfaces EderG. Lomeli, BrandiRansom, AkashRamdas, ThomasDevereaux, EvanReed and AustinSendek; Stanford University, United States

In this work, we combine ab initio simulation with machine learning to build the first model for predicting the kinetics of interfacial reactivity in solid-state Li metal batteries. We first use density functional theory molecular dynamics (DFT-MD) to simulate the time evolution of several solid-state electrolyte (SSE) candidate materials interfaced with Li metal. Unlike state-of-the-art grand potential convex hull calculations for predicting interfacial stability, simulation with DFT-MD explicitly considers kinetic reaction barriers between two phases. We use the resulting data from these simulations to build a data-driven model that uses computationally inexpensive structural and thermodynamic features to predict the DFT-MD kinetic reactivity of these interfaces. This first-of-its-kind model enables more targeted and effective selection of solid electrolytes for solid-state Li metal batteries. Solid-state batteries offer safer and more energy-dense alternatives for energy storage systems. Like current liquid electrolyte batteries, the stability of interfaces between different battery components remains a critical requirement for longevity and device performance. With over 20,000 Li containing inorganic solids in the Materials Project database, the current high throughput technique to assess the chemical compatibility of candidate interfaces between SSEs and battery electrodes consists of a thermodynamic static parameter, the driving force for chemical mixing, with an arbitrary global assumption of a kinetic stabilization barrier. The current version of this kinetic reactivity model outperforms the purely thermodynamic parameter with a significantly lower misclassification of reactive/unreactive interfaces and predicts over 1,000 additional stable candidate interfaces that could be used for metric-specific material searches.

4:30 PM DS06.02.11
Machine Learning Design of More Accurate, Efficient, Stable and Transferable Coarse Grained Free Energy Models BlakeDuschatko[1], XiangFu[2], YuXie[1], AlbertMusaelian[1], SimonBatzner[1], TommiJaakkola[2] and BorisKozinsky[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States

In complex material systems with long time- and length-scale dynamics, standard all-atom simulation techniques often become too expensive. In these settings, state of the art approaches to coarse graining are able to examine system properties at lower resolution with high fidelity. However, a number of practical barriers remain to be overcome in making bottom-up coarse graining approaches viable for addressing realistic problems. In this work, we introduce our recently developed on-the-fly active learning framework for coarse grained free energy models that directly addresses an outstanding challenge in the community of efficient data collection [1]. We demonstrate how this approach allows for optimal selection of training sets, and further examine how uncertainty based active learning opens the door to designing transferable models across structural and chemical spaces. Lastly, we proceed to demonstrate novel techniques for learning the PMF with greater fidelity, efficiency and simulation stability than was previously achievable.

4:45 PM DS06.02.12
Short Range Order Clustering Leveraging New Technologies for Better Mechanical Properties Predictability AxelE. Poisvert[1], StefanosPapanikolaou[1] and MarinicaM. Cosmin[2]; [1]NCBJ-Nomaten, Poland; [2]Commissariat à L'énergie Atomique et Aux Energies Alternatives, France

Chemical short-range order (C-SRO), meaning a sort of clustering depending on the nature of atoms present in the system, influences thermo-mechanical properties in a large variety of complex concentrated alloys (CCA), and in particular, high entropy alloys (HEA). However, short-range order (SRO) characterization and classification approaches, both experimentally and theoretically, have been a challenge, especially due to the fact that this order takes place localy in a range of few neighbors (typicaly less than 10).
SRO and C-SRO are commonly characterized by Warren-Cawley parameters representing a comparison between local and global element concentration. This methods seems a bit archaic in light of all advances made in materials science science thanks to.
In this work we hypothesise that new ways of discriminating SRO, using advances in machine learning and informatics for the characterization of local, chemically induced, distortions, may uncover new properties of ordered systems, and in particular CCAs and HEAs.
We use Molecular Dynamics (MD) and Machine Learning (ML) to implement an innovative method to discriminate C-SRO during MD runs. For this purpose, we leverage a SO(4) bispectrum descriptor in order to link the descriptors with mechanical and physical effects, using the MiLaDy [1] and LAMMPS [2] packages. This study leans on two specific systems, equiatomic NiCoCr and equiatomic CuCoFeNiPd.
We set up the systems using variance constrained semi grand canonical Monte Carlo simulations (VCSGC-MC) at low temperature, allowing reordering in both alloys. Then, the samples are mechanically loaded.
The determination of descriptors after the MD process leads to a distortion score that is determined with both swapped system and random equivalent system in order to compute a statistical distance matrix.
We find that the distortion score can allow the definition of SRO clusters with finer definition than other methods widely available, and then, individual clusters may be extracted and specially investigated. We further find a strong interplay between initial clustering and subsequent stress loading effects, while the local per atom volume representing the strongest predictor of C-SRO.

8:00 PM DS06.03.01
Highly Efficient Crystal Structure Prediction with Universal Neural Network Empirical Potential PaydenBrown[1], TakuyaShibayama[2], SoTakamoto[2], DaisukeOkanohara[2] and JuLi[1]; [1]Massachusetts Institute of Technology, United States; [2]Preferred Networks, Inc, Japan

Crystal structure prediction (CSP) has played a vital role in computational materials discovery for its ability to explore unknown energy landscapes of chemical systems. Crystal structure predictors that utilize ab initio techniques such as density functional theory (DFT) are limited by their computationally expensive and time-consuming calculations. The advent of neural network potentials (NNPs) has opened the door for more efficient CSP and, with recently developed models, can reach the same level of accuracy as DFT. One such NNP is the PreFerred Potential (PFP), a universal NNP that can be applied to any combination of 72 elements. In this work, we develop an evolutionary crystal structure predictor that exploits the computational advantages of PFP.
PFP was paired with our variable-composition CSP algorithm to explore diverse inorganic binary and ternary chemical systems. Numerous crystal structures were discovered that break the known ab initio convex hull for their chemical systems with remarkable efficiency. The average algorithm run-time for binary systems was under 4 hours, resulting in ~800 crystal structures. Random subsets of generated structures were verified with DFT, finding that PFP correctly predicts that a structures energy is above or below the convex hull with ~80% accuracy. The successful and efficient discovery of new stable crystal structures with the technique developed in this work proves its potential to accelerate the discovery of new theoretical crystal structures.

8:00 PM DS06.03.02
Applicability of Universal Neural Network Potential to Organic Polymer Materials HirokiIriguchi, AkihiroNagoya, YusukeAsano and TakuWatanabe; Preferred Computational Chemistry Inc., Japan

With the recent development of materials exploration aided by machine learning (so-called materials informatics), atomistic simulations have been playing an increasingly important role. Density functional theory (DFT) calculations are widely used for accurate atomistic simulations, which usually take a few months due to high computational costs. Molecular dynamics (MD) simulations using classical force fields are much faster than DFT simulations and have been applied for atomistic simulations on nano- to micro-scale. However, the accuracy depends on the parameters of the force field. Therefore, there is a trade-off between computational cost and accuracy between these conventional methods. There are some approaches to calculate materials speedily with accuracy like first-principles calculations, such as density functional tight binding method (DFTB) or reactive force field (ReaxFF), but they have strong parameter dependence and poor versatility because they aim to reproduce specific systems with high accuracy in many cases.
Neural Network Potential (NNP) is a machine learning model that uses the results of first-principles calculations as a data set to infer the energy and force of molecular and crystal structures. While conventional NNPs can only be used in a limited number of material systems for each model because the corresponding structure depends on the training datasets, PreFerred Potential (PFP) was developed with the aim of becoming a universal NNP by efficiently collecting training data and constructing an architecture that reproduces the smooth interatomic potential energy surface. This enables fast calculation of any 72-element combination structure with accuracy equivalent to first-principles calculations, and has already been shown to be effective in material exploration in some areas such as batteries and catalysts. On the other hand, large condensed systems composed of organic molecules, such as liquid solutions and polymers, are conventionally analyzed by MD simulations using classical force fields. Due to its accuracy and universality, PFP can extend the application of atomistic simulation to inorganic/organic interfaces, chemical reactions, and degradation of these systems.
In this presentation, we will show examples of calculations to demonstrate that PFP can be useful not only for inorganic materials but also for organic materials. As a benchmark of the organic systems, we have calculated the density of various organic liquids obtained using PFP. The results are in good agreement with those obtained by DFT. For more practical examples, the thermal decomposition of epoxy resin was analyzed by PFP-based MD simulations. The results were similar to those calculated by ReaxFF, showing that epoxy resins initially produce small hydrocarbon compounds upon fragment decomposition, and that as the reaction temperature increases, the amount of water and hydrogen produced increases through radical reactions. Other examples of calculations made possible by PFP will be discussed.

8:00 PM DS06.03.03
Special Glass Structures for High-Throughput First Principles Studies of Bulk Metallic Glasses SiyaZhu[1], Axelvan de Walle[1], JanSchroers[2], StefanoCurtarolo[3] and HagenEckert[3]; [1]Brown University, United States; [2]Yale University, United States; [3]Duke University, United States

The atomic-level structure of bulk metallic glasses (BMGs) is a key determinant of their properties. A large training dataset is required to construct a machine-learning modeling for the structure and properties of BMGs. However, an accurate representation of amorphous systems in computational studies has traditionally required large supercells that are unfortunately computationally demanding to handle using the most accurate ab initio calculations. To address this, we propose to specifically design small-cell structures that best reproduce the local geometric descriptors (e.g., pairwise distances or bond angle distributions) of a large-cell simulation. We rely on molecular dynamics (MD) driven by empirical potentials to generate the target descriptors, while we use reverse Monte Carlo (RMC) methods to optimize the small-cell structure. The latter can then be used to determine mechanical and electronic properties using more accurate electronic structure calculations. With high efficiency and accuracy of modeling and calculating properties of BMGs, a large and reliable dataset for ML of BMGs can be generated using our method. The method is implemented in the Metallic Amorphous Structures Toolkit (MAST) software package.

8:00 PM DS06.03.04
Quantifying the Lennard–Jones Potential between Two Hard Ellipsoids using Coarse-Grained Deep Learning Techniques ErinWong[1,2], DylanFei[3,2], GeorgiosKementzidis[2], YuefanDeng[2] and MiriamRafailovich[2]; [1]William A. Shine Great Neck South High School, United States; [2]Stony Brook University, The State University of New York, United States; [3]Jericho Senior High School, United States

Equations: Eq. (1) is presented as the 12–6 Lennard–Jones potential: $V_{LJ} = 4\varepsilon_{LJ}[(\sigma/r)^{12} - (\sigma/r)^{6}]$. Eq. (2) is presented as the Gay–Berne potential: $U_{AB} = 4\varepsilon_{AB}\{[\sigma_0/(R_{AB} - \sigma_{AB} + \sigma_0)]^{12} - [\sigma_0/(R_{AB} - \sigma_{AB} + \sigma_0)]^{6}\}$. Eq. (3) is presented as the double summation of the 12–6 Lennard–Jones potential, V_{LJ}, over the individual points that subsume the pairwise rigid bodies.

Classical molecular dynamics (MD) is a highly intensive, $O(n^2)$, computational method for simulating the kinetics, thermodynamics, and structural properties of a many-body system over time. The initialization of such a method requires the use of multiple energy functions, which, in turn, describe the trajectory and momenta of the particles being simulated. We focus on the Lennard–Jones potential (LJP), which governs the van der Waals (vdW) energetics between, specifically, two interacting particles. We seek to modify the potential's conventional form, eq. (1), which fails to accurately model the vdW forces between large and anisotropic particles (ellipsoids). Eq. (3), however, overcomes those shortcomings by treating the ellipsoids as a collection of uniformly distributed points and, in turn, applying a double summation over those points to generate the LJP.

We learn the variables of eq. (2) using a physics-informed neural network (PINN), which, unlike our previously proposed feedforward neural network, assumes a physics-principled training process that, in our case, entails the parametrization of eq. (2). Our goal is to replicate the accuracy of eq. (3) by training our PINN to recognize the relationship between the variables of eq. (2) and the imputed parameters—relative orientation, semi-major/-minor axes, and center—of the two ellipsoids. Our PINN then uses those imputed parameters to generate the corresponding ε_{AB} and σ_{AB} values, thereby streamlining the complexity involved in the computation of eq. (3).

Our ground truth, serving as the basis of our training data, stemmed from the Monte Carlo approximation of eq. (3) and consisted of 2,080,000 potentials. The parameters of our two ellipsoids—relative orientation, semi-major/-minor axes, and center—were uniquely permuted such that no two potentials were generated using the same parameters.

One of the primary concerns about our data's accuracy was the extent to which an ellipsoid could be classified as a rigid body. Therefore, we ran three mini-experiments to verify the equations and code used to generate the ground truth. We referenced the three cases shown by Paramonov & Yaliraki and demonstrated (a) that the number of points per ellipsoid, upon exceeding 15,000, minimally impacted the generated potential and (b) that ground truth generation code proved scientifically sound, emulating the well depth and curvature in all three cases shown by Paramonov and Yaliraki. Moreover, in addressing part (a), we randomly sampled a subset of our ground truth (generated using 30,000 points per ellipsoid) and regenerated those LJP values using 5,000, 15,000, 25,000, and 30,000 points. The mean absolute percentage error (MAPE) started at 2.42% for 5,000 points, indicating, on average, a 2.42% error between a value from the dataset to a newly generated value using our code, but upon exceeding 15,000 points, gradually decreased to 0.96% ($MAPE_{30,000}$), thus confirming the accuracy of our ground truth.

We implemented two models using this ground truth. The first was a black box model, which used the parameters of two ellipsoids to predict the LJP. The second was a PINN that used the same parameters of the two ellipsoids to find the coefficients of ε_{AB} and σ_{AB} through two separate neural networks and tune σ_0 for eq. (2). By employing a combination of Adam and L-BFGS optimization, the PINN was able to achieve a minimum training loss of 0.0004 over 250 epochs. We plan to validate this PINN using a separate testing dataset and further improve upon it by investigating the use of other activation and loss functions.

8:00 PM DS06.03.05
In-Silico Studies on Fibrinogen Domain Adsorption on Polylactic Acid ErinWong[1], MatthewSun[2] and RichardZhang[3]; [1]Great Neck South High School, United States; [2]North Carolina School of Science and Mathematics, United States; [3]Conestoga High School, United States

*All authors contributed equally

Fibrinogen, a vital blood clotting protein, transforms into active fibrin via thrombin activation, creating a scaffold for clots. It is key in interactions with medical device materials, especially those prone to adverse clotting. Investigating material-blood protein interactions, like those with polylactic acid (PLA), which is used for its biocompatibility, can aid in preventing device-induced clots and enhancing safety.
Prior research demonstrates the impact of surface chemistry on adsorbed fibrinogen's conformation, orientation, fiber formation, and platelet adhesion. This is attributed to distinct surface properties of fibrinogen domains: D and central E (C_e) domains are hydrophobic, while the αC domain is hydrophilic. On hydrophobic surfaces like PLA, D and C_e domains strongly adhere (with C_e showing weaker adherence) while the αC domain remains detached, promoting lateral aggregation via αC domain linkage. Conversely, on hydrophilic surfaces, αC domains bind to the C_e domain, reducing lateral aggregation. Additionally, P12, a proven stent coating, reduces fibrinogen fiber count on hydrophobic surfaces and supports endothelial cell growth without adverse effects. P12 obstructs the D domain's hole, impeding fiber formation; it potentially affects αC domains by surface binding as well.
To study this critical interaction between P12 and fibrinogen, we conducted molecular dynamics simulations. In order to lessen the computational cost, the problem was divided into parts for the three fibrinogen domains. For the D and C_e domains, the simulations were identical: run each domain alone in water, each domain face down on PLA, and each domain face up on PLA. By accounting for the different orientations of the domains on PLA, the actual binding configuration for each domain could be deduced as it is currently unknown. For the central complex (αC and C_e domain), umbrella sampling and steered molecular dynamics (SMD) were done to gain insight into the free energy landscape of the complex when the αC domains are separated and to determine the force necessary to pull the αC domain segments apart.
After 4.45 ns of D domain simulation, the total energy of the system was -2.99795e+06. After 6.01 ns of C_e domain simulation, the total energy of the system was -1.38023e+06. Both domains of the fibrinogen protein were shown to have stably folded, with reasonably invariant radii of gyration. Our next steps include running simulations with the D and C_e domains face down and face up on PLA, to examine the lowest energy conformations and chemical behaviors of these surface interactions. Moreover, we will use data from the SMD and umbrella sampling to train a machine learning model to predict whether the αC domain segments will be pulled apart, given various factors such as thermodynamics values and relative orientation.

Atomistic Simulation Incorporated with Science Pedagogy to Advance Machine Learning-Assisted Materials Research LexiHwang[1], MarlenTrigueros[1], PriyanshuLuhar[2] and SungwookHong[2]; [1]California State University, Los Angeles, United States; [2]California State University, Bakersfield, United States

The current study aims to use a guided inquiry-based instruction framework and other evidence-based science strategies to advance materials research in coordination with computational modeling and machine learning approach. For the delivery of our program, guided inquiry-based instruction was used where students generate inquiry from their own experiences into authentic questions and are given opportunities to explore and discover materials processes such as computational synthesis of functional metal nanoparticles and 2D materials. Dynamic representations and manipulation of abstract and unobservable phenomena (e.g., chemical reactions at molecular and atomic levels) will be made available to student scholars where they build molecular structures, run atomistic simulations, and visualize and analyze simulation results via machine learning assisted characterization. We measure students' perception and motivation toward learning materials science and engineering; and machine learning assisted computational design skills using the existing tools and researcher-developed evaluation criteria. Results indicated positive impacts of our pedagogical approached simulation training. Implications and future directions will be discussed. We believe our approach will strengthen a diversity in the community of machine learning-based materials research.

8:00 PM DS06.03.07
Advancing Semiempirical Quantum Chemistry with Extended Lagrangian and Machine Learning MaksimKulichenko; Los Alamos National Laboratory, United States

Although semiempirical quantum chemistry provides better scalability and speed compared to sophisticated *ab initio* methods, Born-Oppenheimer Molecular Dynamics (BOMD) simulations

within semiempirical formalism still suffer from the computational bottleneck of iterative self-consistent field (SCF) optimization at each time step, limiting their applicability to large-scale simulations. An advanced formulation of Extended Lagrangian Born–Oppenheimer Molecular Dynamics (XL-BOMD), implemented in the PyTorch-based semiempirical quantum chemistry code PySeQM software, eliminates the need for SCF optimization by simultaneously propagating the electronic degrees of freedom along with the nuclear motion. The implementation incorporates several key features, including consideration of finite electronic temperatures, the use of canonical density matrix perturbation theory, and an adaptive Krylov subspace approximation for density matrix propagation. With the new XL-BOMD formulated for the Neglect of Differential Diatomic Overlap (NDDO) semiempirical model, we can now simulate large and challenging chemical systems characterized by charge instabilities and low HOMO-LUMO gaps. Applied to molecular dynamics, simulation of 840 carbon atoms, one molecular dynamics time step executes in 4 s on a single GPU.
The PyTorch implementation enables dynamic re-parameterization of semiempirical parameters by interfacing them with machine learning models, thereby enabling training to high-quality ab initio data, including reactive events. This approach leads to enhanced accuracy when compared to using static, pre-optimized semiempirical parameters.

Using TD-DFT to Understand The Photochemistry of Functionalized Organic Systems MoumitaBanerjee and AnakuthilAnoop; Indian Institute Of Technology, India

Our research focuses on the investigation of carboxylic acid photorelease from functionalized systems acting as photocages, utilizing β-carboline and phenothiazine moieties. Specifically, the varying release rates of carboxylic acids from different benzylic positions in the β-carboline moiety and the impact of oxygen on phenothiazine photochemistry are being studied.
Advanced computational methods, such as Density Functional Theory (DFT) and Time-Dependent DFT (TD-DFT), are being employed to analyze electron excitation dynamics through hole-electron distribution and charge density difference visualization.
These insights are not only contributing to the advancement of fundamental understanding but are also holding promise for applications in functional materials, particularly in drug delivery. By these moieties, innovative drug delivery systems are being developed, enabling precise control over drug release for enhanced therapeutic efficacy.

SESSION DS06.04: Machine Learning for Simulation of Materials I
Session Chairs: Grace Gu and Rama Vasudevan
Tuesday Morning, November28, 2023

Autonomous Learning of Atomistic Structural Transitions via Physics-Inspired Graph Neural Networks BamideleAroboto[1], ShaohuaChen[2], Yu-TingHsu[3], BrandonWood[3], YangJiao[2] and JamesChapman[1]; [1]Boston University, United States; [2]Arizona State University, United States; [3]Lawrence Livermore National Laboratory, United States

Materials processing often occurs under extreme dynamic conditions leading to a multitude of unique structural environments. These structural environments generally occur at high temperatures and/or high pressures, often under non-equilibrium conditions, which results in drastic changes in the material’s structure over time. Computational techniques such as molecular dynamics simulations can probe the atomic regime under these extreme conditions. However, characterizing the resulting atomistic structures has proved challenging due to the intrinsic levels of disorder present. Here, we introduce SODAS++, a universal and interpretable graph neural network framework that can accurately and intuitively quantify the transition between any two arbitrary phases. The SODAS++ framework also quantifies local atomic environments, providing one with the power to encode global state information at the atomic level. We showcase SODAS++ for both solid-solid and solid-liquid transitions for systems of increasing geometric and chemical complexity such as elemental metals, oxides, and ternary alloys.

8:45 AM DS06.04.02
Prediction of Forces and Energy Based on Rotational Invariant Spherical Representations. KentoNishio[1], KiyouShibata[2] and TeruyasuMizoguchi[2]; [1]The University of Tokyo, Japan; [2]Institute of Industrial Science, The University of Tokyo, Japan

Although hand-crafted descriptor-based methods have traditionally been used to construct accurate machine learning interatomic potentials, graph neural networks (GNNs), which can be trained end-to-end, have recently attracted attention due to their generality.
GNNs use rotational-invariant geometric features of materials, such as interatomic distances, and bond angles, to model interactions with neighboring atoms [1]. Recently, many efforts have been made to improve the prediction accuracy of equivariant quantities such as interatomic forces by imposing not only invariance but also equivariance on the model [2].
However, imposing equivariance imposes restrictions on the operations in the model and prevents the use of nonlinear transformations, which are particularly important for improving expressiveness. In addition, to express equivariance, higher-order tensor features may be required, and equivariant operations are expensive in terms of computational cost.
In response to these problems, previous studies have taken steps to loosen the restriction on nonlinearity by sampling points on a sphere or to lower the dimensionality of features by approximating equivariant operations [3], and efforts to develop equivariant models with excellent expressive power and computational cost [4].
In this study, we developed a GNN architecture for equivariant prediction with excellent expressiveness and computational cost by using a different method from these studies. We improved the efficiency by converting the rotational equivariant inter-atomic directional information into a rotational invariant representation, eliminating the limitations of nonlinearity, and incorporating efficient geometric message passing [5].
First, to make the directional information between atoms invariant, the coordinates of the neighborhood atoms were transformed using an orthonormal basis defined between two different neighborhood atoms and the central atom. This allows us to obtain directional information between atoms that is invariant to global rotations.
Next, the invariants created by the transformation and the geometric message passing proposed in previous studies were used to update the graph embedding vectors. Note that since only invariant features are used, the embedding itself is an invariant and there are no nonlinearity restrictions when updating it. The geometric message passing proposed in the previous study involves a very expensive operation, as it requires the calculation of the dihedral angles for a quartet of atoms in the material. In this study, the coordinate transformation allows us to efficiently consider higher-order geometric features, thus constituting geometrical message passing with excellent computational cost.
Finally, the predictions were made by extending the embedding vector, which is an invariant, to an equivariant in a manner similar to previous studies. Previous studies have already proven the extension from invariants to equivariants to be general [5].
This presentation will provide an overview of the developed model and the results of validating its accuracy and throughput on several data sets and comparing it to existing models.

9:00 AM DS06.04.03
Investigation of Phase Stability and Ionic Conductivity of Solid Electrolytes $Li_{10}MP_2S_{12-x}O_x$ (M = Ge, Si, or Sn) with Universal Neural Network Potential ChikashiShinagawa, RhotoSawada, KosukeNakago and SoTakamoto; Preferred Networks, Inc., Japan

$Li_{10}GeP_2S_{12}$ (LGPS)-type structures are promising materials for solid electrolytes for all-solid-state lithium-ion batteries with high lithium-ion conductivity. One of the main challenges of these structures is stability. It has been reported that stability can be improved by substituting oxygen for sulfur, but there is a trade-off, as it reduces lithium-ion conductivity. Therefore, it is worth revealing the effects of oxygen substitution on stability and lithium-ion conductivity, and finding the optimal substitution ratio of the oxygen species that balances both properties.

Density functional theory (DFT) calculations have been widely applied to battery materials. However, because of the computational cost of DFT calculations, it is hard to apply for partially substituted structures that require considering various configurations of substituted elements. In contrast, empirical interatomic potentials are much faster than DFT calculations, but it is difficult to construct an empirical interatomic potential which can handle complex structures composed of as much as five elements with enough accuracy.

In this work, we investigated phase stabilities and lithium-ion diffusion barriers of $Li_{10}MP_2S_{12-x}O_x$ (M=Ge, Si, or Sn) with PFP, a neural network interatomic potential which supports any combination of 72 elements. Phase stabilities are calculated considering various configurations of substituted structures, and lithium-ion diffusion barriers are calculated with molecular dynamics (MD) simulations with finite temperatures. The accuracy of PFP was validated by comparing forces with DFT calculations for structures randomly selected from the MD trajectories, and it exhibited good agreement with a mean absolute error of 0.027 eV/Å without fine-tuning for the target system. Our results reproduced that oxygen substitution increases phase stability and increases the lithium-ion diffusion barrier, i.e., decreases lithium-ion conductivity. Analysis of lithium-ion diffusion paths reveals that the disappearance of diffusion channels that are not adjacent to the oxygen atoms increases the lithium-ion diffusion barrier. It suggests that there is a critical mass for oxygen which will close all diffusion paths, and $Li_{10}SnP_2S_{11.5}O_{0.5}$ would be a promising solid electrolyte material, as it balances both stability and lithium-ion conductivity.

9:15 AM DS06.04.04
Benchmarking Optimization of Atomic Structures on Rough Landscapes VaibhavBihani[1], SahilManchanda[1], SrikanthSastry[2], SayanRanu[1,3] and N M AnoopKrishnan[1,3]; [1]Indian Institute of Technology Delhi, India; [2]Jawaharlal Nehru Centre for Advanced Scientific Research, India; [3]Indian Institute of Technology Delhi, India

Efficient optimization of atomic structures is crucial for accurately simulating and understanding the behavior of materials and molecules. Here, we present a comprehensive benchmarking study that evaluates the performance of various optimization methods on atomic structures, encompassing a wide range of atomic interactions. We study gradient-based methods such as Adam, SGD, second-order optimization methods including BFGS and conjugate gradient, molecular dynamic-based techniques like FIRE, Basin Hopping, and simulated annealing, as well as neural methods such as learned optimizers and reinforcement learning-based optimizers. Chosen systems represent diverse atomic interactions, covering various types of potentials, including pairwise potentials such as Lennard-Jones (LJ), three-body angular interactions represented by the Stillinger-Weber potential, Coulombic interactions in the Buckingham potential, and multi-body interactions in the embedded atom potential. We evaluate the performance of each optimization method on different systems, measuring factors such as final energy, computational efficiency, and scalability. Neural techniques leverage the power of neural networks to adaptively optimize the structures and capture complex relationships between atomic interactions. Initial findings suggest that neural methods hold great potential for enhancing the optimization process and achieving higher accuracy in complex atomic systems.

Harnessing the Properties of Equivariant Neural Networks to Understand and Design Materials TessSmidt; Massachusetts Institute of Technology, United States

Atomic systems (molecules, crystals, proteins, etc.) are naturally represented by a set of coordinates in 3D space labeled by atom type. This poses a challenge for machine learning due to the sensitivity of coordinates to 3D rotations, translations, and inversions (the symmetries of 3D Euclidean space). Euclidean symmetry-equivariant Neural Networks (E(3)NNs) are specifically designed to address this issue. They faithfully capture the symmetries of physical systems, handle 3D geometry, and operate on the scalar, vector, and tensor fields that characterize these systems.

E(3)NNs have demonstrated state-of-the-art performance on diverse atomistic benchmarks, such as small molecule properties, protein-ligand binding, and force prediction for heterogeneous catalysis. These networks combine neural network operations with insights from group representation theory. Their success stems from a rigorous foundation, making them more robust, data-efficient, and capable of generalization compared to invariant or non-equivariant neural networks.

In this talk, I will provide an overview of recent applications of E(3)NNs in understanding and designing materials. I will also discuss the expansion of these methods' applicability to new domains and data modalities. Finally, I will explore open questions regarding the expressivity, data-efficiency, and trainability of methods that leverage invariance and equivariance.

10:30 AM DS06.04.06
Predicting Dynamics in Sodium Silicate Glasses using Graph Neural Networks RasmusChristensen, LisbethFajstrup and MortenM. Smedskjaer; Aalborg University, Denmark

Understanding the dynamics of atoms in glasses is crucial for unraveling their transport and dynamical properties, but it is challenging to identify the underlying structural features controlling atom dynamics. Recent studies have used machine learning models such as graph neural networks (GNNs) to predict long-term dynamics, but the focus has so far been on model systems like Kob-Andersen-type Lennard-Jones mixtures. This study extends this approach by using GNNs and molecular dynamics simulations to investigate the dynamics across varying timescales in a realistic system that forms the basis for most industrial glasses, namely sodium silicate glasses. By harnessing the capabilities of graph neural networks, our method provides an effective means for predicting the long-term dynamics of ions in glassy systems based solely on initial atom positions, without relying on handcrafted features. We compare our predictions with those of previously proposed methods. Our findings pave the way for designing glass formulations with tailored dynamical properties.

10:45 AM DS06.04.07
Modeling Phase Transformation in Complex Oxides with Charge-Informed Interatomic Potential PeichenZhong, BowenDeng and GerbrandCeder; University of California Berkeley, United States

Disordered rocksalt materials represent the most promising earth-abundant cathode materials for Li-ion batteries, potentially enabling the scaling of Li-ion energy storage to numerous TWh/year production. These advanced battery materials often comprise multiple elements and exhibit significant site disorder and structure complexity. Mn-rich DRX cathodes have observed a phase transformation from disorder to partial spinel-like order during charge/discharge cycling. To understand this phenomenon and reveal the underlying physics, we employed atomistic modeling with charge information derived from ab-initio calculations.

CHGNet is a novel machine-learning interatomic potential (MLIP) with atomic charge inference from magnetic moments. The explicit incorporation of magnetic moments allows CHGNet to learn and accurately represent the orbital occupancy of electrons, thereby enhancing its ability to describe both atomic and electronic degrees of freedom. We fine-tuned the pre-trained universal CHGNet within the Li-Mn-Ti-O-F chemical space using high-fidelity DFT calculations. The fine-tuned CHGNet was then applied to $Li_{1.1-x}Mn_{0.8}Ti_{0.1}O_{1.9}F_{0.1}$ DRX system, using charge-informed molecular dynamics to investigate the structural ordering change, charge distribution, and electrochemical properties of the transformed DRX compounds.

11:00 AM DS06.04.08
Scaling Up Equivariant Potentials: From Fragments Towards Exascale Simulations AlbertMusaelian[1], AndersJohansson[1], SimonBatzner[1] and BorisKozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch Research and Technology Center, United States

Great progress in accuracy and data efficiency has been made in machine learning interatomic potentials (MLIPs) thanks to equivariant models, which leverage the symmetries of the underlying physics to learn rich geometric representations. But while MLIPs have long promised to bring ab-initio accuracy to calculations that could not possibly be conducted with methods like DFT, the need for representative training data from quantum methods has often restricted MLIPs' application too far from the regimes in which DFT is practical. Further, architectural limitations in the most accurate models have impeded their scaling and speed.

In this talk, we present recent developments on how Allegro—a machine learning architecture we recently developed to retain the benefits of equivariance while omitting previous schemes, like message passing, that limit computational performance—can scale to larger length-scales, longer time-scales, larger datasets, and scale up from fragments to complex systems. In particular, I will discuss techniques to improve simulation stability and thus the ability to run long timescale simulations; speed optimizations including variable cutoffs and a simplified multi-path tensor product; and how the Allegro architecture facilitates scaling model capacity for diverse, large data. Indications of its ability to scale up from large databases of fragments to complex systems never seen in the training data will be demonstrated using an example in biochemistry.

11:15 AM DS06.04.09
Machine Learned Interatomic Potential for Atomic Simulation of Dislocation in Ceramics ShihaoZhang and ShigenobuOgata; Osaka University, Japan

Dislocations in ceramics are rapidly catching interest owing to their exciting application potential for dislocation toughening of intrinsically brittle ceramics and functional property tailoring, and thus are now perceived as promising atomic-scale entities for next generation device applications [1-3]. However, understanding at the atomic scale of the dislocation behaviors in ceramics is still lacking. The traditional empirical interatomic potential of ceramics usually suffers the bad transferability and low accuracy. In this work, we reported the development of machine learned interatomic potential for the atomic simulation of dislocation in ceramics, i.e., zinc oxide (ZnO), gallium nitride (GaN), and strontium titanate (SrTiO3), yielding ab initial accuracy and large-scale atomic simulation (millions of atoms). The machine learned interatomic potentials describe well the core structure and slip barrier of dislocation in these ceramics comparing with the results of first-principles calculation and experiment. Finally, the indentation-induced dislocation nucleation and propagation in ceramics were studied using the developed

interatomic potential, in good agreement with the nanoindentation experimental results. This study not only demonstrates the effectiveness of machine learned interatomic potentials in the analysis of plastic deformation of ceramic materials, but also provides new insights into the dislocation-dominated deformation behavior of ceramics. Authors acknowledge the JSPS Postdoctoral Fellowships for Research in Japan (Standard) and the Grant-in-Aid for JSPS Research Fellow Grant No. 22F22056.

Vibrations for Free: Fast Calculations of Vibrational Free Energies in Solid Solutions with Machine Learned Force Fields KasperTolborg and AronWalsh; Imperial College London, United Kingdom

Alloys and solid solutions form an integral part of modern-day technology ranging from structural materials to semiconductors and catalysts. Recent years have seen a renewed interest in compositionally complex materials with the advent of high entropy alloys and compounds [1]. First principles calculations of their compositional phase diagrams can significantly aid the design and understanding of these complex materials.

Compositional phase diagrams are typically calculated from first principles using cluster expansion methods, in which effective cluster interactions are fitted to internal energies of a set of representative configurations calculated from density functional theory (DFT). Configurational entropy is then incorporated through Monte Carlo simulations at longer length scales. Despite calculations showing that vibrational entropic contributions are important [2], these effects are largely neglected due to their computational cost, and when included they are typically based on approximate bond-length-bond-strength relations [3].

Here, we introduce a method for fast calculations of vibrational free energies from machine learned force fields (MLFF). For cluster expansion construction, a large series of structural relaxations are performed, but only the final energies are used. Here, we use the energies, forces and stresses already available from these geometry relaxations to train an MLFF for a given solid solution, which is benchmarked against DFT lattice dynamics simulations. With this force field in hand, we perform lattice dynamics calculations and extract vibrational free energies for each configuration from which we construct a temperature dependent cluster expansion model.

We apply our method for simple solid solutions and demonstrate predictions of phase diagrams in significantly improved agreement with experiments. This paves the way for easy calculations of vibrational free energies of solid solutions allowing for more realistic predictions of materials thermodynamics from first principles [4].

11:45 AM DS06.04.11

Defect Density Minimization in ALD Passivation Layers by Bayesian Optimization Sinan OzgunDemir[1,2], GülDogan[1,3], UtkuCulha[1,4], KahramanKeskinbora[1] and MetinSitti[1,5,6]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]University of Stuttgart, Germany; [3]Robert Bosch GmbH, Germany; [4]Technical University of Munich, Germany; [5]ETH Zürich, Switzerland; [6]Koc University, Turkey

Atomic layer deposition (ALD) is a highly efficient and effective method for providing conformal coating to sensitive materials and related surfaces, such as integrated circuits. While ALD has demonstrated its applicability across a wide range of materials and geometries, it is also crucial to achieve defect-free layers for better corrosion protection. This objective is heavily influenced by a multitude of fabrication parameters, resulting in a high-dimensional and cross-correlated parameter space that renders conventional optimization techniques impractical.
To address this challenge and optimize the process parameters, we propose a probabilistic machine learning approach utilizing Bayesian Optimization (BO) with Gaussian Processes (GPs). Our approach leverages BO's data-efficient learning scheme to identify the optimal deposition parameters in just three iterations, leading to defect minimization in an ALD-Al_2O_3 passivation layer. Furthermore, our methodology enables the analysis of the impact of each process parameter on defect density, thereby providing insights into which parameters should be tuned for improved performance under varying conditions.
The presented study showcases the time and cost efficiency of optimizing ALD layers using our proposed approach. Our findings highlight the effectiveness of Bayesian Optimization in material science and fabrication technologies, offering a valuable tool for optimizing diverse materials and processes.

SESSION DS06.05: Machine Learning for Simulation of Materials II
Session Chairs: Mathieu Bauchy and Tess Smidt
Tuesday Afternoon, November28, 2023
Sheraton, Second Floor, Back Bay A

1:45 PM *DS06.05.01

Using Reinforcement Learning for Manipulating and Synthesizing Thin Films BenjaminSmith[1], AnahitaKhojandi[1], AyanaGhosh[2], SergeiV. Kalinin[1], EvaZarkadoula[2], PanchapakesanGanesh[2] and RamaK. Vasudevan[2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Recent progress in reinforcement learning (RL), and in particular the combination of traditional RL methods with deep neural networks for function approximation, has resulted in tremendous advances in gameplay and sequential decision-making tasks. However, the applications of RL to materials simulation has been limited and best, largely due to difficulties stemming from the very large data requirements for traditional RL.

Here, we explore the application of RL within simulations and experiments, focused on the manipulation of structures within ferroelectric materials. We show that utilizing RL agents, it is possible to learn optimal defect positioning within a lattice-based ferroelectrics simulation environment modeled with nearest neighbor interactions. Investigation of the agent's policy reveals underlying information about the length scales of interactions between defects in the simulation. We then proceed to a more complex molecular dynamics environment of the synthesis of Tellurene, and proceed to run thousands of simulations of deposition of Te to assemble into Tellurene, and then employ off-policy RL to learn appropriate actions to maximize the crystallinity and target phase of the resultant structure. Finally, results on manipulation of materials experimentally with RL implemented on a microscope are discussed, with a view towards the need for better integrating simulations in such design and characterization workflows. This work was supported by Center for Nanophase Materials Sciences (CNMS), which is a US Department of Energy, Office of Science User Facility at Oak Ridge National Laboratory.

BroGNet: A Graph Neural SDE for Learning Brownian Dynamics SureshBishnoi, JayadevaJayadeva, SayanRanu and N M AnoopKrishnan; Indian Institute of Technology Delhi, India

Neural networks (NNs) that exploit strong inductive biases based on physical laws and symmetries have shown remarkable success in learning the dynamics of physical systems directly from their trajectory. However, these works focus only on the systems that follow deterministic dynamics, for instance, Newtonian or Hamiltonian dynamics. Here, we propose a framework, namely Brownian graph neural networks (BroGNet), combining stochastic differential equations (SDEs) and GNNs to learn Brownian dynamics directly from the trajectory. We theoretically show that BroGNet conserves the linear momentum of the system, which in turn, provides superior performance on learning dynamics as revealed empirically. We demonstrate this approach on several systems, namely, linear spring, linear spring with binary particle types, and non-linear spring systems, all following Brownian dynamics at finite temperatures. We show that BroGNet significantly outperforms proposed baselines across all the benchmarked Brownian systems. In addition, we demonstrate zero-shot generalizability of BroGNet to simulate unseen system sizes that are two orders of magnitude larger and to different temperatures than those used during training. Altogether, our study contributes to advancing the understanding of the intricate dynamics of Brownian motion and demonstrates the effectiveness of graph neural networks in modeling such complex systems.

Neural Network Potential for Arbitrary Combination of 72 Elements Trained Against Large Scale Dataset SoTakamoto and ChikashiShinagawa; Preferred Networks, Inc., Japan

The development of neural network-based interatomic potentials has garnered growing interest in recent years. The field is rapidly progressing due to the availability of large datasets and aims to address challenging issues, including predicting complex phenomena such as chemical reactions and multi-component systems.
We have developed a neural network potential called PFP (Preferred Potential) Version 0, which can be applied to arbitrary combinations of 45 elements. Our in-house developed NNP architecture and datasets allow PFP to be applied to a wide range of substances with a single model, without the need for separate training for each specific system. In our previous publication, we demonstrated PFP's capabilities by applying it to a diverse range of materials systems, including a Li-ion battery cathode material, metal-organic frameworks, phase transition of Cu-Au alloys, and catalyst search for the Fischer-Tropsch reaction.
Continuing to develop the PFP architecture and dataset, we have spent 1,650 GPU years creating a dataset composed of 33 million DFT-calculated atomic structures. The latest PFP version, v4.0.0, supports 72 elements, which make up over 99.9969% of all materials on Earth and covers a majority of the periodic table. We have confirmed that the new version of PFP reproduces energy surfaces with better accuracy when compared to its previous version. In particular, we have demonstrated significantly improved reproducibility of the energy ordering of bulk crystal structures. This gives us accurate composition phase diagrams of multi-element mixtures.
We believe that our work in developing a universal potential applicable to a broad range of phenomena will greatly accelerate computer-based materials discovery.

3:15 PM DS06.05.04
Absorption and Dynamics of Gas Molecules in Metal-Organic Frameworks: Application of a Universal Neural Network Potential TakuWatanabe, HirokiIriguchi and AkihiroNagoya; Preferred Computational Chemistry Inc., Japan

Metal-organic frameworks are a class of nanoporous materials with extensive chemical and structural diversity deemed to hold promise in a variety of applications. One of the critical challenges of MOFs is their stability against chemical species present in the environment. Many of the MOFs are known to be unstable even to the humidity in the air. There have been extensive theoretical and experimental studies on the investigation on water-stable MOFs.
The development of machine learning potentials is rapid and becoming increasingly popular in the field of molecular simulations. They are becoming applicable to a wide range of materials including alloys, oxides, sulfides, surfaces, and molecules. However, the tremendous diversity of chemical and physical diversity of MOFs presents challenges to be modeled accurately. Preferred Potential (PFP) implemented on Matlantis™ is a recently developed neural network potential with its unique feature of universality even compared to other existing machine learning potentials.
In this paper, we present our study on the detailed examination of the chemical reactions leading to the degradation of selected MOFs using PFP. Some of the MOFs do indicate clear degradation pathways upon exposure to humidity under specified conditions. IRMOF-1 (a.k.a MOF-5) is well-known for its sensitivity to humidity at room temperature. Molecule dynamics simulations showed that IRMOF-1 remains stable under a mildly high temperature of 400 K with an external strain. Even under the highly humid condition of 8 wt.% water, the structure remains stable at room temperature for the simulation of 2 ns. Clear degradation was observed at high temperatures and strained conditions under high humidity. Other selected MOFs were also tested under the same simulation condition but some of them did not exhibit any degradations. The observed trend of stability is consistent with the known trend in the literature.
We also examine the trends in the preferred adsorption sites of gas species using grand canonical Monte Carlo simulations. Since PFP can treat both chemisorption and physisorption in a unified fashion, the adsorption behavior can be correctly captured regardless of the type of molecular interactions. For instance, MOF-74 contains open metal sites when properly dehydrated, and they play important roles in the interactions with guest molecules. Such hydration/dehydration behavior can be correctly captured without employing a highly tailored reactive potential. With this capability, the impact of the presence of defects in the MOF is examined and elucidated. Finally, we will discuss the implications of these characteristics to practical applications.

3:30 PM DS06.05.05
Equivariant Neural Network Potentials for Modelling Dynamics and Structure of Oxide Supported Metal Nanoparticles CuauhtémocN. Valencia, MathiasS. Nissen, WilliamB. Lomholdt, Matthew HelmiLeth Larsen, ThomasW. Hansen and JakobSchiotz; Technical University of Denmark, Denmark

Molecular Dynamics (MD) simulations require a model for the interatomic interactions that is both accurate and computationally inexpensive. Density Functional Theory (DFT) offers good accuracy and decent computational performance for small systems, and *ab-initio* molecular dynamics (AIMD) is now possible based on DFT. However, many simulations require system sizes and/or simulation times that makes AIMD impossible.

Machine learning potentials can be used to generate inter-atomic potentials for specific systems, with accuracy close to that of DFT and computational efficiency close to that of classical interatomic potentials [1]. While such machine learning potentials have been used to extend the size and time scale of MD simulations to obtain adequate sampling of structures and thermodynamical properties, they suffer from the need of very large training sets and are dependent on the quality of the rotationally invariant descriptors used as input to the neural networks [2]. Some of these problems can be relieved with Equivariant Neural Networks, where vector quantities can be used directly as input to the network, and then processed in a rotationally equivariant way by the network.

We use equivariant neural networks to simulate catalytic metal nanoparticles supported by metal oxides, focusing on two independent scientific problems. First, we studied the heat transport between gold nanoparticles and TiO_2 support and show that the interface acts as a barrier for heat transport. This barrier determines the amount of heating that a nanoparticle undergoes when irradiated by the beam of an electron microscope and is therefore of paramount importance for understanding and limiting beam damage and beam influence in high-resolution electron microscopy.

Secondly, we investigated how the lattice mismatch between platinum nanoparticles and the substrate relaxes in the interface, and how this influences the stress on the surface of the nanoparticle. Platinum is the main catalyst for the oxygen reduction reaction in fuel cells, and the catalytic activity is very sensitive to the strain of the platinum surface [3], which may be manipulated by using the right substrate.

We tested both the NequIP [4], a message-passing equivariant graph neural network, and Allegro [5], a strictly local equivariant graph neural network by the same group of authors. We found that NequIP produced slightly superior performance, and as we did not need the strict locality for parallel large-scale MD we chose to proceed with NequIP. We initially trained the networks with data from small AIMD simulations of similar systems. We then use a committee of five neural network potentials to evaluate the uncertainty of MD simulations and augment the training set with structures that are poorly described. In this way we obtain neural network potentials that are both transferable and reliable, and with the possibility of gauging their accuracy using query by committee.

Strategic Optimization of Deep Learning Potentials to Model Catalyst Dynamics SumanBhasker Ranganath and JohannesVoss; SLAC National Accelerator Laboratory, United States

Machine learning interatomic potentials (MLIPs) trained on quantum mechanical simulation datasets are promising to study the evolution of catalytic processes at extended time and length scales, rendering accuracies comparable to the reference method at a reduced cost.[1] MLIPs approximate the underlying potential energy surface (PES) by learning solely on the correlation between the atomic coordinates and energies, forces in the training dataset. The potentials optimized via appropriate active learning schemes could be applied to identify unexplored regions of the PES, for example to predict novel catalyst morphologies, binding configurations, reaction pathways, and to further model their evolution at specific thermodynamic conditions.[2] However, strategies to optimize MLIPs through incremental dataset expansion guided by relevant uncertainty metrics in an active learning framework are not well recognized.

In this work, a minimal structured dataset is compiled by accounting for the factors commonly encountered in catalysis to train a base artificial neural network (ANN) potential. The atomic positions and energies from single point calculations using density functional theory, of the smallest model metal surface-adsorbate interface is transformed to training set using Chebyshev

descriptor implemented in aenet.[3] We propose a strategy to educate the models on forces based on displacements of selective atoms. The trained base potential predicts energies, forces, and binding strengths of both relaxed and unrelaxed larger unit cells with average RMS errors of 4 meV/atom, 0.15 eV/Å, and 0.1 eV/atom respectively.

It gets challenging to apply the model, for example to predict catalyst dynamics at reaction conditions, as its ability to extrapolate to regions beyond the trained (near) equilibrium datapoints of the PES is very limited. We employ deep ensembles[4] to investigate possible uncertainty driven active learning protocols to upgrade the base model. The spread in predicted energies, forces between the ensemble members correlates with the errors with respect to reference values[5] when a reliable data splitting strategy is used to train the ensemble, and hence is used as a metric to ascertain uncertainty bounds. An apt solution is offered to generate effective ensemble members trained on extended datasets. Strapping an ANN ensemble with tools such as molecular dynamics allows for effective sampling of the configuration space.[6] A better approximation of the PES is attained by iterative retraining of the ensemble on highly uncertain datapoints of the explored configuration space. Influence of the choice of uncertainty drivers on the evolution of deep ensemble potentials will be discussed. Approaches to further equip the ensemble, on the levels of both data as well as ANN model will be presented.

Modelling Phase Transformations and Diffusion in Doped Na-Ion Conductors using Machine Learned Interatomic Potentials JohanKlarbring[1,2] and AronWalsh[1]; [1]Imperial College London, United Kingdom; [2]Linkoping University, Sweden

Machine learned interatomic potentials (MLIP) have become an indispensable tool in computational materials science, promising to extend the accessible length and timescales of ab initio molecular dynamics (AIMD), while retaining an accurate description of the relevant interactions. The last decade has seen a tremendous increase in the accuracy, data efficiency and scalability of the MLIPs. Consequently, their applications are being pushed towards increasingly complex materials and phenomena.

Here, we present an application of the Allegro [1] MLIP, a recently developed local E(3)-equivariant graph neural network potential, to a set of promising Na-ion conductors based on sodium thiophosphate, Na_3PS_4 [2]. Specifically, we study the $Na_{3-x}Sb_{1-x}W_xS_4$ system, where aliovalent W-dopants are introduced along with charge-compensating Na-vacancies in order to facilitate Na-ion diffusion. Describing this system and the relevant physical phenomena using an MLIP will require it to describe (1) the diverse local chemical environments of an alloy, (2) ionic diffusion and (3) structural phase-transformations.

In the talk, we showcase how the trained Allegro MLIP performs on this demanding set of tasks. In particular, we use large scale MD simulations to accurately reproduce the known tetragonal-to-cubic phase transformations, including the decrease of the critical temperature, Tc, with increasing W-concentration. We discuss the origin of this decrease in Tc, and the experimentally proposed differences between the local and average structure of the cubic phase [3]. We further show results on properties related to Na-ion diffusion and compare them to experimental and AIMD based results from the literature.

4:15 PM DS06.05.08
Using Symmetry-Equivariant Neural Networks (ENNs) to Uncover Symmetry-Implied Missing Information ElyssaHofgard[1], RayWang[2,1] and TessSmidt[1]; [1]Massachusetts Institute of Technology, United States; [2]University of California, San Diego, United States

In this talk, we demonstrate how Symmetry-Equivariant Neural Networks (ENNs) can identify sources of symmetry breaking in diverse physical data and uncover symmetry-implied missing information unbeknownst to the researcher. Symmetry and symmetry-breaking is crucial for understanding complex physical systems (e.g. phase transitions in materials and the discovery of the neutrino). Physical systems adhere to Curie's Principle–stating that when effects show certain asymmetry, this asymmetry must be found in the causes that give rise to them. ENNs are built to preserve symmetry and thus obey the same principles [3].
Recorded data can appear to deviate from strict symmetry constraints, so recent studies emphasize the importance of relaxing equivariance to balance model bias with capturing complex patterns [4-6]. Here, we present a complementary approach showing that fully equivariant models can be used for real-world problems where symmetry may be broken due to some noise, external forces, or other asymmetries in the environment. We benchmark our against state-of-the-art approximately equivariant networks in [4]. These methods can be applied to materials science, where approximate symmetry commonly arises due to structural defects, strain, or phase transitions. Understanding and characterizing these deviations from perfect symmetry are crucial for investigating material properties and behavior.

Scalable Parallel Algorithm for Graph Neural Network Potentials in Molecular Dynamics Simulations YutackPark, JaesunKim and SeungwuHan; Seoul National University, Korea (the Republic of)

Machine-learned potentials have emerged as a preferred method for addressing the scale limitations inherent in *ab initio* molecular dynamics (MD) simulations. Early-stage machine-learned potentials utilized invariant, atom-centered descriptors to encode the atomic environment. Recently, however, attention has been drawn to graph-based neural network interatomic potentials (GNNs), especially those of the equivariant type. These GNNs generally surpass descriptor-based models in accuracy and can efficiently manage multi-component systems. However, the message propagation in GNNs inherently makes them challenging to integrate with spatial decomposition, a conventional parallel algorithm used in MD. To the best of our knowledge, no GNN package currently supports distributed-memory parallelism in MD. Consequently, the length scale that GNNs can study is restricted by the memory size of a single processor.
In implementing spatial decomposition of GNNs, two problems arise when two atoms connected by a graph edge belong to different processors. The first problem occurs when inferencing the atomic energy using the GNN. The message-passing layers in the GNN require atomic features of connected atoms, which become inaccessible due to spatial decomposition. The second problem arises when calculating the atomic forces by automatic differentiation derivatives of the energy (for instance, Autograd module in PyTorch). Force calculation requires gradient information of neighbor atoms, necessitating non-trivial evaluation and communication of partial derivatives for disconnected edges. To address these issues, we present SEVENN (Scalable EquiVariance-Enabled Neural Network), an implementation of a parallel algorithm that integrates GNNs with spatial decomposition. The baseline GNN model is the same as NequIP, and we employed the LAMMPS package for spatial decomposition. To optimize the parallel implementation, we have included a communication routine for GNNs with multiple GPUs, leveraging NVIDIA GPUDirect® technology for fast inter-GPU communication.
To assess the parallelization efficiency of our algorithm, we conducted MD simulations for SiO_2 up to 100,000 atoms on A100 GPU clusters. We tested up to 5 message passing layers and 32 GPUs, where intensive communication of atomic features and gradient information between processors occurs in each message passing layer. SEVENN demonstrated over 80%-90% parallel efficiency when scaling the number of atoms proportionally with the number of GPUs. This result indicates that the simulation using SEVENN can be linearly scaled up to accommodate a large number of atoms. We believe that this study paves the way for the application of GNNs in large-scale simulations.

8:00 PM DS06.06.01
Optimization of Aluminum Frame Design for Commercialization of Perovskite Tandem Solar Modules: A Deep Learning Surrogate Model Approach Dong-woonHan and SeongtakKim; Korea Institute of Industrial Technology, Korea (the Republic of)

Perovskite cells have a lower manufacturing cost and higher efficiency compared to conventional silicon cells. However, perovskite materials are vulnerable to heat and moisture. Using only perovskites leads to a short lifespan, making commercialization challenging. Therefore, development of perovskite-silicon tandem cells, as an intermediate stage, is ongoing for commercialization purposes. On the other hand, in the silicon solar cell market, the size of wafers used in solar cell manufacturing is increasing, leading to larger module sizes. However, when applying the conventional aluminum frame, sagging can occur due to its own weight and external pressure. If the cells deform under the load, it can lead to an increase in dead cells due to internal cracks and damage, resulting in a decrease in charging rate and efficiency. Therefore, in this study, we conducted frame design optimization for large-area modules to facilitate the commercialization of perovskite tandem solar modules. We established five factors to determine the configuration of the commercial aluminum frame. We generated a total of 243 cases with 5 factors at 3 levels each using experimental design methodology. The module was assumed to use M10 cells with a power rating of 585W. We applied a wind pressure of 2,400Pa to the front area of the module and performed finite element analysis taking into account the self-weight. The stress and amount of deflection shown in the cell and frame were confirmed. Subsequently, we utilized artificial intelligence to train on the results of the finite element analysis, generating a surrogate model capable of mimicking the interpretation outcomes. As a result, we designed an aluminum frame for the module that minimizes deflection and weight under the applied load.

8:00 PM DS06.06.02
Data-Driven & Multiscale Approaches to Characterize & Optimize the Manufacturing Process of Powder Compaction SangilHyun, JinhwaPark, Ga-AeRyu and YoonsooHan; Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

For computer simulations to characterize the powder compaction, a continuum approximation approach based on the Drucker-Prager Cap model has been widely used for manufacturing various shapes of ceramic powder-based devices. The model can effectively describe the effective physical properties required for various individual materials and complex manufacturing processes. However, some realistic parameters required in this empirical model are limited to obtain by experimental methods due to inaccurate and highly-costed measurements on various specific conditions. To minimize these limitations, we developed a virtual data-generating scheme based on the multiscale analysis of the powder compaction. The homogenization method is introduced to determine the effective properties of the powder from a theoretical model of particle size distributions, and applied to a macroscopic continuum limit. In addition, we developed a digitized and automatic workflow accompanying these multi-scale simulation techniques to characterize and optimize the powder compaction process. This virtual data-driven design method can automatically generate the required data by adjusting process variables to provide optimal shapes or conditions for the desired requirements.
In this work, we introduce an automatic generation platform of virtual data for the press forming process under various manufacturing conditions for optimal design. In the wide range of manufacturing technology based on powder materials, this multiscale and data-driven approach can accelerate the optimal process for complex geometry and operating conditions. The ceramic manufacturing platform (called *VECTOR*) is developed to provide the optimization digital tools customized for fundamental study as well as industrial needs.

8:00 PM DS06.06.03
Exploration of New Materials for Nonlinear Optical Crystals using Materials Informatics KosukeShirai[1], TomoyukiTamura[1] and Ming-HsienLee[2]; [1]Nagoya Institute of Technology, Japan; [2]Tamkang University, Taiwan

Recently, materials design approaches that introduce materials informatics have become extremely important in materials science. MI methods can accelerate the design of new materials by using machine learning to predict physical properties with accuracy comparable to density-functional-based first-principles calculations and with computational speeds an order of magnitude faster.
Among them, the Atomistic Line Graph Neural Network (ALIGNN) [1], which considers distance and angle information, has been shown to significantly improve feature representation between atoms and prediction accuracy. However, there is a tradeoff between prediction accuracy using deep learning such as ALIGNN and the number of training data. For many practical materials, it is difficult to obtain sufficient prediction accuracy because of the small amount of property data that is available, due to computational costs.
In this study, we introduce transfer learning into ALIGNN to construct a sufficiently accurate property prediction model on a small data set by pre-training on a large amount of property data already obtained from databases and other sources.
Nonlinear optical materials are promising materials that have an important role in expanding the wavelength range of lasers.
Among them, there is an urgent need to develop ideal materials that simultaneously satisfy a wide band gap, a large second harmonic generation (SHG) susceptibility, and an appropriate birefringence. Nonlinear optical susceptibility and birefringence can be obtained by electric field calculations using density functional perturbation theory, but they remain computationally expensive.
Therefore, in this study, we predict nonlinear optical susceptibility and birefringence from a small data set by using ALIGNN and transfer learning.
ALIGNN and transfer learning were implemented in PYTORCH [2], a Python library. First, nonlinear optical properties were calculated with the CASTEP code [3] for about 500 structures obtained from the Inorganic Crystal Structure Database (ICSD) [4] including B and Ge. Then, thousands to tens of thousands of structural data and properties (band gap, refractive index, DOS) data that are close to the composition of the 500 structures were obtained from the Materials Project Database (MPD) [5] as pre-training data and prediction models were constructed for each of them. We predicted the nonlinear optical susceptibility and birefringence by training only the final layer of the optimized ALIGNN model. Finally we screened from various compositions and structures by using the predictive models of nonlinear optical properties constructed.

Physics-Controlled Data Perturbation for One-Shot High-Fidelity Data Reconstruction HadiMansourifar, LingChen, JaydeepThik, YuqingZhou, PaulSchmalenberg, ErcanM. Dede and DebasishBanerjee; Toyota Research Institute of North America, United States

High-fidelity design is essential to capture intricate details, optimize performance, and understand local phenomena within many scientific disciplines, including materials simulation. Nevertheless, obtaining such data experimentally is often challenging and time-consuming. To address this issue, low-fidelity data are calculated as a computationally efficient alternative. Afterward, high-fidelity reconstruction is performed using the deep learning approaches. However, due to the limitations in obtaining a large number of low/high fidelity pairs for training generative models, one-shot learning is inevitable in this context. This paper introduces a novel idea for high-fidelity one-shot reconstruction based on physics-controlled data perturbation. The proposed approach leverages well-known partial differential equations (PDEs) with 2D solutions, like the heat equation and Burgers equation, to perturb low/high fidelity paired simulations for augmenting new data pairs. In fact, the proposed PDE-based perturbation technique reduces the need for a vast collection of paired data to efficiently train a generalizable generative model via synthesizing data variations from single, high/low fidelity paired inputs.
Our experimental results show that physics-controlled data perturbation can easily outperform traditional data augmentation in a one-shot high-fidelity reconstruction task. By leveraging the knowledge embedded in different PDEs and their solutions, we enable the generation of out-of-boundary augmented data for training a more generalizable generative model. The experimental results demonstrate the efficacy of our approach, showcasing its potential for enhancing high-fidelity reconstruction in various material research applications.

8:00 PM DS06.06.05
Evaluate Deep Learning Discrepancies Between High Fidelity and Low Fidelity Simulations PrachiGarg[1], ShaonDas[1], KristoferG. Reyes[2,1] and BaishakhiMazumder[1]; [1]University at Buffalo, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

Utilization of deep learning (DL) models has shown promising results in extraction of structural information from complex, three-dimensional atomistic data obtained from Atom Probe Tomography (APT). The primary requirement for DL models is a substantial amount of training data. To overcome this limitation, we propose the use of simulated training data. However, an open question arises regarding the level of accuracy (fidelity) that the synthetic training data should possess.
The objective of this research is to investigate the relationship between the fidelity of synthetic training data and the performance of the DL model when applied to real APT data. By varying the fidelity of the synthetic data, we assess the impact on the accuracy and reliability of the DL model's structural predictions. Through our findings, we aim to provide insights into the optimal fidelity requirements for synthetic training data to achieve accurate and robust results when analyzing real APT data. This research contributes to the advancement of DL-based approaches for extracting valuable structural information from atomistic data, enhancing our understanding of complex materials, and enabling more precise analysis in various scientific fields.

8:00 PM DS06.06.06
Machine Learning Approach to Time-Series Analysis of SARS-CoV-2 Spike Glycoproteins under Varying pH and Temperature Conditions ParthJain[1,2], MelvinThu[3,2], ZiyuanNiu[2], MiriamRafailovich[2] and YuefanDeng[2]; [1]Bergen County Academies, United States; [2]Stony Brook University, The State University of New York, United States; [3]Great Neck North High School, United States

As the SARS-CoV-2 pandemic persists, it's vital to evaluate how environmental factors such as temperature and pH affect the virus's molecular structure. Molecular dynamics (MD) simulations are commonly used to study nanoscale interactions. However, their computational complexity limits their suitability for larger-scale, longer-term modeling. Our research focuses on developing a machine learning (ML) approach that leverages supervised training on SASA (solvent accessible surface area) MD simulation data to predict properties of SARS-CoV-2 spike glycoproteins (S-proteins). SASA quantifies the accessible surface area around a protein, which plays a crucial role. Changes in these values over time provide insights into protein stability, folding behavior, and the virus's pathogenicity under specific conditions.[1]

We performed MD simulations of the S-protein using GROMACS. The protein structure (PDB: 6VXX) was modeled with the CHARMM27 force field. The explicit solvent was represented by a 20x20x20 nm3 box (SPC/E water model) at 1.02 g/cm3 density. The simulation was conducted at 37°C, with energy minimization via steepest descent. We employed canonical (NVT) and Parrinello-Rahman pressure coupling (NPT) methods with a 2 fs time step.

We denoised and processed data using Fast Fourier Transforms (FFT) to convert time-series SASA data into a frequency domain, enabling the identification of cyclic patterns. ML models, including k-Nearest Neighbors (k-NN), Long Short-Term Memory Neural Networks (LSTMs), and Convolutional Neural Networks (CNNs), are subsequently trained on 1,500 ns of MD SASA data to predict changes as a function of time. This large dataset allowed us to thoroughly test each model's performance across varying sample sizes. Prior research has indicated that larger datasets enhance the accuracy of the k-NN model.[2] LSTMs were also chosen to provide a contrasting approach to the k-NN and CNN models, which are known for their higher sensitivity in extracting categorical features and capturing patterns in data.[3] We ran the ML models on SASA data of the S-protein at temperatures of 3°C, 20°C, and 37°C and pH values of 1, 2 , 3, 4, and 5, and used an 80-20 train-test split. The k-NN model demonstrated the greatest accuracy in forecasting simulation data out of three models, whereas the LSTM model performed poorly, likely requiring more training data to make accurate predictions. In the future, in vitro experiment results will be able to validate the accuracy of the ML models for long-term predictions and their efficacy as a replacement for computationally expensive MD simulations.

8:00 AM DS06.07.01
Efficient Crystal Structure Prediction using Universal Neural Network Potential and Genetic Algorithm TakuyaShibayama, HideakiImamura, KatsuhikoNishimra, ChikashiShinagawa and SoTakamoto; Preferred Networks, Inc., Japan

Crystal Structure Prediction (CSP) based on quantum chemistry calculations is used to discover new materials in various materials fields. However, its applicability is limited by its massive computational cost. An accurate and universal machine learning potential would greatly reduce the computational cost and enable CSP to investigate a wide range of realistic materials. We have developed a CSP system using the versatile and efficient NNP named Preferred Potential (PFP). The latest version, PFP v4.0.0, has been released with improved accuracy, enabling more precise CSP studies.

Our CSP system uses PFP and genetic algorithms (GA) to perform local optimization and evaluation of 10,000 samples within an hour using 100 GPUs (equivalent to 10,000 GPU hours). We modified the GA implemented in the Atomic Simulation Environment (ASE) library by extending the sampling algorithms, as well as mutation and crossover. We improved the GA sampler by considering the similarities between CSP and multi-objective optimization problems, and expanded the non-dominated sorting genetic algorithm II (NSGA-II) for crystal structure search, which is specifically designed for multi-objective optimization. To manage trials effectively and in parallel, we employed Optuna, an open-source software framework for hyperparameter optimization.

We performed CSP search for several binary systems and evaluated new crystal candidates using density functional theory (DFT) calculations. More than 10 structures are confirmed as newly found inorganic crystals, which break known convex hulls of the Materials Project database. The new crystals are discovered in systems such as Ti-O, Li-In, Ca-P, and Mg-Pd. More than 50% of the candidate structures suggested by the CSP system using PFP were confirmed by DFT calculations. These results demonstrate the effectiveness of PFP and GA-based CSP in accelerating materials discovery and design. We have also tested our CSP system on a high-performance computing environment using the MN-Core deep learning accelerator, which provided comparable performance to the NVIDIA V100 GPU.

8:15 AM DS06.07.02
Property-Structure-Process Relationship Trees and Contextual Understanding of Scientific Manuscripts using Large Language Models of Artificial Intelligence MaciejTomczak[1], DanielCieslinski[1], PaydenBrown[2], YangJ. Park[2], JuLi[2] and StefanosPapanikolaou[1]; [1]National Centre for Nuclear Research, Poland; [2]Massachusetts Institute of Technology, United States

The ever expanding corpus of scientific manuscripts contains vast amount of knowledge and descriptions of various experimental settings. As new articles are published daily, it is impractical for any single individual to grasp all that information. However, for each manuscript, the scientific human mind further trains a tree of connections between Properties (eg. hardness, strength, conductivity of materials), Structures (eg. crystalline type, defect content, composition) and Processes (eg. annealing, cold work). This tree of PSPs represents the human strategy for dimensional reduction in processing scientific manuscripts, and requires to quickly and efficiently find required information in the published works and compare it with similar texts or other sources.

Recent advancements in natural language processing (NLP) have given rise to high-performing foundation models, in particular large language models (LLM) such as OpenAI’s GPT-4. These powerful models are capable of complex tasks such as text summarization and creative content generation. However, utilization of these models comes at a significant computational cost and contextual understanding is commonly limited. In this work, we develop small and efficient fine-tunable models for capturing PSPs in scientific manuscripts, using Elsevier's database. We

also propose to incorporate the Retrieval Augmented Generation (RAG) approach alongside our fine-tuning methods for ensuring a more robust and reliable model for capturing PSPs in scientific manuscripts.

We investigate the statistics of various ways of fine-tuning LLMs, and also extract PSPs in pre-defined sets. Using texts focused only on nuclear materials research from Journal of Nuclear Materials, we evaluate LLMs of different sizes and different strategies to determine their suitability as knowledge bases for scientists.

8:30 AM DS06.07.03
Atomistic Insights into CO Oxidation on Pt Single Crystals with Machine-Learned Force Fields and Spectroscopy ClareY. Xie[1], CameronJ. Owen[1], GengnanLi[2], AnibalBoscoboinik[2] and BorisKozinsky[1]; [1]Harvard University, United States; [2]Brookhaven National Laboratory, United States

Dynamic mechanistic insights into CO oxidation are crucial for optimizing catalyst design and controlling chemical conversion processes, especially for reactions like water-gas-shift (WGS). Several experimental investigations have demonstrated oscillatory behavior in this reaction, wherein the local coverage of chemisorbed O or CO can lead to markedly different reactivity. However, atomistic insight to confirm this hypothesis is inaccessible given the spatial and temporal resolutions of experimental techniques. Coupling this with the poor scaling of ab initio methods means that the mechanisms governing this disparate behavior cannot be determined with (1) atomic resolution, and (2) under proper time- and length scales for comparison to experiment. Understanding CO oxidation in this context is essential for gaining fundamental insights into the mechanisms governing chemical conversion at surfaces, and ultimately providing guidance for effective catalyst design and operating procedures. Therefore, accelerated computational methods that retain high accuracy are necessary to resolve the structure-performance relationship of these catalytic systems.

In this work, we investigate the mechanisms of CO oxidation on Pt(111) and Pt(100) surfaces using reactive molecular dynamics (MD) simulations powered by machine-learned force fields coupled with spectroscopic experiments. We employ the FLARE code, which accelerates sampling of expensive ab initio training data via its active-learning module, which can then be used to train a MLFF for use in production MD. The model is first validated against theoretical benchmarks on the coverage effects and site dependency of CO adsorption on Pt(111) and Pt(100), and subsequently used to study the transient kinetics of CO oxidation reactions as a function of temperature and relative coverage of CO and O. In addition to revealing the timescales of these processes, our simulations provide direct insight into the dominating mechanisms when either CO or oxygen is covering the surface. Moreover, we show that our MLFF is capable of capturing mesoscopic reconstruction of the Pt(100) surface, which is also modulated via exposure to these adsorbates.

We compare our findings with experimental results from operando spectroscopy and spectrometry, where the oscillatory behavior in CO oxidation is observed through pulsing CO on Pt(111) and Pt(100) with O_2 in the background. Our work thus provides atomistic understanding of the structure-performance relationship of the Pt(111) and Pt(100) surfaces in CO oxidation, which is crucial for optimizing the design of catalysts and developing better control strategies for optimal reaction conditions.

8:45 AM DS06.07.04
Applying Virtual Reality Technology and Neural Network Potentials for Molecular Dynamics Simulations in Industrial R&D KatsuhisaYoshida, TeruoHirakawa and YoshishigeOkuno; Research Center for Computational Science and Informatics, Resonac Corporation, Japan

Neural Network Potentials (NNP) is a cutting-edge technique in computational materials science. This method employs atomic-level potentials learned from the ab-initio method to efficiently perform reactive molecular dynamics (MD) simulations with many atoms. As a result, NNP-MD can consider complex chemical systems such as organic-inorganic interfaces with water solvents.

However, analyzing the results of calculations with the software on a simple computer display, as in classical MD simulations, is difficult due to the large number of atoms involved in NNP-MD simulations. This difficulty has limited the analysis of MD calculations to the statistical level, even though atomistic-level observations are essential for understanding the origin of phenomena. Overcoming this limitation is essential for efficient academic research and industrial research and development (R&D).

To address this problem, we have employed virtual reality (VR) technology with a head-mounted display to analyze classical MD trajectories at an atomic scale, such as the motion of molecules at the interface of an inorganic substrate. VR technology not only assists computational science experts in analyzing calculation results but also dramatically supports phenomenological understanding by non-experts. Additionally, we found that VR technology is an effective communication tool between experts and non-experts, which is crucial for accelerating material R&D.

In this study, we apply VR technology to analyze complex catalytic reactions calculated by NNP-MD simulations and study the impact of the combination of VR and NNP-MD on industrial R&D. We employ Suzuki-Miyaura Cross-Coupling in water solvent with an atomically rough Rd substrate surface as an example of a complex chemical system.

By replaying the NNP-MD trajectory in VR, we could identify sites on the Pd substrate where chemical surface reactions occur, approach those reaction points, and observe the reaction step-by-step. As a result, VR proved to be a powerful tool for understanding the multi-step interfacial reactions obtained with NNP-MD. However, we realized that while NNP-MD has the advantage of observing the atomic behavior of chemical reactions, it is difficult to understand the physical origin of the reactions. Therefore, it is necessary to employ ab-initio calculations to gain a deeper understanding of physics.

From an industrial perspective, the combination of NNP-MD and VR should effectively share intuitive images of chemical reactions and accelerate materials R&D, as we have found in the case of classical MD.

9:00 AM DS06.07.05
Analysis of Monolayer to Bilayer Silicene Transformation in $CaSi_2F_x$ (x<1) using Universal Neural Network Potential AkihiroNagoya, TakuWatanabe and HirokiIriguchi; Preferred Computational Chemistry, Inc., Japan

Silicene is a silicone (Si) counterpart of graphene, a typical two-dimensional (2D) material which consists of a honeycomb structure of carbon. Silicene is predicted to have a Dirac cone-type electronic structure similar to that of graphene, and has been extensively studied as a promising material for ultra-energy-saving, high-mobility devices. In addition, silicene, graphene, and other 2D materials in the form of nanoribbons and nanodots have been investigated for applications in batteries and biological imaging. For practical applications, further development of fabrication techniques for silicene-derived structures is necessary because the monolayer structure is unstable under air due to the lack of vertical sp^3 bonds.
Synthesis of 2D materials by chemical exfoliation of three-dimensional (3D) crystals with layered structures is a convenient top-down method. Calcium disilicide ($CaSi_2$) consists of alternating monolayers of silicene (MLSi) and calcium, where wet-chemical exfoliation can be applied to produce MLSi derivatives. A solid state reaction due to fluorine (F) diffusion into $CaSi_2$ leads to a phase transformation from MLSi to bi- or tri-layered silicene (BLSi and TLSi) sandwiched between non-conducting CaF_2 layers. This structure prevents exposure to the atmosphere and improves the stability of the materials. The thermodynamic mechanism of the phase transformation was investigated in the previous study using density functional theory (DFT) calculations and cluster expansion for MLSi and BLSi of $CaSi_2F_x$($0<x<1$). However, the analysis of the reaction dynamics, which is important for nano-structure fabrications and battery development, was not feasible due to the high computational cost.
Machine learning potentials have been increasingly applied to various atomistic simulations. The Preferred Potential (PFP) implemented on Matlantis™ is a recently developed graph neural network potential with its unique feature of universality. PFP is trained on large DFT datasets, including not only stable crystals and molecules, but also surfaces and disordered structures. As a result, it is applicable to reaction analysis and molecular dynamics of various materials without compromising accuracy.
In this study, we have applied PFP to analyze the mechanism of the phase transformation of $CaSi_2$ due to fluorine diffusion. Firstly, the phase stability of $CaSi_2F_x$ in ML and BL structures is studied as a function of the fluorine ratio x. A few hundred of $CaSiF_x$ structures were generated using the *icet* package and the convex hull of the formation energy is evaluated using PFP. The results show that PFP reproduces the previous study using DFT: ML structure becomes unstable with increasing fluorine ratio, and BL structure becomes more stable for $x > 0.6$. This phase transformation is due to the charge imbalance of the ionic $CaSi_2$. With increasing electronegative fluorine atoms, strong ionic bonds are formed between F^- and Ca^{2+}, while the formal charge of Si^- becomes neutral. This result indicates that PFP is applicable to our system with DFT accuracy, although the stability depends on both ionic and covalent sp^3 electronic nature. Following this result, we have performed molecular dynamics simulations of stable structures on the convex hull. During the MD simulations at 800 K for more than 1 ns, interlayer diffusion of Si atoms are observed at the defects in the layered structure associated with the formation of CaF_2. These results reveal the dynamics of phase transformation of $CaSi_2F_x$, and demonstrate the accuracy and universality of PFP for materials with variable compositions, such as battery materials, alloys and solid solutions.

9:15 AM DS06.07.06
Accelerating the Discovery of Two-Dimensional Interfaces with Graph Neural Network and Evolutionary Search JiananZhang[1], AdityaKoneru[1,2], SubramanianSankaranarayanan[1,2] and CarmenM. Lilley[1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Machine learning (ML) methods have attracted considerable attention in the field of materials science due to their flexibility, accuracy, and efficiency compared to traditional simulation approaches for material discovery. Among the various ML methods available, graph neural networks (GNNs) have emerged as a prominent technique for predicting material properties. This is attributed not only to recent advancements in GNNs but also to the inherent correlation between atomic structures and graphs.

One significant challenge in harnessing the remarkable properties of two-dimensional (2D) materials is the occurrence of defects during synthesis, such as grain boundaries (GBs). Predicting the realistic atomic structure of GBs and their impact on material properties is a complex task that surpasses the capabilities of conventional trial-and-error methods, owing to the vast design space involved.

In this abstract, we propose a combination of GNN and evolutionary search methods to address this challenge. We originally developed a search workflow based on genetic algorithms (GA) for exploring 2D GBs applied to graphene and silicene. The workflow involves transforming GBs into graphs and utilizing graph isomorphism checks to identify multiple material states during the GA searches, and multiple novel silicene GBs were predicted. Separately, we developed a GNN architecture capable of predicting the energy of 2D GB structures, which serves as an efficient and accurate surrogate for computationally expensive quantum mechanical simulations. We utilized datasets generated from quantum mechanical simulations for training and testing the GNN model. The high accuracy of the GNN model on the test set demonstrates its ability to provide reliable estimations of quantum mechanical calculations.

In the work presented here, the research combines the GA search with this GNN surrogate, to fully leverage an automated design search. Using this method, we successfully uncovered previously unreported GBs in blue phosphorene. Additionally, the flexibility of the GNN approach allowed us to generalize the method to other 2D materials, thus expediting the process of discovering novel materials.

JARVIS-Leaderboard—A Comprehensive Benchmark of Materials Design Methods KamalChoudhary; National Institute of Standards and Technology, United States

Reproducibility and validation are major hurdles for scientific development across many fields. Materials science in particular encompasses a variety of experimental and theoretical approaches that require careful benchmarking. Leaderboard efforts have been developed previously to mitigate these issues, however, a comprehensive comparison and benchmarking on an integrated platform with multiple data-modalities with both perfect and defect materials data is still lacking. This talk introduces the JARVIS-Leaderboard, an open-source and community-driven platform that facilitates benchmarking and enhances reproducibility. The platform allows users to set up benchmarks with custom tasks and enables contributions in the form of dataset, code, and meta-data submissions. We cover the following materials design categories: Artificial Intelligence (AI), Electronic Structure (ES), Force-fields (FF), Quantum Computation (QC), and Experiments (EXP). For AI, we cover several types of input data, including atomic structures, atomistic images, spectra, and texts. For ES, we consider multiple ES approaches, software packages, pseudopotentials, materials, and properties, comparing results to experiment. For FF, we compare multiple approaches for material property predictions. For QC, we benchmark Hamiltonian simulation using various quantum algorithms and circuits. Finally, for experiments, we use the round-robin approach to establish benchmarks. Currently, there are 1008 contributions to 225 benchmarks using over 100 different methods, and the leaderboard is continuously expanding. The JARVIS-Leaderboard is available at the website: https://pages.nist.gov/jarvis_leaderboard .

10:30 AM DS06.07.08
Probing Structural Heterogeneity of Disordered Materials with Machine Learning Interatomic Potentials and X-Ray Absorption Spectroscopy WonseokJeong, WenyuSun, LiwenWan, TrevorM. Willey, MichaelH. Nielsen and Tuan AnhPham; Lawrence Livermore National Laboratory, United States

The precise determination of atomic structural information in functional materials holds transformative potential and broad implications for emerging technologies. Spectroscopic techniques, such as X-ray Absorption Near-Edge Structure (XANES), have been widely used for material characterization. However, extracting chemical information from experimental probes often intractable in disordered or heterogeneous systems. We present an integrated approach that combines atomic simulation, machine learning interatomic potentials, data-driven approaches and XANES calculations to investigate the chemical speciation of amorphous carbon nitride systems as a case study. We discuss the development of machine learning potentials that can efficiently explore the vast configurational space of amorphous carbon nitrides. By employing statistical methods, this structural database enables the elucidation of the most representative local structures, including carbon and nitrogen hybridization, and how they evolve with chemical compositions and density. Our simulations indicate that structure of amorphous carbon nitrides is highly complex, exhibiting non-linear and unexpected behavior at medium density and nitrogen concentration. Density functional theory (DFT)-based XANES simulations were carried out to establish a correlation between local structure and spectroscopic signatures. This serves as the basis for both forward and inverse models; the former predicts XANES spectroscopy when provided with macroscopic properties of density and chemical composition, while the latter enables a high-fidelity interpretation of local chemical motifs from experimental measurements. Although our framework is specifically applied to XANES and carbon nitrides, the approach described herein is readily adaptable to other experimental probes and materials classes.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. Funding was provided by LLNL Laboratory Directed Research and Development (LDRD) Program Tracking No. 22-ERD-014.

10:45 AM DS06.07.09
Thermomechanical Properties of SiC Ceramics using Convolutional Neural Network Potentials: An MD Study MayurP. Singh and SatishKumar; Georgia Institute of Technology, United States

The excellent thermomechanical properties of SiC have made it an attractive material for applications at extreme environment such as space entry vehicles subjected to high temperatures. There has been extensive study and modelling of phases of SiC phases, most popular of which includes the 3C-SiC and 6H-SiC phases. These studies have led to the development of empirical potentials for the SiC phases. MD studies have been performed for studying SiC's properties using these empirical potentials but failed to capture the phase transformations of SiC at various temperatures. Machine Learning potentials are very promising to address this challenge. Neural network potentials (NNPs) have shown great promise at capturing complex physics of interatomic forces with ab-initio accuracy. In this work, we use Convolutional Neural Network potentials trained on DFT computed structures for the various phases of SiC and investigate the variation in thermal expansion coefficients of SiC at various temperatures. Our CNN potentials constructs 3D images of the atomic neighborhood for 3D convolution to predict the forces and energy. We implement this potential into the JAX-MD software package to perform MD simulations to take advantage of the Just-in-Time compilation and native GPU support of JAX-MD.

11:00 AM DS06.07.10
Training Protocol and Applications of Data-Driven Interatomic Potentials Based On Random Structure Searching WilliamC. Witt; University of Cambridge, United Kingdom

Data-driven (or machine-learned) interatomic potentials have become an increasingly vital tool for the computational materials scientist. Created from the results of small quantum-mechanical calculations, such potentials enable first-principles-accurate simulations on unprecedented length- and time-scales. This talk will summarize recent work towards automated production of Atomic-Cluster-Expansion-type potentials, where the training protocol is adapted from the random structure searching approach to atomistic structure prediction.

11:15 AM DS06.07.11
Learning an Ab Initio-Based Bond Order Potential to Investigate Mechanical and Thermal Properties of Bismuthene Partha SarathiDutta[1,2], AdityaKoneru[1,2], SukritiManna[1,2], AdilMuhammed[1,2], KarthikBalasubramanian[1,2], Troy DavidLoeffler[1,2], HenryChan[2] and SubramanianSankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Bismuthene is a two-dimensional layer of bismuth arranged in a honeycomb lattice configuration. It possesses some unique properties – for example, it is a topological insulator which means it is conductive or allows electrons to flow on the edges but acts as an insulator in its bulk. Also, bismuthene has a direct bandgap, strong light-matter interaction, and its optical properties can be tailored by varying its layer thickness which makes it an exciting candidate for optoelectronics applications. Despite its technological significance, there is a scarcity of models that can accurately describe the structure and energetics of bismuthene. Using a Tersoff formalism and leveraging the recent advances in reinforcement learning, we introduce a potential model that captures the structures and energetics of several different bismuthene polymorphs. The training data consisted of ab-initio calculations of the crystal lattice structure, cohesive energy, equation of state, elastic constants of five polymorphs, and phonon dispersion curve of the most stable low-buckled structure of bismuthene. We deploy our in-house reinforcement learning-based continuous-Monte Carlo Tree Search Algorithm (c-MCTS) because of its suitability to model complex non-linear interatomic interactions and proven performance in solving high-dimensional parameter space optimization problems. The RL-optimized bond order potential model performs well in capturing the crystal lattice structure and energetics of all the polymorphs. It especially gives an excellent prediction of the elastic constants of the low-buckled polymorph and a reasonable agreement between the phonon dispersion predicted by the model relative to the DFT reference training data. The optimal parameters are used to study the mechanical behavior, mechanical performance in electronic or optoelectronic applications, and thermal properties of

bismuthene for applications in microelectronics.

11:30 AM DS06.07.12
Accurate Prediction of Melting Temperatures with Deep-Neural Network Atomistic Potentials WissamA. Saidi, ChristopherM. Andolina and PanduWisesa; University of Pittsburgh, United States

Understanding melting behavior is essential for applying and developing a given material under various environmental conditions. Further, elucidating the nature of these materials at extreme states is essential for creating accurate analytical models, from predicting seismological activities to designing high-performance functional materials. While replicating intense temperatures and pressures is known to be experimentally challenging, less is known about the accuracy of first-principles modeling due to the intrinsically low scalability of first-principles methods. Herein, we assess the melting temperature accuracy of first-principle methods accelerated with deep neural network atomistic potentials (DNPs) in various systems, including single-element materials and magnesium oxide. We contrast the DNP results with existing density functional theory and experimental studies. We show that the temperature predictions have significant fluctuations, particularly at higher pressures and similarly for smaller system sizes typically employed by first-principles calculations. We suggest that our flexible approach to developing DNPs can be readily adapted to create specialized DNPs capable of creating robust, versatile potentials that describe solid, liquid, and phase transition from solid to liquid under various extreme conditions.

11:45 AM DS06.07.13
Connectivity Optimized Nested Graph Networks for Crystal Structures RobinRuff, PatrickReiser and PascalFriederich; Karlsruhe Institute of Technology, Germany

Graph neural networks (GNNs) have been applied to a large variety of applications in materials science and chemistry [1]. Here, we recapitulate the graph construction for crystalline (periodic) materials and investigate its impact on the GNNs model performance. We suggest the asymmetric unit cell as a representation to reduce the number of atoms by using all symmetries of the system. This substantially reduced the computational cost and thus time needed to train large graph neural networks without any loss in accuracy. Furthermore, with a simple but systematically built GNN architecture based on message passing and line graph templates, we introduce a general architecture (Nested Graph Network, NGN) that is applicable to a wide range of tasks [2]. We show that our suggested models systematically improve state-of-the-art results across all tasks within the MatBench benchmark [3]. Further analysis shows that optimized connectivity and deeper message functions are responsible for the improvement. Asymmetric unit cells and connectivity optimization can be generally applied to (crystal) graph networks, while our suggested nested graph framework will open new ways of systematic comparison of GNN architectures.

1:45 PM DS06.08.01
Using Machine-Learning Assisted Design for Reduction of the Quantum Decoherence in Room-Temperature Integrated Quantum Photonics PabloA. Postigo; University of Rochester, United States

The development of on-chip, CMOS-compatible quantum photonics is critical for future scalable quantum communications, quantum computing, and quantum sensing. Integrated photonic waveguides, photonic resonators, and single-photon emitters are essential building blocks for such a purpose. In this talk, I will present how machine learning (ML) can enhance the quantum properties of these building blocks, specifically the indistinguishability (*I*) of the generated single photons, with a further decrease in quantum decoherence. The model has been numerically evaluated through finite-difference time-domain (FDTD) simulations, showing consistent results. Also, we explored a hybrid slot-Bragg nanophotonic cavity to generate indistinguishable photons at RT from various quantum emitters through a combination of numerical methods. To relax the fabrication requirements (slot width) for near-unity *I*, we used an ML algorithm that provides the optimal geometry of the cavity. [1] Finally, we have developed a theory for estimating *I* in a two-emitter system with strong dephasing coupled to a single-mode cavity. We have derived an analytical expression of *I* as a function of the distance between the emitters, cavity decay rate, and pure dephasing rate. The results show how the requirements of the cavity for high *I* change with the strength of the dipolar interaction. We propose a new interpretation of the *I* value, which allows us to estimate its behavior with larger systems (i.e., systems with more than two emitters). We performed numerical simulations of five dipole-coupled emitters to find the optimal configuration for maximum *I*. For the optimization process, we developed a novel ML scheme based on a hybrid neural network (NN)-genetic algorithm (GA) to find the position of each emitter to maximize *I*. [2] The optimization procedure provides perfect *I* (i.e., $I = 1$) in arbitrary low Q cavities, offering relaxation of the cavity parameters and favoring emission from quantum emitters at room T.

2:00 PM DS06.08.02
Lattice Thermal Conductivity of Pb-Te Alloy System with Neural Network Potential Wen JayLee[1], Nan YowChen[1,2], Kuan PengChen[1], Wei ChunTang[2], You YiLin[2], Kuo PingLiao[2], Wei ChiehZeng Chien[2], Yu ChiehLo[2], Nien TiTsou[2] and An ChengYang[1,2]; [1]National Center for High-Performance Computing, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

Thermoelectric materials are a category of substances capable of producing electrical power through temperature gradients. The efficiency of these materials is often assessed using the dimensionless thermoelectric figure of merit, Z. $Z=S^2\sigma\kappa^{-1}$, is calculated from the Seebeck coefficient (S), Electrical conductivity (σ), and thermal conductivity (κ). Improving the electrical transport properties has proven successful by manipulating carrier concentration and employing dopants, while reducing lattice thermal conductivity can be achieved through the introduction of defect and the creation of nanostructures. This study employs molecular dynamics simulations to calculate the lattice thermal conductivity. To enhance the reliability of these simulations, we have developed an innovative Pb-Te force field utilizing machine learning techniques. The forthcoming presentation will show the results of the lattice thermal conductivity across various temperature.

2:15 PM DS06.08.03
Dissociation of CO_2 and CO on MgO (001) Surface as Described by Machine Learning Based Atomistic Potentials. ChristopherM. Andolina[1] and WissamA. Saidi[1,2]; [1]University of Pittsburgh, United States; [2]National Energy Technology Laboratory, United States

The use of heterogeneous catalysis for dissociating carbon dioxide (CO_2) is a research endeavor of substantial interest in energy conversion and environmental protection. In particular, the dissociation of CO_2 on metal oxide surfaces has received considerable attention due to their potential for mitigating greenhouse gas emissions by converting CO_2 into value-added chemicals (*e.g.*, carbon monoxide). Magnesium oxide (MgO) is a promising candidate for CO_2 dissociation due to its high basicity and stability under high-temperature and high-pressure environments. However, the detailed mechanism of CO_2 dissociation on MgO surfaces remains poorly understood. We aim to elucidate CO_2 dissociation on MgO surfaces using DeePMD-kit with DeepPot-SE approach atomistic potentials. We leverage the high fidelity of these potentials with the much lower computational costs to density functional theory to accurately describe adsorption energies, chemical energy barriers, and extensive supercell molecular dynamics simulations at various temperatures and monolayer compositions. Further, expanding machine learning atomistic potentials to model catalytic processes on the atomic scale will improve chemical insight into these abundant materials' (MgO or other oxides) role in critical industrial and environmental applications.

Capturing Short-Range Order in High-Entropy Alloys with Machine-Learning Potentials YifanCao, KillianSheriff and RodrigoFreitas; Massachusetts Institute of Technology, United States

Chemical short-range order (cSRO) is recently reported to strongly influence the mechanical properties of various high-entropy alloys (HEA). However, the intricate nature of cSRO has made it challenging for current machine-learning potentials (MLP) to capture this feature, and many proposed approaches lack quantitative analysis of MLP performance on this task. In this work, we propose a generalized strategy to construct first-principles training databases and effectively train MLPs capable of characterizing cSRO in HEAs. We demonstrate this strategy by quantitatively analyzing the MLP performances in reproducing cSRO effects in various properties of CrCoNi HEA, including defect properties and phase stability.

3:45 PM DS06.08.05
Autonomous Molecular Diffusion Agent using Deep Reinforcement Learning TianSang, Ken-ichiNomura, RajivK. Kalia, AiichiroNakano and PriyaVashishta; University of Southern California, United States

Diffusion in solids is known to be a slow process and often becomes a rate limiting process in key chemical reactions. Unlike crystalline solids where dislocations and grain boundaries offer well-defined “diffusion highway,” the lack of similar structural motifs in amorphous or glassy materials poses a great scientific challenge. Transition State Theory is widely used approach to explorer the complex energy landscape and reaction kinetics, however obtaining an accurate reaction coordinate depends on the system of interest and often requires domain expert knowledge. To tackle this problem, we have developed Molecular Autonomous Pathfinder (MAP) framework based on Deep Reinforcement Learning (RL) technique. Our framework employs Deep Q-Network architecture and distributed online learning to asynchronously collect experiences sampled by multiple RL agents. After training MAP agents, they provide atomistic configurations and the energy profile of efficient diffusion pathways. Subsequently, we apply time-parallel nudged elastic band method to refine the corresponding diffusion time. In this talk, I will discuss recent applications of MAP framework on molecular diffusion in silicates and polymeric materials.

4:00 PM DS06.08.06
Comparison of an RL-Trained Model for Silicene with State-Of-The-Art Physics-Based and ML Models Partha SarathiDutta[1,2], AdityaKoneru[1,2], AdilMuhammed[1,2], SukritiManna[1,2], KarthikBalasubramanian[1,2], HenryChan[2], Troy DavidLoeffler[2,1] and SubramanianSankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Silicene is a promising two-dimensional material consisting of a single layer of silicon, has a honeycomb lattice configuration, and has many similarities with graphene. Silicene has potential applications in transistors, flexible optoelectronic applications, energy storage, catalysis, sensors, quantum computing, spintronics, etc. There exist many potential models to perform dynamical simulations of Silicene. However, most of these models have been trained to a limited number of ab-initio data and therefore do not capture all the properties of all the Silicene polymorphs. Using a computationally cheap Tersoff formalism, we demonstrate that one can significantly improve upon the existing parameterizations using the advances in ML approaches. The training data for five different polymorphs of Silicene were computed using ab-initio calculations and our objective was to fit the crystal lattice structure, cohesive energy, equation of state, and elastic constants of all the polymorphs as well as the phonon dispersion of the most stable polymorph. We choose an in-house reinforcement learning (RL) based continuous-Monte Carlo Tree Search (c-MCTS) to solve this complex, non-linear, high-dimensional, multi-objective problem and get the optimum tersoff potential parameters. The optimization problem involves a trade-off between exploitation (navigating local search space of parameters for better fitting) and exploration (searching unexplored search space with the hope of getting better parameters). We use a reward mechanism wherein the reward was decided based on the agreement between the target property and the predicted property for a given set of potential model parameters. Our RL-trained potential parameters improve upon the performance of several existing models and adequately describe many of the properties of Silicene. We will discuss and compare the performance of our model with state-of-the-art physics-based and ML models for Silicene. We demonstrate that the RL-trained model performs very well in describing the thermal and mechanical properties of Silicene polymorphs. This opens a plethora of opportunities for studying the mechanical flexibility (for flexible electronics), thermal management, thermoelectric applications, strain engineering (for strain-tailored devices), and nanoelectromechanical systems (NEMS) of Silicene.

4:15 PM DS06.08.07
Exploring Zeolite Interatomic Potentials Through Multi-Reward Reinforcement Learning AdityaKoneru[1,2], HenryChan[2], SukritiManna[2,1], Troy DavidLoeffler[1], DebdasDhabal[3], ValeriaMolinero[3] and SubramanianSankaranarayanan[2,1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States; [3]The University of Utah, United States

Zeolites belong to a versatile class of materials often used in applications such as catalysis and separations. Despite the advancements in experimental characterization techniques, our understanding of the possible metastable phases and growth mechanisms of zeolites has remained elusive. Molecular dynamics is a useful tool for exploring this vast and diverse materials landscape, but its usefulness relies on accurate interatomic potentials capable of predicting the time evolution and dynamics of zeolite polymorphs. Recently, state-of-the-art machine-learned models like GAP and NNPScan are developed with the use of large datasets (both feasible and hypothetical zeolite polymorphs), which provide an accurate description of structural features and energetics. However, the lack of explicit encoding of physics and limited computational efficiency due to increased model complexity makes them difficult to use in large-scale simulations. On the contrary, there are simple classical models like BKS, CHIK, Soules, Tersoff, ReaxFF that can model a small subset of the diverse zeolite dataset but with more emphasis on experimentally realized structures. In this talk, we present our Muti-Reward Reinforcement Learning (RL) framework and demonstrate its success in building a simple empirical model of silica suitable for long length and time scales simulations. Our framework has navigated the high dimensional potential energy surface of BKS, Soules, Tersoff and achieved accuracy without sacrificing model efficiency.

4:30 PM DS06.08.08
StriderNET: A Graph Reinforcement Learning Approach to Optimize Atomic Structures on Rough Energy Landscapes VaibhavBihani[1], SahilManchanda[1], SrikanthSastry[2], SayanRanu[1,3] and N M AnoopKrishnan[1,3]; [1]Indian Institute of Technology Delhi, India; [2]Jawaharlal Nehru Centre for Advanced Scientific Research, India; [3]Indian Institute of Technology Delhi, India

Optimization of atomic structures presents a challenging problem, due to their highly rough and non-convex energy landscape, with wide applications in the fields of drug design, materials discovery, and mechanics. Here, we present a graph reinforcement learning approach, StriderNET, that learns a policy to displace the atoms towards low energy configurations. We evaluate the performance of StriderNET on three complex atomic systems, namely, binary Lennard-Jones particles, calcium silicate hydrates gel, and disordered silicon. We show that StriderNET outperforms classical optimization algorithms and enables the discovery of a lower energy minimum. In addition, StriderNET exhibits a higher rate of reaching minima with energies, as confirmed by the average over multiple realizations. Finally, we show that StriderNET exhibits inductivity to unseen system sizes that are an order of magnitude different from the training system.

4:45 PM DS06.08.09
Predicting the Dynamics of Atoms by a Surrogate Machine-Learned Simulator MathieuBauchy; University of California, Los Angeles, United States

Molecular dynamics (MD) is a workhorse of computational material science. However, the inner-loop algorithm of MD (i.e., numerically solving the Newton’s law of motion) is computationally expensive. Here, we introduce a surrogate machine learning simulator that is able to predict the dynamics of liquid systems with no prior knowledge of the interatomic potential or nature of the Newton’s law of motion. The surrogate model consists of a graph neural network (GNN) engine that is trained by observing existing MD-generated trajectories. We demonstrate that the surrogate simulator properly predicts the dynamics of a variety of systems featuring very different interatomic interactions, namely, model binary Lennard-Jones system, silica (which features long-term coulombic interactions), silicon (which comprises three-body interactions), and copper-zirconium alloy (which is governed by many-body interactions). The development of machine-learned surrogate simulators that can effectively replace costly MD simulations could expand the range of space and time scales that are typically accessible to MD simulations.

Graph Neural Networks to Predict Ordering-Dependent Properties from Multicomponent Crystal Structures JiayuPeng, JessicaKaraguesian, JamesK. Damewood, DanielSchwalbe

Koda and RafaelGómez-Bombarelli; Massachusetts Institute of Technology, United States

Multicomponent perovskite oxides are an essential class of inorganic materials with diverse applications, where the ordering of cations can profoundly influence their physical and chemical properties. Unfortunately, the discovery and optimization of such oxides have been significantly hindered by their compositional and structural complexity. State-of-the-art brute-force experimental or computational methods can hardly resolve such complexity efficiently. Even one multicomponent oxide composition can have tens to hundreds of cation orderings, which are too expensive for brute-force high-throughput screening.

To boost the high-throughput screening of multicomponent perovskite oxides, graph neural network models can be used to effectively predict material properties from the connections of atoms in crystal structures, allowing efficient computational discovery over a vast search space. However, while these models have been demonstrated to capture the compositional dependence of material properties across a broad chemical space, it is unclear whether such models can also effectively learn the ordering dependence of similar properties for a given composition. In addition, structures after costly density functional theory (DFT) relaxations have been dominantly used for training and leveraging such graph neural network models, which cannot truly eliminate the prohibitive cost of DFT in high-throughput screening.

In this work, we developed graph neural network models to accurately predict key cation ordering−dependent properties of multicomponent perovskite oxides from DFT-unrelaxed cubic perovskite structures. Essentially, models that infer material properties by indirectly learning the thermodynamics of mixing lead to lower errors than those that predict these properties directly. Moreover, equivariant neural networks better capture the ordering dependence of such properties than their symmetry-invariant counterparts due to their higher expressivity in distinguishing the difference between the coordination environments and symmetries of various orderings. Lastly, using contrastive losses in the training of these models further increases the prediction accuracy by facilitating an optimal balance between capturing both the compositional and structural dependence of material properties. Overall, this work highlights an effective strategy for designing machine learning models with optimized robustness and generalizability for discovering multicomponent materials.

8:45 AM DS06.09.02
Screening for the Effect of Material Stability and Flexibility in Metal-Organic Frameworks for Gas Adsorption Properties ChanghwanOh, ShuwenYue, AdityaNandy and GianmarcoTerrones; Massachusetts Institute of Technology, United States

Metal-organic frameworks (MOFs) are promising materials with diverse applications, including gas separation and storage. Their reticular nature consisting of inorganic secondary building units and organic linkers allow vast combinatorial design space. There exist many hypothetical MOF databases, but their stability in real-world applications is often unknown. Therefore, we use virtual high-throughput screening of hypothetical MOF database to search vast combinatorial space and find optimal MOFs that are stable and have optimal gas adsorption properties. This study consists of two parts: 1) training machine learning (ML) models for MOF stability and 2) investigating the effect of MOF flexibility in gas adsorption. We use bulk modulus as an indicator of mechanical stability and utilize molecular mechanics to calculate bulk moduli of hypothetical MOFs. We train and test ML models for predicting bulk moduli of MOFs and identify the key features governing high mechanical stability for MOFs. We also investigate the effect of flexibility of MOFs in gas adsorption, since the behavior of guest molecules within MOFs is significantly influenced by the flexible degrees of freedom, such as breathing, swelling, and linker rotation. Additionally, the adsorbed guest molecules have been observed to impact framework motion and pore size. However, in many molecular simulation studies of MOFs, the framework is assumed to be rigid to reduce computational costs. To understand how framework motion influences guest molecule behavior, we present a quantitative assessment focusing specifically on the linker rotation while keeping all other modes of framework motion constant. Through this study, we provide a range of property values, such as diffusivity and gas working capacity, that indicate the uncertainty of guest molecule behavior associated with linker rotation.

9:00 AM DS06.09.03
Multi-Scale Modeling of Plasticity with Machine Learning Algorithms ArmandJ. Barbot[1,2], HisashiKashima[1] and RiccardoGatti[2]; [1]Kyoto University, Japan; [2]Universite Paris-Saclay, ONERA, CNRS, Laboratoire d'etude des Microstructures, France

In crystals, plasticity is governed by dislocations, extended linear defects unavoidably present in the atomic structure. While in most crystalline systems, plasticity is governed by the multiplication of pre-existing dislocation, nucleation of dislocations is the leading mechanism in the plastic deformation of small crystalline systems (below 100-200 nm, such as metallic and semiconductor nanopillars, nanowires, nanofilms and nanoparticles). In addition, nucleation can play an important role in hindering cracks propagation by blunting the crack tip. To model and to predict nucleation of dislocation, Molecular Dynamics (MD) is a suitable tool, but it has the drawback of being limited to size of few dozens of nanometers. To simulate plasticity in larger systems, mesoscale simulations, such as the Discrete Dislocation Dynamics method (DDD) [1], are also developed. This method focuses on the evolution and interactions of the dislocation lines without considering each individual atom. This allows to simulate systems from up to 10-20µm. However, there is yet no reliable model able to implement the nucleation of heterogeneous dislocations, i.e. occurring at the surface of the material, for systems larger than a few dozens of nanometers, inaccessible by MD simulations. Implementing this phenomenon at mesoscopic scale would allow a better understanding of sub-micrometer crystal plasticity and crack propagation.

Here, we propose a multi-scale approach to implement the nucleation of heterogeneous dislocations at the mesoscopic scale from MD simulations data. We focused here on developing a nucleation criterion, obtained by training a machine learning (ML) algorithm with MD data, to nucleate a dislocation in mesoscopic simulations.
We built our database deforming with MD for Nickel (Ni) crystals of different sizes and shapes (from 1000 to 100000 atoms and with cubic and Wulf-like shapes) imposing a uniaxial compression along (001), tracking dislocation nucleation events in each simulation (nucleation occurs when a drop in potential energy–strain curve is observed). The choice of Ni was motivated by the reliability of its potential, however the proposed method is compatible with any potential. From this, we train a machine learning model to predict dislocation nucleation from: (i) the strain (ii) the potential energy (iii) the system size (i.e., the number of atoms) and (iv) and the image of the initial shape of the system.
As the system is deformed, the model performs, at every applied strain interval of $\Delta\gamma$=0.0004, predictions of whether or not a nucleation will occur during the next strain interval. Our model attains a total accuracy of 74% and is able to predict 75% of nucleation events. In practice, 82% of the nucleation predictions are estimated earlier than the ground truth. It means that on average, the model begins to predict the following nucleation of dislocation at an applied strain of γ=0.005 before it actually occurs.

While we are working to improve the predictions by using a PINN approach, our model reliably predicts most of the nucleation events and can be already used as a nucleation criterion for mesoscopic simulations.
In conclusion, we developed a machine learning-based criteria which will allow from MD simulation data to know when to implement a nucleation of dislocation in mesoscopic simulation.
This project is supported by a JSPS Grant-in-Aid for JSPS fellow (Grant No. 22F22708).

Forward and Inverse Fuzzy Analysis for the Nolinear Transient Heat Transfer Problems RuifeiPeng and YiyangLiu; Shenyang Institute of Automation, Chinese Academy of Sciences, China

Driven by the insufficiency investigation of nolinear transient heat transfer problems with fuzzy uncertain parameters, this paper attempts to present efficient numerical approaches for the forward and inverse fuzzy analysis of nolinear transient heat transfer problems. The inverse fuzzy problem is formulated as a series of α-level strategy-based inverse interval problems, which are described by optimization problems and are solved utilizing particle swarm method. Forward interval analysis required in inverse interval analysis is conducted by solving two optimization problems via modified coordinate search algorithm. To alleviate heavy computational burden, dimension-adaptive sparse grid (DSG) surrogate is embedded in optimization process. The surrogate is constructed on a solid platform of high fidelity deterministic solutions, which is provided by finite element method and temporally piecewise adaptive algorithm. Eventually, membership functions of fuzzy parameters can be obtained by fuzzy decomposition theorem with interval bounds acquired at each of α-sublevels. Parallelization is realized for the construction of DSG and implementation of particle swarm method for a further computation reduction. Various numerical tests are provided to verify the effectiveness of proposed approaches, and the proposed results agree well with reference.

9:30 AM DS06.09.05
Transfer Learning in Machine Learning for Materials Science: Enhancing Predictions and Discovery SatadeepBhattacharjee[1], KishalayDas[2], PritamDas[3], PawanGoyal[2], Seung-CheolLee[4] and NiloyGanguly[2]; [1]Indo Korea Science and Technology Center, India; [2]Indian Institute of Technology Kharagpur, India; [3]Kookmin University, Korea (the Republic of); [4]Korea Institute of Science and Technology, Korea (the Republic of)

Transfer learning, a powerful machine learning technique, has revolutionized materials science research by enabling the development of accurate predictive models for various material properties [1,2]. In this presentation, two different transfer learning-based works [3,4] will be presented, focusing on addressing the specific challenges in materials science applications.

The first part is a semi-supervised machine learning approach to predict hydrogen storage capacity in metal hydrides. To overcome data scarcity and high feature dimensionality, transfer learning is achieved through an autoencoder. By using elementary features, the autoencoder effectively learns a compact and informative latent space, thus capturing essential features of the data. A multi-layer perceptron (MLP) is then employed to predict the hydrogen storage capacity based on the learned representations. Physically significant features and Pearson correlation functions are included to identify materials with improved storage capacity. The predictions made by the combined autoencoder-MLP model are validated by density functional theory-based calculations and show the potential of transfer learning in accelerating the development of new and efficient materials for hydrogen storage.

In the second study, we showcase transfer learning in conjunction with a graph neural network where we introduce CrysXPP [4], a deep-learning framework designed to rapidly and accurately predict electronic, magnetic, and elastic properties of diverse materials. Addressing the challenge of limited property-tagged datasets, transfer learning is harnessed through an intelligently designed autoencoder named CrysAE. By effectively capturing crucial structural and chemical properties from a large collection of crystal graph data, CrysAE significantly reduces prediction errors. Additionally, a feature selector is incorporated to enhance the interpretability of the model's predictions. Notably, CrysXPP consistently outperforms conventional density functional theory (DFT) methods when provided with limited experimental data. Extensive experiments are used to determine the importance of various design steps in the model. In addition, we make available to the research community the large pre-trained model CrysAE, which allows researchers to refine it with small, property-annotated data sets and achieve superior performance in various applications with limited data sources.

Predicting Solvent-Dependent Optical Properties of Organic Molecules using Machine Learning with Physics-Based Descriptors EricM. Collins, HadiAbroshan, MathewD. Halls and AnandChandrasekaran; Schrödinger, United States

The development of optoelectronic materials has garnered substantial interest due to its wide range of potential applications, including organic light-emitting diodes (OLEDs), bioimaging, and fluorescent dyes. Thus, understanding and controlling the optical and photophysical properties of chromophores and fluorophores are important in both industrial and academic research across various disciplines. By leveraging physics-based simulations, researchers have made significant strides in the rational design of organic materials with specific photophysical characteristics, such as high photoluminescence quantum yields (PLQY) and control over the absorption and/or emission wavelengths. However, the computational methods employed to compute these excited-state properties, such as time-dependent density functional theory (TD-DFT), face challenges due to their high computational cost and scaling limitations, rendering them inadequate for large-scale screening of organic materials. Additionally, many of these properties are solvent-dependent, introducing further complexity to accurately model these compounds in solution. To overcome these challenges, this work aims to develop accurate quantitative structure-property relationship (QSPR) models to efficiently predict the photophysical behavior of organic compounds. We utilize an extensive collection of optical properties of over 20,000 organic chromophore-solvent pairs derived from scientific literature and databases to train our models. We evaluated both traditional and deep-learning QSPR models and identified models which can make accurate predictions by considering molecular descriptors of both the chromophore and the solvent. To further enhance the generalizability and predictive power of our models, we incorporated physically relevant descriptors derived from density functional theory (DFT) calculations. By developing machine learning models that are both accurate and informed by fundamental physical principles, we enable efficient screening of optical and photophysical properties for the design of novel materials.

10:30 AM DS06.09.07

High-Throughput Electronic Structure Prediction of Materials using Machine-Learned Extended Hückel Tight-Binding Models SuvoBanik[1,2], QunfeiZhou[3], SrilokSrinivasan[2], SubramanianSankaranarayanan[2] and PierreT. Darancet[2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States; [3]Northwestern University, United States

Accurate knowledge of electronic structures is crucial for high-throughput materials screening and inverse design of materials for many applications, including thermal transport, tunable electronics, and sensing. Electronic structures play a crucial role in determining the magnetic, electrical, and optical responses across different classes of materials, such as transition metals, low-dimensional materials, and especially materials with defects. While first-principles calculations based on Density Functional Theory (DFT) have demonstrated the numerical accuracy required for predicting the electronic structure, the principal challenge lies in their scalability, particularly in systems with heterogeneity and sizes that expand much beyond their unit cell representation, which makes them intractable for high-throughput applications. The Extended Hückel (eH) tight-binding method is a semiempirical quantum chemistry method that can predict a qualitatively correct electronic picture of materials with computational ease and clarity. While earlier studies have demonstrated the efficacy of the eH model in predicting electronic structures (e.g., phases of the Sr–Ti–O family), there is currently no generalized parameterization workflow to accurately parameterize eH tight-binding models across a broad class of materials. In this work, we leverage machine learning to develop a workflow that parametrizes the eH tight-binding model by mapping complex atomic configurations to tight-binding Hamiltonians and comparing them with the DFT-predicted electronic structure from material databases. We demonstrate the efficacy of our workflow in predicting electronic structures across different elemental systems such as C, Ge, Si, and P of different phases and dimensionalities. The predicted Hamiltonian by the parameterized eH model allows us to evaluate the electronic structures of two-dimensional B in the presence of defects and large-scale phase change materials (GexSbyTez) in both crystalline, amorphous, and mixed phases.

10:45 AM DS06.09.08

Understanding Ionomer Membrane Morphology Through Computational Analysis of Small Angle Scattering Experiments and Coarse-Grained Molecular Dynamics Simulations JasonMadinya, NitantGupta, StephenKronenberger and ArthiJayaraman; University of Delaware, United States

Ionomer membranes are widely used in fuel cells and water electrolyzers due to their superior mechanical properties and ion transport capabilities. The ion transport within these membranes is dictated by the morphology of the ionomer hydrophilic domains. While it is known that the nanophase structure of these ionomer hydrophilic domains changes with the extent of hydration and other processing techniques, the structural evolution of these domains during processing is not well understood. Small-angle scattering (SAS) measurements are often used to characterize the structure of the membrane at various length scales and provide insights into the structural evolution of the ionomer domains at various conditions. In this talk, I will present ongoing work from the Jayaraman lab that seeks to elucidate the structural evolution of ionomer domains using a physics-based bottom-up (i.e., analysis of simulated structures using molecular models), and a data-driven top-down (i.e., analysis of scattering data) computational approaches.
First, we will describe the top-down approach which involves computational analysis of one-dimensional and two-dimensional small angle scattering profiles to interpret the structure of ionomer hydrophilic domains. Then we will describe the bottom-up computational approach using the Martini 2 coarse-grained model and molecular dynamics simulations to study self-assembly of ionomer chains at varying extents of hydration. These simulations link the ionomer chain design (sidechain placement, dispersity in spacing, backbone length, etc.) to the ionomer hydrophilic domain morphology as well as the distributions of domain sizes and shapes at varying hydration levels. Towards the end of the talk, we will show how we are connecting these bottom-up and top-down approaches to produce a convergent understanding of shapes and sizes of ionomer hydrophilic domains and the molecular packing within these domains.

PYSEQM2.0: GPU-Based Fast Semiempirical Mechanics for Ground and Excited States NikitaFedik, MaksimKulichenko, NicholasLubbers, KiptonBarros, BenjaminNebgen and SergeiTretiak; Los Alamos National Laboratory, United States

Recent advancements in atomistic machine learning model have showcased significant progress in chemistry and material science. However, these approaches often face challenges when applied to unexplored regions of chemical space. Interatomic potential models, for instance, lack crucial electronic structure information, often leading to limited transferability. To address these limitations, our research group has been dedicated to developing PYSEQM (Pytorch-based Semiempirical Quantum Mechanics), a differentiable physics model that combines domain knowledge of semiempirical quantum mechanics with machine learning as a corrective tool. Paired with atomistic neural network backend, PYSEQM allows backpropagation through Hamiltonian, replacing atom-type dependent constants with structure-aware parameters generated on-the-fly.
This presentation will span the release of PYSEQM2.0 which expands capabilities to excited states through iterative solutions in Krylov subspace and dynamics beyond the ground state. GPU-based batched Davidson algorithm extends simulations to large organic molecules relevant to photovoltaics, organic solar cells and photoinduced processes.

11:15 AM DS06.09.10
Machine Learning Accelerated Computational Design of Materials and Processes FedorGoumans, MattiHellstrom, PaulSpiering, MariaJ. Aliaga and NicolasOnofrio; Software for Chemistry & Materials, Netherlands

Machine learning (ML) can accelerate computational materials research & discovery in several ways, often in complimentary approaches. We will discuss a few directions where we can leverage ML to design new materials and their integrated use in devices and chemical reactors.
The central framework in the Amsterdam Modeling Suite (AMS) enables the exploration of potential energy surfaces (PESs), mechanical, and electronic properties at several levels of theory. The central AMS driver supports advanced PES explorations, molecular dynamics (MD) and Grand Canonical Monte Carlo (GCMC), based on energies and forces from engines. With this driver-engine set up, on-the-fly machine learned potentials such as NequIP [1], general purpose and universal graph neural network potentials such as ANI-1ccx [2], M3GNet [3] and CHGNet [4], and can be immediately used to calculate many useful processes and properties such as reaction pathways, viscosity, shear stress, or chemical vapor deposition.

The ParAMS module in AMS provides a comprehensive framework to build training data from DFT engines and optimize ReaxFF and DFTB parameters, with machine learning potentials to follow soon.

With different levels of electronic structure methods available in AMS, we are exploring ML methods to predict properties more efficiently for molecular materials. Examples for OLED applications include training DFTB transfer integrals on DFT data, TDDFT(B) luminescence and excitonic properties on accurate qsGW+BSE calculations, and predicting novel molecules that have the desired optical and electronic properties yielding the best OLED device performance in multiscale simulations.[5]

For catalysis, we can accelerate the multiscale workflow [6] through employing ML for reaction exploration, and by building surrogate models for a faster integration between kinetic Monte Carlo and Computational Fluid Dynamics.

We will briefly discuss where we envision future ML developments to accelerate materials discovery, including battery and polymer applications.

A Physics Domain of ML's Applications for Accelerating Large Scale Simulations: Microstructure and Property Evolution in Nuclear Fuels ShenyangHu[1] and BenjaminBeeler[2]; [1]Pacific Northwest National Laboratory, United States; [2]North Carolina State University, United States

Monolithic UMo fuel is under development for converting highly enriched ^{235}U fuels currently used in high-power research reactors in the United States to low enriched ^{235}U fuels. The UMo fuel due to the radiation damage of high energy neutrons and fission fragments undergoes a large microstructure change such as grain refinement and gas bubble volumetric swelling, which dramatically impacts the thermomechanical properties and fuel performance. The microstructure change evolves strongly coupled multiphysics which have different length and time scales. In this work, a microstructure dependent rate theory is used to describe the evolution of radiation defects and their clusters. A random walk model is used to describe the fast diffusion of defects and species on grain boundaries. A phase-field model is used to describe the evolution of non-equilibrium gas bubbles. And the crystal plasticity model is used to describe the elastic-plastic deformation in polycrystalline structures. We developed an integrated model to capture these multiphysics coupling for predicting the kinetics of gas bubble swelling and creep. Simulation results demonstrate that swelling kinetics and creep rate depend on a broad space of model parameters and a large scale simulation is needed to capture the important length and time scales in the representative physics domain. We will discuss and explore the potential application of ML for accelerating the large scale simulation.

11:45 AM DS06.09.12
Active Learning of Continuum-Scale Mechanics by Guiding Discrete Dislocation Dynamics Simulations NicholasJulian, NithinMathew and DannyPerez; Los Alamos National Laboratory, United States

Extracting a model of continuum-scale material dynamics from lower-scale simulations of the underlying deformation process has the potential to improve the accuracy of crystal-plasticity simulations and uncover new causal relationships between features and behavior. However, the cost of adequately exploring the underlying parameter space can be prohibitive and difficult to predict a priori. By representing the continuum-scale model as a Gaussian process, a measure of uncertainty may be embedded which can be used to guide parameter space exploration through a method known as Bayesian optimization. In this talk, we demonstrate our adaptation of Bayesian optimization to extract a continuum-scale crystal plasticity flow rule from meso-scale discrete dislocation dynamics in terms of microstructural feature parameterizations.

Elements of Modern Industry-Grade Crystal Structure Prediction KiranSasikumar, HannoDietrich, DzmitryFiraha and MarcusNeumann; Avant-Garde Materials Simulation GmbH, Germany

"Do not be afraid to launch a product without machine learning. Machine learning is cool, but it requires data, and if not absolutely required for your product, do not use it until you have data." -- paraphrasing Google's rules of machine learning [1].

Commercially relevant scientific applications requiring high-quality predictions at a reasonable computational cost often also suffer from the lack of a diverse database of experimental or high-fidelity simulation results. This necessarily stifles the development of machine learning focused solutions. The commercial product would then inevitably involve integrated machine learning and physics-based simulation workflows, where high-fidelity training data generation is done on-the-fly based on the requirements of the application.

In this presentation, we discuss the application-driven development of a scientific workflow for organic crystal structure prediction (CSP) and pharmaceutical solid form risk assessment, where machine learning is simply one cog in a larger machinery that is primarily driven by physics-based models [2]. Historically, the development of this scientific workflow was driven by the industry need to foresee cases of disappearing polymorphs, which are occasions when a crystal structure that has been prepared and marketed for years is unexpectedly superseded by a thermodynamically more stable polymorph, rendering the initial crystal structure almost impossible to obtain [3]. Despite the relative rarity of such events, famous cases such as the drug compounds ritonavir and rotigotine, where costly reformulations were required to manufacture the product again, underlined the commercial need for extensive screening of solid-state forms.

We introduce the key elements of modern industry-grade organic CSP, focusing on a) reference data generation and fragment-based force field parameterization, b) a comparison of parametric and machine learnt force fields, c) multi-fidelity statistics and machine learning (ML) for structure selection in the CSP funnel, d) accurate free energy predictions, and e) high- throughput optimization for solving the structures of what are often poor experimental powder diffraction imaging data. Overall, we argue that ML and ML-adjacent concepts, including high quality data generation and high-throughput optimization, form just a few cogs in a larger machinery for the prediction of free energies of organic crystal structures, and in general for accelerated materials modeling. Physics-based multi-fidelity models are not going out of fashion anytime soon.

Quantifying Chemical Short-Range Order in Metallic Alloys RodrigoFreitas; Massachusetts Institute of Technology, United States

Metallic alloys often form phases - known as solid solutions - in which chemical elements are spread out on the same crystal lattice in an almost random manner. The tendency of certain chemical motifs to be more common than others is known as chemical short-range order (SRO) and it plays a prominent role in alloys with multiple chemical elements present in large concentrations due to their extreme configurational complexity (e.g., high-entropy alloys). Short-range order renders solid solutions "slightly less random than completely random", which is a physically intuitive picture, but not easily quantifiable due to the sheer number of possible chemical motifs and their subtle spatial distribution on the lattice. In this talk I'll present a multiscale method to predict and quantify the SRO state of an alloy with atomic resolution, incorporating machine learning techniques to bridge the gap between electronic-structure calculations and the characteristic length scales of SRO. The result is an approach capable of predicting SRO domain sizes in agreement with experimental measurements, and to comprehensively correlate SRO with fundamental quantities such as local lattice distortions.

Accelerating Simulations of Nanoalloy Catalysts using Machine Learning SergeyKozlov, ArravindSubramanian and YifanLi; National University of Singapore, Singapore

Heterogeneous catalysts are used to drive the majority of the chemical reactions in the industry. Almost always the surface area of such catalysts needs to be increased using nanostructuring to make them more exposed to the reactants. However, nanostructuring is also known to profoundly affect the properties of the catalysts through nanoconfinement effects and the generation of low-coordinated active sites. Since the atomic-scale characterization of heterogeneous catalysts remains challenging using modern experimental techniques, simulations have been playing an increasingly important role in the understanding of the nanostructuring effects on the catalytic activity. However, such simulations face three main challenges: 1) significant model size, 2) complex design of catalyst models to mimic the experimental materials, and 3) the necessity to analyze numerous active sites with diverse properties. For example, surfaces of alloy nanoparticles (nanoalloy) catalysts expose active sites with different catalytic activities and compositions, which are hard to deduce from the experimental data. Moreover, the structure of the alloys and the composition of the active sites on their surface is known to change depending on the reaction conditions.
In this work, we show how machine learning can help tackle the two last challenges in the simulations of nanoalloys on the example of Pd-Pt catalysts for hydrogen evolution reaction. Namely, we optimized the machine learning method based on local environment fingerprints for precise prediction of binding energies of H atoms on 100+ diverse sites exposed on the surface of 1.5 nm Pd-Pt alloy nanoparticles composed of 140 atoms. Thus, the fingerprint method enabled evaluation of the catalytic activity of the entire surface of Pd-Pt particles in hydrogen evolution reaction in fractions of a second. Moreover, the developed method also allowed us to investigate the effects of the reaction environment and the electrode potential on the surface composition of Pd-Pt nanoalloys. We achieved this by incorporating the contribution of H binding energies calculated using the fingerprint technique into previously developed lattice Hamiltonian [1] used to determine the most thermodynamically stable chemical orderings in $(Pd\text{-}Pt)_{140}$ nanocrystallites. Our simulations combining density functional theory, machine learning, and lattice Hamiltonian approach reveal how Pd segregates on the surface of Pd-Pt particles under high H coverage and electrode potentials below reversible hydrogen electrode potential. Thus, the developed machine-learning methods are demonstrated to greatly facilitate computational studies of the structure and catalytic activity of nanoalloys, which will increase the reliability of the computational rational design of such catalysts.

Quantitavely Accurate Modeling of the Phase Spaces of Alkali Metals and Their Alloys using Machine Learning MgciniK. Phuthi and VenkatasubramanianViswanathan; University of Michigan, United States

Alkali metals are important materials in batteries and other applications. Their alloys have interesting eutectic properties with applications as functional materials hence the importance in modeling them accurately. Machine Learning Interatomic Potentials (MLIPs) have significantly improved over other methods of modeling materials by being scalable, accurate and computationally efficient. Their accuracy however is limited by the data used to train them, typically Density Functional Theory(DFT) data generated using active learning which can fail to accurately model some systems. In this work we argue first that DFT can accurately model alkali metals due to their simple electronic structure, include complex electride phases at extreme pressure. Continuing off of our previous work on calculating properties of lithium with exceptional accuracy, we show that compact datasets can be transferred between chemically similar systems using simple transformations, eliminating the need for weeks of active learning to develop potentials for sodium. Finally, we calculate the properties of Na-Li alloys to investigate how MLIPs model phase separation and entropy calculations.

Block Sparsity Promoting Algorithm for Efficient Construction of Cluster Expansion Models for Multicomponent Alloys KrishnamohanThekkepat[1,2,3] and Seung-CheolLee[1,2,3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]KIST School, Korea University of Science and Technology, Korea (the Republic of); [3]Indo-Korea Science and Technology Centre, India

First-principles based electronic structure methods like density functional theory (DFT) with remarkable accuracy and sophistication have played an important role in the discovery and development of high-performing materials that drive technological breakthroughs. However, most recent breakthroughs, especially in materials for storage, conversion and transport of energy were reported in alloys, often with more than 1 additive element. Modelling multicomponent alloys becomes prohibitively expensive with DFT due to the exponential explosion in the configurational space (10^{10}-10^{25}) of these alloys. Combining DFT calculation data with machine learning methods can overcome this issue. One of the most successful combinations of both is the development of cluster expansion method.[1] Cluster expansion Hamiltonians can be used to sample the vast configuration space of alloys at reduced costs and extract finite temperature thermodynamic properties via Monte Carlo Simulations.[2] Over the years, several algorithms ranging from simple regression to sophisticated Bayesian compressive sensing have been applied to train cluster expansion models for binary and ternary alloys from DFT energies.[1] However, modelling larger and complicated multicomponent alloys is still expensive due to requirements of large training sets (~10^4).

We present a new compressive sensing-based algorithm for efficient construction of cluster expansion Hamiltonians of multicomponent alloys. The proposed algorithm constructs highly sparse and physically reasonable models from a carefully selected small training set of alloy structures. When compared with conventional fitting algorithms, the proposed algorithm achieves similar accuracy with a significantly smaller training set. We demonstrate this on 4 different alloy systems, namely Ag-Au, Ag-Au-Cu, Ag-Au-Cu-Pd, and (Ge,Sn)(S,Se,Te). For the ternary and quaternary alloys, the reduction in training set size is shown to be at least 50%. The resultant sparse models from training can sample the configuration space at least 3x faster and also reproduce known ground state orderings and order-disorder transitions. The new algorithm has been implemented in the Lattice Atomic Configuration Simulation (LACOS) package developed in-house. We have implemented special workflows to construct cluster expansion Hamiltonians starting from generating training structures for DFT calculations to validation of fitted models. Finite temperature Monte Carlo simulations can also be carried out to extract thermodynamic properties. Our code is designed to truly enable high-throughput multicomponent alloy thermodynamics by reducing the cost associated with model construction and configurational sampling.

Quantitative Assessment of Local Chemical Ordering in Atomistic Simulations of High-Entropy Alloys KillianSheriff, YifanCao and RodrigoFreitas; Massachusetts Institute of Technology, United States

High-entropy alloys (HEAs) exhibit exceptionally good combinations of properties recently reported to correlate with chemical short-range ordering (cSRO). However, in atomistic

simulations, their state of cSRO has only been so far characterized using the Warren-Cowley parameters. Yet, this approach is incomplete as distinct local atomic configurations sharing the same chemical concentration are indistinguishable. Here, we propose a generalized framework, based on graph-convolution neural networks equivariant to E(3) symmetry operations, statistical mechanics, and information theory, capable of completely identifying the set of distinct local atomic binding environments and their associated population densities in HEAs. This approach leads to a quantitative characterization of the cSRO state and provides a predictive framework for evaluation of cSRO domain sizes, thus offering novel avenues to explore the relationships between processing, structure, and properties in HEAs.

Accelerated Training of Cluster Expansion Models for Simulating Complex Oxides in High-Temperature Energy Conversion Applications JonasKaufman, Yu-TingHsu, KyoungE. Kweon and BrandonWood; Lawrence Livermore National Laboratory, United States

The cluster expansion is a reduced order model widely used to approximate the energetics of crystalline materials in large-scale thermodynamic and kinetic simulations. These models are typically trained on data from first-principles calculations, which act as the primary bottleneck in this method. Efficient generation of training data becomes increasingly challenging for complex, many-component oxide systems, which are often relevant in energy applications. In addition, the combinatorial explosion of cluster expansion basis functions necessitates a careful approach to model construction and fitting. Here, we navigate these issues in modeling lanthanum strontium cobalt ferrite (LSCF), a key material of interest for electrodes of high-temperature solid oxide fuel cells and electrolysis cells for hydrogen technology. Cluster expansions are constructed for LSCF and secondary oxide phases that appear as degradation products in device applications. High-throughput density functional theory calculations are performed within an active learning scheme, where Gaussian process regression is applied to identify optimal regions of configuration space to sample. Using a common set of training data, we benchmark various approaches to fitting the cluster expansion as well as alternative, nonlinear lattice models such as neural network alloy Hamiltonians. We also discuss the application of our models in kinetic Monte Carlo simulations as part of a broader multiscale modeling effort.

Short-Range Order in Group IV Alloys: Insights from First-principles Calculations and Machine Learning Based Atomistic Simulations ShundaChen, XiaochenJin and TianshuLi; George Washington University, United States

Group IV alloys are promising silicon-compatible versatile materials for electronic, photonic, and topological quantum applications. However, the determination of their structural properties remains elusive and challenging. By combining statistical sampling from extensive first-principles density functional theory (DFT) calculations, we show that group IV alloys exhibit a wide range of complex short-range order (SRO) behaviors within its entire investigated composition range[1-3]. SRO is further predicted to substantially affect the electronic properties of group IV alloys[1-3] and its presence in group IV alloys is recently experimentally confirmed by different characterization techniques. To extend the spatiotemporal scale of atomistic modeling to enable a side-by-side comparison with advanced characterization methods such as atom probe tomography, we further develop machine-learning interatomic potentials for the alloys. We show that the machine-learning interatomic potentials not only can accurately reproduce the results based on DFT calculations, but also enable a discovery of new, interesting SRO structural properties that are not easily accessible by DFT calculations. Our results shed more light on the mysterious SRO structural properties of group IV alloys.

Deep Material Network for Thermal Conductivity Homogenization DongilShin, PeterJ. Creveling, ScottA. Roberts and RemiDingreville; Sandia National Laboratories, United States

The agile and accurate material simulation model is in demand for rapid material analysis and design. Especially a computational analysis model for multiphysics and multiscale applications is of major interest. Recently, Deep Material Network (DMN) has shown itself to be a powerful approach for the material's reduced-order modeling because of its ability to extrapolate the constitutive equations and its orders of lower computational cost. DMN learns the homogeneous pathway from the linear constitutive relation data and can be used as a reduced-order model for predicting the non-linear constitutive equations. However, currently, all the DMN work has been done only on the elastic mechanical problems. In this study, DMN has been explored to handle thermal conductivity analysis. By building the DMN architecture corresponding to the thermal conductivity homogenization, we have shown that the DMN can be expanded to different physics, which is essential to dealing with multiphysics problems. We had predicted the two-scale problem's homogenized response, corresponding to the thermal conductivity of the woven structure. To consider the woven structures' orthotropic properties, micromechanics-based DMN network parameters have also been updated to reflect the material's orientation. The trade-off of increasing the DMN network parameters, corresponding to the complexity of the homogenization process, has also been studied. We believe our material model will open new chances for multiphysics-multiscale design and analysis for composite materials and, furthermore, to explore the material design space with sufficient agility and accuracy. Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Atomistic Insights into The High Temperature Dislocation Dynamics of Cu using a Bayesian Force Field from First Principles CameronJ. Owen[1], AmirhosseinNaghdi Dorabati[2,3], AndersJohansson[1], DarioMassa[2,3], StefanosPapanikolaou[2] and BorisKozinsky[1]; [1]Harvard University, United States; [2]Nomaten CoE, Poland; [3]Ideas NCBR, Poland

High temperature dislocation dynamics present a difficult simulation task for existing classical and ab initio methods due to the required accuracies and length-scales. These limitations ultimately prohibit advanced understanding of plastic deformation of materials under relevant stimuli. Here, we develop a Bayesian machine-learned force field (MLFF) from ab initio (first principles) training data that extends quantum-mechanical accuracy to large length-scale molecular dynamics simulations which permit reliable description of high-temperature dislocation dynamics in Cu and direct comparison to experimental observations. In concert, a general and intuitive training protocol is defined for construction of MLFFs for the description of dislocations, which can be employed for other systems of interest. The resulting MLFF provides excellent predictions of both static bulk properties (e.g. bulk modulus and elastic tensor), stacking fault energies, and the dynamic evolution of edge and screw dislocations, as well as cross-slip mechanisems and activation energy across a broad range of temperatures and applied shears. Such simulations allow for the unbiased, atomistic insight into plastic deformation under various stimuli, helping to ultimately explain experimental observations through an atomic-lense.

Convolutional Autoencoder and Koopman Operator-Based Markov Chaining for Time Series Forecasting of a Large-Scale Dissipative Particle Dynamics System for Thrombosis Modelling AkhilSamavedam[1], YicongZhu[2] and YuefanDeng[2]; [1]Westlake High School, United States; [2]Stony Brook University, The State University of New York, United States

Background: Cardiovascular disease (CVD) is the world's leading cause of death, responsible for over 17.9 million deaths annually. The majority of CVD-related deaths are caused by thrombosis, the formation of a blood clot in a vein or artery that impedes the circulatory system. Therefore, it is necessary to create accurate platelet and flow dynamics models to simulate the thrombosis process effectively. Multiscale modeling (MSM) combines various spatiotemporal resolutions in order to achieve high accuracy while simultaneously reducing the computational cost. Preceding works defined MSM models involving Dissipative Particle Dynamics (DPD) for the Poiseuille flow of blood in the vessel and Coarse-Grained Molecular Dynamics (CGMD) for the fluid-platelet interface. However, these simulations are highly computationally intensive due to the large amount of DPD calculations performed on fluid particles at high resolutions with negligible benefits. It is necessary to find an accelerated solution to the fluid modeling aspect of the simulation.

Methods: We define the DPD system as a 3D velocity field on a defined particle plane 391.2 μm long x 21.3 μm wide. The velocity field is represented by a tensor of size (4200, 244, 3) for a total of 3074400 elements. The simulation is discretized in timestep increments of 250 μs with a corresponding state tensor at each timestep. In order to utilize a Koopman Operator to model time series evolution, we derived a series of observable functions that accurately reflect the state of the system in a lower dimensional space than the state tensor. We derived these functions by implementing a Convolutional Autoencoder (CAE) to learn a 256-element latent representation of the state tensor and consider spatial relationships in the velocity field; this latent vector acts as the observable function. We used Extended Dynamic Mode Decomposition (EDMD) to derive an approximated Koopman Operator (aKO). EDMD is performed by taking the product of a matrix of latent vectors for each state tensor time step joined as columns with the Moore-Penrose pseudoinverse of a time-shifted variant of this matrix. In order to model the time series evolution, the observable function at a discrete time is multiplied by the Koopman operator to predict the next observable function. This process forms a Markov chain where the model's

current state is the only consideration in predicting the future state.

Results: CAE-aKO resulted in a speed increase of 390x for single-step prediction, a value that increased linearly to 3570x for nine steps. CAE-aKO also achieved high accuracy with an average RMSE value of 0.1372 across 3 million elements and an average MAE of 0.1065. These averages were calculated across predictions ranging from 1-9 timesteps (250 μs - 2.25 ms) into the future. We attribute the majority of the prediction error to flaws in the CAE's learned latent vectors, as the aKO presented low errors in latent vector time series prediction when the latent vectors are not converted back to state tensors.

Discussion and Future Work: We assessed the viability of a non-physics-guided approach to time series forecasting of a large-scale system with complex spatiotemporal relationships. CAE-aKO learned an accurate underlying representation of the state tensor and was able to accurately model the evolution of the system with minimal drops in accuracy as multiple steps of prediction were performed. Future work will focus on refining the CAE architecture to minimize reconstruction loss and then use CAE-aKO to produce new data upon which to calculate aKOs for larger time steps, allowing for greater speedups in modeling methodology that allow for simulations to move from predicting on time scales of milliseconds to larger scales of seconds and minutes.

Acknowledgments: This project was supported by Stony Brook University's Garcia Center for Polymer Research and the Garcia Scholars Program.

Artificial Intelligence Guided Materials Discovery of Two-Dimensional Magnets TrevorD. Rhone[1], RomakantaBhattarai[1], HaralambosGavras[1], BethanyLusch[2], MishaSalim[2], MariosMattheakis[3], DanielLarson[3], YoshiharuKrockenberger[4] and EfthimiosKaxiras[3]; [1]Rensselaer Polytechnic Institute, United States; [2]Argonne National Laboratory, United States; [3]Harvard University, United States; [4]NTT Basic Research Laboratory, Japan

The discovery of van der Waals (vdW) materials with intrinsic magnetic order in 2017 has given rise to new avenues for the study of emergent phenomena in two dimensions. In particular, monolayer CrI_3 was found to be ferromagnetic. Other vdW transition metal halides were later found to have different magnetic properties. How many vdW magnetic materials exist in nature? What are their properties? How do these properties change with the number of layers? A conservative estimate for the number of candidate vdW materials (including monolayers, bilayers and trilayers) exceeds ~10^6. Recent studies show that artificial intelligence (AI) can be harnessed to discover new vdW Heisenberg ferromagnets based on $Cr_2Ge_2Te_6$ [1, 2]. In this talk, we will harness AI to efficiently explore the large chemical space of vdW transition metal halides and to guide the discovery of magnetic vdW materials with desirable spin properties [3]. That is, we investigate crystal structures based on monolayer Cr_2I_6 of the form A_2X_6, which are studied using density functional theory (DFT) calculations and AI. Magnetic properties, such as the magnetic moment are determined. The formation energy is also calculated and used as a proxy for the chemical stability. We show that AI, combined with DFT, can provide a computationally efficient means to predict the thermodynamic and magnetic properties of vdW materials. We use semi-supervised learning to mitigate the challenge of data scarcity in AI-guided materials discovery. This study paves the way for the rapid discovery of chemically stable magnetic vdW materials with applications in spintronics, data storage and quantum computing.

Accelerated Continuum Crystal Plasticity and Phase Field Microstructure Modeling using U-Net DierkR. Raabe; Max Planck Institute for Iron Research, Germany

An overview of various continuum-level machine learning based models for microstructure evolution is presented, focussing on crystal plasticity and phase field methods [1, 2].
For accelerating mechanical boundary condition treatment for heterogeneous solids we propose a deep neural network as a fast surrogate model for local stress calculations in inhomogeneous linear or non-linear elasto-viscoplastic materials, using U-Net. We show that the surrogate model predicts the local stresses with <4% mean absolute percentage error for the case of heterogeneous elastic media and a mechanical contrast of up to factor of 1.5 among neighboring domains, while performing 100-500 times faster than spectral solvers. The model proves suited for reproducing the stress distribution in geometries different from those used for training. In the case of elasto-plastic materials with up to 4 times mechanical contrast in yield stress among adjacent regions, the trained model simulates the micromechanics with a MAPE of 6.4% in one single forward evaluation of the network, without any iteration. The results reveal an efficient approach to solve non-linear mechanical problems, with an acceleration up to a factor of 8300 for elastic-plastic materials compared to typical finite element solvers.
A similar approach was chosen for phase-field models: these are costly when applied to large, complex systems [3,4]. To reduce the computational costs, a U-Net surrogate model has been developed. Training input is obtained from the results of the numerical solution of initial-boundary-value problems based on the Fan-Chen model for grain microstructure evolution. The trained network is applied recursively on initial order parameters to calculate the time evolution of the phase fields. The results are compared to the ones obtained from the conventional numerical solution in terms of the errors in order parameters and the system's free energy. The resulting order parameter error averaged over all points and all simulation cases is 0.005 and the relative error in the total free energy in all simulation boxes does not exceed 1%.

Machine Learning-Aided First Principles Calculations of Free Energies RyosukeJinnouchi[1], FerencKarsai[2] and GeorgKresse[3,2]; [1]Toyota Central R&D Labs., Inc., Japan; [2]VASP Software GmbH, Austria; [3]University of Vienna, Austria

The free energy of atoms and molecules in condensed matter is an extremely important property. Knowledge of free energy allows quantitative evaluation of a wide variety of physical properties, such as coexistence points of different phases, concentration of minority species, redox levels of atoms and molecules in condensed matter, and thermodynamic stability of reaction intermediates. However, accurate first-principles calculations of free energies are extremely challenging. Since free energies are not observable, the free energy difference between a known system and a real system of interest must be calculated in large-scale molecular dynamics simulations using thermodynamic perturbation theory (TPT) or thermodynamic integration theory (TI). Recently, machine-learned force fields (MLFFs) have enabled efficient computation of free energies [1-3]. By using MLFFs as surrogate models, computationally difficult TI from a known system to a real system becomes feasible. Errors in MLFF can also be corrected by TPT and TI. Machine-learned models can be also used to correct inexpensive low-level first-principles results, such as results by semi-local exchange-correlation functionals, to obtain accurate but expensive theoretical results [4]. Here, we show three applications of the ML-framework to the free energies in aqueous solutions and interfacial systems: hydration free energies of ions in water, redox potentials of transition metal ions in water, and hydration free energies of adsorbates on the surface of platinum catalysts. All examples demonstrate that MLFFs enable efficient statistical sampling necessary for accurate computations of free energies.

Understanding and Designing the Frustration in Super-Ionic Conductors aided by Machine Learning ShuoWang[1,2], YunshengLiu[1] and YifeiMo[1]; [1]University of Maryland, United States; [2]Massachusetts of Institute of Technology, United States

Frustration is a physical phenomenon in which plenty competing states exsit with similar energy levels. The frustration in super-ionic conductors enables their exceptionally high ionic

conductivities. Although atomistic modeling reveals a wide range of specific mechanisms in causing the frustration, a long-standing challenge is that analyzing many disordered configurations of the atomistic systems and their energies using first principles computation is computationally expensive. With the aid of machine learning interatomic potential to provide atomistic energies of individual atoms, we proposed density of atomistic states (DOAS) as quantitive analytics to elucidating, characterizing, and understanding the frustration mechanisms involving a diverse range of locally disordered atomic configurations. Using Li-ion conductors as model systems, the DOAS quantitatively characterizes the onset and degree of disordering, reveals the local configurational disorder and energetics in causing the frustration, and reveal how the frustration of atomistic states enhances ion diffusion. Furthermore, materials design strategies aided by the DOAS are devised and demonstrated for new super-ionic conductors. As demonstrated, the combination of atomistic modeling and machine learning can extend and empower conventional physics analytics for unraveling fundamental mechanisms and for guiding material design.

A Machine Learning Based Computational Approach for Prediction of Cation Distribution in Spinel Crystal YingFang and GuofengWang; University of Pittsburgh, United States

Spinel ferrites with a general chemical formula of AB2O4 (A, B = Fe, Mg, Co, Ni, Cu, or Al) have interesting and technologically relevant magnetic and electrical properties. The crystal structure of spinel AB2O4 can be viewed as a superlattice consisting of eight (2x2x2) face-centered cubic unit cells with the lattice sites occupied by oxygen ions. In addition, one eighth of the tetrahedral and one half of the octahedral sites of the lattice are occupied by the A and B cations. In a normal spinel structure, all A ions will lie at the tetrahedral sites whereas all B ions at the octahedral sites. By contrast, half of the B ions will lie at the tetrahedral sites, whereas the octahedral sites are occupied by both A and B ions in an inverse spinel structure. Varying from the normal to inverse structures, the cation distribution in spinel AB2O4 could be quantified using degree of inversion which is the fraction of the tetrahedral sites occupied by B ions.

It has been found that both cation chemistry and degree of inversion play an important role in technically relevant properties of spinel oxides. In this study, we have developed and applied a machine learning based computational approach to predict the equilibrium cation distribution in multi-cation spinel oxides at high temperature. The computational approach integrates the construction of datasets consisting of the energies calculated from the density functional theory of the spinel oxides with various cation distributions, the training of the support vector machine model to derive relationship between system energy and structural features, and atomistic Monte Carlo simulations to sample the thermodynamic equilibrium structures of spinel crystal as a function of temperature We have applied our computational approach to predict the cation distributions for material systems of single spinel $CoFe_2O_4$, $NiFe_2O_4$, $MgAl_2O_4$, $MgFe_2O_4$, and double spinel $MgAl_{2-x}Fe_xO_4$. Our predictions are found to agree well with available experimental results. Therefore, this study presents a reliable computational approach that can be extended to study the variation of cation distribution with processing temperature and chemical composition in complex multi-cation spinel oxides.

9:30 AM DS06.11.06
Coupling Between Moiré Patterns in Twisted Bilayer Graphene and Nanofluidics: A Deep Neural Network Approach ChenxingLiang and NarayanaAluru; The University of Texas at Austin, United States

Twisted bilayer graphene at the magic angle has garnered attention due to its intriguing superconductivity and correlated insulator behavior resulting from strong electronic correlations. However, the impact of the electronic properties due to Moiré Patterns in twist bilayer graphene on the structural and dynamic properties of water remains largely unexplored. This knowledge gap stems from computational challenges associated with simulating large unit cells using density functional theory. In this study, we present an approach utilizing a deep neural network potential (DP) model. The DP model is trained using a dataset obtained from ab initio molecular dynamics simulations of water on various large twist angle bilayer graphene. Our DP model accurately characterizes key water properties, such as OH bond length, HOH bond angle, and power spectra, on top of magic angle twisted bilayer graphene. Leveraging this model, we investigate the structural and dynamical properties of water on bilayer graphene with various twist angles, ranging from 1.08° to 9.43°. By analyzing the effects of these twist angles and their corresponding electronic properties, we gain insights into the nanofluidic behavior of water. This exploration opens avenues for future research, focusing on harnessing the unique properties of twisted bilayer graphene to control and optimize nanofluidic behavior.

Efficient Generation of Materials Data for Machine Learning Shyue PingOng, JiQi and Tsz WaiKo; University of California, San Diego, United States

The biggest bottleneck to machine learning (ML) for materials science is the generation of training data. In this talk, I will discuss various approaches to efficiently generate and use materials data to develop ML models. For instance, I will demonstrate the use of universal interatomic potentials to pre-generate a large configuration space of structures, as well as a DImensionality Rduced Encoded Clusters with sTratified (DIRECT) sampling approach to create a robust training set for an ML interatomic potential (MLIP). I will also discuss the application of multi-fidelity techniques to maximize the return on scarce, high quality data. While a major focus of this talk will be on MLIP development, I will also highlight the applicability of these techniques to other ML-enabled applications.

10:45 AM DS06.11.08
Combining DFTB and Structure-Mapping for the Prediction of Transition Paths in Deactivation of ZnO@Cu Catalysts ArtemSamtsevych, ChiaraPanosetti, ChristophScheurer and KarstenReuter; Fritz Haber Institute der MPG, Germany

Solid–solid transformations are common in nature and in the aging of functional materials. Understanding the origin of these complex phenomena at the atomistic level is a pre-requisite for the design of long-living active materials. For example, catalysts undergo structural and compositional changes during aging, leading to a decline of their catalytic activity and selectivity. Understanding such transformations is necessary to rationally develop mitigation strategies.

From the energetical point of view, the involved activated processes can be modeled as transitions between basins on a complex, high-dimensional free energy surface (FES). Chain-of-states methods optimize presumed pathways between two structural endpoints on FES towards the minimum energy pathway (MEP), yielding transition state estimates. Using the harmonic approximation to transition state theory (hTST), one can estimate reaction rate constants from the location of saddle points on the FES. However, there are two pitfalls that exist in this scheme that typically limit the extent of accessible spatial and time scales. First, the number of possible transition pathways that must be evaluated grows exponentially with system size and, second, ab initio methods, like density functional theory (DFT), are still too computationally expensive to cover the enormously large region of interest in the configurational space.

The first problem can be solved using advanced techniques for the generation of the initial pathway(s) or, in other words, the mapping of atomic structures onto each other. This can be achieved either by purely geometrical methods (mapping of atomic positions and cells) or by topology-based methods, which map the graphs of interatomic bonds. Both approaches are complementary to each other and generate a diverse set of mappings. The combination of mapping algorithms with the chain-of-states method has recently been merged into a generalized workflow.

To tackle the second problem, we harness the power of machine learning (ML) and incorporate it into an approximate, semi-empirical electronic structure model resulting from Density Functional Tight Binding (DFTB) theory [1]. By doing so, we are able to achieve energetics and electronic properties with an accuracy comparable to DFT at a fraction of the cost. Such an approach is realized by means of DFTB parametrization with a Gaussian Process Regression repulsive potential (GPrep-DFTB) [2].

Previous theoretical and experimental studies have shown that ZnO tends to form a graphitic-like overstructure on a Cu surface (catalytically active system) if it is deposited in thin layers. However, the thicker the ZnO phase grows, the more a wurtzitic ZnO structure, which is catalytically less active, becomes favored [3-5]. We will present the combination of mapping algorithms along with GPrep-DFTB to investigate the phase transformations involved in the aging process in ZnO@Cu catalysts.

11:00 AM DS06.11.09
Accelerating Crystal Structure Prediction of Properties of Organic Salts via Machine Learning EthanP. Shapera[1], Dejan-KresimirBucar[2], RohitPrasankumar[3] and ChristophHeil[1]; [1]Graz University of Technology, Austria; [2]University College London, United Kingdom; [3]Intellectual Ventures, United States

We demonstrate a machine learning-based approach to accelerating crystal structure prediction of organic salts. Use of crystal graph singular values reduces the number of features required to describe a crystal by more than an order of magnitude compared to the full crystal graph representation. We construct machine learning models using the crystal graph singular value representations in order to predict the volume, enthalpy per atom, and metal versus semiconducting phase of DFT-relaxed organic salt crystals based on randomly generated unrelaxed crystal structures. Initial base models are trained to relate 89,949 randomly generated structures of salts formed by varying ratios of 1,3,5-triazine and HCl with the corresponding volumes, enthalpies per atom, and phase of the DFT-relaxed structures. We further demonstrate that the base model is able to extrapolate to new chemical systems with the inclusion of as few as 2,000 crystal structures from the new system. After training a single model with a large number of data points, extrapolation can be done at significantly lower cost. The constructed machine learning models can be used to rapidly screen large sets of randomly generated organic salt crystal structures and efficiently downselect the structures most likely to be experimentally realizable.

11:15 AM DS06.11.10
Symphony: Symmetry-Equivariant Point-Centered Spherical Harmonics for Generating Molecules Song EunKim, AmeyaDaigavane, MarioGeiger and TessSmidt; Massachusetts Institute of Technology, United States

In-silico generation of diverse molecular structures has emerged as a promising method to navigate the complex chemical landscape, with direct applications to inverse material design and drug discovery. However, 3D molecular structure generation comes with several unique challenges; generated structures must be invariant under rotations and translations in 3D space, and must satisfy basic chemical bonding rules. Inspired by the success of machine learning models for generating coherent text and audio, there is much interest in building similar 'generative models' for 3D molecular structures.
One of the first successful attempts was G-SchNet, an autoregressive model that uses message-passing with rotationally invariant features to generate 3D structures of small molecules. At each iteration, a focus node is selected as the center of a 3D grid, then all pre-existing atoms collectively decide on the next atom's position within this grid. In this manner, G-SchNet generates molecules one atom at a time, completing molecular fragments into entire molecules. This construction raises several interesting questions; first, can we more accurately capture complex geometric motifs, and second, can we simplify the process of placing each atom without breaking symmetry via auxiliary tokens?
Here, we present our work on Symphony, an E(3)-equivariant autoregressive generative model. E(3)-equivariant neural networks that utilize higher-order rotationally-equivariant features have recently shown improved performance on a wide range of atomistic tasks. Motivated by these results, Symphony builds on G-SchNet by using message-passing with higher-order equivariant features. This allows a novel representation of probability distributions via spherical harmonic signals.
We will discuss the state of molecular generation models today and where Symphony sits amongst this rapidly changing landscape. We highlight several challenges we observed when developing Symphony, closely related to error accumulation and out-of-distribution generalization issues of machine learning methods. We present several applications of Symphony in generating small molecules and transition metal complexes, identifying key components of our model as well as areas of improvement. In particular, we demonstrate how higher-order equivariant features can model complex geometrical motifs which were unable to be captured by preceding methods such as G-SchNet. Finally, we discuss how hierarchical generation and building richer datasets beyond QM9 are important avenues to benchmark and improve generative models for molecules.

11:30 AM DS06.11.11
Accelerating Excited-States Calculations using Active Learning Configuration Interaction for Cyclic Organic Molecules WooSeokJeong; Korea Institute of Energy Research (KIER), Korea (the Republic of)

Understanding the electronic excited states of organic materials is key to the design of optoelectronic, photocatalytic and photovoltaic devices. For molecular systems, multiconfigurational methods can be used to compute the excitation states of such molecules as electronic correlations are included. A conceptually simple and robust approach among the multiconfigurational methods is the selected configuration interaction (SCI) theory, which utilizes only the energetically important electronic configurations for Configuration Interaction (CI) calculations. Compared to the Full Configuration Interaction (FCI) theory, SCI calculations can save a significant amount of computational cost, allowing to tackle much larger systems of interest. However, the success of the SCI calculations depends on how important configurations are selected, so different approaches have been introduced. To address this challenge, we developed the Active Space Configuration Interaction (ALCI) method [1] to predict the lowest singlet–singlet vertical excitation of several polycyclic aromatic hydrocarbons (i.e., acenes and pyrene), inspired by the Machine Learning Configuration Interaction (MLCI) approach [2] used for ground state calculations of small molecules. In the ALCI approach, a binary classification machine learning model is employed to identify candidate important configurations for subsequent SCI calculation during iterative CI calculations. It has been shown that our approach can accurately predict the excitation energies compared to CASCI results for relatively small- and medium-sized systems (i.e., active spaces up to (16e, 16o)), and capture the general trend of excitation energies of the systems up to (26e, 26o), for which a complete active space CI (CASCI) calculation is not yet affordable. In this talk, we present an updated scheme of the ALCI approach to predict excited states of various cyclic organic molecules in the QUEST database [3]. The updates include several features: First, unimportant configurations identified near the importance metric in previous cycles are recycled to obtain more accurate results. Second, any transition, not just for the lowest singlet-singlet transition, can be selected for calculation. Third, GPU-supported ML algorithms (i.e., LightGBM, XGBoost, Gaussian Process, ANNs) are implemented to speed up the ML training/prediction steps. We will also analyze the identified important/unimportant configurations to discuss what importance metric would be appropriate.

Search Trees in Large Continuous Action Spaces for Multiscale Modeling and Design of Materials SuvoBanik[1], Troy DavidLoeffler[2], SukritiManna[2], HenryChan[2] and SubramanianSankaranarayanan[2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Modeling materials at various scales is of utmost importance in a diverse array of practical applications, allowing us to predict and gain insights into the favorable properties of novel materials, including super-hardness, electronic behaviors, and catalytic potential, among others. The understanding of material properties is intricately linked to the underlying structure and the potential energy landscape. Any approach to material modeling encompasses two key aspects: (a) the use of high-dimensional potential energy models to accurately predict material properties and (b) the navigation of the energy landscape to identify atomistic configurations that possess these desired traits. While first-principles-based approaches have demonstrated accurate property predictions, scalability remains a significant challenge, particularly in systems with heterogeneity and sizes that extend to scales with significant practical implications. Traditional potential energy models provide a cost-effective alternative, but their parameterization becomes challenging due to the dimensionality and continuous nature of search space. Additionally, the complexity of the energy landscape, exhibited by these potential models, makes it difficult to navigate toward local minima corresponding to metastable phases or locate global minima for inverse design problems. The high dimensionality of these problems necessitates the implementation of efficient approaches that can effectively explore the search space, capture the diversity of polymorphs, and converge toward desired properties. Drawing inspiration from the remarkable success of tree search algorithms in policy-driven reinforcement learning for games like Chess, Shogi, and Go, we have developed a continuous search space adaptation of Monte Carlo Tree Search to address these challenging material design problems. Our contribution to this continuous space adaptation includes modifying the rewards scheme to enhance exploration, implementing a "funneling" scheme for improved exploitation, and incorporating adaptive sampling during playouts to achieve efficient and scalable search. Using standardized high-dimensional artificial landscapes, we have successfully benchmarked our approach against popular metaheuristics-based global optimization techniques and state-of-the-art policy gradient methods. Our applications include exploring high-dimensional potential energy models of representative systems, such as nanoclusters of elements like Al, C, and Cu. Additionally, we have demonstrated the ability of our method to predict global minima crystal structures in systems with different dimensionalities and compositions, ranging from 0D (Au nanoclusters) to 2D (MoS2) and oxides like TiO2. Furthermore, we have extended our approach to addressing representative continuum-scale modeling problems, such as minimizing fabrication costs in welded joints or optimizing the weight of tension/compression springs. Additionally, we have applied our method to playing high-dimensional video games, showcasing its versatility. Future applications include implementing these algorithms to facilitate the discovery, exploration, and learning of synthesis pathways driven by protocols to enhance the understanding of phase transformations in material systems.

Data-Oriented Constitutive Models for Polycrystalline Metals AlexanderHartmaier, RonakShoghi and JanSchmidt; Ruhr-Universität Bochum, Germany

In classical constitutive modeling, the response of a material to mechanical loads is described by explicit mathematical expressions for the relations between stress and strain or strain-rates. Such mathematical formulations can become rather intricate, e.g., when describing history-dependent plasticity on the level of single-crystalline regions, as it is done in crystal plasticity. Yet, typically, such closed-form constitutive models do not take into account microstructural features, as grain size and shape or the crystallographic texture. This situation is rather unsatisfactory from a materials science point-of-view, as it is known that such microstructural features do not only control the mechanical behavior of a material but, moreover, they can be subject to change during plastic deformation. In this work, two approaches are highlighted how microstructure-sensitive data on plastic deformation of polycrystals are used to train numerically efficient machine learning models as constitutive relations that can directly be applied in finite-element models of engineering structures.

Subdiffusive Vacancy Dynamics in Complex Concentrated Alloys: Insights from Kinetic Monte Carlo Simulations and Machine Learning KamranKarimi and StefanosPapanikolaou; Nomaten CoE, Poland

Chemically complex alloys (CCAs) have attracted significant attention due to their remarkable thermo-mechanical properties, often attributed to “core” effects such as sluggish diffusion, entropic contributions, and lattice distortions. In this study, we probe the microstructural kinetics of two exemplary equiatomic, single-phase, face-centered-cubic (FCC) alloys, NiCoCr and NiCoCrFeMn and perform a comparative study with the behavior observed in pure-Ni FCC metal. Employing long-time kinetic Monte Carlo (kMC) simulations, we examine the dynamics of atomic vacancies within these alloys driven by thermal fluctuations. Our findings reveal a significant deviation from the standard diffusive behavior observed in pure Ni, as vacancies in both concentrated alloys exhibit subdiffusive dynamics. This subdiffusive phenomenon is a signature of dynamical sluggishness in CCAs and can be characterized by long power-law-distributed rest periods. We demonstrate that these long wait times directly result from the broad distribution of energy barriers owing to the underlying lattice distortions in these complex alloys.

Building upon the results from our kMC framework, we train neural networks to classify defects based on machine-learning-based atomic descriptors. The surrogate model is further utilized to predict associated diffusion paths and energy barriers under thermal activation. We implement a customized kMC code that systematically incorporates the neural network's outcomes, allowing us to efficiently evolve dynamics of defects in atomistic configurations.

2:15 PM DS06.12.03
Characterizing Cu-Ni Surface Segregation and Oxidation with Machine-Learning Accelerated First-Principles Simulations and *In Situ* ExperimentsPanduWisesa[1], MengLi[1], MatthewCurnan[2,1], Jeong WooHan[2], JudithC. Yang[1] and WissamA. Saidi[1]; [1]University of Pittsburgh, United States; [2]Pohang University of Science and Technology, Korea (the Republic of)

Comprehensively understanding oxidation mechanisms including surface reconstruction, interfacial segregation, and oxide growth on metallic and alloyed interfaces is crucial for preventing corrosion, manufacturing interfaces via layer-by-layer deposition, and elucidating catalytic reactions. However, the multiple competing simultaneous reactions constituting oxidation processes, in tandem with the heterogeneous binding affinities of different atom composition combinations, preclude facile kinetics and dynamics characterization via simple oxidation models such as Cabrera-Mott. Varying the partial pressure of oxygen and temperature on Cu-Ni alloyed surfaces can generally control prevalence of oxidized phases, such as c(2x2) and missing row reconstructions (MRRs). However, complete knowledge of such phase evolutions, how to control phase stability in applications, and the multidisciplinary methodology required to comprehensively characterize related energetics and kinetics are not currently available.
Pursuant to modeling such oxidation processes on Cu and Cu-Ni surfaces, this research resolves first-principles density functional theory (DFT) results, which are then leveraged to optimize deep neural-network potentials (DNPs). DNPs are subsequently implemented to complete molecular dynamics (MD), Monte Carlo (MC), and hybridized Grand Canonical Monte Carlo (MD/GCMC) simulations. These techniques model the relative energetic favorability of differently oxidized Cu and Cu-Ni surfaces, while developing kinetically relevant concentration profiles for Ni and O segregation across their layers. Interfacial oxidation dynamics are comprehensively described through stochastic time series analyses, identifying phase transformations as discrete breaks in structural features and cross-correlating different diffusion mechanisms with phenomenological observations. Experimental *in situ* environmental transmission electron microscopy (ETEM) visualizes and corroborates simulated surface oxidation and segregation modelling outcomes.

2:30 PM DS06.12.04
Assessing Al Ordering in CHA Zeolites with Organic Structure-Directing Agents AlexanderJ. Hoffman[1], MingrouXie[1], CeciliaParis[2], ManuelMoliner[2] and RafaelGómez-Bombarelli[1]; [1]Massachusetts Institute of Technology, United States; [2]Instituto de Tecnologia Quimica, Spain

Zeolites are microporous aluminosilicates within which molecules can diffuse and react. Frequently, these reactions occur at Brønsted acid sites, which form when Al^{3+} is substituted for Si^{4+} in framework tetrahedral sites (T-sites). The net anionic charge from Al substitution is balanced by a proton (H^+) on an O atom adjacent to the Al substitution to form the Brønsted acid site. The positions of Al within the framework dictate the properties of zeolites; for example, CHA zeolites with the same composition (Si/Al ≈ 15) but with different fractions of Al sharing 6-membered rings (6-MR) have different turnover rates (per H^+) for methanol dehydration [1, 2]. Therefore, controlling the distribution of Al within zeolites is a crucial step to controlling the properties of these zeolites.
Zeolite crystals are synthesized using structure-directing agents (SDAs), which are typically cationic and are either organic (OSDA; e.g., tetramethyl ammonium, TMA^+) or inorganic (e.g., Na^+). The size of these SDAs directs the formation of the void spaces of zeolites to produce different frameworks [3], while the locations of cationic centers in the SDAs guide the placement of anionic Al in the framework [4, 5]. Here, we use several computational tools to assess the stabilities of Al distributions as guided by OSDAs in CHA zeolites. The CHA framework has only one symmetrically unique T-site at which Al can be substituted (in a unit cell with 36 T-atoms); however, the addition of one Al breaks the symmetry of the unit cell. As such, the addition of more Al leads to growing numbers of distinct Al arrangements, with up to 13294 unique arrangements with Si/Al = 5 (6 Al substitutions in the unit cell). We use density functional theory (DFT) to optimize CHA structures substituted with different amounts of Al with and without charge-balancing OSDAs. These DFT data are used to train an equivariant graph neural network forcefield (NNFF) with the PaiNN architecture [6] to compute energies and perform optimization calculations on OSDA configurations for all the Al arrangements at low Si/Al ratios where combinatorics render rigorous DFT studies infeasible.
DFT calculations on Al distributions without any cationic SDAs in the framework favor Al distributions that maximize the average Al-Al distance, which indicates that Coulombic repulsion between anionic Al substitutions encourage Al separation. Similarly, DFT calculations of a sample of zeolites with cationic OSDAs show that the most favorable arrangements of Al involve those with short distances between the cation in the OSDA and nearby Al. The NNFF accurately captures the Coulombic interactions between charge centers in these structures to map the most likely Al distributions for a zeolite produced with a given OSDA. Such a workflow should enable a more rapid assessment of Al distributions in zeolites to tailor synthesis approaches and optimize Al distributions for different applications.

Deep Learning-Based Multimodal Analysis for Intelligent Characterization of Chemical Vapor Deposition-Grown Transition Metal Dichalcogenides ShivaniBhawsar, Abdus SalamSarkar and Eui-HyeokYang; Stevens Institute of Technology, United States

Deep learning (DL) offers a large set of tools and algorithms to analyze and extract features from the data. These can expedite the identification of nanomaterial optical and physical properties for efficient characterization. DL techniques have been used to address two-dimensional (2D) materials discovery [1], characterization [2], and determination of properties [3]. However, insufficient data generally cause overfitting, affecting accuracy [4,5].
Here, we present a generative deep learning-based solution that generates an arbitrary amount of 2D material samples when trained on only a limited amount of data. We used the resulting dataset to identify and segment MoS_2, WS_2, WSe_2, Fe:MoS_2, and Fe:WSe_2. We utilized a deep learning model along with optical and spectroscopic tools to determine the thickness and uniformity of the materials. The trained network extracted graphical features such as contrast, color, shapes, flake sizes, and their distributions from a dataset consisting of optical data and the Raman and photoluminescence (PL) spectra from chemical vapor deposition (CVD)-grown MoS_2, WS_2, WSe_2, Fe:MoS_2, and Fe:WSe_2 and mechanical exfoliated MoS_2, WS_2, and WSe_2. We also utilized an atomic force microscope (AFM) to collect thickness data, which provided information of the number of layers.
The image preprocessing on the dataset resized images to a standardized format, and normalized pixel intensities to ensure consistency, and implemented noise reduction algorithms to enhance image quality. We used deep generative models, *i.e.*, variation autoencoder (VAE), and generative adversarial network (GAN), to generate data for expanding small amounts of experimental datasets. The filtering algorithms were applied to the experimentally collected 2D images to identify graphical features including t the area, location, color, coverage distributions, and optical features including contrast variation.
We plan to use convolutional neural networks and attention mechanisms in the convolutional neural networks to enhance the model’s performance. This research will enable effective, high-throughput scanning of CVD-grown 2D materials.

A Machine Learning Based Approach to Solve the Aerosol Dynamics Coagulation Model OnochieC. Okonkwo[1,2], RahulPatel[3], RavindraGudi[3] and PratimBiswas[2]; [1]Washington University in St. Louis, United States; [2]University of Miami, United States; [3]Indian Institute of Technology Bombay, India

Solving aerosol dynamic models accurately to obtain the size distribution function is often computationally expensive. Conventional artificial neural network (ANN) models offer an alternative procedure to solve the aerosol dynamic equations. However, conventional ANN models can result in violation of aerosol mass conservation. To further enhance accuracy and reduce computational time, a hybrid ANN approach to solve the aerosol coagulation equation is developed, validated, and demonstrated. The methodology and assumptions for the development of the hybrid ANN model which provides an analytical closed form solution for aerosol coagulation is described. The ANN model is trained and validated using a dataset from an accurate sectional model. Following this, the hybrid ANN aerosol model is used to describe the evolution of aerosol in a furnace aerosol reactor. The hybrid ANN model results are compared to the accurate sectional and moment coagulation models. The hybrid ANN coagulation model prediction was found to accurately describe the evolution of aerosol size distribution at a computational cost which is slightly more than the moment model but orders of magnitude less than the sectional model.

3:45 PM DS06.12.07
Leveraging Active Learning in Restricted, Discretized and Predefined Design Spaces for NMR Peak Prediction RamseyIssa and TaylorD. Sparks; University of Utah, Salt Lake City, United States

Active learning provides a strategy that allows us to intelligently select data points in our design space, that will provide machine learning models with maximum information. Since Density functional theory and Quantum simulations typically require costly computational resources and are very time consuming, active learning allows us to drastically reduce computational time and cost by selecting key points in the design space that reduce global uncertainty. This strategy leads to the development of a model that can quickly and adequately predict desired outputs from DFT using the fewest number of simulations. Typically, the use of acquisition functions to select informative points, leads to arbitrary solutions in the design space that we might not be interested in simulating. Here, we restrict our search to distinct, discretized and a predefined list of pyrochlore $La_2(Sn_xZr_{1-x})_2O_7$ candidates avoiding arbitrary solutions. The predefined list of candidates results in 531 possible configurations upon the addition of Sn atoms into the 16-position crystal structure where we predict NMR peak position. We utilize a gaussian process as our surrogate model and compare three iterative point selection methods on this dataset. The three active learning strategies compared are random selection as a baseline, maximum predicted model uncertainty, and maximum-value entropy search acquisition function selected sampling.

4:00 PM DS06.12.08
Benchmarking Equivariant Graph Neural Network Potentials for Atomistic Simulations UtkarshPratiush, SureshBishnoi, JayadevaJayadeva, SayanRanu and N M AnoopKrishnan; Indian Institute of Technology Delhi, India

Graph neural networks (GNNs) have revolutionized the representation learning of graph-structured data in diverse domains. In atomic simulations, GNNs exhibit immense potential for capturing intricate interatomic interactions and predicting potential energy surfaces. Equivariant graph neural networks (EGNNs) excel in modeling the symmetries inherent in atomic systems, making them ideal for atomistic simulations. However, the lack of comprehensive benchmarking studies hampers their evaluation against other state-of-the-art potentials. To bridge this gap, we present a systematic benchmarking framework for EGNN potentials in atomic simulations. Our contributions include a standardized dataset encompassing diverse atomic systems, evaluation of six EGNN potentials, and a comprehensive benchmarking framework with various metrics. We assess energy predictions, forces, and structural properties, enabling an objective analysis of EGNN potential capabilities and limitations. Our research facilitates informed selection and development of accurate and efficient potential energy models. The results and insights presented herein will greatly benefit researchers and practitioners in the atomistic simulation field.

4:15 PM DS06.12.09
Inverse Design of Upconverting Nanoparticles via Deep Learning on Physics-Infused Heterogeneous Graphs EricSivonxay[1], LucasAttia[1,2], XiaojingXia[1], BrettA. Helms[1], EmoryChan[1] and SamuelM. Blau[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Massachusetts Institute of Technology, United States

Heterostructured core-shell lanthanide-doped upconverting nanoparticles (UCNPs) have unique optical properties, capable of near-infrared excitation to yield visible and ultraviolet emissions. UCNPs have broad applications ranging from biosensing and super-resolution microscopy to 3D printing. Factors affecting the nonlinear photophysical properties of UCNPs include number of shells, shell thicknesses, dopant concentrations, and surface ligands, defining a vast chemical design space. While kinetic Monte Carlo (kMC) simulations allow for reasonably accurate in silico prediction of optical properties, calculations scale poorly with particle size and dopant loading, constraining the search for UCNPs with desirable properties to be fundamentally Edisonian. Despite the potential to use deep learning (DL) to navigate this space more efficiently, UCNPs previously had neither a viable structural representation for DL (they are unlike molecules, crystals, proteins, text, or images) nor sufficient data for DL (individual photophysical kMC simulations can take weeks). Here, we report efforts to overcome these challenges by combining high-throughput data generation with nanoparticle representation learning. We construct the first large dataset of over 10,000 simulated UCNP spectra with bespoke high-performance lanthanide energy transfer kMC driven by automated workflows on HPC resources. We investigate random forest, MLP, CNN, and GNN ML architectures, eventually converging on a physics-infused heterogeneous GNN as our best-performing model. We then use the trained GNN to perform inverse design of UCNP heterostructure via gradient-based optimization - maximizing UV emission under 800 nm illumination as a function of number of shells and maximum nanoparticle size, identifying novel structures with far higher predicted emission than any in our training data. To the best of our knowledge, this is the first time that data generation, representation development, and DL-enabled optimization have been performed in a novel space end-to-end.

4:30 PM DS06.12.10
A Machine Learning-Based Constitutive Modeling of Plastic Behavior in Polycrystalline Materials using Crystal Plasticity Simulations Including Strain Hardening RonakShoghi and AlexanderHartmaier; Ruhr-Universität Bochum, Germany, Germany

Machine learning (ML) algorithms can provide an effective way of modeling complex material behavior, including plasticity. With their ability to analyze vast amounts of data and identify patterns, these advanced computational techniques can capture relationships between microstructure and mechanical properties and enable an accurate yet flexible description of material behavior. The importance of high-quality training data in machine learning cannot be overstated, as it directly impacts the performance and reliability of the resulting models. Therefore, finding an optimal data generation strategy for the training of ML yield functions and strain-hardening models is essential to ensure their accuracy and reliability. Our work revealed that Support Vector Machines (SVM) can be used as machine learning yield functions and can be successfully trained for materials with significant plastic anisotropy, like polycrystals with a Goss texture, using only 300 data points. The training data was carefully selected to cover a wide range of loading conditions in full 6-dimensional space. The accuracy and reliability of the trained ML yield functions were assessed using a variety of statistical measures, including mean squared error and confusion matrix. As the next step, the optimal training data strategy was employed for generating training data using micromechanical modeling. This allowed for further consideration of microstructural parameters like crystallographic texture or grain size in the input data for the training of the ML yield function. Moreover, this data also contains information of the strain-hardening behavior of the material. A database containing simulation data and metadata was developed, making it easier to train and refine the ML model. From this database, a proper data-oriented formulation for strain hardening was developed, which complements the previously established yield function. This study demonstrated the potential of ML algorithms as powerful tools for modeling complex material behavior. The careful selection and generation of training data, as well as the inclusion of microstructural parameters and work-hardening effects, were crucial for achieving reliable and accurate ML yield functions and strain-hardening models.

4:45 PM DS06.12.11
Data-Driven Failure Assessment Diagram Approach for Tubing and Casing Steel Grades MohamedElkhodbia and ImadBarsoum; Khalifa Univeristy, United Arab Emirates

The objective of this study is to propose a data-driven approach to obtain an accurate J-based fracture assessment diagram (FAD) by creating a large database of J-based FAD curves for various cracks and materials in tubing and casing that are widely used in downhole applications, and then utilizing artificial neural networks (ANNs) to obtain the appropriate FAD curve shape. Methods, Procedures, Process: The proposed steps include selecting the crack shapes and materials of interest, creating an FEA model with geometry, boundary conditions, mesh, and loading conditions, and finding the critical limit load for plastic collapse. Next, elastic (Je) and elastic-plastic (Jep) FEA analyses are conducted for each crack shape as a function of applied load, and a J-based FAD is developed for all crack shapes, materials, and limit loads. Lastly, data-driven techniques such as artificial neural networks (ANNs) are used to predict the FAD shape. Results, Observations, Conclusions: The study highlighted the effectiveness of a data-driven FAD model by comparing it with the empirical FAD, emphasizing the advantages of the data-driven approach. ANNs accurately captured the FAD shape from the validation set, demonstrating their potential in understanding material behaviour. The comprehensive dataset offered

valuable insights for better decision-making in material selection, design, and safety considerations. Streamlined and automated structural analysis processes led to more efficient decisions concerning inspections, repairs, and infrastructure development. This work sets itself apart from previous studies by employing machine learning techniques to generate FADs, providing an extensive dataset and practical applications in refineries and plants for managing and maintaining critical infrastructure. The data-driven FAD model aids engineers and maintenance professionals in predicting structural integrity under various conditions, which is crucial for mitigating potential failures, reducing risks of leaks, and optimizing inspection schedules and repair strategies. The model also supports the design of safer and more reliable pipeline systems. Novel/Additive Information: The significance of the subject matter is evident through the key technical contributions to the downstream industry, enhancing structural integrity assessment accuracy and preventing failures while reducing environmental risks. This paper presents a novel approach by employing machine learning techniques, specifically ANNs, to generate datadriven FADs, providing an extensive dataset and practical applications in refineries and plants for managing and maintaining critical infrastructure. The data-driven FAD model improves structural integrity assessment accuracy, reduces environmental risks, and optimizes maintenance schedules, adding to the state of knowledge in the petroleum industry

Materials Informatics for Computational and Machine Learning (ML)-Assisted Design: An Overview for Polycrystalline Metals and Mechanical Metamaterials PinarAcar, ShengLiu, EnderEger, MohamedElleithy, HengduoZhao and MatthewLong; Virginia Tech, United States

In this talk, we will present an overview of the computational methods developed by our group to design metals and metamaterials for enhanced mechanical performance by modeling them in terms of micro-scale (~10^{-6} m) features. First, we present numerical approaches to quantify the crystallographic texture and grain topology of polycrystalline metals. Similarly, a shape descriptor approach is developed to model the topology of mechanical metamaterials. Following the development and integration of such computational characterization approaches into numerical homogenization schemes to obtain mechanical properties, design optimization problems are developed and solved to design underlying microstructures of polycrystalline metals and mechanical metamaterials for improved mechanical performance.

Next, the talk will focus on the impact of manufacturing-related uncertainty arising from the imperfections and defects during the processing and fabrication of materials on reliability and mechanical performance. We will discuss how to develop design under uncertainty formulations to address forward and inverse design problems in order to improve the elasto-plastic properties of polycrystalline metals and mechanical metamaterials. Additional topics will cover the integration of Artificial Intelligence (AI)/Machine Learning (ML) techniques into physics-informed material models to accelerate the design of material systems processed with conventional and additive manufacturing techniques. We will demonstrate applications of forward and inverse design problems for polycrystalline metals using ML-driven design approaches. The AI/ML methods will also be used for mechanical metamaterials to identify their mechanical property spaces showing all possible values of the selected properties.

Improved Prediction of Adsorption Energies and Vibrational Frequencies of Molecules Adsorbed on Monometal Catalyst Surfaces by Machine Learning using Structural Descriptors KeigoNakamura and MasakuniOkamoto; Hitachi Ltd., Japan

Designing surfaces of metallic catalyst is essential to improve the efficiency of reaction. Recently prediction of intermediate states of adsorbates by using both first-principles calculation and machine learning has been attracted much attention. First-principles calculations for adsorbates on surfaces have been performed, and various databases of adsorption energies have been reported[1]. In order to improve the accuracy of the prediction by machine learning, various descriptors have been developed[2]. Structures of both metal surfaces and adsorbates could affect the adsorption energies. We thus focus on the structural descriptors for machine learning to predict the adsorption energies and vibration properties of adsorbates on metals. We used a surface slab model which has (3 or 5)-layer mono metal (Ti, V, Cu, etc) fcc surface and evaluated the adsorption energies and vibrational frequencies of adsorbates (C, H, N, CO, etc) by first-principles calculation.
We calculated from first-principles more than 7000 surface structures which were employed for prediction of adsorption energies and vibrational frequencies. We evaluated the accuracy of prediction based on several machine learning techniques and found that structural descriptors such as bulk lattice parameter, *d*-band center and width of the surface model are effective to improve the accuracy compared to the prediction using only composition descriptors. The prediction accuracies of the mean squared error were improved from 0.161 to 0.136. The importance of structural descriptors was examined using the “permutational importance”. The lattice parameter and *d*-band center were turned out to contribute highly to the prediction of adsorption energy.

Prediction of Toughness in Heterogeneous Materials using Machine LearningA. N.S. Sadi and ZubaerM. Hossain; University of Delaware, United States

Composites or heterogeneous materials have a wide range of applications in the fields of aerospace, structural materials, biomedical, energy conversion devices, high-temperature materials, etc. But the effective properties of composites, in particular, toughness and strength are hard to predict as a function of their constituent properties. By definition, heterogeneous materials contain different shapes, sizes, compositions, and material or phase distributions at different length scales, making iterative experiments inefficient, time-consuming, and expensive to use for this purpose. In this work, the toughness of heterogeneous brittle material is investigated using a combination of continuum scale simulations and machine learning techniques. Our goal is to predict the configurations (or different structural and material parameters) of the composite that optimize its effective toughness. The continuum simulations are based on the variational phase-field modeling of fracture, and we applied the novel surfing boundary condition, which allows adequate time for the crack to propagate, enabling evaluation of the critical energy release rate or toughness. In particular, we focus on understanding the criteria for deflection vs. penetration for a number of composite configurations and identify the structural or material descriptors that define the criteria. Using the descriptors, we develop supervised machine learning models for predicting the toughness of the composite. The models are trained using data sets, collected from continuum simulations and are used to ascertain the toughness-structure correlation for a number of unexplored variants of the configurations. This talk will discuss the findings and highlight the need for applying machine learning tools to predict the toughness of a composite, for an arbitrary choice of structural and material parameters.

Neural Networks with Optimized Neuron Activation Functions and Without Nonlinear Optimization or How to Prevent Overfitting, Cut CPU Cost and Get Physical Insight All at Once SergeiManzhos and ManabuIhara; Tokyo Institute of Technology, Japan

In machine learnng (ML) applications in the fields of materials science, computational chemistry, and elsewhere, neural networks (NN) play a prominent role. For applications ranging from machine-learned interatomic potentials to DFT functionals to structure-property relations, they offer a high expressive power and generarity (black-box character). However, they require optimization of a large number of nonlinear parameters, leading to a high CPU cost and the dangers of overfitting. These disadvantages become more severe as the dimensionaltity of the feature space increases and the data density necessarily becomes low. As many ML techniques, NNs also do not provide physical insight.
We will present a method to construct NNs with rule-based definitions of parameters which permits dispensing with non-linear parameter optimization altogether. We also construct optimal neuron activation functions for the problem at hand that are different for different neurons, thereby increasing the expressive power of the NN. It is the absence of the need to deal with nonlinear optimization that makes this meaningful (contrary to backpropagation that works best with the same neuron activation function for all neurons). The neuron activation functions are easilty obtained from an additive Gaussian process regression [1] in redundant coordinates that are neuron arguments.
As a result, we ontain a method that combines the expressibe power of an NN with the robustness of a linear regression: we will demonstrate on the examples of the fitting of interatomic potentials that the NN does not suffer from overfitting as the number of neurons is increased beyond optimal [2]. We will also show that by modifyng the rules with which the NN parameters are defined, one can easily obtain an orders of coupling representation (often used in physics and computational chemistry under the names many-body and N-mode representation, respectively) [3] which also helps generate elements of insight [4] while maintaining the generality of the method.

Employing Deep Neural Networks and High-Throughput Computing for The Identification and Prediction of Vein-Like Structures JunboNiu, XinxinMa, BinMiao, ZhiyuChi and FeilongWang; Harbin Institute of Technology, China

In this investigation, we leverage Convolutional Neural Networks (CNNs) to engineer a simple segmentation and recognition algorithm specialized for the delineation of complex, network-like morphologies—often termed "vein-like structures (VLSs)"—in Scanning Electron Microscopy (SEM) imagery. These intricate formations frequently appear during the nitriding treatment of medium- to high-carbon alloy steels. To navigate the multifaceted characteristics of such architectures, we synergize CNN-based methodologies with high-throughput thermodynamic computations via Thermo-Calc. This integration aims to quantify both the theoretical upper bounds and the empirical values of the VLSs. By establishing neural network models for both theoretical upper bounds and empirical measurements, we bridge the gap between thermodynamics and thermo-kinetics in the nitriding process. Applying this amalgamated predictive schema to 8Cr4Mo4V steel, we effectuate a groundbreaking departure from conventional paradigms that exclusively depend on thermodynamic calculation-based diffusion models. The emergent model yields transformative implications for the metallurgical sector, paving the way for the refinement of future nitriding algorithms and enhancements in nitriding methodologies.

Prediction of Li-Dendrite Growth with Physics-Informed Neural Network and Transformer Model Yi-ChiaHan[1], Chun-WeiPao[1] and Chih-HungChen[2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

The growth of lithium-dendrite at anodes has long been a well-known hindrance limiting the development of lithium-ion batteries. Gaining a deeper understanding of the mechanism behind dendrite growth is a challenging yet pivotal task. Although phase-field models (PFM) have proven to be an effective numerical approach for modeling Li dendrite growth behaviors compatible with experiments in time and length scales, seeking for a computationally efficient surrogate model still remains imperative due to the computationally demanding fine meshes required for PFM. Recently, deep learning (DL) has demonstrated promising potential in learning dynamical systems. Herein, we introduce two DL models to capture the spatial and temporal evolution of Li dendrite growth, ion concentrations, and electrostatic potential of Li metal anode upon charging. The first model integrates the physics-informed neural networks (PINNs) with PFM. In the learning phase, we train our PINNs model to learn PFM with imposed governing equations and boundary conditions so as to retain consistency with physics laws. In the second model, we develop a transformer, originated from Natural Language Processing (NLP), for the prediction of dynamic evolution of lithium dendrite growth. We utilize embedded dynamical systems as input sequences and predict Li deposition based on past time steps with stochastic initial conditions. The results obtained from both models yield notable consistency with those from numerical models. While further efforts are required to delve deeper into the application of deep learning in PFM, our findings propose an alternative platform for exploring phase-field of Li-dendritic morphology.

Point defects in 2D materials are driving their opto-electronic performance. Color centers in 2D materials have been for instance, of interest for quantum sensing and networking applications. Most of the possible defects in 2D materials are however uncharacterized making defect design towards a specific application very challenging. On the other hand, first principles computations have made tremendous progresses in modeling the opto-electronic properties of point defects. Here, we report on a large computational database of point defects in WS_2. The database contains electronic structure data for more than 700 charged defects in WS_2 made by tungsten and sulfur substitutions from elements across the periodic table. We will show how to use this unique data set to search for new quantum defects presenting bright emission in the telecom and spin multiplicity. Importantly, we will report on the synthesis and scanning tunneling microscopy and spectroscopy of one of our quantum defect candidates; demonstrating good agreement with the theoretical high-throughput prediction and confirming the *in silico* discovery of an entirely new quantum defect with high potential for applications in WS_2.

10:45 AM EL01.01.02
Quantum Defects in 2D Transition Metal Dichalcogenides for THz-Technologies JingdaZhang, GokiEda and Su YingQuek; National University of Singapore, Singapore

Two-dimensional (2D) transition metal dichalcogenides (TMDs) offer significant advantages for optically addressable defect systems, making them a promising host platform for spin-triplet transition metal impurities with remarkably large zero-field splitting (ZFS) ranging from sub-THz to THz. These defects can serve as the building blocks for quantum information systems and can potentially function as single-photon THz emitters if controlled population inversion is achieved. We employ first-principles materials discovery based on Density Functional Theory

(DFT) to identify the most suitable spin-triplet defects in 2D TMDs, followed by constrained DFT combined with group theory analysis to demonstrate the excited-state dynamics and its ability to perform THz qubit operations. Additionally, we propose a novel theoretical design for THz quantum emitters driven by near-infrared excitation. Our research broadens the scope of advancements in quantum information science and lays a robust foundation for their integration with THz technologies.

11:00 AM EL01.01.03
Probing Te Vacancies as a Source of the Chiral Anomaly in Layered Dirac Materials $ZrTe_5$ and $HfTe_5$ElizabethPeterson, ChristopherLane and Jian-XinZhu; Los Alamos National Laboratory, United States

The layered Dirac materials $ZrTe_5$ and $HfTe_5$ have been the subject of vigorous investigation in recent years to experimentally observe signatures of quantum anomalies in their transport. These materials exhibit negative longitudinal magnetoresistance (NLMR)—a reduction in the resistivity when parallel electric and magnetic fields are applied to a sample—that is speculated to be direct evidence of an asymmetry in the number of left- and right-handed carriers, or a *chiral anomaly*. If this is indeed the case, these materials would serve as a tractable tabletop testbed to probe cosmological theories of quantum anomalies and symmetry breaking that arises when moving from classical to quantum field theories.

Despite a wealth of experimental evidence of NLMR in $ZrTe_5$ and $HfTe_5$, in addition to a temperature-induced change in the sign of the Hall coefficient, the microscopic mechanism driving this anomalous transport behavior remains an open question. Prior first-principles calculations have demonstrated that strain drives a series of transitions between topological states, from a strong topological insulating, to a Dirac semimetallic, to a weak topological insulating state, which explains the diversity of experimental reports of different topological states in these materials. Further, it has been experimentally observed that off-stoichiometric, Te-deficient $ZrTe_5$ exhibits a stronger NLMR than pristine stoichiometric $ZrTe_5$. To determine if these materials truly exhibit a chiral anomaly, a rigorous modeling of the transport properties of $ZrTe_5$ and $HfTe_5$ in the presence of Te vacancies is necessary.

In this work we determine the effect of Te vacancies on the electronic and transport properties of $ZrTe_5$ and $HfTe_5$. From a systematic series of first-principles density functional theory calculations we demonstrate the effect of Te vacancies both as a source of defect states and as an effective intrinsic source of strain. We further perform ab initio-based transport calculations in the strong magnetic field regime with an eye towards unravelling the origin of their anomalous transport properties and to probe their utility as testbeds for the observation of quantum anomalies.

Atomic Defects in 2D Materials for Quantum Technologies PankajK. Jha; Syracuse University, United States

Novel materials are the backbone of any technology. In this talk, I will discuss 2D materials that can be exfoliated down to a monolayer as well as grown layer by layer, with applications ranging from the generation of quantum light to the detection of single photons at visible and near-infrared wavelengths. In the first part of the talk, atomic defects (also known as color centers) in boron nitride as a promising candidate for single photon sources at room temperature will be discussed [1,2]. Experimental results ranging from the nanometric localization of hBN color centers [3] and sub-poissonian photon distribution to observing near-transformed limited lines will be presented [4]. I will conclude by sharing our near-term and long-term vision for hBN color centers interfaced with other 2D semi- and superconductors for sensing and photon detection applications.

Macroscopic-Monolayers Excitons and Polaritons HuiDeng; University of Michigan, United States

Transitional metal dichalcogenides (TMD) monolayers of composition MX2 (M =Mo,Wand X = S, Se) form a class of semiconductor with unique optical properties and unprecedented flexibility for engineering and integration. They exhibit many novel phenomena and promise new device concepts. However, TMD monolayers of high optical qualities have been limited to micron-sized flakes produced by low-throughput and labor-intensive processes, whereas large-area films are often affected by surface defects and large inhomogeneity. We show a rapid and reliable method to synthesize multi-millimeter-sized TMD monolayers of uniform, high optical quality using 1-dodecanol encapsulation combined with gold-tape-assisted exfoliation [1]. We demonstrate the utility of our encapsulated monolayers by scalable integration with arrays of photonic crystal cavities with varying parameters, all forming polaritons with the same monolayer. We furthermore show the dependence of stimulated relaxation and long-range transport of the polaritons on the photonic crystal parameters.

Near-Field Imaging of Interlayer Exciton in Strained Van Der Waals Heterostructure SoyeongKwon, Jin MyungKim, Peiwen J.Ma, WeilinGuan and SungWooNam; University of California, Irvine, United States

Recent discoveries on atomically thin Van der Waals materials have suggested new strategies for optoelectronic devices with reduced dimensionality and high elastic modulus. In particular, transition metal dichalcogenides (TMDs) and their vertical heterostructures host in-plane and out-of-plane interlayer excitons which can be tailored through strain engineering. In this talk, we investigated the interface phenomena in uniaxially strained TMD heterostructure. We prepared $MoSe_2/WSe_2$ heterostructure on an elastomeric substrate with near zero twist angle and performed photoluminescence and reflectance measurements. We found the signature of interlayer excitons and compared their behaviors in unstrained and strained regions in far-field optical characterizations. Furthermore, near-field mapping and spectroscopic methods of photo-induced force microscopy enabled nanoscale analysis of interlayer exciton coupling controllable with the strain magnitude. These results suggest that strain-modulated electronic and optical properties of twisted TMD/TMD heterostructures will be utilized for modifying interlayer exciton trapping and diffusion behaviors.

2:15 PM EL01.02.03
How to Improve the Luminescence and Valley Polarization Properties of Large-Area Monolayer MoS_2 Films Grown by Chemical Vapor Deposition?PoulabChakrabarti[1], FaihaMujeeb[2] and SubhabrataDhar[2]; [1]University of Maryland, United States; [2]Indian Institute of Technology Bombay, India

The development of future valley-based electronics or valleytronics requires a high degree of valley polarization (VP) in large area monolayer (1L)-MoS_2. Though it is possible to synthesize 1L-MoS_2 films with large area coverage, VP property of as-grown films is found to be very poor. Here, using temperature dependent photoluminescence (PL), polarization resolved PL and Raman spectroscopy, we investigate the effect of in situ vacuum annealing as well as the relaxation of strain on the luminescence and the VP properties of large area single layer MoS_2 films grown on *c*-sapphire and SiO_2/Si substrates by a microcavity based chemical vapor deposition (CVD) technique. The study shows that the strain as well as the physisorption of air molecules at the sulfur vacancy (V_S) sites play key roles in governing the optical quality of CVD grown 1L-MoS_2. Removal of air molecules from the V_S sites enhances the relative strength of the A-exciton/trion transition as compared to the broad defect luminescence (DL) band arising from those defects at low temperatures. It has also been found that such removal helps in improving the VP property of the film. Relaxation of biaxial tensile strain, which has been achieved by post growth transferring of 1L-MoS_2 film from the sapphire to a SiO_2/Si substrate by a polystyrene

assisted transfer process, is also found to be helpful to get back the high polarization character (~80%) of the K-valleys. The study further shows that the transfer process not only facilitates the removal of physisorbed air molecules from the V_S sites but also puts in place a long-lasting capping layer on 1L-MoS_2 that shields the film from reacting with air and hence enhances the relative yield of A-exciton/trion transition by suppressing the sub-bandgap DL transition. The study thus creates an opportunity to use CVD grown large area 1L-MoS_2 for the development of optoelectronic as well as valleytronic devices for practical applications for the future.

2:30 PM *EL01.02.04
Light Scattering and Emission from Hetero-Structures AndreaC. Ferrari; University of Cambridge, United Kingdom

Heterostructures based on layers of atomic crystals have a number of properties often unique and very different from those of their individual constituents and of their three dimensional counterparts. The combinations of such crystals in stacks can be used to design the functionalities of such heterostructures. I will show how Raman spectroscopy can be used to fingerprint such heterostructures, and how these can be exploited in novel light emitting devices, such as single photon emitters, and tuneable light emitting diodes

Single Photon Emitters in 2D Materials BerendT. Jonker and Hsun JenJ. Chuang; Naval Research Laboratory, United States

Single photon emitters (SPEs), or quantum emitters, are key components in a wide range of nascent quantum-based technologies. A solid state host offers many advantages for realization of a functional system, but creation and placement of SPEs are difficult to control. We describe here a novel paradigm for encoding strain into 2D materials to create and deterministically place SPEs in arbitrary locations with nanometer-scale precision [1]. We demonstrate the direct writing of SPEs in monolayer WSe2 using an atomic force microscope nano-indentation process. This quantum calligraphy allows deterministic placement and real time design of arbitrary patterns of SPEs for facile coupling with photonic waveguides, cavities and plasmonic structures. Because monolayer WSe2 is a direct gap semiconductor, SPE emission at a given wavelength is often intermixed with classical light resulting from conventional excitonic recombination, reducing the purity of the quantum emission as quantified by the second order autocorrelation function g(2)(t=0). We show that this undesirable classical emission, arising primarily from defect bound excitonic processes, can be significantly suppressed by electrostatic gating [2] or incorporating the WSe2 layer in a simple van der Waals heterostructure [3]. Suppression of this classical emission allows a more accurate assessment of the quantum emission character, and results in values of g(2) as low as 0.07 at low temperature. In addition, the SPE intensity at a given wavelength can be strongly modulated by changing the polarity of the gate bias, a feature of technological importance for practical applications. Initial results for SPEs in hBN will also be summarized, time permitting.

Defect Formation in Two-Dimensional Carbon-Doped Hexagonal Boron Nitride Tsz WingTang, HongweiLiu, YuyinLi, JunWang and ZhengtangLuo; Hong Kong University of Science and Technology, China

Tsz Wing Tang, Hongwei Liu, Yuyin Li, Jun Wang, and Zhengtang Luo
[1]Department of Chemical and Biological Engineering, the Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong, 999077, P.R. China

Visible-range single photon emitters (SPEs) from monolayer hexagonal boron nitride has demonstrated exceptional optical performance as a candidate for quantum optical technology application. However, the controllability of the carbon defect engineering in hBN has remained elusive, including the unadjustable SPE density, unconfined wavelength, and low uniform yield. Thus, the integration into on-chip quantum devices has suffered. Here, by precisely controlling the carbon incorporation via diffusion from molten copper during chemical vapor deposition (CVD) growth, we demonstrate a strategy to engineer the defect density in hBN, and achieve high uniform SPEs with confined emission wavelengths in hBN. By controlling the carbon diffusion rate, we observed an increase in carbon doping level and provided evidence for achieving high-yield uniform single photon emitters in hBN down to monolayer limit. Our method enables the density of SPE creation to become adjustable, from hBN monolayer samples, with high uniformity and confined wavelength. This method stimulates a significant step forward to integrating advanced two-dimensional (2D) material engineering into on-chip quantum devices.

The authors acknowledge the support from RGC (16304421).

Defect systems with in-gap electronic states are of high interest in atomic-scale photon emission applications with use in, e.g., quantum sensing and quantum networks. We investigate a two-dimensional material system that is treated within an ultrahigh vacuum environment to produce dense regions of chalcogen defectivity [1], and subsequently dope the system with a transition metal of interest that has been selected for its theoretically predicted optical transition and strong transition dipole moment. The chalcogen-substituted defect is formed at the atomic scale via tip-induced diffusion and subsequently visualized with scanning tunnelling microscopy. Scanning tunnelling spectroscopy, collected in an autonomous fashion using Gaussian process regression techniques [2], reveals anticipated in-gap states that are further verified with differential conductance maps paired with simulations obtained by density functional theory. High-throughput defect screening enables the selection of a handful of promising candidates, where the fabrication and investigation of one of these systems is shown to be experimentally obtainable.

Integrated Quantum Photonics with 2D Materials GalanMoody, KamyarParto, MichaelChoquer and SahilPatel; University of California, Santa Barbara, United States

Optically active defects in 2D materials, such as hexagonal boron nitride and transition metal dichalcogenides, are an attractive class of quantum light emitters with high brightness, room-temperature operation, and tunability with external strain and electric fields. In this presentation, I'll introduce this field and discuss recent progress and challenges in engineering 2D quantum emitter properties through photonic, optoelectronic, and optomechanical device integration. I'll present exciting results from my group in which we have engineered arrays of 2D emitters, integrated them with dielectric metasurfaces and silicon nitride photonic resonators for bright emission, and achieved high-speed modulation using optomechanical resonators based on surface acoustic waves. I'll conclude with an outlook on the future of 2D materials for quantum information science and technologies, including challenges and opportunities for the community.

SESSION EL01.04: Imaging Strain and Defects in 2D Materials

Using Four-Dimensional Scanning Transmission Electron Microscopy to Determine the Strain Profiles and Thermal Expansion Coefficient of Polycrystalline Epitaxial WSe_2TheresaM. Kucinski and MichaelT. Pettes; Los Alamos National Laboratory, United States

Thermal transport properties can be greatly impacted by the presence of grain boundaries and interfaces in two-dimensional (2D) materials. Previous techniques for determining the thermal expansion coefficient of 2D materials lacked the necessary spatial resolution in temperature measurements. We present a nanoscale approach to overcome this obstacle using Four-Dimensional Scanning Transmission Electron Microscopy (4D-STEM) and analysis by local statistical quantification of crystallographic parameters to determine the thermal expansion coefficient for epitaxial WSe_2 (2D material). From this approach, we determined the localized structural parameters as a function of temperature with high precision by analyzing the histogram of peak positions in a virtual peak profile. Experimentally, WSe_2 was heated through a temperature range (18ºC to 564ºC) using 4D-STEM to observe temperature-induced structural changes to WSe_2 which can be performed without additional alterations or destruction to the sample. From this analysis methodology, we determined lattice parameters with sub-picometer accuracy, microstrain, and coherent crystalline domains, (related to the sample thickness). The robustness of combining 4D-STEM measurements with quantitative structural analysis for 2D materials is illustrated by the direct determination of thermal expansion coefficients for epitaxial WSe_2.

Probing Spatiotemporal Modulation of Strain in Van Der Waals Materials YichaoZhang; University of Illinois Urbana-Champaign, United States

Transmission electron microscopy presents a unique opportunity to investigate the modulation of strain in both space and time. In this talk, I will discuss our electron-microscopy based methods for studying the impact of atomic- to nanoscale strain and defects on the properties of van der Waals materials. We utilize ultrafast electron microscopy to spatially map the nanoscale softening of vibrational modes near crystal step edges in response to strain induced by in situ laser excitation. This effective bond-stiffness reduction arises from both the modified force field at the step edge and the ultrafast anisotropic expansion in the layer stacking direction, as verified by our finite-element model. Additionally, we report a novel, simple technique for strain patterning in 2D materials using amorphous, holey silicon nitride substrates with periodic surface topography. The formation of regularly undulating tessellation patterns manifests as diffraction-contrast patterns. We measure up to 2% isotropic, tensile strain in the freestanding regions in the 2D flakes. Atomistic simulations reveal that the 3D elastic deformation is driven by interactions between the 2D crystal and the underlying substrate. Our results highlight the remarkable sensitivity of electron-imaging methods in probing the effects of atomic- to nanoscale heterogeneous strain and defects that influence the overall material properties and functionalities.

9:15 AM EL01.04.03
Atomic Defect Measurement by Lateral Force Microscopy YuchengYang[1], KaikuiXu[1], LukeHoltzman[2], KristynaYang[1], JamesHone[2], KatayunBarmak[2] and MatthewR. Rosenberger[1]; [1]University of Notre Dame, United States; [2]Columbia University, United States

Defects in two-dimensional (2D) materials impact important material properties, such as doping in semiconductor and localized quantum emission in semiconductors and insulators. A routine defect measurement technique is critical for understanding defect-property relationships and therefore essential for optimizing material performance. However, progress in understanding these critical relationships is hindered by the limitation of the existing defect characterization techniques. The existing techniques, such as conductive atomic force microscopy (CAFM) and scanning tunneling microscopy, cannot distinguish the out-of-plane defect location and require an electrically conductive sample for defect measurement in 2D materials without introducing additional defects. Here, for the first time, we demonstrate that lateral force microscopy (LFM) in ambient conditions can observe atomic defects in 2D materials. We improve the sensitivity of LFM through the consideration of cantilever mechanics and demonstrate the importance of minimizing tip-sample contact area for defect measurements. The defects observed with LFM are confirmed to be atomic defects based on a direct comparison of LFM with CAFM. Based on the Prandtl-Tomlinson model, LFM only interacts with the material surface. Thus, by comparing directly with CAFM defect measurement at the same region on $MoSe_2$, we found that the surface selenide site defects are conductive defects. We also show defect measurements on other transition metal dichalcogenides, WSe_2 and MoS_2. Due to the purely mechanical nature of LFM, LFM does not require a conductive pathway for defect measurement. Thus, LFM can also observe atomic defects on insulating 2D materials, such as hexagonal boron nitride (hBN). We show that LFM can differentiate high-quality hBN and low-quality hBN by measuring the intrinsic defect density in the hBN. To further establish the utility of LFM defect measurements, we introduced post-growth defects by annealing hBN in air and showed that increasing annealing temperature increases surface defect density in hBN exponentially, consistent with the Arrhenius equation. Our demonstration of a purely mechanical defect characterization technique not only provides new insight into the defects in electrically conductive materials but also enables routine defect-property determination for insulating materials. This new defect characterization technique will accelerate materials research in defect engineering.

9:30 AM *EL01.04.04
Imaging 2D Moirés at Deep Sub-Angstrom Resolution KaylaX. Nguyen[1,2], Chia-HaoLee[1], YiJiang[3], YichaoZhang[1], PritiKharel[1], YueZhang[1], ArendM. van der Zande[1] and PinshaneY. Huang[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Oregon, United States; [3]Argonne National Laboratory, United States

A challenge in the study of 2D moirés is that they are highly inhomogenous across length scales, containing defects and strains that vary from site-to-site. In addition, solving the atomic structure is challenging because atoms in the moiré are separated by sub-angstrom distances in projection images, thus requiring deep sub-angstrom spatial resolution. While electron ptychography has demonstrated access to the deep sub-angstrom regime, this technique has required expensive, delicate aberration-corrected electron microscopes. Here, we demonstrate sub-angstrom resolution electron ptychography of 2D materials in an uncorrected scanning transmission electron microscopy (STEM). We demonstrate the power and flexibility of electron ptychography by showing that it can achieve sub-angstrom resolution across a broad range of microscope conditions to uncover details of the moiré structure. Counterintuitively, we find that geometric aberrations actually benefit electron ptychography because they produce structured beams that are more dose-efficient for ptychography than focused, aberration-free probes. This work should dramatically expand the ability to study 2D moirés with atomic precision.

10:30 AM *EL01.04.05
Unraveling the Impact of Adventitious Carbon on Pit Formation in Monolayer MoS2 XiaolinZheng; Stanford University, United States

Forming pits on molybdenum disulfide (MoS_2) monolayers is desirable for (opto)electrical, catalytic, and biological applications. Thermal oxidation is a potentially scalable method to generate pits on monolayer MoS_2, and pits are assumed to preferentially form around undercoordinated sites, such as sulfur vacancies. However, studies on the thermal oxidation of MoS_2 monolayers have not considered the effect of adventitious carbon (C) which is ubiquitous and interacts with oxygen at elevated temperatures. Herein, the effect of adventitious C on the pit formation of MoS_2 monolayers during thermal oxidation is studied. The in situ environmental transmission electron microscopy measurements herein show that pit formation is preferentially initiated at the interface between adventitious C nanoparticles and MoS_2, rather than only sulfur vacancies. Density functional theory (DFT) calculations reveal that the C/MoS_2 interface favors the sequential adsorption of oxygen atoms with facile kinetics. These results illustrate the important role of adventitious C on pit formation on monolayer MoS_2.

11:00 AM EL01.04.06
Conductive Atomic Force Microscopy as a Routine, Fast and Reliable Method for 2D Material Atomic Defect Characterization KaikuiXu[1], MatthewR. Rosenberger[1], MadisenHolbrook[2], JamesHone[2], KatayunBarmak[2], LukeHoltzman[2] and Abhay NarayanPasupathy[2]; [1]University of Notre Dame, United States; [2]Columbia University, United States

Defects are very influential on material behavior in terms of mechanical, electrical, optical and chemical properties. In two-dimensional materials, defects are inevitable because of impurities[1], thermodynamic equilibrium, or non-optimized growth conditions. Previous research has revealed that defects could act as carrier donors, recombination centers, or electrochemical reaction sites, thus inducing n-type doping, trap states, or increasing the material chemical activity[2]. However, the quantitative effect of defects on material behavior remains insufficiently studied, largely because we lack a simple and routine method to characterize the defect densities. The common defect detection methods, such as Transmission Electron Microscopy (TEM), Scanning Tunneling Microscopy (STM), and Raman Spectroscopy, have practical disadvantages rendering them not ideal for routine defect quantification. Specifically,

TEM requires complicated sample preparation, and frequently induces additional defects during the detection process itself, causing complex interpretation of experimental results. STM relies on strict environmental conditions and time-consuming experiments, making it difficult to operate quickly on different samples. Raman spectroscopy does not locate atomic defects accurately at the nanoscale, and is not sensitive to defects at low density levels.

Here, we show that conductive atomic force microscopy (CAFM) is a swift, simple, reliable and routine technique to characterize atomic defects. CAFM operates with ease under ambient environment, and does not require complicated sample preparation. We conduct CAFM measurement on $MoSe_2$ and WSe_2 bulk samples, finding that the sample electrical bias significantly influences defect appearance. Optimizing the sample bias enables CAFM to differentiate multiple types of atomic defects by their distinct appearance. We also show that CAFM can locate defects with true atomic resolution. To show the reliability of CAFM, we conduct both STM and CAFM defect measurement on $MoSe_2$ and WSe_2 crystals from the same growth batch, i.e., crystals with the same growth conditions, and compare the results to each other. We show that both CAFM and STM consistently reveal similar atomic defects. Also, both techniques reveal an additional kind of 10-nm-scale "large" defect. Such consistency between CAFM and STM indicates that the two techniques reveal defects in a similar fashion. Quantitatively, to determine the precision of our density results, we use a statistic model applying Poisson distribution to defect locations because the defect locations are random, which is confirmed by Moran's Index based on the locations of more than 2000 defects measured by CAFM in a 250nm×240nm area. As a result, the density results of atomic defects and 10-nm-scale "large" defects obtained by CAFM and STM match with each other closely. Therefore, the qualitative (defect type differentiation) and quantitative (density results) consistency between CAFM and STM on TMD crystals from the same growth batch shows that CAFM is a reliable, accurate and precise technique for detecting defects in two-dimensional materials. Realization of a routine defect detection method opens many opportunities for exploring the influence of defects. The related fields can range from material science to electronics, chemical engineering and beyond.

Imaging and Probing Point Defects in Gate-Tunable Two-Dimensional Semiconductors via Scanning Tunneling Microscopy TianhuiZhu, CarlosGonzalez, KejunLi, QirongYao, ZhehaoGe, YuanPing, AimingYan and JairoVelasco Jr.; University of California, Santa Cruz, United States

With the recent advances in two-dimensional (2D) materials, semiconducting 2D transition metal dichalcogenides (TMDs) have shown potential as the next generation nanoelectronics to keep up with Moore's law. Since the performance of semiconductor devices can be greatly affected by defects and gating, the ability to control defects in these 2D materials in a gate tunable device becomes vital. The species and density of defects depend on the growth method as well as the postgrowth device fabrication processes. In this talk, I will present atomically resolved images of the defects and show how their local electronic properties are modulated by the application of a gate electric field. Chemical vapor deposition (CVD) is used in this study to reliably produce 2D TMD monolayers while allowing for defect engineering. We use a low-temperature scanning tunneling microscope (STM) to study the point defects in a CVD-grown 2D TMD monolayer that is implemented in a heterostructure with gate tunability. First, the identification of the defects is realized by combining scanning probe microscopy with density functional theory (DFT) calculations. Next, the effect of a gate electric field is explored and compared to DFT modeling. Our results will provide guidance on future defect engineering in gate-tunable 2D TMD based devices.

This research is supported by the Gordon and Betty Moore Foundation award #10.37807/GBMF11569.

11:30 AM EL01.04.08

Ambient Atom to Bond Spectroscopy of Twinned Graphite Grain Boundary via STM NirjharSarkar[1,2], PrabhakarBandaru[1] and RobertDynes[1]; [1]University of California, San Diego, United States; [2]University of California, Riverside, United States

Practical devices in semiconductor industry operate under ambient conditions and are progressing towards low-dimensional dirac materials like graphene and carbon nanotubes (CNTs). The dimensional reduction from bulk to 1D introduces amplified quantum effects from edges and defects affecting device performance. In this work, we achieve finest resolution under ambient conditions to probe the mechanical strength and the electronic local density of states (LDOS) of individual atoms and bonds of the most common grain boundary (GB) favorably grown in graphene/graphite using scanning tunneling microscopy (STM). We show how the role of bias dependent flat band states contributes toward resolving the typical STM imaging clarity issues with defects. Surface elastic deformation due to tip-proximity reveals the comparable inter-layer van der Waals (VDW) strength of GB and grains.

11:45 AM EL01.04.09

Dopant Identification of Nitrogen-Doped Graphene on Pt (111) via Simultaneous Atomic Force Microscopy and Scanning Tunneling Microscopy TaegeunYoon[1], HyunminKang[1], Jeong AhSeo[2], AndreasHeinrich[2], Hyo WonKim[3], JungseokChae[2] and Young JaeSong[1]; [1]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of); [2]Ewha Womans University, Korea (the Republic of); [3]Samsung Advanced Institute of Technology, Korea (the Republic of)

Nitrogen (N) doped graphene has been gained prominence as a candidate for catalysis, electronic devices or sensors by keeping the advantages of significant properties of graphene along with additional physical or chemical features. The atomic configurations of the dopant, however, show numerous variations with each doping type manifesting distinct properties and features. Hence, identifying and controlling the bonding arrangements is highly crucial for further applications. In this work, we present a schematic distinguishment on two specific nitrogen defects; Graphitic-N and pyridinic-N. N doped graphene was grown on a Pt (111) surface using pyridine precursors, followed by low-energy electron diffraction (LEED) and X-ray photoelectron spectroscopy (XPS) for confirmation on graphene growth in a larger scale. Atomically resolved simultaneous scanning tunneling microscopy (STM) and atomic force microscopy (AFM) *via* qPlus sensor depicted complementary distinctions on the atomic and electronic structures between both defects. Electronic structure near graphitic-N site showed noticeable bulge with a vacancy-like morphology or a more distinctive protrusion in the center, while $\triangle$f image showed little difference from pristine graphene. Pyridinic-N, despite of its carbon-vacancy-based structure, did not showed typical vacancy-like electronic topography, with a characteristic protrusive configuration in $\triangle$f image. Corresponding theoretical calculations *via* density functional theory (DFT) further verified the experimental data. In addition to the discernment on the two defects, effects of Pt substrate and a plausible growth mechanism are suggested, through which the numerical proportions of the defects and dissociated pyridine precursors can be explained. This study will provide further in-depth understanding for application-driven research for graphene devices with controlled defects.

SESSION EL01.05: Strain Engineering the Quantum Behavior of 2D Materials

1:30 PM *EL01.05.01

Investigating Quantum Materials with *In-Situ* Strain JohannaPalmstrom; Los Alamos National Laboratory, United States

Electronic material properties are closely linked to the properties of the underlying crystal lattice. For instance, ferroelectric materials break spatial inversion symmetry and ferromagnetic materials break time reversal symmetry. With strain, i.e., deformations of the crystal structure, we can deform the lattice and have large effects on the electronic behavior of materials. This coupling between the electronic behavior and strain can be probed with measurements of the elastoresistivity, i.e., the relation between strain a material experiences and the induced resistivity change. Recently it has been shown that *in-situ* tunable strain is an effective knob to drive a topological phase transition by tuning the band gap and forcing a band crossing in the transition metal pentatellurides, $ZrTe_5$ and $HfTe_5$. In this talk, I will show how strain can be used as a conjugate field for electronic order in the prototypical electron doped iron pnictide superconductor, $Ba(Fe_{1-x}Co_x)_2As_2$ and as a tuning parameter for the topologically driven anomalous Hall effect in the Weyl semimetal Mn_3Sn. I will also discuss applications to 2D systems and preliminary *in-situ* strain measurements paired with large magnetic fields in the transition metal pentatellurides.

2:00 PM EL01.05.02

Curvature-Enhanced Localised Emission from Dark States in Wrinkled Monolayer WSe_2 at Room Temperature SebastianWood, FilipeRichheimer, TomVincent, VivianTong, AlessandroCatanzaro, YamengCao, OlgaKazakova and FernandoA. Castro; National Physical Laboratory, United Kingdom

Localised emission from defect states in monolayer transition metal dichalcogenides is of great interest for optoelectronic and quantum device applications. Recent progress towards high

temperature localised emission relies on the application of strain to induce highly confined excitonic states. In this study we consider freestanding wrinkles of monolayer tungsten diselenide (WSe_2), which exhibit room temperature emission from states up to 150 meV below the main A-exciton emission of flat material. Using tip-enhanced optical spectroscopy we are able to probe this emission with nanoscale resolution revealing that it arises from the wrinkle apex and has an out-of-plane transition dipole. The Raman scattering and photoluminescence spectra show no evidence of substantial in-plane strain associated with the localised emission, this is supported by strain calculations based on simple materials engineering considerations. Our results cannot be accommodated within the dominant paradigm in published literature based on strain-localised emission and/or exciton funnelling. Rather, we propose that curvature, instead of in-plane strain, of the 1L WSe_2 offers a more appropriate means of understanding these results.

Whilst it has been shown elsewhere that in-plane tensile strain results in narrowing of the WSe_2 bandgap and is associated with highly localised emission, the distinction between in-plane strain and bending strain has not been adequately explored. The case of free-standing wrinkles is an instructive example since such buckling delaminations form under compressive strain, where the out-of-plane deflection acts to minimise the in-plane strain. This is supported by a simple evaluation of the local strain based on nanoscale surface topography measurements. Our tip-enhanced spectroscopy instrument uses side-illumination to probe the sample using out-of-plane optical polarisation so to explain our observations we propose the existence of a manifold of spin-forbidden excitonic states that we are able to access as a result of local symmetry breaking due to geometric curvature.

The results of this study suggest curvature engineering of 1L WSe_2 as an effective route towards localised emission at high temperature, and an alternative strategy to the pursuit of increasing in-plane stretching strain to confine excitons. The spectral features we report at room temperature show energetic confinement comparable with reports of single photon emission in 1L WSe_2 so photon antibunching experiments are an interesting area for future study. It is also significant that the emission we report here originates from optical coupling to spin-forbidden dark states, which are typically long-lived and therefore of potential interest for quantum information technologies. The out-of-plane transition dipoles for this emission are also relevant for many proposed applications of TMDs for plasmonic circuits and on-chip photonic devices, which require the coupling of light into ‘horizontal’ waveguides. This is in contrast to the typically-observed free bright excitons in TMDs, which have in-plane dipoles that efficiently couple light in/out of thin film devices structures in a ‘vertical’ direction. Furthermore, the localised emission we observe exhibits semi-continuous spatial variation in the spectral positions of the peaks so we speculate that it may be possible to tune the emission through the local curvature of the 1L WSe_2.

2:15 PM EL01.05.03
Localized Excitons in Monolayer WSe_2 on Nano-Roughness Glass Substrates YaraGalvão Gobato[1], CaiqueSerati de Brito[1], CesarRibahi[1], D.F. Franco[2], M.Nalin[2], B.Rosa[3], StephanReitzenstein[3], AndreyChaves[4] and IngridBarcelos[5]; [1]Universidade Federal de São Carlos, Brazil; [2]Institute of Chemistry, São Paulo State University—UNESP, Brazil; [3]Technische Universität Berlin, Germany; [4]Universidade Federal do Ceará, Brazil; [5]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil

Two-dimensional (2D) transition metal dichalcogenides (TMDs) materials are attractive systems with strong spin-valley coupling and excitonic effects. Nano-strain and defects engineering in TMDs play an important role in controlling their optical properties, particularly for generating atomic defect-based single-photon emitters, which are the platform to develop on-chip integrated single-photon sources for quantum information technology[1].
Here, we have investigated optical and magneto-optical properties of a monolayer WSe_2 on Tb^{3+}- borogermanate glasses with different Tb^{3+} concentrations. Our results show that by using a simple method of a lithography-free approach, it is possible to generate nano-roughness glasses to localize excitons by local strain in a monolayer WSe_2. Remarkably, the photoluminescence (PL) reveal several stable sharp doublet emissions with small line jittering effects and with typical fine-structure splittings of ≈ 760 μeV from the same quantum dot (QD)-like emitters which are associated with an anisotropic electron–hole exchange interaction. In addition, the correlation function was measured for some emission lines and displayed a clearly effect of photon antibunching. In order to investigate in more detail the nature of these emission peaks, we have also measured circularly polarization-resolved PL under magnetic field (Faraday and Voigt configurations). Under perpendicular magnetic field, the extracted g-factor values for these PL peaks are ∼8.4–9.8. Under parallel magnetic field, a clear red-shift for several emission peaks was observed for both circularly polarized PL detections. In general, our results suggest that nano-rough engineering on glass substrates is a promising tool for exploring single emitters for possible integration with photonics systems in quantum information technology[1].

2:30 PM *EL01.05.04
Strain Engineering of Proximity Interaction for Controlling Polarization of Quantum Light Emitters HanHtoon; Los Alamos National Laboratory, United States

An ability to control the polarization of the single photons generated by the quantum light emitters holds the key to the realization of non-reciprocal single-photon devices, deterministic spin-photon interfaces, and complex quantum networks. To date, such control is usually achieved via coupling of the quantum emitters to the complex photonic/meta-structures. Achieving circularly polarized light emission is significantly more difficult than achieving linearly polarized light emission as it often requires more sophisticated structures, injection of spin-polarized carriers/excitons, or application of high magnetic fields. “Proximity effects” – the class of phenomena by which an atomically-thin material borrows properties of an adjacent material (such as magnetism) via quantum mechanical interactions – has recently been explored to achieve this highly desired polarization control. By coupling transition metal dichalcogenides with various bulk and 2D magnetic materials, exciting effects such as strong enhancement of valley Zeeman splitting and spin-dependent charge transfer have been demonstrated. However, chiral light emission without spin-polarized carrier/exciton injection at zero magnetic field remains elusive to date. Here in this talk, we will first demonstrate that chiral quantum light sources with a high degree of circular polarization (>0.9) and 80% single-photon purity *can* be realized by strain-engineering the WSe_2\$NiPS_3$ heterostructures with nanoscale indentations. Through state of art scanning diamond NV microscopy experiments and temperature-dependent magneto-photoluminescence studies, we show that the chiral quantum light emission arises from magnetic proximity interactions between localized excitons in the WSe_2 monolayer and out-of-plane magnetization of AFM defects in $NiPS_3$, both of which are co-localized by the strain field arising from the nanoscale indentations. Interestingly, a similar chiral localized excitonic emission is also observed in our more recent experiment performed on WSe_2/$MnPS_3$ and WSe_2/$FePS_3$ heterostructure with nano-indents. Furthermore, we demonstrated that the application of the same strain engineering approach (i.e nanoindentation) to WSe_2/$CrPS_4$ heterostructure lead to the emission of linearly polarized quantum light reflecting the magnetic order of $CrPS_4$. These observations reveal that local strain engineering can be utilized not only to create quantum emitters but also to manipulate local proximity interaction for control of their PL polarization.

The Interlayer Interaction of Rotated Graphene Breaks the Barrier for Intense Lithium Intercalation Resulting in Li_2C_2 Formation. TerezaM. Paronyan; Hexalayer LLC, United States

The demand for Li-ion rechargeable batteries exponentially grows due to their ability to restore the charge and provide consistency in the voltage in long-term cycling. Graphitic Carbon materials are successfully used as an active anode material in Li-ion Batteries (LIB) due to the sp^2 electronic configuration of hexagonal Carbon. They remain the safest, most cost-efficient, and environmentally stable anode material providing high-power density and energy in long-term cycling compared to any other active materials. Besides many advances, graphitic carbon faces the challenge of intercalating larger amounts of Lithium due to prohibited Van-der Waals interlayer forces that limit the capacity of those batteries.
HeXalayer develops a new type of incommensurate layered graphene consisting of over a 5° angle of closely packed rotated layers that serves as an advanced active anode for LIBs. The unique structural and binding features of pristine layered graphene will be discussed as beneficial for extreme Lithium diffusion.
The advanced anodes perform up to 2,100 mAh/g reversible capacity as evidence of Li_2C_2 formation once initial graphene layers are freely stacked with an average interspace distance of 3.32-3.45Å. The study battery evaluation shows the feasibility of this graphene use as an advanced anode for the next generation of lightweight, fast charging powerful batteries.

4:00 PM EL01.06.02
Exploring Moire Lattice Reconstruction using a Tight Binding Derived Force Model DanielPalmer, NaheedFerduous, GabrielBrown, TawfiqurRakib, KittithatKrongchon, LucasWagner and HarleyJohnson; University of Illinois at Urbana-Champaign, United States

Lattice reconstruction in moire materials has proven to be difficult to study from first principles given the relatively large system sizes and strong electron correlation. While classical potentials are computationally tractable, these models lack an explicit dependence on electronic degrees of freedom. To overcome these obstacles, we present one orbital and four orbital semi-empirical total energy tight-binding parameterizations for twisted Bilayer Graphene (tBLG). To approximately account for strong electron correlation, we fit the interlayer pairwise correction energy to diffusion Quantum Monte Carlo (QMC) total energy data for a range of disregistries and interlayer separations. Our method of parameterization is generally transferable to other 2D heterostructures. The resulting parameterization enables large scale calculations, incorporating both electronic and lattice degrees of freedom with total energies that are more accurate than DFT-fit models. The models are used to relax structures of tBLG with twist angles as low as 0.88 degrees and systems containing as many as 16,876 atoms. At this scale, the calculation is orders of magnitude faster than recent density functional theory results. We find significant differences in the resulting relaxed structures relative to structures relaxed using empirical potentials. The differences in the relaxed geometries result in a broadened and shifted flat band magic angle regime. We also show that the magic angle regime size and location depend on the method of relaxation.

4:15 PM EL01.06.03
Deep Elastic Strain Engineering of Free-Standing 2D Materials and Twisted Van Der Waals Heterostructures YingHan[1,2], KeCao[3], ShizheFeng[4], ZhipingXu[4] and YangLu[1,5]; [1]City University of Hong Kong, China; [2]Pennsilyvinia State University, United States; [3]Xidian University, China; [4]Tsinghua University, China; [5]The University of Hong Kong, China

Due to the outstanding physical and chemical properties, two-dimensional (2D) materials, such as graphene and hexagonal boron nitride (hBN) hold great promise for a variety of mechanical, electrical, optical and many other functional applications. Van der Waals (vdW) heterostructures make 2D flexible electronics device possible with unique properties, especially twisted vdW heterostructures. Furthermore, applying mechanical strain to 2D material could lead to unusual and tunable physical properties for unpreceded strain engineering applications. However, due to the experimental limitation, introducing large uniform strain into 2D materials remains a great challenge. Recently, by developing a protocol for sample transfer, shaping and straining, we report the elastic properties and stretchability of free-standing single-crystalline monolayer graphene grown by chemical vapor deposition [1], with sample-wide elastic strain up to ~6% and Young's modulus close to theoretical value ~1TPa. Similarly, we demonstrate that large elastic deformation can be also achieved in free-standing h-BN monolayers [2], twisted bilayer graphene[3] and other emerging twisted vdW structures, allowing for unprecedented functional 2D material applications. Our results show that graphene, h-BN, twisted bilayer graphene and other emerging twisted vdW structures have outstanding mechanical properties. The near ideal mechanical strength and resilience of 2D materials and van der Waals heterostructures reported here, as well as our uniform, reversible, dynamic strain controlling mechanism, would facilitate the practical elastic strain engineering (ESE) applications, as well as piezoelectric electronics and flexible electronic.

4:30 PM EL01.06.04
Electric Field Control of Interfacial Ferroelectric Switching in Twisted 2D Semiconductors Hung-ChangHsu[1], Hao-YuChen[1], Yi-HanLee[1], HsiangLee[1], Bo-HongWu[1], Yi-FengChen[1], Ming-YangLi[2] and Ya-PingChiu[1,1]; [1]National Taiwan University, Taiwan; [2]Taiwan Semiconductor Manufacturing Company, Taiwan

The stacking configuration of twisted 2D material plays a crucial role in determining their moiré electronic properties, such as strong correlation, quantum confinement, and ferroelectric behavior. Transitioning from one stacking configuration to another involves energy conversion, typically influenced by external interactions such as electric fields. In the case of a twisted-stacking transition metal dichalcogenide bilayer, there exist two commensurate domains with opposite interfacial ferroelectric polarizations. The atomic structure of the domain wall between these domains exhibits a strain gradient, which can respond to a vertical electric field through flexoelectric effects, thereby inducing a change in the stacking configuration. In this study, we demonstrate the ability to manipulate this domain wall by applying a local electric field using a scanning tunneling microscopy tip, thereby controlling the interfacial ferroelectric switching. This ability to control the stacking configuration of twisted 2D materials opens up possibilities for novel twist-stacked 2D devices that incorporate both structural and electronic moiré superlattices.

Reversibly Modifying The Structure of Graphite Moiré Domain Walls via STM-Tip Induced Deformations NirjharSarkar, PrabhakarBandaru and RobertDynes; University of California, San Diego, United States

Highly oriented pyrolytic graphite may be the only known monatomic crystal with the ability to host naturally formed moiré patterns on its cleaved surfaces, which are coherent over micrometer scales and with discrete sets of twist angles of fixed periodicity. Such an aspect is in marked contrast to twisted bilayer graphene and other multilayered systems, where the long-range coherence of the moiré is not easily maintained due to twist angle disorder. We investigate the electronic and mechanical response of coherent graphite moiré patterns through inducing external strain from scanning tunneling microscopy tip-induced deformation. Consequently, unique anisotropic mechanical characteristics are revealed. For example, a lateral widening of one-dimensional domain walls (DWs) bridging Bernal (ABA) and rhombohedral (ABC) stacking domains (A, B, and C refer to the atomic layer positioning), was indicated. Further, in situ tunneling spectroscopy as a function of the deformation indicated a tendency towards increased electrical conductance, which may be associated with a higher density of electronic states, and the consequent flattening of the electronic energy band dispersion. Such features were probed across the DWs, with implications for strain-induced electronic modulation of the moiré characteristics.

Mechanically Gated Transistor via Flexoelectric Engineering of Two-Dimensional Materials BoyuanHuang and JiangyuLi; Southern University of Science and Technology, China

Silicon-based field effect transistors (FETs) have underpinned the information revolution in the last 70 years, and there is a strong desire for new materials, devices and architectures that can help sustain the computing power in the age of big data and artificial intelligence. Inspired by the Piezo channels, we develop a mechanical gated transistor (MGT) abandoning electric gating altogether, achieving ON/OFF ratio over three orders of magnitude under a mechanical force of hundreds nN. The two-terminal device utilizes flexoelectric polarization induced by strain gradient, which modulates the carrier concentration in a Van der Waals (vdW) structure significantly, and it mimics Piezo channels for artificial tactile perception. This simple device concept can be easily adapted in a wide range of semiconducting materials, helping promoting the fusion between mechanics and electronics in a similar way as mechanobiology.

8:45 AM EL01.07.02
The Tensile Strain Effect of In_2Se_3 Ferroelectric-Semiconductor Field-Effect Transistor Fabricated on a PI Substrate TaebinLim, JunmiLee and JinJang; Kyung Hee University, Korea (the Republic of)

Recently, the ferroelectric-semiconductor field-effect transistor (FS-FET) has been attracting a lot of attention for its application as an artificial synapse in neuromorphic systems and next-generation memory chips. The presence of polarization states in the ferroelectric-semiconductor (FS) allows for the implementation of hysteresis without the need for functional materials for the gate insulator, such as electrolyte ion migration, charge trapping, or ferroelectric materials. This advantage makes it suitable for highly integrated chips, as high-quality amorphous gate insulators such as SiO_2 and Al_2O_3 can be used.
In_2Se_3 is a representative ferroelectric 2-dimensional material for semiconductors. It has a small electron effective mass (e*), resulting in high electron mobility. The α and γ phases of In_2Se_3 have been reported to have a non-symmetric structure and exhibit out-of-plane (OOP) and in-plane (IP) ferroelectricity, making them excellent candidates for FS-FET applications. In_2Se_3 exhibits great potential as a candidate for next-generation neuromorphic or memory chips.
However, in order to apply it to flexible and wearable devices, there is a need to study the effect of strain of two-dimensional In_2Se_3 layer with the FS-FET structure. Therefore, it is necessary

to develop techniques that allow for controllable application of strain to FS-FET and accurately measure its electrical characteristics.
In this work, we present an In_2Se_3 FS-FET fabricated on PI substrate. The In_2Se_3 layer consists of the γ phase, which exhibits ferroelectric characteristics. As a result, the fabricated In_2Se_3 FS-FET, even with a conventional SiO_2 gate insulator, shows a hysteresis window of 36.8 V (with ±40 V of gate voltage sweep range) in the transfer curve. In_2Se_3 FS-FET exhibits an on/off ratio of 10^5 in the transfer curve at V_{DS} = 1.0 V, demonstrating excellent electrical performance. Because it was fabricated on a flexible PI substrate, we can precisely apply tensile strain and measure its electrical characteristics. We applied tensile strain using cylindrical structures with radius of 1, 2, and 3 mm, and analyzed the variation in the transfer curve.
Our strategy for applying strain to the In_2Se_3 FS-FET can be a promising approach for studying the effect of strain on two-dimensional ferroelectric materials.

Anisotropic Electronic Transport in Strain Superlattices in Graphene PreethaSarkar[1], YingjieZhang[1], OnurTosun[2], PinshaneY. Huang[1], NarayanaAluru[1], MatthewGilbert[1] and NadyaMason[1]; [1]University of Illinois Urbana Champaign, United States; [2]Rice University, United States

Strain superlattices in two-dimensional van der Waals materials can modify the electronic band structure via valley-polarized pseudomagnetic fields. In this talk, we report low temperature charge transport measurements on a graphene strain superlattice (SL) generated by stacking graphene on a self-assembly of dielectric nanospheres (NS). Previously [1], strain-tunable dips were observed in the two-probe conductance of these graphene SLs, as a consequence of SL miniband effects. We now report observations of anisotropies in the Hall and non-local transport characteristics of these graphene-NS systems. This anisotropic transport behavior might indicate an underlying symmetry breaking and lifting of the valley degeneracy in these systems.

Enhanced Resistive Switching and Record Dielectric Breakdown of Defect Engineered hBN via Ammonia Incorporation AnkitS. Rao[1], Sumank. Mandal[1], MajidAhmadi[2], BartKooi[2], PavanNukala[1] and SrinivasanRaghavan[1]; [1]Indian Institute of Science, India; [2]University of Groningen, Netherlands

Multilayer hexagonal boron nitride (hBN) has been touted as a versatile material for electronic devices as it can be used as a capacitive layer for resistive random-access memory (RRAM) devices and as a dielectric substrate for two-dimensional (2D) semiconductor devices. The performance of these devices based on multilayer hBN are impacted by the defects incorporated when grown via chemical vapor deposition (CVD). Insights into the effect of defects on resistive switching characteristics and dielectric breakdown is essential in enhancing the performance. This work focuses on improving the switching properties of multilayer hBN by incorporating ammonia (NH_3) during the CVD process to regulate the nucleation density and grain size of hBN. By varying the partial pressure of NH_3, low nucleation density and high edge growth of hBN grain is achieved resulting in 4-order reduction in nucleation density and (x70) larger grain sizes for same growth times. The multilayer hBN obtained at these conditions by increasing the growth time is used to fabricate MIM (Ti/hBN/Cu) devices. When compared with hBN grown without NH3 at same conditions, the devices exhibit upto 4 orders reduction in read currents, 3 orders improvement in variability of current during endurance measurements, 2 orders of improvement in retention, switching energies in the range of fW, lower leakage paths and high current on/off ratios of 10^8. Also, the dielectric breakdown of multilayer hBN is impacted by the defects as they provide pathways for leakage. A post growth annealing (PGA) process at various NH3 partial pressures (pNH_3) is employed to modify the defect configurations and control the defect densities. The structural improvement of hBN results in drastic improvement in the breakdown field strength (V_{BD}) to a record high value of 13.1 MV/cm for a 2nm thick CVD hBN. The nature of this defect healing process is found to be thermodynamic in nature and reversible by reversal in the partial pressures of NH_3.

Bulging and Poking of 2D Materials NanshuLu; The University of Texas at Austin, United States

Bulging and poking of suspended thin films are widely used mechanical tests. They became particularly popular for characterizing atomically thin 2D materials, together with spontaneously formed nano-bubbles and nano-tents. The atomic thinness and smoothness of 2D materials pose new challenges to the bulging and indentation tests as well as models. Through scaling analysis and accurately solving the Föppl-von Kármán (FvK) theory, we unveil what sets the in-plane strains and work of adhesion in terms of their shape characteristics. Through a parent-satellite bubble system, we are able to uncover the transition from membrane theory to plate theory and from Griffith-type interface to cohesive-zone-type interface formed with the supporting substrate. With coarse-grained molecular dynamics (CGMD) simulations, we can reveal when continuum mechanics ultimately breaks down. Moreover, we find that recent indentation results on suspended 2D materials do not follow the well-known load-cubic-deflection relation that is widely accepted for linear elastic sheets. We identify a single dimensionless governing parameter—the sliding number—defined by comparing the sheet tension (that drives the slippage) with the interfacial traction (that resists the slippage). We also propose a more accurate load-deflection model for the extraction of 2D material modulus and its interfacial shear strength.

Study of Contact Metals to Transition Metal Dichalcogenides AlexanderL. Mazzoni[1], WendySarney[1], PatrickTaylor[1], MariaG. Sales[2], PeterLitwin[2], YangchenHe[3], JoshuaEickhoff[3], RobertBoyd[3], DanielA. Rhodes[3], StephenMcDonnell[2], SinaNajmaei[1] and MadanDubey[1]; [1]U.S. Army Research Laboratory, United States; [2]University of Virginia, United States; [3]University of Wisconsin–Madison, United States

Confinement in two-dimensional materials leads to unique properties, including near-room temperature quantum material characteristics and excitonic condensation in transition metal dichalcogenide (TMD) van der Waals layers. Exciting new materials-by-design strategies for the novel structural properties of TMDs allow for highly tunable stacks and twisted configurations. One challenge standing in the way of developing these materials into useful devices is the lack of low resistance ohmic contacts.

In metal-TMD contacts the Fermi level is usually pinned, resulting in a Schottky barrier that impedes the movement of electrons and limits device performance. A recent report discusses using the semimetal bismuth deposited by e-beam evaporation as a contact to MoS_2 [1]. The use of a semimetal contact changed the character of the metal induced gap states, raising the Fermi level into the conduction band for MoS_2 beneath the Bi contact. While they made a significant advancement toward the quantum limit in contact resistance to TMDs, using ultra high vacuum deposition techniques to deposit the metal, such as molecular beam epitaxy, could allow further control over the metal-TMD interface properties.

Our current research is working toward exceeding the state-of-the-art for 2D material contacts, focusing initially on WSe_2 with Bi contact layers deposited via molecular beam epitaxy. We will show this technique leads to a uniform Bi layer on silicon dioxide and WSe_2, in contrast to Bi deposited via a standard cleanroom high vacuum evaporator. We investigate the Bi-WSe_2 interface electrically via field-effect transistor structures and report on the wide-ranging electronic properties of the devices when using WSe_2 synthesized by different growth methods.

11:00 AM EL01.07.07
Mobility Enhancement of Monolayer WS_2 from Biaxial Tensile Strain JerryA. Yang, RobertK. Bennett, LaurenA. Hoang, ZhepengZhang, KamilaJ. Thompson, AndrewJ. Mannix and EricPop; Stanford University, United States

Two-dimensional (2D) semiconductors have attracted significant interest due to their unique electronic and mechanical properties, based on their atomically thin structure. Among these, monolayer tungsten disulfide, WS_2, is a promising channel for 2D field-effect transistors due to its favorable combination of wide band gap for low leakage current, good electron and hole mobilities, controllable synthesis, and ambipolar conduction [1], [2]. However, how strain affects its electronic properties remains largely unknown.

Mechanical strain modulates the energy band structure of 2D semiconductors, and previous computational studies have predicted that strain can increase the electron mobility due to reduced transport effective masses and reduced intervalley electron-phonon scattering [3]. Experimentally, a recent study has found that even 0.7% uniaxial tensile strain can double the mobility of monolayer MoS_2 [4]. However, mobility improvements in WS_2 due to strain have not yet been experimentally demonstrated.

Here, for the first time, we study the effect of externally applied biaxial strain on the electrical characteristics of WS_2 field-effect transistors on flexible substrates. We first pattern a Ti/Au (5 nm/40 nm) back-gate stack onto 125-μm thick polyethylene naphthalate (PEN) substrates, then deposit ~16 nm Al_2O_3 gate dielectric. We grow WS_2 by chemical vapor deposition on a *c*-plane sapphire substrate and transfer the material onto the samples with an approach similar to Ref. [5]. We define the channel using an O_2 plasma etch and pattern Ni/Au (5 nm/40 nm) source and drain contacts. Lastly, we encapsulate the transistors with an AlO_x (10 nm) layer similar to Ref. [6], which serves as a final anneal and passivation layer.

We apply strain to our samples using a custom-designed five-point crossbeam biaxial tensile strain tool similar to Ref. [7]. The PEN sample is attached to an acrylic cruciform which is biaxially strained while the electrical and optical characteristics of the fabricated devices are measured *in situ* from 0.1% to 0.4% strain. We confirm strain transfer with Raman and

photoluminescence spectroscopy, showing that Raman 2LA(M) and A^0 exciton peaks shift by 13 ± 5 cm^{-1}/% strain and 120 ± 61 meV/% strain, respectively, which is consistent with previous experimental literature on biaxially strained WS_2 [7]. We also show that the AlO_x encapsulation layer significantly alters the strain rates of the first-order Raman E' and A_1' modes in WS_2.

We demonstrate a ~1.5x improvement of electron mobility and transistor current at 0.3% biaxial tensile strain, and a ~0.3 V negative threshold voltage shift averaged over 60 devices. This improvement occurs at about half the strain magnitude compared to earlier reports of uniaxial strain for MoS_2 [4]. Through DFT simulations of the strained WS_2 band structure, we attribute this improvement to increased energy separation between K and Q conduction band valleys, which reduces intervalley electron-phonon scattering.

This work represents the first report of biaxial strain effects on the electronic properties of a monolayer TMD, showcasing the utility of strain engineering 2D materials for improved electrical performance. Future work will include exploring the effects of biaxial tensile strain on flexible WS_2-based circuit performance. This work was in part supported by the NSF Graduate Research Fellowship program (J.A.Y.), by the Stanford Graduate Fellowship (R.K.A.B.) and by the Stanford SystemX Alliance (other authors).

11:15 AM EL01.07.08
Strain-Induced Performance Enhancement in 2D Material Transistors YueZhang, KellyHwang, MohammadA. Hossain and ArendM. van der Zande; University of Illinois Urbana Champaign, United States

Strain is a powerful technique for engineering the quantum properties of materials, which is important to both science and technology. For example, in CMOS manufacturing, a common approach for enhancing mobility in silicon transistors is through process-induced thin-film stress[1]. A recent idea is to apply the process-induced strain technique to engineer strain in 2D materials through the deposition of thin film stressors[2]. However, there are still knowledge gaps in understanding how the films interact to modify the strain and doping in 2D materials, the ultimate limits of applicable strain, and their impact on the material properties and transport in 2D transistors. Understanding these interactions are important for the heterogeneous integration with two-dimensional semiconductors into CMOS technologies.

Here, we present a device-compatible method to pattern and engineer strain in 2D monolayers using process-induced strain and propose a traction-separation model to understand and design the mechanics. Moreover, we demonstrate the process-induced enhancement of current density and field effect mobility of monolayer MoS_2 transistors. First, we investigate the strain transfer mechanism in stressor-capped 2D materials. We evaporate magnesium oxide stressor onto large, continuous monolayer MoS_2, and use lithography to pattern structures. We use Raman spectroscopy to quantify the local strain and doping,[3] while systematically varying the stressor thickness and size. After stressor deposition, there is a constant doping concentration change of 5×10^{12} cm^{-2} and a linearly increasing strain with stressor thickness, up to a value of 0.65%. The doping is uniform under the stressor, but the strain profile depends strongly on the shape and size of the stressor. We show that the strain profile is well described by a traction-separation model of strain transfer across the MoS2-substrate interface[4]. We implement this model in finite element simulation and demonstrate the ability to predict the strain profile and extract the effective traction at the 2D interface to be 1.3 MPa/µm. Finally, we demonstrate the utility of process induced strains and the modeling to predict and design arbitrarily complex strain profiles in 2D monolayers.

Next, we investigate how process-induced strain affects carrier transport in monolayer MoS_2 transistor. We measured the electrical transfer curve onto the same 2D channel while sequentially depositing stressors of increasing thickness. Before stressor deposition, the devices showed mobility of 20 cm^2/Vs, and current density of 30 µA/µm. With increasing strain, the carrier mobility and the current density continuously increased. At 0.5% strain, the current density is enhanced by 60%, due to the enhanced carrier mobility of 40% and the decreased threshold voltage. This enhancement is comparable with theoretical prediction[5] and bending 2D transistors on soft elastomer substrates[6].

These results demonstrate a powerful device compatible approach to strain engineering 2D materials , and a generalizable method to unravel the interaction of CMOS processes with the material properties and device performance of 2D materials. These approaches are important in both the heterogeneous integration of 2D materials into More than Moore technologies. Moreover, these techniques open up new opportunities for leveraging patternable and anisotropic strain for quantum phenomena in 2D materials like exciton funneling, single quantum emitters, spintronics and moiré engineering.

Identifying and Engineering Defects in 2D Semiconductors JamesHone; Columbia University, United States

This talk will describe ongoing efforts to identify the types and locations of point defects in transition metal dichalcogenide single crystals grown by self-flux and chemical vapor transport techniques. These efforts combine STM imaging, multi-mode AFM imaging (conductive AFM, lateral force microscopy), and elemental analysis of bulk crystals. Imaging is performed on cleaved bulk crystals and exfoliated flakes from one to a few layers thick. In order to unambiguously determine defect locations, we introduce intentional substitutional defects at the metal and chalcogen sites. These studies guide efforts to further purify these materials, leading to improved optical and electronic performance.

SESSION EL01.08: Mechanics of 2D Materials

Designing Slip and Strain into 2D Material Heterostructure Devices ArendM. van der Zande; University of Illinois at Urbana Champaign, United States

Mechanical strain and deformation offer an unprecedented ability to tailor the symmetry and structure of 2D materials and resulting electronic properties, making it important to diverse technologies like heterogeneous integration with CMOS, stretchable electronics, and engineering quantum systems. Across applications, understanding the nanoscale mechanics will enable the prediction and design of strain dependent properties and integration into devices. Here, we utilize atomic to micro scale imaging to unravel the breakdown of continuum mechanics and new scaling laws in the atomic limit, and their influence on the electronic properties of 2D materials. We will cover examples including: (1) Demonstrating designable strain using thin film stressors, which can be used to spatially pattern the electronic structure of 2D materials or interfacial heterostrain tuning of the moire superlattice. (2) Imaging the nanoscale shape of bends in 2D heterostructures and discovering the scaling laws that define interlayer slip at van der Waals interfaces, enabling membranes orders of magnitude more deformable than conventional thin films, (3) Leveraging these insights to demonstrate the feasibility of strain and deformation engineering for applications such as mobility enhancement in 2D transistors, deformable transistors, and reconfigurable nanoelectromechanical systems.

2:00 PM EL01.08.02

Measuring Mechanical Properties of Two-Dimensional Nanosheets using *In-Situ* Tensile TestJi CheolByen[1], Seong-GuHong[1], DoyeonKim[2] and Myeong SeokKo[1]; [1]University of Science and Technology KRISS, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of)

2D materials are being intensively researched and used industrially worldwide due to their excellent transmittance, thermal conductivity, and electron mobility. The future applications include high-speed transistors, flexible display touch panels, solar cells, etc. Understanding the unique physical properties of 2D materials is essential for their industrial utilization. On the other hand, the evaluation method of the mechanical properties of 2D materials is performed by depositing them on a specific substrate due to the specificity of their shape. However, this measurement method is influenced by the interaction with the substrate, resulting in the measurement results being affected. The techniques that can be used to measure under conditions where substrate effects are excluded are atomic force microscopy (AFM), nanoindentation, bulge testing, etc. Also, these measurement methods are ex-situ techniques, which means they cannot monitor the actual testing process, so the disadvantages of these measurement methods are that various factors that may occur during nanoscale measurement can be reflected in the measurement results. Additionally, the load-displacement data measured by AFM nan indentation may have a large error in the measured load due to the uncertainty in the AFM cantilever spring constant, which is a disadvantage. These reasons make it difficult to trust the results obtained from the measurement techniques listed above. On the other hand, in-situ measurement technology is a technology that uses MEMS devices to compensate for the limitations of the previous ex-situ measurement technology. The in-situ measurement technology performs tests within an electron microscope, observes the testing process, and analyzes the test results through post-processing of images after the measurement. For example, at the University of Hong Kong, CVD graphene was transferred to a push-to-pull (PTP) device using a wet transfer method with PMMA. Then, the measurement area was cut out from the rest of the area using a focused ion beam (FIB), and the PMMA that was covered was removed to produce the CVD graphene tensile test piece. The produced CVD graphene tensile test piece was used to measure the Young's modulus and tensile strength by inducing deformation through in-situ tensile testing based on SEM. However, the previously described method of producing the specimen also involves cutting it artificially using FIB, leading to physical damage. Therefore, it is necessary to improve the production of the specimen so that physical damage does not occur. This study improved the previously mentioned physical damage to 2D materials by using a dry transfer method instead of the physical transfer method. The pristine 2D material was mechanically transferred and then transferred to a substrate using the self-made transfer system with the PTP (Push-to-Pull) method, avoiding physical damage to the substrate. To increase the yield of substrate production, E-beam lithography was used to create PMMA clamping areas 3.5μm away from suspended areas. The remaining PMMA was then removed by exposing it to acetone for 2 hours. The 2D material on the suspended area was prevented from collapsing by going through a critical point dryer process. The samples were tested for Young's modulus of 2L and 3L graphene using low-voltage SEM, and the results showed Young's modulus of approximately 1 TPa for both. The reliability of the test was determined by comparing the obtained force-displacement curves with the actual SEM images.

2:15 PM EL01.08.03
Advancing Nanoindentation Analysis for Characterizing the Mechanical, Elastic and Interfacial Properties of Two-Dimensional Materials YifanRao[1], KaiLiu[2] and NanshuLu[1]; [1]The University of Texas at Austin, United States; [2]Tshinghua University, China

2D materials, such as graphene and Molybdenum disulfide (MoS2), offer tremendous potential for future devices due to their atomic-level thinness, intrinsic flexibility, and strain-engineered properties. A thorough understanding of their mechanical, elastic, and interfacial properties is crucial for the successful design of functional 2D devices. However, this task presents challenges, as the ultra-thin nature and relatively large surface areas of 2D materials render them highly sensitive to elasto-capillarity, particularly at small sizes. The nanoindentation technique has demonstrated significant advantages, especially in simultaneously measuring the mechanical, elastic, and interfacial properties of 2D materials, as well as controlling local strain distribution. Nonetheless, the accurate interpretation of the measured indenting-force-to-deflection curves is hindered by the lack of suitable theoretical models. In this study, we have developed a comprehensive model for the nanoindentation of suspended 2D materials, taking into account various factors such as pretension, probe size, probe-suspended-membrane interaction, and interfacial sliding between the 2D materials and substrates in the supported region. Additionally, we have creatively proposed a minimum force method to select the zero points of the indenting-force-to-deflection curves in practical applications. By applying our model to analyze these curves, we have successfully determined the Young's modulus of the 2D materials, the interfacial shear strength against the supporting substrate, as well as the fracture strength of the 2D materials simultaneously. Our theoretical model for nanoindentation tests has provided accurate insights into the deformation and failure behaviors of 2D materials.

Novel Ferroelectric and Optoelectronic Responses in 2D Semiconducting Transition Metal Dichalcogenides by Defect and Strain Engineering Nai-ChangYeh[1,1,2], DuxingHao[1], Wei-HaoChang[2], Chen-HsuanLu[1], Yann-WenLan[2] and Ting-HuaLu[2]; [1]California Institute of Technology, United States; [2]National Taiwan Normal University, Taiwan

Ferroelectric materials are important components for modern electronic applications, particularly in high-density data storage, microwave devices, pyroelectric sensors, non-volatile memories. Recently, ferroelectricity has been observed in a two-layer van der Waals (vdW) interfaces using marginally twisted two-dimensional (2D) materials that lack polar point groups in their parent lattices, such as hexagonal boron nitride (h-BN) and transition metal dichalcogenides (TMDs). For 2H-TMDs in the monolayer limit, the D_{3h} point group preserves the centrosymmetry so that there is no out-of-plane polarization nor ferroelectricity. On the other hand, if mirror symmetry breaking is introduced, such as in the distorted-1T phase, emergence of ferroelectricity may occur. However, due to domains of randomly orientated spontaneous polarization, a tip-induced flexoelectric training field would be needed to achieve polarization alignment before ferroelectricity could be detected by scanning probe microscopy. To date, robust ferroelectric responses of monolayer 2H-TMDs on device scales have not been reported.

Here we present our new discovery of giant magnetic field-induced ferroelectric responses and novel optoelectronic responses in monolayer MoS_2-based field effect transistors (FETs). We attribute the physical origin for the giant field-induced ferroelectric responses to combined effects of sulfur vacancies-induced centrosymmetric breaking and excess electric/magnetic dipole moments as well as asymmetric thermal relaxations between the top and bottom sulfur layers on a substrate at low temperatures (< 20 K). We further demonstrate that nanoscale strain-engineering of monolayer MoS_2 can induce significant centrosymmetric breaking regardless of the presence of sulfur vacancies, which can enhance the ferroelectric responses. We also observe sensitive responses of the ferroelectric signals from the monolayer MoS_2-FETs to light excitations as a function of the photon frequency, polarization, and orbital angular momentum, suggesting strong interactions of excitonic polaritons with carriers in the 2D-TMDs. The physical mechanisms for these novel findings and potential ferroelectric and optoelectronic applications based on monolayer TMD-FETs will be discussed.

This work was jointly supported by the National Science Foundation in the US, and the National Science and Technology Council and the Ministry of Education in Taiwan.

4:00 PM EL01.08.05
Bendable Membranes Based on Silicene and Silicene-Stanene Heterostructures ChristianMartella[1], ChiaraMassetti[1,2], Daya SagarDhungana[1], EmilianoBonera[2], CarloGrazianetti[1] and AlessandroMolle[1]; [1]CNR Institute for Microelectronics and Microsystems, Italy; [2]Università degli Studi di Milano-Bicocca, Italy

Two-dimensional (2D) materials exhibit a variety of physical properties with potential exploitation in nanotechnology [1]. In particular, when reduced in the form of 2D bendable membranes, they hold promises in the framework of flexible electronics, photonics and related applications including wearable and strain-responsive devices. Here, we demonstrate the realization of bendable membranes based on Xenes, [2] the monolelemental class of 2D materials, and Xene heterostructures. Starting from silicene and silicene-stanene heterostructure grown by molecular beam epitaxy [3], we show that it is possible to transfer them onto arbitrary flexible substrates [4], thus making feasible the realization of bendable membranes. The application of macroscopic mechanical deformations induces a strain-responsive behavior in the Raman spectrum of silicene. Under tensile strain, the bendable membrane shows Raman frequency shift comparable to other promising flexible systems, like those based on transition metal dichalcogenides, and high stability up to one thousand bending cycles. We also show that the membranes under elastic tension relaxation are prone to form microscale wrinkles displaying a local generation of strain in the silicene layer consistent with that observed under macroscopic mechanical deformation. Moreover, optothermal Raman spectroscopy measurements on wrinkled silicene reveal a curvature-dependent heat dispersion larger than that observed in the unstrained case [5]. Finally, as compelling evidence of the technological potential of the silicene membranes, we demonstrate that they can be readily introduced into a lithographic process flow resulting in the definition of flexible device-ready architectures, e.g. piezoresistor, and thus paving the way to a viable advance in a fully silicon-compatible technology framework. The work is within the ERC-COG 2017 Grant N0. 772261 "XFab" and ERC-PoC 2022 Grant N. 101069262 “XMem”.

Study of Internal and Interfacial Properties of 2D Nanomaterials for Understanding Toughening Mechanisms in Ceramic Nanocomposites CristinaLopez Pernia[1], XingLiu[2], ChristosE. Athanasiou[2], JunLou[3], HuajianGao[1,4,5], NitinP. Padture[1] and BrianW. Sheldon[1]; [1]Brown University, United States; [2]Georgia Institute of Technology, United States; [3]Rice University, United

States; [4]Nayang Technology University, Singapore; [5]A*STAR, Singapore

Despite his exceptional properties, such as high hardness, chemical and thermal stability, ceramics have long been recognized by their inherent brittleness. To overcome this challenge, ceramic nanocomposites reinforced with nanotubes or nanoplatelets have emerged as promising materials with enhanced mechanical properties, including improved toughness and strength. Designing and engineering advanced ceramic-based materials with tailored toughness, enable their application in a wide range of industries, including aerospace, energy, and electronics. The main challenge for these materials is still controlling and optimization of the toughening mechanisms. Most of the reported efforts are primarily associated with tailoring the microstructure and dispersion of the filler and studying the influence of processing parameters (powder processing methods, sintering conditions…) and nanoplatelet nature (loading content, aspect ratio, orientation throughout the ceramic matrix…) on the resulting microstructure and mechanical properties. However, microstructural features like the nanostructure-matrix interface properties, residual stresses, etc are still key aspects that has not been deeply explored.
Studying the role of interfacial bonding between nanoplatelets and ceramic matrices, interlayer spacing in the 2D nanomaterials and even surface functionalization techniques can provide essential knowledge for enhancing the interfacial strength and stress transfer across the composite. However, in this sense there is still a lack of studies on the impact of interfacial properties on the overall mechanical performance of these materials. This work seeks shedding light on the role of the nanoscale interaction for toughening the composites.
Through a simple experimental approach involving a lap shear configuration the interplay between the 2D nanostructures and the ceramic matrix is evaluated. Reduced graphene oxide (rGO) films are attached to Al_2O_3 ceramic substrates using polymer-derived ceramic as an intermediate layer. The lap shear tests are conducted under varying compressive loads to evaluate the influence of mechanical stress on the interfacial performance, friction, and toughening behavior. rGO films of different thicknesses are also considered in order to assess the influence of interlayer sliding on the mechanical behavior of these composites.

The Interplay of Intra-and Inter-Layer Interactions in Bending Rigidity of Ultrathin 2D Van Der Waals Crystals YingchunJiang[1], SrividhyaSridhar[2], ZihanLiu[1], DingliWang[1], JiaDeng[1], Huck BengChew[2] and ChanghongKe[1]; [1]Binghamton University, The State University of New York, United States; [2]University of Illinois at Urbana-Champaign, United States

Bending/flexural rigidity is one of the fundamental mechanical properties of mono- and few-layered two-dimensional (2D) van der Waals crystals (e.g., graphene, molybdenum disulfide (MoS_2) and hexagonal boron nitride (hBN)) that are of great importance to the pursuit of a variety of their applications. Continuum mechanics break down in bending stiffness calculations of these 2D crystals because their layered atomistic structures are uniquely characterized by strong intralayer bonding coupled with weak interlayer interactions. The lack of experimental measurements and the wide scattering of reported values in the literature pose additional challenges to scientific understanding and practical applications of these 2D materials. In this talk, we will present our recent research on quantitative measurements of bending stiffness of pristine monolayer or few-layer graphene, hBN, and MoS_2 flakes and elucidate how the bending rigidities of these 2D crystals are governed by their structural geometry, and intra- and inter-layer bonding interactions. Atomic force microscopy (AFM) experiments on the self-folded conformations of these 2D materials on flat substrates show that the bending rigidity of MoS_2 significantly exceeds those of graphene or hBN of comparable layers, despite its much lower tensile modulus. Even on a per-thickness basis, MoS_2 possesses similar bending stiffness to hBN and is much stiffer than graphene. Density functional theory (DFT) calculations reveal that this high bending rigidity of MoS_2 is due to its large interlayer thickness and strong interlayer shear, which prevail over its weak in-plane bonding. The high bending rigidity of ultrathin MoS_2 is of particular significance for its electronic applications, as it is less prone to out-of-plane structural instabilities, such as wrinkles and ripples, which can impact the material's electrical properties. The superior bending rigidity of MoS2 makes it a promising building block for robust nanoelectronics and sensors.

Piezoelectric Electrostatic Superlattices in Monolayer MoS_2AshwinRamasubramaniam[1] and DoronNaveh[2]; [1]University of Massachusetts-Amherst, United States; [2]Bar Ilan University, Israel

Modulation of electronic properties of materials by electric fields is central to the operation of modern semiconductor devices, providing access to complex electronic behaviors and greater freedom in tuning the energy bands of materials. Here, we explore one-dimensional superlattices induced by a confining electrostatic potential in monolayer MoS_2, a prototypical two-dimensional semiconductor. Using first-principles calculations, we show that periodic potentials applied to monolayer MoS_2 induce electrostatic superlattices in which the response is dominated by structural distortions relative to purely electronic effects. These structural distortions reduce the intrinsic band gap of the monolayer substantially while also polarizing the monolayer through piezoelectric coupling, resulting in spatial separation of charge carriers as well as Stark shifts that produce dispersive minibands. Importantly, these minibands inherit the valley-selective magnetic properties of monolayer MoS_2, enabling fine control over spin-valley coupling in MoS_2 and similar transition-metal dichalcogenides.

First-Principles Investigations of Quantum Defects in Two-Dimensional Transition Metal Dichalcogenides WeiruChen[1], YihuangXiong[1], JohnC. Thomas[2], ArchanaRaja[2], AlexanderWeber-Bargioni[2] and GeoffroyHautier[1]; [1]Dartmouth College, United States; [2]Lawrence Berkeley National Laboratory, United States

Quantum defects, considerred as artificial atoms embedded within host materials, are key components in realizing applications in quantum information science. Low-dimensional materials, such as transition metal dichalcogenides (TMDs), are particularly promising hosts due to their inherent quantum confinement nature, long projected spin coherence time, and strong spin-orbit coupling (SOC). In this study, we focus on two common point defects in monolayer tungsten disulfide (WS_2): vacancies and carbon substitutions. We used computational modeling techniques along with hybrid functionals and SOC, factoring in the nonunique exact exchange fraction characteristic [1] of low-dimensional materials, to analyze the thermodynamic stability and electronic structures of these defects. Our results, combined with experimental characterizations, provide new insights into the properties of these defects, encouraging further research into the understanding and design of quantum defects in TMDs.

8:00 PM EL01.09.02
***In Situ* Observation of Wrinkle Evolution in Suspended 2D Materials**JingzhuoZhou[1], YuanHou[1], JuzhengChen[1], MengyaZhu[1] and YangLu[2]; [1]City University of Hong Kong, Hong Kong; [2]The University of Hong Kong, Hong Kong

Mechanical properties of atomically thin materials play a crucial role in the fabrication and stability of atomic-scale devices. As the thinnest materials in nature, two-dimensional (2D) materials can hardly tolerate compressions, so they are vulnerable to instability in response to geometrical restrictions such as shifting from planar structure to out-of-plane wrinkling. The complex instability pattern is determined by the intrinsic bending properties and external boundary conditions. However, because the dynamic instability process of 2D materials is elusive, their crucial instability conditions and morphological evolution remain enigmatic. Here, we develop an in-situ shearing experiment for suspended 2D materials include graphene and MoS_2 by employing the push-to-shear strategy. We comprehensively examine the reversible wrinkling-smoothing process and demonstrate that 2D materials under shearing have a dual instability that includes continuous wavelength decrease and snap-through period-halving bifurcation, respectively. This dual instability, governed by the materials' geometry and the elastic nonlinearity, makes it possible to measure the bending stiffness of single-layer 2D materials. Furthermore, we investigate the changes in optical properties of 2D materials within instability using shear straining. These findings not only provide direct evidence of dual instability of 2D materials, also raise new opportunities for shear-strain engineering of 2D devices.

TEM Dark Field Analysis on the Atomic Scale Reconstruction in Twisted Trilayer Graphene DaesungPark, Sang HwaPark, Jae HeonLee, Sang MoYang and HyobinYoo; Sogang University, Korea (the Democratic People's Republic of)

Interfaces formed by joining two van der Waals (vdW) crystals has offered a new route to access exotic electronic behaviors. The interplay between twist-tunable length scale of moire superlattice and underlying atomic scale reconstruction has been key to understand such unconventional electronic behaviors. In the twisted bilayer graphene, for instance, periodic rearrangement of atoms with the moire length scale was reported to be responsible for many exotic phenomena including anomalous electronic transport in small twist angle ($\theta<1°$) and the strongly correlated behavior in magic angle ($\theta\sim1.1°$). On the other hand, atomic configuration in twisted trilayer graphene and its correlation with the recently reported unconventional

superconductivity has yet to be investigated. Although robust superconductivity in the twisted trilayer graphene has been reported by multiple groups, their insight onto the atomic and moire structure remains elusive due to the complicated nature of the interlayer interaction in trilayer system. The reconstruction between the top and bottom layers through the middle layer in addition to that between the two adjacent layers should be considered to understand the atomistic details of twisted trilayer graphene.
In this study, we utilized the transmission electron microscopy (TEM) dark field (DF) imaging technique to investigate the reconstructed moiré lattice in twisted trilayer graphene. Assuming only a single event of electron scattering with the thin specimen, the intensity of TEM DF image can be interpreted as kinematical diffraction intensity variation in real space. Moreover, by obtaining the tilt-series DF images, one can monitor the change in such diffraction intensity as a function of the deviation from the exact Laue condition. We found that the atomic rearrangement occurs in all three layers, resulting in an array of commensurate domains of Bernal and rhombohedral stacking orders competing with each other.

8:00 PM EL01.09.04
Defect-Induced Bound States in the Continuum Band of Nanoribbons VicentaSanchez and ChuminWang; Universidad Nacional Autonoma de Mexico, Mexico

Bound states in the continuum (BICs) can be induced by structural defects or impurities [1]. These bound states have numerous applications in devices as solid-state lasers [2], sensors [3], and narrowband filters [4]. In this work, we report a detailed study of BICs in a finite nanoribbon with defects. This study was carried out by means of the Kubo-Greenwood formula and tight-binding Hamiltonian, as well as a real-space renormalization plus convolution method [5]. The calculated density of states reveals the presence of a BIC, whose localization degree was quantified by the participation ratio [6]. In addition, significant changes in the electronic transport and localization are found when a small second-neighbor hopping integral between the impurities and neighboring atoms is considered. Moreover, this study shows the sensibility of such BICs to short-range hopping integrals. Finally, BICs in finite second-neighbor square lattices have also been analyzed by using a new convolution theorem [7].

This work has been partially supported by projects UNAM-IN112522, UNAM-IN110823 and CF-2023-I-830. Computations were performed at Miztli of DGTIC-UNAM.

Exploring Local Doping in CVD-Grown Graphene on Sapphire Through Correlative Kelvin Probe Force Microscopy and Raman Spectroscopy Techniques IlkaHermes[1] and SimonasKrotkus[2]; [1]Leibniz Institute for Polymer Research Dresden e.V., Germany; [2]Aixtron SE, Germany

Graphene, transition metal dichalcogenides and synthetic 2D materials offer a vast potential for novel (opto-) electronic devices, membranes and energy storage among others. In particular, industrial application of 2D materials in high-performance nanoelectronics require homogeneous distributions of electrical properties on the nanoscale. Advanced atomic force microscopy (AFM) techniques like Kelvin probe force microscopy (KPFM) and conductive AFM (cAFM) resolve local surface potential and conductivity with a nanometer resolution and directly relate this information to the materials surface structure [1, 2]. Here, I present a correlative KPFM and µRaman study on wafer-scale monolayer graphene on an insulating sapphire substrate prepared via chemical vapor deposition. The use of high temperature H_2-annealed sapphire instead of pristine sapphire improves the resulting graphene film by reducing the overall density of strain-induced wrinkles and increasing the crystal quality [3]. We found the annealing-induced sapphire steps introduce a heterogeneous surface potential distribution on the graphene monolayers caused by spatially variant p-doping concentrations. The decreased p-doping concentration at the position of underlying step edges suggest that a change in substrate-film interaction leads to the highly heterogenous surface potential distribution.

Vanadium-Vacancy Defect Complexes in Monolayer Tungsten Diselenide JingdaZhang, LeyiLoh, MichelBosman, GokiEda and Su YingQuek; National University of Singapore, Singapore

We present a comprehensive study of the formation of defect complexes of vanadium substitutional dopants and selenium vacancies in monolayer tungsten diselenide. Different defect complexes were identified and analyzed by the statistical treatment of scanning transmission electron microscope (STEM) datasets. Using density functional theory (DFT) calculations, we studied the thermodynamic stability of these defect complexes under experimental growth conditions. Both theory and experiment reveal that vanadium substitutional defects lower the formation energy of surrounding selenium vacancies. Increasing the vanadium concentration results in a larger density and average size of the vanadium-vacancy complexes. Nevertheless, the formation of larger complexes requires higher energy costs, and the most commonly observed defect complex configuration consists of a single vacancy adjacent to a vanadium defect. Our results pave the way for exploration of engineering impurity-vacancy complexes by substitutional doping in 2D TMDs.

Investigating the Influence of Grain Boundaries on Thermal and Electrical Conductivity in Two-Dimensional Molybdenum Disulfide AyuIrie[1], AnikeyaAditya[2], ShogoFukushima[3], Ken-ichiNomura[2], FuyukiShimojo[1], AiichiroNakano[2], RajivK. Kalia[2] and PriyaVashishta[2]; [1]Kumamoto University, Japan; [2]University of Southern California, United States; [3]Tohoku University, Japan

Transition metal dichalcogenides (TMDCs) have emerged as key semiconductors with tremendous potential for future semiconductor devices. Understanding the impact of defects, such as grain boundaries (GBs), on the thermal and electrical transport properties of two-dimensional (2D) TMDC materials is crucial for their application in energy-harvesting devices based on the thermoelectric effect. In this study, we employed nonequilibrium molecular dynamics simulations and first-principles quantum-mechanical calculations to investigate the thermal and electrical transport properties across and along GBs in a monolayer of the prototypical TMDC material, MoS_2. The results reveal the presence of an interfacial phase (or interphase) located within ~3.5 nm around a GB, exhibiting distinct anisotropic transport properties compared to the perfect crystal. Specifically, the interphase exhibits an 80% reduction in thermal conductivity across the GB, while 17% enhancement along the GB, relative to the perfect crystal. On the other hand, the electrical conductivity appears to be enhanced in both directions. These unique thermal and electrical transport properties exhibited by GB interphases hold key to thermoelectric applications of 2D TMDCs. By manipulating the arrangement of GBs, it is possible to achieve reduced thermal conductivity and enhanced electrical conductivity in these materials. Consequently, atomically thin van der Waals materials, such as MoS_2, show great promise as candidates for thermoelectric devices.

8:00 PM EL01.09.08
Manipulating Thermal Transport of Atomically Thin Crystals via Multiscale Defects MingyuJang[1], JeonginYeo[1], SeongukYang[1], SungkyuKim[2] and JoonkiSuh[1,1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Sejong University, Korea (the Republic of)

Semiconducting two-dimensional (2D) materials such as transition-metal dichalcogenides (TMDs) have attracted tremendous interest toward near-future applications in nanoelectronics, optoelectronics and thermoelectrics. For those applications, both deeply understanding and actively tuning their thermal transport is of crucial importance in that it intimately impacts the thermal management and energy consumption of devices. Given with the ultra-thin nature of 2D materials, defect engineering becomes much more powerful, so it can be a strategic approach to manipulate their thermal conduction on demand where defect generally acts as a phonon scattering center. In this presentation, we report highly tunable thermal conductivity of monolayer molybdenum disulfide (MoS_2) via multiscale defects, *i.e.*, mesoscale grain boundaries and atomic-scale point defects. Experimentally, thermal conductivity of defect engineered MoS_2 is measured by opto-thermal Raman thermometry by monitoring the temperature and power dependences of corresponding Raman peak shift. We found that the thermal conductivity of single- and poly-crystalline monolayer MoS_2 can be manipulated by additionally introducing point defects which is highly controllable by helium ion beam irradiation. Furthermore, we can decouple the effects of point defects and grain boundaries by analysing single- and poly-crystalline specimen. Our work can provide important insight for controlling thermal properties of 2D materials and the use of monolayer TMDs in the thermal management in modern electronics and energy harvesting devices.

8:00 PM EL01.09.09
Ultrahigh Photoresponse in Double-Strained Monolayer MoS_2 Films with Domain Adjustments Ye SeulJung[1], Ji YeonKim[1], Jae WooPark[1,2], WenhuShen[1] and Yong SooCho[1]; [1]Department of Materials Science and Engineering, Yonsei University, Korea (the Republic of); [2]Samsung Electronics Co. Ltd., Korea (the Republic of)

Strain engineering of two-dimensional (2D) transition metal chalcogenides, which aims primarily to tune the bandgap of a semiconductor with modulations of lattice strain, has emerged as a practical way to enhance their electrical and optical properties. Herein, we propose a flexible optoelectronic device based on large-scale monolayer MoS_2 film optimized with maximum tensile strain (via double strain engineering) and domain orientation (relative to the parallel electrodes). Controllable in situ strain spanning a compressive-to-tensile strain range of ±1.27% was applied to the domain-aligned MoS_2 monolayer as the 2D layer were transferred onto a polymer substrate bent concavely or convexly. To extend the benefit by the in situ tensile strain, we applied second strain by post-bending the resulting photodetectors to produce the final tensile strain of +1.80%. Another key achievement is the adjustment of electrode positions depending on the domain orientation to produce maximum polarization field with minimum energy bandgap. As an optimal light-sensing performance, the maximum photoresponsivity of 1142 A W^{-1} was attained for the double-strained sample, representing a ~130-fold increase relative to that for the unstrained one. This value corresponds to the highest value compared to those for any reported 2D-material-based visible photodetectors.

8:00 PM EL01.09.10
Boundaries; Kink Versus Ripplocation in Graphite, MAX phases and Other Layered Solids KaustubhSudhakar[1], GabrielPlummer[2], GarrittJ. Tucker[2] and MichelW. Barsoum[1]; [1]Drexel University, United States; [2]Colorado School of Mines, United States

Kink boundaries, KBs, in metals are well defined entities that at low disregistry angles are identical to low angle grain boundaries, LAGBs. The latter are comprised of basal dislocations aligned normal to the basal planes in such a way that their strain fields cancel. A ripplocation is best defined as an atomic scale ripple. When ripplocations on adjacent planes nest, they define a ripplocation boundary, RB. Two oppositely signed adjacent RBs define a ripplocation band. Until recently, most RBs have been classified as KBs. In layered crystalline solids, LCS, when deformation is confined in two independent directions, with no possibility of twinning, most KBs should be classified as RBs. Herein, we show that in LCSs, RBs: i) are not atomically sharp; their strain fields are considerably delocalized, especially in comparison to KBs, ii) delaminate at high curvatures; iii) form nanobridges, and iv) are highly strained and, if not trapped, fully reversible. At extreme curvatures, the bonds are sundered and the RBs are no longer reversible and are reminiscent of KBs at the macroscopic scale. The distinction is important because whether delaminations nucleate and/or a material is highly strained has important and crucial ramifications on its deformation and ultimate failure.

8:00 PM EL01.09.11
New Intercalant Order in TaS_2 Achieved by Pulsed Laser Heating YangZhang[1], JoshuaLee[2], ThomasSutter[2], MarinPrecner[3], GoranKarapetrov[3], AnshulKogar[2] and IsmailEl Baggari[1]; [1]Harvard University, United States; [2]University of California, Los Angeles, United States; [3]Drexel University, United States

Transition metal dichalcogenides (TMDs) have attracted significant interest due to their rich electronic states and intriguing properties. Among TMDs, tantalum disulfide (TaS_2) stands out as an archetypical system, showcasing multiple superstructures contributed by charge density waves (CDW), such as sqrt(13x13) superstructures in 1T-TaS_2 and 3x3 in 2H-TaS_2 [1, 2]. In addition to the CDW, recent works have demonstrated another avenue for exotic superstructural harvest: the intentional doping through chemical intercalation within the van der Waals (vdW) gap, a process that also entails stoichiometric modification [3, 4].

Here, we discover a new 2x2 superstructure distinct from well-known chemically intercalated phases of TaS_2 with the assistance of pulsed laser heating. Employing *in situ* selected area electron diffraction (SAED) and atomic-resolution scanning transmission electron microscopy (STEM), we reveal the reversible order-disorder transition occurring at around ~483 K. Furthermore, we unveil a robust modulation of atomic density in real space, explicitly elucidating the origin of the 2x2 superstructure. Additionally, the local fluctuations in the chemical order at the nanoscale is observed. These results could pave the way to further refine the phase diagram of intercalated TaS_2 and provide insights into the atomic origin of the chemical ordering.

Defect State Characterization for p-Si-$WS_{2+\delta}$ Devices using Frequency-Scanned Deep Level Transient Spectroscopy Mohd SamimReza, AnannyaMathur and MadhusudanSingh; Indian Institute of Technology Delhi, India

Transition metal dichalcogenides (TMDs), such as tungsten disulfide (WS_2), exhibit interesting and technologically relevant optoelectronic characteristics owing to the strong dependence of the bandgap on the dimensionality of the growth[1]. Previous scientific investigations have tended to focus on samples grown using chemical vapor deposition (CVD), with well-known limitations such as poor surface coverage, uncontrolled stacking, and device demonstrations have tended to employ electron-beam lithography for patterning, even for reasonably large flake sizes[2]. In practical two-terminal devices with a vertical transport geometry, nearly 100% surface coverage is essential. Usual methods employed for this purpose involve the use of reactively sputtered thin films, or using composite targets, which often results in sulfur-deficient film growth[3], followed by sulfurization. In this work, we have carried out growth of WS_2 using a simplified two-step growth process involving sulfurizing a DC-sputtered (Angstrom Engineering Evovac, 10^{-3} Torr) tungsten film (200Å with a growth rate ~ 0.5 Å/s,) over a SiO_2 substrate (University Wafers). Sulfurization (500 mg, Sigma Aldrich) was carried out in a a custom-designed twelve-zone horizontal split furnace (Quazar Technologies, 750–950 °C) under Ar flow (0–400 sccm). X-ray diffraction (Rigaku Ultima IV, Copper Kα = 1.54Å) scans revealed hexagonal WS_2 growth. Raman spectra (Renishaw inVia) revealed an in-plane (E^1_{2g}) and out-of-plane (A^1_g) vibrational modes at ~344.20/cm and ~414.92/cm, confirming the multilayer WS_2 growth[4]. Field-emission scanning electron microscope (FESEM, JEOL JSM-7800F Prime) scans indicate the growth of a pin-hole-free film. Energy dispersive X-ray (EDX, Oxford) analysis revealed a stoichiometry of W:S close to 1:2. Devices were fabricated in an analogous manner by directly sulfurizing pre-deposited tungsten on p-Si (B-doped, 1-10 Ohm-cm, Siegert Wafer), followed by silver contact metallization. A pulsed voltage source (33600A, Agilent) was was synchronized with charge measurements (6514 System Electrometer, Keithley) in frequency-scan deep-level transient spectroscopy (DLTS) measurements at various temperatures, 25, 40, and 60 °C. A defect cross-section of ~$2.37x10^{-13}$ cm^2 and a defect level of ~0.43 eV below the conduction band was inferred from constant capacitance analysis[5,6]. This trap state may be attributed to the sulfur excess or diffusive migration of boron during sulfurization process. We are currently carrying out higher resolution DLTS measurements to resolve the nature of the trap states.

Two-Dimensional Monolayer Monochalcogenide Lateral Superlattices JingrongJi[1], Zi-AngGao[2], Shiva PrasadPoudel[3], SalvadorBarraza-Lopez[3], KaiChang[2] and StuartS. Parkin[1]; [1]Max Planck Institute, Germany; [2]Beijing Academy of Quantum Information Sciences, China; [3]University of Arkansas, Fayetteville, United States

Two-dimensional heterostructures show the unconventional physical properties and have the huge potential applications in the electronics devices. Compared to the vertical heterostructures, lateral heterostructures are less explored due to the limitation of the fabrication methods and the difficulties in obtaining the high-quality heterostructures. Moreover, the existing work of the lateral heterostructures mostly only focus on the structures consisted by graphene family and transition metal dichalcogenides and the growth mechanism are even less discussed. Therefore, the exploring of the growth mechanism of the lateral heterostructures and superlattices are essential for fabricating the high-quality heterostructures. Here we report the molecular beam epitaxial growth and scanning tunneling microscope characterization of monolayer lateral heterostructures and superlattices consisted by two kinds of materials belonging to group IV monochalcogenide- SnTe and PbTe. We put forwards a surficial molecular diffusion mechanism to explain the defects in two dimensional lateral superlattices and present the achievements on the well-suppressed defects interdiffusion interface and controllable width of the superlattices. Based on the ferroelectricity in monolayer SnTe and paraelectricity in monolayer PbTe, our work provides the foundation of the future researches on the electronic properties and the potential applications in the ferroelectric devices in this two-dimensional monolayer SnTe/PbTe lateral superlattices.

8:00 PM EL01.09.14
Modulation of The Electronic and Transport Properties of MoS_2 Nanoribbons and Flakes via Strain and Vacancy NammeeKim, HeesangKim and SuejeongYou; Soongsil University, Korea (the Republic of)

The strain effects on the edge-state transport of a MoS_2 zigzag nanoribbon, and the vacancy effect on the electronic and transport properties of MoS_2 nanoflakes are investigated numerically using a six-band tight-binding model with KWANT, where the strain effect was absorbed into the modified hopping coefficients.
For metallic edge-states in the zigzag nanoribbon, introducing both an intrinsic spin-orbit coupling and local exchange field effects breaks the spin degeneracy and spin inversion symmetry to enable spin selective transport. Changes in the energy dispersion of the metallic edge-states due to uniaxial strain are asymmetric with respect to the strain direction. Transitions from metallic to insulating edge modes occur for a tensile strain of approximately 5% along the x-direction, but no such transition has been observed up to a tensile strain of 10% along the y-direction. The edge-current transmission and spin-polarized edge-currents are determined primarily by details of the energy dispersion of edge-states and are strongly affected by the incident energy of carriers for a given strain. The fully spin-polarized edge-currents can be obtained by modulating both the Fermi energy and gate potential.
The energy band structures are modified by changing the shape, size, vacancy rate, and vacancy distribution of the flakes, resulting in additional energy states in the energy bandgap region. For large flakes, the effects of their geometric shape are found to be negligible, because shape effects on the density of states (DOS) decrease with increasing flake size. The positions and DOS of these additional in-gap states are strongly related to the vacancy rate as well as to the distribution of vacancies. The number of in-gap states and the magnitude of the density of these states are both proportional to the vacancy rate. However, if the rate is high enough for vacancy clusters to form, the transmission is somewhat degraded at certain incident energies, owing to backscattering and capture of carriers by the clusters. Since the current transmission is determined primarily by the detailed energy band structure, the in-gap states due to vacancies enable the realization of low-energy currents in devices based on low-dimensional materials. The results provide useful information to implement a spin-polarized current as a potential solution for wearable spin devices

***Ab-Initio* Calculations on Thermal Strain-Induced Dimerized Phase in Monolayer $IrTe_2$**SungminSong, PyungjinPark, JesunJang and Seung-HoonJhi; Pohang University of Science and Technology, Korea (the Republic of)

Two-dimensional materials are sensitive to external strain and may undergo strain-induced phase transitions depending on thickness. In particular, $IrTe_2$ has been shown to exhibit superconducting properties at nanometer-scale thickness [1]. However, as the thickness of $IrTe_2$ decreases further, it becomes susceptible to thermal strain from the substrate. Studies on monolayer $IrTe_2$ have shown that various phases appear depending on the types of substrates with respective thermal strain properties [2,3]. To see the intrinsic strain properties of monolayer $IrTe_2$ induced by thermal effect, firstly we study the stability of the phase transitions from electronic and phononic perspectives. In addition, we calculate the thermal expansion coefficient of monolayer $IrTe_2$. Our calculations show that pristine monolayer $IrTe_2$ tends to take on a dimerized phase at temperature ~ 630 K and strain , which is not observed in bulk $IrTe_2$. This finding suggests a possibility of engineering the phase transition of two-dimensional materials using the thermal strain with suitable substrates and of designing desired functionality of two-dimensional materials.

Thermal Effusion of Water and Carbon Oxides from Multilayered Graphene Oxide Thin Films DouglasS. da Silva, GustavoA. Viana, RafaelMerlo, JoséM. da Silva Filho and FranciscoC. Marques; UNICAMP, Brazil

Over the last years, several techniques have been developed for the production of graphene, such as direct physical exfoliation of graphite and epitaxial growth from SiC surfaces [1, 2,3]. Regardless of the adopted producing protocol, the resulting GO is an insulating material of both physical and chemical characteristics very different from those of pristine graphene. Due to this, the implementation of processes able to efficiently remove the presence of oxygen-containing functional groups is imperative to convert the GO properties as close as possible into those of pristine graphene. Generally, these cleaning processes are called “reduction”, and the resulting sample “reduced GO” (rGO). Here we report on water (H_2O) and carbon oxides (CO and CO_2) effusion from multilayered graphene oxide (GO) films during thermal reduction. The effusion of molecules as a function of temperature was monitored through the thermal desorption spectroscopy (TDS) technique in GO thin films prepared by evaporating a colloidal solution of GO at 70 °C. This method of preparation of GO films ensures a homogeneous GO deposition on different substrates and reduces the presence of adsorbed/trapped H_2O molecules between adjacent GO planes. That allows the observation of additional effusion mechanisms, which would be otherwise masked by a strong signal due to effusion of adsorbed/trapped H_2O molecules. Thermal reduction process, ranging from room temperature to ~1000 °C, was performed in a high-vacuum system with a mass spectrometer to monitor the outgassed species in real time. A collective outgassing of H_2O, CO_2, CO species is observed and centered at approximately 230°C. Above 400°C, CO_2 and CO are the only observed outgassed species. Multiple origins for water outgassing were inferred from the TDS spectrum asymmetry, revealing an intricate superposition of mechanisms. The thermal treatment also reduces both the GO interlayer separation and the film surface roughness.

Controlling Morphology and Excitonic Disorder in Monolayer WSe_2 Grown by Salt-Assisted CVD Methods ReynoldsDziobek-Garrett and ThomasJ. Kempa; Johns Hopkins University, United States

Chemical synthesis is a compelling alternative to top-down fabrication for controlling the size, shape, and composition of two-dimensional (2D) crystals. Precision tuning of 2D crystal structure has broad implications for the discovery of new phenomena and the reliable implementation of these materials in optoelectronic, photovoltaic, and quantum devices. However, precise and predictable manipulation of the edge structure in 2D crystals through gas-phase synthesis is still a formidable challenge. Here we demonstrate a salt-assisted low-pressure chemical vapor deposition method that enables tuning W metal flux during growth of 2D WSe_2 monolayers and, thereby, direct control of their edge structure and optical properties. The degree of structural disorder in 2D WSe_2 is a direct function of the W metal flux, which is controlled by adjusting the mass ratio of WO_3 to NaCl. This edge disorder then couples to excitonic disorder which manifests as broadened and spatially varying emission profiles. Our work links synthetic parameters with analyses of material morphology and optical properties to provide a unified understanding of intrinsic limits and opportunities in synthetic 2D materials.

8:45 AM EL01.10.02
Unveiling the Dynamics of Defect Activation and Migration in Monolayer MoS2 under Strain DivyaNechiyil, GokulM. A and AtikurRahman; IISER Pune, India

The remarkable capacity of two-dimensional (2D) materials to endure substantial strains and their ability to tune optoelectronic properties under strain positions them as highly promising contenders for flexible device applications requiring exceptional performance. The impact of defects within 2D materials on their optoelectronic response to strain is a significant factor to consider. In this context, we present an experimental study that sheds light on the role of intrinsic defects in monolayer MoS2 regarding the properties of strain-induced photoresponse. We observed an enhancement in photocurrent, electron mobility and the emergence of persistent photoconductivity in the presence of strain. Our findings suggest that the activation of defects at

distinct strain values plays a pivotal role in augmenting the photoresponse of the material. The results also suggest defect migration in the presence of prolonged exposure to strain, which indicates a lowering of defect migration energy under strain. Our study unveils the significant role played by intrinsic defects in monolayer MoS2 in shaping the properties induced by strain. These findings not only deepen our understanding of the material but also open up exciting new possibilities for the development of multifunctional ultra-thin flexible devices in the next generation of applications.

9:00 AM EL01.10.03
Ultra-Stable Plasmon-Enhanced Optical Nanospectroscopy for Defect Analysis of 2D Materials RyoKato[1,2], TokiMoriyama[3], TakayukiUmakoshi[3], Taka-akiYano[1,2], TakuoTanaka[2,1] and PrabhatVerma[3]; [1]Institute of Post-LED Photonics, Japan; [2]RIKEN, Japan; [3]Osaka University, Japan

Plasmon-enhanced Raman and optical nanospectroscopy, which achieves true nanometric spatial resolution in optical microscopy, has been employed for chemical characterization of materials in various research field, such as biology and 2D materials. While plasmon-enhanced optical nanospectroscopy has found its innovative multidimensional nanoscale applications in the recent past, it has a vital glitch in imaging large-sized samples, even for samples with the size of a few micrometers. This is because it is challenging to maintain stable optical signal of a sample during long-time measurement, especially when using an atomic force microscopy (AFM)–based plasmon-enhanced optical nanospectroscopy system. The instability of the scattered signal originates from thermal and vibrational drift of the metallic nanotip with respect to the focus spot of the incident light as well as the focus position in the optical axis. Because of these uncontrollable drifts, conventional plasmon-enhanced optical nano-imaging must be completed typically within 30 min; otherwise, optical signal deteriorates beyond the acceptable level. The restriction of measurement time indeed limits the use of plasmon-enhanced optical nanospectroscopy for advanced analysis, such as quality evaluation of optoelectronic devices, high-resolution imaging of biological cells, which requires large field of view.
In this work, we present ultrastable plasmon-enhanced optical nanospectroscopy setup that has a home-built feedback system to compensate possible drift in all three dimensions [R. Kato et al., Science Advances (2022)]. This technical development we achieved overcomes the long-standing issue of the system drift, and thus the imaging time is no longer limited by the mechanical drift. Our ultrastable optical nanoimaging system enables characterization of nanoscale defects in micrometer-sized WS_2 layers at a high pixel resolution down to 10 nm without losing substantial optical signal. Owing to the ultrastable nanospectroscopy system, we could reveal that the defect density on the surface of WS_2 layers in large area equivalent to the device scale was indeed higher than the previously reported defect density of the smaller area. Furthermore, such long-duration plasmon-enhanced optical imaging led us to find rare properties of the materials, such as unique defects of WS_2, which one can easily miss with conventional systems. The present work paves the way for nanoscale optical spectroscopy and imaging of large-sized samples not only for optoelectronic devices but also biological cells, heterogeneous catalysis.

9:15 AM EL01.10.04
Resonance Raman Spectroscopy of Plasma-Treated Monolayer MoS_2RodrigoG. Costa, Andréd. Barbosa, FernandoL. Freire and MarceloE. da Costa; PUC-Rio, Brazil

Molybdenum disulfide (MoS_2) is a highly promising two-dimensional (2D) material, with applications in diverse fields such as optoelectronics and high-performance Li-S batteries. Defect engineering plays a pivotal role in fine-tuning the optical and electrical properties of 2D materials. This study investigates the controlled introduction of defects into MoS_2 monolayers through plasma treatments utilizing nitrogen and helium gases, enabling tailored properties for specific applications. We utilize resonance Raman spectroscopy, photoluminescence spectroscopy, and atomic force microscopy to investigate and characterize these defects. The samples are grown via Chemical Vapor Deposition (CVD).

Photoluminescence spectroscopy is utilized to investigate the optical properties of the MoS_2 monolayers. The main excitons change their intensity ratio for different treatment times, which is another defect-related phenomenon. Furthermore, atomic force microscopy enables detailed morphological analysis, contributing to the comprehensive characterization of the samples.

Resonance Raman spectroscopy reveals gradual changes in the MoS_2 monolayer's Raman spectra as the nitrogen plasma treatment time increases. We employ longitudinal acoustic LA(M) intensity, second-order 2LA(M) and 2LA(K) intensity, and full-width at half-maximum variations as quantitative figures of merit to assess defect density. This is particularly useful in heavily doped samples where photoluminescence is not present.

Additionally, we conducted plasma treatment with helium ions to further expand our understanding of defect engineering in MoS2. Comparing the effects of different plasma sources provides valuable insights into defect formation and properties tuning.

Laser Induced Oxidation and Defect Formation in 2D Materials NicholasGlavin; Air Force Research Laboratory, United States

High throughput characterization and processing techniques are becoming increasingly necessary to navigate multivariable, data-driven design challenges for sensors and electronic devices.. In this talk, a high-throughput approach for designing and customizing 2D materials that enable novel, multifunctional properties is presented. This technique involves the use of laser-processing to locally-induce crystallization, oxidation, and defect formation in 2D materials such as transition metal dichalcogenides, modifying local electronic and optical properties. Coupled with high-throughput characterization, this allows for the rapid evaluation of structure-property relationships and subsequent device design. This same process can be implemented in a roll-to-roll configuration to allow for manufacturing of ultralow cost 2D sensor devices for a host of different sensing environments, including the detection of pathogens.

Numerical Simulation of Strain Variations in Graphene AronCummings[1], ZahraKhatibi[2], JoseGarcia[1] and StephanRoche[1,3]; [1]ICN2, Spain; [2]Trinity College Dublin, Ireland; [3]ICREA, Spain

Graphene is a highly promising material for a variety of applications, and in many of those, defects, strain, and strain variations can play a fundamental role in the material properties and resulting device performance. Here we present our group's use of numerical simulations to examine the role of defects and strain variations in a few different scenarios, related to the spintronic and photothermoelectric properties of graphene. We make use of linear-scaling numerical simulation techniques to study systems containing many millions of atoms, thus reaching the experimental scale.

Owing to its small spin-orbit coupling and high carrier mobility, graphene has proven to be a highly efficient transporter of spin, with measured spin diffusion lengths in the tens or hundreds of microns. It is predicted that phonon scattering or local strain variations will serve as the ultimate limiting factor in spin transport. Here we present our use of numerical simulations to explore the upper limit of spin transport in graphene arising from thermally- and substrate-induced corrugations and strain variations.

Graphene is also extremely promising for its use as a high-speed, low-power photodetector in next-generation optical communications technologies. The performance of such photodetectors is ultimately limited by the interaction between hot electrons and dynamic strain variations, i.e., phonons. Defect-mediated electron-phonon interactions can also play a crucial role in the photodetector performance. Here we employ a time-dependent version of our numerical simulation tool to study the relaxation of hot carriers in graphene, mediated by the presence of both phonons and defects, and we explore avenues for optimizing the resulting photodetector performance.

Finally, we discuss a positive aspect of local strain variations in graphene – the electrical generation of pure spin currents via the spin Hall effect. By combining tailored local strain with spin-orbit coupling, we aim to significantly enhance the spin Hall effect in graphene. Here we will present our numerical simulations of this effect, and discuss its potential applicability for future low-power memories based on spin-orbit torque.

Strain Tunable Quantum Thermoelectrics in Semi-Dirac Silicene KalpanaPanneerselvam and BhaskaranMuralidharan; Indian Institute of Technology, Mumabi, India

The merging of K and K' points into a common M point through the synergic application of covalent addition and strain engineering becomes evident in a semi – Dirac semimetal that hosts the massless and massive fermions at the same point in the momentum space due to the existence of linear band dispersion along Γ-X direction and a parabolic band dispersion along Γ-Y direction (Zhong et al., 2017). Bringing the scenario of $t_2 = 2t_1$ (the relative strength of the hopping parameters) by oxygenating the silicene leads to the shifting of the Dirac points towards the Γ-point and the remaining deviation from the semi-Dirac point can be fine-tuned with the application of small compressive strain (δ = 0.1%) along armchair direction. The bandgap opening at M point by achieving $t_2 > 2t_1$ with the increase of compressive strain (δ = 3%) manifests itself by enhancing the power factor and the thermoelectric figure of merit (Mawrie et al., 2019). Theoretical analysis in the present work based on Landauer - Büttiker formalism offers the perspectives of how to modulate the thermal properties of a two-dimensional materials via functionalization and strain engineering which paves the way for designing a thermoelectric nano device based on semi-Dirac silicene that can be operated to yield the maximum power with the best thermoelectric efficiency.

Strain Effects on Thermal Conductivity of 2D Materials using the Optothermal Raman Technique MicahVallin[1,2], MichaelT. Pettes[1] and RichardZhang[2]; [1]Los Alamos National Lab, United States; [2]University of North Texas, United States

2D materials have gained more focus in the studies of materials science, often due to their properties compared to their bulk material counterparts, including a change in thermal conductivity. These changes in thermal conductivity from bulk materials to 2D materials has prompted investigations into the thermal properties of 2D materials in order to determine their suitability for applications such as energy sustainability. Because of this interest in 2D materials, there have been efforts to tune the properties of 2D materials in order to achieve a desired effect for a device; such tuning efforts methods include doping, adding layers to the 2D material, and strain. In studying the thermal conductivity of 2D materials, very little work has been done on the relationship between applied strain and thermal conductivity. This discussion aims to provide a comprehensive review on the effects of strain on the thermal conductivity of 2D materials using tin diselenide (SnSe2) and graphene on a copper (Cu) substrate. The experiments were performed using a Razorbill UC200 cryogenic stress-strain instrument in order to induce strain given a voltage input and the thermal conductivity was measured using the optothermal Raman technique while also taking conduction, radiation, and substrate resistance effects into account. Raman dependence measurements due to power are measured for every strain voltage input in order to determine the overall shift in thermal conductivity due to induced strain. The preliminary results for SnSe2 indicate that there is a shift of the Raman power dependence term (χP) from 0.004 18 cm−1 /µW at no strain induced to 0.003 48 cm−1 /µW at 0.5% strain induced, while preliminary theoretical results for graphene indicate a shift in the phonon dispersion when a 1% strain is induced to the unit cell; these indicate that shifts in the thermal conductivity due to strain is likely large enough to be observable experimentally.

1:45 PM EL01.12.02
Anomalous Size Effect and Strain Enhanced Thermal Transport in Dislocated vdW Nanowires YinLiu[1], LeiJin[2], TribhuwanPandey[3], HaoyeSun[2], DarylChrzan[2], LucasLindsay[4], JieYao[2] and JunqiaoWu[2]; [1]North Carolina State University, United States; [2]Department of Materials Science and Engineering, University of California Berkeley, United States; [3]Department of Physics, University of Antwerp, Belgium; [4]Advanced Materials Science and Technology division, Oak Ridge National Laboratory, United States

Dislocations are crystallographic defects which can significantly thermal property of materials. The engineering and control of dislocations is important for thermal management in optoelectronic devices as well as improving thermoelectric properties. Here, we explore the effect of dislocations on thermal conduction using van der Waal (vdW) germanium sulfide nanowires with an Eshelby twist as a model system. Contrary to the expectation that dislocations decrease thermal conduction, we reveal the thermal conduction enhancement resulting from dislocations through the anomalous dependence of the thermal conductivity on the diameters of the dislocated nanowires. Our TEM imaging and 4D STEM strain analysis, in combination with theoretical modeling and DFT calculations suggest that dislocations possess a disassociated structure with mixed screw and edge characteristics and the enhancement results from the dislocation induced compressive strain. Our findings expand the fundamental understanding about dislocation-phonon interactions and provide key insight into the implementation of dislocation and strain engineering to tune thermal conduction in materials.

2:00 PM EL01.12.03
Sensing Disturbance in Magnetic Order of $NiPS_3$ with Spin-Correlated Ultra-Sharp Exciton Emission TaiC. Trinh[1], RabindraBasnet[2], VigneshChandrasekaran[1], XiangzhiLi[1], AndrewC. Jones[1], JinHu[2] and HanHtoon[1]; [1]Los Alamos National Laboratory, United States; [2]University of Arkansas, Fayetteville, United States

A van der Waals correlated antiferromagnet, metal phosphorus trichalcogenides (MPX_3, M = Mn, Fe, Ni; X = S, Se), have emerged as promising candidates for next-generation spintronics and quantum information technologies. Nickel phosphorus trisulfide ($NiPS_3$) is a notable member of this family and has been extensively studied for its unique properties, including the emergence of an ultra-sharp photoluminescence (PL) peak at ~1.476 eV below the Néel temperature of 150 Kelvin. While the highly anisotropic, linearly polarized emission of this PL peak has been shown to be directly correlated to the long-range spin order of $NiPS_3$, its ultra-narrow linewidth of a few hundred µeV has led to the speculation that it originates from a coherent many-body exciton state. Observations of multiple phonon-bound states and the formation of exciton-polaritons also create more excitement as they present new possibilities for the design and control of correlated electron systems.

Aiming to understand how disturbances in the magnetic order of NiPS3 could influence the characteristics of this spin-correlated exciton emission, we conducted temperature-dependent

polarization-resolved PL studies on alloyed $Ni_{1-x}Mn_xPS_3$ compounds, with Mn doping percentage x varying from 0 to 0.22. As the Mn content increases, we observe a reduction in the intensity of the ultra-sharp PL emissions, accompanied by a broadening of the PL linewidth from 0.57 meV (spectrometer resolution limit) to 4.2 meV. Notably, at x = 0.22, the previously sharp peak becomes negligible. Moreover, the degree of polarization also decreases as the Mn doping percentage increases. Temperature-dependent PL measurements reveal that the sharp emissions vanish at lower temperatures with higher Mn doping. These findings are consistent with prior studies of $Ni_{1-x}Mn_xPS_3$ alloy, revealing a highly sensitive dependence of the spin-flop transition on the inclusion of Mn impurities. We are currently conducting Magneto-PL and Raman spectroscopy experiments to gain further insights into this material system. Our studies clearly show that the spin-correlated exciton emission of $NiPS_3$ can serve as a sensitive sensor for the disturbance of the long-range spin order.

2:15 PM EL01.12.04
Pseudomagnetic Gauge Field-Based Waveguides using Graphene ShrushtiK. Tapar and BhaskaranMuralidharan; Indian Institute of Technology Bombay, Bombay, India

The Scaling on-chip interconnects pose unprecedented challenges as node technology advances. Interconnect materials such as copper, when used at smaller sizes, have greater effective resistivity, so they dissipate more heat. Graphene, a quantum material with high thermal conductivity, mobility, and elasticity, is an ideal material for interconnects. The zero-band gap and zero backscattering for normal incidence in graphene limit its ability to exhibit strong confinement for waveguide operationality. Here, we are proposing a way for localizing carriers in graphene by generating a powerful on-chip magnetic field. In graphene, applied non-uniform strain produces strong pseudo potential and pseudo magnetic gauge fields attributed to the change in bond length. The strain profiles in which the curl of the pseudo vector potential is non-zero produce a Pseudo magnetic field (PMF). The PMF forms the pseudo–Landau Levels and increases the local density of states in the deformed region [1]. A wave-guided medium is created according to the strain profile by localizing the carriers within the deformed region [2]. We showed the confinement of carriers (in a nm scale) and the effect gets stronger with increasing strain value. The maximum value of strain considered is under the elastic limit. The waveguide shape can be tuned by varying strain profiles. The proposed graphene waveguide is robust against defects and impurities. The numerical simulation of graphene waveguides was based on the Tight binding method and scattering matrix approach.

Strain Engineering of Metal Thio(Seleno)phosphates for Nonlinear Photonics and Photodetection AbhishekMukherjee[1], MorganBlevins[1], MichaelSusner[2], MarkPolking[3] and SvetlanaV. Boriskina[1]; [1]Massachusetts Institute of Technology, United States; [2]Air Force Research Laboratory, United States; [3]Lincoln Laboratory, Massachusetts Institute of Technology (MIT), United States

We present an experimental and computational study of engineering in-situ strain in two-dimensional metal thio(seleno)phosphate materials aiming to unlock and enhance their fundamental magnetic, electronic, ferroelectric, and flexoelectric properties. The material families under study include MPX3 (X = S, Se) materials and materials with P2X6 (X = S, Se) structural sublattice. The single-crystalline thio(seleno)phosphates exhibiting layered structure have been synthesized by vapor transport techniques reported in previous literature [1] and exhibit a wealth of promising nonlinear optoelectronic and magnetic properties, including bulk photovoltaic effect, second harmonic generation, and (anti)ferromagnetic response [1]. We will describe the process of fabricating optoelectronic cells from these materials via mechanical exfoliation as well as the process of engineering the in-situ strain fields with large, localized strain gradients in these cells by material bending, wrinkling, and nano-lithography [2]. Strain gradient mapping with Raman spectroscopy reveals the limits and advantages of different strain-engineering strategies, while the strain-induced linear and nonlinear optical responses and the surface polarization effects can be characterized by atomic force microscopy, second harmonic generation experiments, and spatially-resolved electrical current measurements.

This research has been supported by the Army Research Office (W911NF-13-D-0001, for the strain-engineering fundamentals development), Lincoln Laboratory, Massachusetts Institute of Technology Advanced Concepts Committee (ACC-777, for the cell design and fabrication process development), and the US Department of Energy (DE-FG02-02ER45977, for the development of a custom-designed optoelectronic microscopic measurement setup), and a Draper Fellowship to Morgan Blevins.

Ultrafast Self-Localisation and Exciton Formation in Next-Generation Metal Halide Semiconductors LauraHerz; University of Oxford, United Kingdom

Metal halide semiconductors have emerged as attractive materials for solar cells with power-conversion efficiencies now exceeding 25%. Ultrafast optical probes of photoconductivity dynamics have played a pivotal role in uncovering the mechanisms underpinning the superior light-harvesting performance of this materials class.
Here, we further report on ultrafast charge-carrier self-trapping in lead-free silver-bismuth semiconductors[1-4] which promise lower toxicity and potentially higher barriers against ion migration than their more prominent lead-halide counterparts. We examined the evolution of photoexcited charge carriers in the double perovskite $Cs_2AgBiBr_6$ using a combination of temperature-dependent photoluminescence, absorption and optical pump−terahertz probe spectroscopy.[1] We observe rapid decays in terahertz photoconductivity transients that reveal an ultrafast, barrier-free localization of free carriers on the time scale of 1.0 ps to an intrinsic self-trapped small polaronic state. We further demonstrate the novel lead-free semiconductor Cu_2AgBiI_6 which exhibits a low exciton binding energy of ~29 meV and a lower and direct band gap near 2.1 eV,[2,3] making it a significantly more attractive lead-free material for photovoltaic applications. However, charge carriers in Cu_2AgBiI_6 are found to exhibit similarly strong charge-lattice interactions[3,4]suggesting a link with the presence of AgBi. Further work examining five compositions along the $AgBiI_4$–CuI solid solution line (stoichiometry $Cu_{4x}(AgBi)_{1-x}I_4$) shows that increased Cu^+ content enhances the band curvature around the valence band maximum, resulting in lower charge-carrier effective masses, reduced exciton binding energies, and higher mobilities, as well as partly mitigating the extent of such ultrafast self-localisation.[4] Self-trapping therefore emerges as a clear challenge for this class of materials.

We also discuss the charge-carrier photoconductivity dynamics in layered, 2D perovskites that have been found to improve the stability of metal halide perovskite thin films and devices.[5] We show that the 2D perovskite PEA_2PbI_4 exhibits an excellent long-range mobility of 8.0 cm^2 $(V\ s)^{-1}$, ten times greater than the long-range mobility determined for a comparable 3D material $FA_{0.9}Cs_{0.1}PbI_3$. These values shows that the polycrystalline 2D thin films already have single-crystal-like qualities. We further demonstrate that PEA_2PbI_4 and BA_2PbI_4 exhibit unexpectedly high densities of sustained populations of free charge carriers, surpassing the Saha equation predictions even at low temperature.[6] These findings provide new insights into the temperature-dependent interplay of exciton and free-carrier populations in 2D MHPs. Furthermore, such sustained free charge-carrier population and high mobilities demonstrate the potential of these semiconductors for applications such as solar cells, transistors, and electrically driven light sources.

Extracting Higher-Order Effects and the Related Multi-Particle Dynamics in Perovskites from Pump-Probe Spectroscopy ShabnumMaqbool[1,2], PratyushGhosh[1], SatyawanD. Nagane[2], NeilGreenham[1], RichardFriend[1], SamuelD. Stranks[2] and AkshayRao[1]; [1]Cavendish Laboratory, University of Cambridge, United Kingdom; [2]University of Cambridge, United Kingdom

Lead halide perovskites are in the limelight due to their excellent semiconductor properties, making them ideal for photovoltaic and optoelectronic applications. The emergence of perovskites as a sought-after semiconductor owes to their unique electronic band structure, inherent defect tolerance, increased conversion efficiencies, synthetic flexibility, and easy and cost-effective processibility. Lead halide perovskites show near-unity PL quantum yield, narrow emission bandwidth, high solar cell efficiencies, etc. All these properties are due to the nature and dynamics of the excited states. For an exclusive understanding of a one-to-one correlation between excited state dynamics and the material properties, different time-resolved pump-probe spectroscopic techniques are used wherein a probe pulse interacts with the charge carriers, and subsequently, information can be extracted about the charge carrier transport, recombination dynamics, and carrier phonon interactions, nature of quasiparticles, etc. Various pump-probe techniques, such as transient absorption [1], time-resolved Terahertz [2] spectroscopies, etc., have been utilized to explore the excited state properties. However, these techniques do not provide a distinction of higher-order effects due to multi-particle excitations from the single-particle signatures present in the material of interest. To infer multi-particle dynamics, fluence dependent measurements are usually performed, while a very low pump intensity measurement is considered to have the information regarding single-particle dynamics predominantly. The presence of multi-particle dynamics can be inferred from a fluence-dependent material response. We employ an analysis methodology, by following Pavel et al. [3], to decouple the single- and multi-particle dynamics in transient absorption data by employing the perturbative description of light-matter interaction

[4]. To arrive at this, we performed fluence-dependent TA measurements on thin films of the perovskite system $FA_{0.79}MA_{0.16}Cs_{0.05}Pb(I_{0.83}Br_{0.17})_3$ (bandgap~770 nm, where FA is formamidinium and MA is methylammonium), which have a high degree of polycrystallinity [5]. We observe a dominant contribution from the single-particle dynamics (Chi3) to the raw TA data, with contributions from multi-particle (Chi5 and Chi7) dynamics. We aim to ascribe these higher-order responses (Chi5 and Chi7) to different physical processes to probe quasiparticle interactions such as Auger recombination, carrier multiplication, multiphonon scattering, polaron formation, and bandgap renormalization in perovskites.

Addressing the Charge Carrier Trapping Mechanism in $CsPbBr_3$ NCs Brener RodrigoDe Carvalho Vale, ClaudevanA. Sousa, DiegoS. da Silva, Andre FelipeVale Fonseca, Luiz GustavoBonato, DiogoB. de Almeida, JeffersonBettini, AnaF. Nogueira and LazaroA. Padilha; Universidade Estadual de Campinas, Brazil

Perovskite nanocrystals (PNC) have been studied in recent years because of their interesting optical properties, which include high photoluminescence quantum yield (PLQY). However, despite the large number of reports on the effects of quantum confinement on the optical and electronic properties in PNCs, the literature still lacks information regarding the size dependence of the charge carrier trapping rate. To solve this puzzle, we investigate exciton dynamics for PNCs, with sizes ranging from 5 to 12 nm, using transient absorption spectroscopy (fs-TAS) and time-resolved photoluminescence (TR-PL) measurements. By combining both techniques, we were able to cover the dynamics with six orders of magnitude in time. Charge carrier trapping was observed to occur only on the nanosecond timescale. By considering the charge carrier trapping, and radiative recombination rates, we were able to quantify PLQY for these PNCs. The results show that PLQY increases with PNC size, which can be due to the reduction of the surface-volume ratio. We also observed that after carrier trapping and excitonic recombination, the PL decay is dominated by a very slow decay emission channel, which is related to detrapping. Our findings open new routes to take charge-carrier trapping mechanisms into account and precisely measure the PLQY of nano-structured materials and evaluate the effectiveness of surface passivation methods as well as investigate the basic phenomena in such materials.

Exciton Transport in $CsPbBr_3$ Nanocrystal Solids WilliamTisdale; Massachusetts Institute of Technology, United States

In semiconductors, exciton or charge carrier diffusivity is typically described as an inherent material property. Here, we show that the transport of excitons (i.e., bound electron-hole pairs) in $CsPbBr_3$ perovskite nanocrystals (NCs) depends markedly on how recently those NCs were occupied by a previous exciton. Using fluence- and repetition-rate-dependent transient photoluminescence microscopy, we visualize the effect of excitation frequency on exciton transport in $CsPbBr_3$ NC solids. Surprisingly, we observe a striking dependence of the apparent exciton diffusivity on excitation laser power that does not arise from nonlinear exciton-exciton interactions nor from thermal heating of the sample. We interpret our observations with a model in which excitons cause NCs to undergo a transition to a metastable configuration that admits faster exciton transport by roughly an order of magnitude. This metastable configuration persists for ~microseconds at room temperature, and does not depend on the identity of surface ligands or presence of an oxide shell, suggesting that it is an intrinsic response of the perovskite lattice to electronic excitation. The exciton diffusivity observed here (>0.15 cm^2/s) is considerably higher than that observed in other NC systems on similar timescales, revealing unusually strong excitonic coupling in a NC material. The finding of a persistent enhancement in excitonic coupling between NCs may help explain other extraordinary photophysical behaviors observed in $CsPbBr_3$ NC arrays, such as superfluorescence. Additionally, faster exciton diffusivity under higher photoexcitation intensity is likely to provide practical insights for optoelectronic device engineering.

Ultrafast Charge Carrier Dynamics in Solar Cell Materials OmarF. Mohammed; King Abdullah University of Science and Technology (KAUST), Saudi Arabia

The separation and collection of photo-generated charge carriers in light-harvesting devices are limited by the losses and ambiguous dynamical events at the surfaces and interfaces of the absorber layers.1-3 These events occur in ultrafast time scales and can only be visualized selectively in space and time by scanning ultrafast electron microscopy (the sole technique capable of surface-selective visualization of light-triggered carrier dynamics at nanometer and femtosecond scales). In this method, the surface of the photoactive materials is excited by a clocking optical pulse and the photo-induced changes will be directly imaged using a pulsed electron beam that generate secondary electrons with a couple of electron volts energy, which are emitted from the very top surface of the material in a manner that is extremely sensitive to the localization of the electron and hole on the photoactive material surfaces. This powerful technique along with ultrafast laser spectroscopy allow us to directly and precisely investigate and decipher the trajectory of charge carriers on materials surfaces and interfaces in real space and real time. Through this work, we have optimized the properties of photoactive materials for applications in light-harvesting devices that led to the world-record solar cell devices based on perovskite crystals. Moreover, we have clearly demonstrated in space and time how the surface orientations, surface oxidation and passivation can significantly impact the overall dynamical processes of photo-generated charge carriers in optoelectronic materials.4-5 Finally, I will talk about our recent ground-breaking work in X-ray imaging technology that include cutting-edge materials discovery, heavy-atom engineering, state-of-the-art characterization and efficient (nearly 100%) interfacial energy transfer between sensitizers and scintillators that has led to the development of novel X-ray imaging screens with outstanding sensitivity, ultralow detection limit, unprecedented spatial image resolution and low-cost fabrication, with potential applications in medical imaging, industrial monitoring and security screenings. 6-9

Enhanced Lattice Dynamics in a Single-Layered Hybrid Perovskite ZhuquanZhang[1], JiahaoZhang[2], Zi-JieLiu[1], NabeelDahod[1], WatcharapholParitmongkol[1], NiamhBrown[1], AlexiaStollmann[1], Woo SeokLee[1], Yu-CheChien[1], ZhenbangDai[2], KeithA. Nelson[1], WilliamTisdale[1], AndrewRappe[2] and EdoardoBaldini[3]; [1]MIT, United States; [2]University of Pennsylvania, United States; [3]The University of Texas at Austin, United States

Layered hybrid perovskites have attracted much attention in recent years due to their emergent physical properties and exceptional functional performances, but the coexistence of lattice order and structural disorder severely hinders our understanding of these materials. One unsolved problem regards how the lattice dynamics are affected by the dimensional engineering of the inorganic frameworks and the interaction with the molecular moieties. Here, we address this question by using a combination of high-resolution spontaneous Raman scattering, high-field terahertz spectroscopy, and molecular dynamics simulations. This approach enables us to reveal the structural vibrations and disorder in and out of equilibrium and provides surprising observables that differentiate single- and double-layered perovskites. While no distinct vibrational coherence is observed in double-layer perovskites, we discover that an off-resonant terahertz pulse can selectively drive a long-lived coherent phonon mode through a two-photon process in the single-layered system. This difference highlights the dramatic change in the lattice environment as the dimension is reduced. The present findings pave the way for the ultrafast structural engineering of hybrid lattices as well as for developing high-speed optical modulators based on layered perovskites.

Nonlinear Optical Properties of Colloidal Perovskite Nanocrystals ClaudevanA. Sousa[1], Luiz GustavoBonato[1], EduardoGonçalves[1], Brener RodrigoDe Carvalho Vale[1], ArthurAlo[1], DiogoAlmeida[2], LuizF. Zagonel[1], AnaF. Nogueira[1] and LazaroPadilha[1]; [1]Universidade Estadual de Campinas, Brazil; [2]Universidade Federal do ABC, Brazil

Colloidal perovskite nanocrystals (PNCs) have been explored in the last years because of their remarkable linear optical properties, such as high photoluminescence quantum yield, narrow emission spectra, and high tunability in the visible range. Most recently, several reports have claimed that this class of nanomaterials also possesses outstanding third-order nonlinear optical

properties, such as high two-photon absorption cross-section and high nonlinear refractive index. In this work, we investigate the size dependence of the nonlinear optical response in a series of cubic-shaped CsPbBr3 PNCs and show that their nonlinear optical response is not particularly high. Different from what it has been claimed in the literature, we show that no experimental evidence that supports the claim that the nonlinear refractive index for these PNCs is larger than those observed for other semiconductors. When all possible sources of artifacts are eliminated from the results, we observe that the measured magnitude of the intrinsic nonlinear refractive index varies between 10^{-14} and 10^{-13} cm^2/W, the same order of magnitude obtained for bulk semiconductors with similar bandgap energy. Differently from isolated PNCS, we show that, when grouped in superlattices, these nanomaterials can present unique nonlinear optical response due to collective effects.

Ultrafast Nano-Imaging Resolving Structure, Coupling and Dynamics of Matter on its Natural Length and Time Scales MarkusRaschke; University of Colorado Boulder, United States

Understanding and ultimately controlling the properties of matter, from molecular to quantum systems, requires imaging the elementary excitations on their natural time and length scales. To achieve this goal, we developed scanning probe microscopy with ultrafast and shaped laser pulse excitation for multiscale spatio-temporal optical nano-imaging. In corresponding ultrafast movies we resolve the fundamental quantum dynamics from the few-femtosecond coherent to the thermal transport regime. I will discuss specific examples visualizing in space and time the nanoscale heterogeneity in competing structural and electronic dynamic processes that define the performance in perovskite photovoltaics or energy dissipation in 2D heterostructures. I will then extend the discussion to new forms of photon-matter hybrid states that emerge from confining light on the nano-scale to new regimes of nonlocal and quantum nonlinear nano-optics. As a perspective I will show that we are at the cusp of the ultimate goal of functional imaging and control, to link macroscopic properties to microscopic interactions in materials at their fundamental spatio-temporal levels using light.

Unraveling Ultrafast Dynamics in Mixed-Phase Hybrid Metal Halide Perovskites RebeccaL. Milot; University of Warwick, United Kingdom

Metal halide perovskites are promising materials for many optoelectronic applications, particularly solar cells. However, the standard materials used in many high efficiency devices (e.g. 3D materials such as methylammonium lead triiodide, $MAPbI_3$) are unstable under ambient conditions due to their sensitivity to a number of environmental factors including humidity and light. To address stability issues, layered or quasi-2D materials are incorporated into 3D perovskite thin films as either a mixture or a capping layer. However, these materials can greatly alter the optoelectronic properties since the exciton binding energies in 2D perovskites can be as high as 100s of meV, meaning that a large population of excitons can be present at ambient temperatures.[1]

Since the beginning of the perovskite field about a decade ago, ultrafast spectroscopy techniques including optical pump/THz probe spectroscopy (OPTP) have provided vital information about the charge transport and charge-carrier dynamics in metal halide perovskites.[2] For these newly-developed mixed 2D/3D materials, however, understanding charge transport can be challenging using just one spectroscopic technique due to the presence of multiple materials and photoexcited species. To untangle the contributions from all of these different species, we have used a combination of visible transient absorption spectroscopy (TAS) and OPTP. While TAS can easily distinguish the excited states of various phases of 2D and 3D perovskites, OPTP is sensitive only to mobile free charge carriers and can be used to evaluate the charge-carrier mobility and separate excitonic effects when compared to TAS data. With this combination of techniques, we have evaluated various lead-based 3D perovskite thin films which have been treated with phenylethylammonium salts in order to preferentially form Ruddlesden-Popper phases at the surface of the films. In addition to finding that the charge-carrier dynamics are sensitive to the film preparation method, we distinguish between bulk and surface passivation effects and query charge transfer between 2D and 3D species.

4:00 PM EL02.02.06
Probing Polaronic Effects via Optical Pump – Terahertz Range Raman Probe GuyReuveni[1], SelinaNöcker[2,1] and OmerYaffe[1]; [1]Weizmann Institute of Science, Israel; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Understanding the impact of excited electrons on structural dynamics is essential for comprehending various macroscopic phenomena, for example, carrier mobility. The investigation of polarons has predominantly relied on indirect probing techniques such as temperature-dependent photoluminescence and carrier mobility measurements. Alternatively, time-dependent X-ray diffraction methods have been employed, but they often involve complex instrumentation.

In this study, we present a cutting-edge optical setup that directly probes lattice distortions induced by excited electrons. Our state-of-the-art approach involves a visible pulsed pump and continuous off-resonance Raman probe, enabling a direct detection and differentiation of polaronic effects. I will demonstrate the effectiveness of this table-top optical setup mainly on $BiVO_4$ single crystal, showing clear signatures of small polarons.

Visualizing Polaron Formation in Lead Halide Perovskite Quantum Dots by Time-Resolved Serial Crystallography KartikAyyer; Max Planck Institute for the Structure and Dynamics of Matter, Germany

Excitonic polaronic fields in metal halide perovskites (MHPs) are of intense research interest as a possible mechanism to explain their unique light harvesting and light emission properties. Quantum dots (QDs) of such materials exhibit additional size-dependent variations in their optoelectronic properties like the Stokes shift. We report the observation of signatures of polaronic deformation fields in CsPbBr3 QDs upon single resonant excitation by adapting the technique of time-resolved serial femtosecond crystallography at X-ray free electron lasers (XFELs). This method allows one to observe changes to the three dimensional shape of diffracted Bragg peaks from these quantum dots upon optical excitation which are, in turn, exquisitely sensitive to inhomogeneous lattice deformations in the particle.

Due to this sensitivity we were able to observe statistically significant changes in the average deformation field after resonant excitation with, on average, one photon per particle. Initial modelling shows evidence for optical-phonon-like deformations and indicates a larger extent of the electron polaron compared to the hole polaron, as well as an anisotropic spatial distribution of the deformation field due to confinement effects.

4:30 PM *EL02.02.08
Spatiotemporally Following Charge, Heat and Their Coupling at the Nanoscale in Energy Conversion Materials StephanieHart[1], LeoM. Hamerlynck[1], ErinMoloney[1], RongfengYuan[1], HannahWeaver[1], AidanO'Beirne[2], HenriqueBucker Ribiero[2], FinnBabbe[3], JamesUtterback[1], LiviaBelman-Wells[1], AlexKing[1], AdamWeber[3], MasakazuIwai[3], ScottK. Cushing[4], TonyHeinz[2] and NaomiS. Ginsberg[1]; [1]University of California, Berkeley, United States; [2]Stanford University, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]California Institute of Technology, United States

Ultrafast optical stroboscopic scattering microscopy (stroboSCAT) is emerging as an incisive technique to probe not only photogenerated electronic excitations and their transport as a function of nanoscale material structure, but also to simultaneously and distinctly probe the thermal energy generated and its transport, with temperature change sensitivity down to 100 mK. This ability opens opportunities to not only properly characterize each form of coexisting energy, but also to investigate the coupling and interconversion of charge to heat and heat to charge. After illustrating the mechanistic information accessible via carrier density-dependent transport in silicon, I will show a range of examples to support these abilities of interest for thermoelectric and photoelectrochemical applications. I will show how structural armchair anisotropy in black phosphorus generates energy transport anisotropies useful for thermoelectrics and describe how these processes are altered in the 2D limit. I will also show a series of structure-transport relationships in candidate photoelectrode transition metal oxides for photocatalysis and in natural photosynthesis. Finally, I will show how a related approach also enables investigation of solution phase reaction products and their transport.

Ultrafast Quasiparticle Dynamics at Complex Interfaces from Different Angles: Opportunities and Challenge JuliaStähler[1,2]; [1]Humboldt-Universität zu Berlin, Germany; [2]Fritz Haber Institute, Germany

Our group investigates elementary processes in materials and at their interfaces by several different types of ultrafast techniques. In this presentation, I will highlight the strengths and weaknesses of ultrafast optical transient absorption and angle-resolved photoelectron spectroscopy as well as introduce our new approach to time-resolved scanning near field optical microscopy (SNOM):

Dynamic screening of quasiparticles in WS_2 monolayers: We unravel the influence of quasiparticle screening in the non-equilibrium exciton dynamics of monolayer WS_2 by femtosecond time-resolved reflectance contrast measurements and a simple, comprehensive model that provides a complete picture of the competing phenomena governing the exciton dynamics in WS_2 upon photoexcitation. Particularly, we unveil the specific impact of excitons and carriers on the renormalization of the quasi-free particle band gap through screening, the exciton binding energy, and the linewidth broadening [1,2].

Real photodoping: ultrafast surface metallization of ZnO: The advent of photoinduced phase transitions (PIPT) and the investigation of their non-equilibrium dynamics on ultrafast timescales coined various fashionable terms like hidden phases, new phases of matter, or photodoping. I will discuss these terms using the example of ZnO that undergoes a semiconductor-to-metal transition upon real photodoping at very low excitation densities [3]. Notably, the hidden, metallic phase has no equivalent in the equilibrium phase diagram and shows decay dynamics on ultrafast timescales, but can also be retained and metastable [4].

Time-resolved SNOM in the visible at kHz repetition rates: The compatibility of SNOM with pulsed sources is hampered by the requirement of a high-repetition rate imposed by lock-in detection. We developed a sampling method, called quadrature-assisted discrete (quad) demodulation [5], which releases this constraint. It will be shown how this enables the usage of tuneable kHz sources not only for near-field imaging in pseudoheterodyne mode, but also for ultrafast pump-probe studies.

8:30 AM *EL02.03.02
New Ultrafast Optical and Structural Probes in Material Science KeithA. Nelson; Massachusetts Institute of Technology, United States

New methods for optical control and observation of electronic, spin, and lattice degrees of freedom have enabled previously inaccessible study of light-induced phase transitions and other transformations. Several such methods will be discussed.
Strong terahertz-frequency light fields have recently been used to drive far-from-equilibrium excursions and material transformations. Detailed understanding of the underlying mode-mode interactions involved can be obtained through 2-dimensional THz spectroscopy. Off-diagonal peaks in 2D THz spectra, as in other 2D spectra, directly reveal mode-mode couplings that are invisible to linear spectroscopy. Until recently, a single 2D spectrum typically required several days of data acquisition time because two time variables, the (interpulse) time between two THz pulses and the temporal profile of the nonlinear THz signal field induced by the incident pulses, needed to be scanned point-by-point on the two time axes. Instead, the entire time-dependent THz signal profile can be measured in a single laser shot using several hundred optical “readout” pulses with different time delays that are all overlapped spatially with the THz signal field in an electro-optic crystal and then directed to different regions of a multi-pixel detector. In recent work, systematically incremented THz magnetic field polarizations relative to the crystallographic axes of canted antiferromagnets were used to record 144 2D spectra in less than 24 hours, introducing *2D THz polarimetry* which revealed a previously unknown but likely ubiquitous mechanism for coupling between different magnon modes in this material class (*arXiv*:2207.07103; *arXiv*:2301.12555). Similar methodology has been used for true single-shot THz and optical measurements of a photoinduced transition into a metastable phase of TaS_2 at low temperatures (*Sci. Adv.* **8**, eabp9076).
New advances and results in x-ray diffraction and spectroscopy at x-ray free-electron lasers (XFELs) will be discussed very briefly. A THz-induced transient ferroelectric (FE) structure in low-temperature $SrTiO_3$ has been studied using two inverted THz generation crystals to drive the crystal with single-cycle THz fields of inverted polarity. The resulting inverted x-ray scattering signals recorded at wavevectors near but not on Bragg diffraction peaks revealed that the THz-induced FE rearrangements occur predominantly in pre-existing polar nanoregions, a key mechanistic insight not accessible through earlier optical measurements (*Science* **364**, 1079). In separate measurements in the extreme UV (EUV) transient grating facility at the FERMI beamline (*Sci. Adv.* **5**, eaaw5805), crossed EUV pulses generated coherent magnons with 50-100-nm wavelengths whose time-dependent oscillations revealed magnon dispersion in this often inaccessible wavevector range. Coherent driving of high-wavevector phonons, magnons, and other excitations with spatial periods <10 nm is anticipated.
Finally, very recent development (*arXiv*:2209.13897) of a method for *laser generation of shock waves without damage to the optically irradiated region of the sample* permits significant structural control to be incorporated into ultrafast measurements conducted at high repetition rates. A shock wave can be generated nondestructively and propagated into a pristine sample region where THz, optical, and/or x-ray pulses are used for ultrafast measurements. The shock-induced strain duration is ~1 ns, so ultrafast measurements can be conducted with quasi-DC strains whose magnitudes (up to 3%, ~10 GPa pressure) can be specified. Multimodal control using strain plus THz and/or optical excitation pulses can be used to guide materials into new phases or other states of interest. Repeated shock delivery to the same sample region also permits detailed study of fatigue, where macroscopic material failure occurs only after many shocks. X-ray imaging may permit characterization of the nanoscale defects that accumulate prior to failure.

Magnons, or spin waves, are a subject of intense research aimed at both uncovering fundamental physics and paving the way towards applications such as spintronics [1]. Traditionally, magnons have been studied using scattering spectroscopy techniques such as Brillouin light scattering (BLS), inelastic neutron scattering (INS), and resonant inelastic x-ray scattering (RIXS). Combined, these techniques cover wavevector ranges from <0.03 nm^{-1} (BLS) and >0.5 nm^{-1} (INS/RIXS), thereby leaving the wavevector gap from 0.03 to 0.5 nm^{-1} inaccessible. Furthermore, these techniques typically rely on scattering of thermal magnons, limiting the study of coherent magnons to microwave or femtosecond laser techniques. The wavevector of coherent magnons is limited by the need to fabricate nanostructures in the former case and by the optical wavelength in the latter case. We present an ultrafast coherent magnon spectroscopy technique based on the extreme ultraviolet transient grating (EUV-TG) approach developed at the free-electron laser facility FERMI [2], that bridges the wavevector gap between BLS and INS/RIXS while providing a way to excite coherent magnons with wavelengths in the nanometer range without resorting to extensive fabrication. Furthermore, as a time-resolved method, it is not limited by spectrometer resolution, and allows for the direct measure of damping parameters. Upon excitation, transient magnetic gratings [3] where excited in Fe-Gd ferrimagnetic multilayer samples by crossed femtosecond EUV pulses, and detected by diffraction of a time-delayed EUV probe pulse whose wavelength was tuned to the N-edge of Gd. The rapid change in the magnetic anisotropy following the excitation drove spin precession and launched coherent magnons at the wavelength dictated by the transient grating period. By varying the pump wavelength from 25 – 42 nm, the magnon wavevector was varied from 0.07 – 0.12 nm^{-1}. In combination with optical measurements at zero wavevector, magnon dispersion curves were constructed. We also report a drastic change in the magnon response between samples with compensated and perpendicular magnetic anisotropy, arising from slight changes in the Fe-Gd ratio. In addition, we have produced transient magnetization gratings with a period as small as 17 nm, which opens the prospect for ultrafast control of magnetism on the sub-10 nm spatial scale, which is necessary for applications such as magnetic memory.

Transient Nanoscopy of Exciton Dynamics in Two-Dimensional Transition Metal Dichalcogenides JingangLi and CostasP. Grigoropoulos; University of California, Berkeley, United

States

The electronic and optical properties of 2D transition metal dichalcogenides (TMDCs) are dominated by strong excitonic resonances. Exciton dynamics plays a critical role in the functionality and performance of many miniaturized 2D optoelectronic devices. While time-resolved photoluminescence and transient absorption spectroscopies are widely used to characterize the exciton lifetime and transient behaviors of TMDC layers, the measurement of local excitonic responses at the nanoscale remains challenging.
Here, we report a near-field transient nanoscopy to probe exciton dynamics beyond the diffraction limit. Exciton recombination and exciton-exciton annihilation processes in monolayer and bilayer MoS_2 are studied as the proof-of-concept demonstration. Moreover, with the capability to access the local exciton dynamics, we directly observe the strain-induced suppression of exciton-exciton annihilation in a nano-wrinkled MoS_2 flake. Such nanoscale resolution highlights the potential of our optical nanoscopy for fundamental investigation of exciton physics and further optimization of functional devices. Our results further demonstrated the capability to probe carrier behaviors in other nanoscale materials and devices, which is of great significance to understanding the optoelectronic properties and practical functionality of semiconductor nanostructures.

Floquet Engineering of Two-Dimensional Materials by Time-Periodic Light Field ShuyunZhou; Tsinghua University, China

Time-periodic light-field can dress the electronic states of quantum materials, providing fascinating opportunities for transient modification of the electronic band structure with light-induced emergent phenomena [1]. In this talk, I will present our recent experimental progress on the Floquet engineering of two-dimensional materials by time-periodic light field using time- and angle-resolved photoemission spectroscopy. Using black phosphorus as an example, I will present the light-induced engineering of the transient electronic structure upon near-resonance pumping with intriguing light polarization dependence, which reflects the pseudospin selectivity [2]. By further pushing the specifications of the pump pulses, the light-induced electronic structure renormalization can be further enhanced, and insights for extending Floquet engineering to more materials will be discussed.

Out-of-Equilibrium Insights into Condensed Matter - Experimental Opportunities at Bernina/SwissFEL HenrikLemke; Paul Scherrer Institute, Switzerland

Functional transitions in materials can be effectively prbed by ultrafast X-ray probes. Their structual sensitivity for electronic or magnetic structure in condensed matter systems gives insight into complex processes. Dedicated instumentation and examples for experiments at Benrina/SwissFEL will be presented.

A Time Domain View of 2D Van Der Waals Interfaces XiaoyangZhu; Columbia University, United States

Interfaces of two dimensional (2D) van der Waals (vdW) crystals, formed from mechanical transfer stacking or chemical vapor deposition, constitute the most versatile material platforms for the exploration of new physical phenomena, particularly emergent quantum phases. Here we apply femtosecond pump-probe spectroscopy/microscopy to develop a time-domain view of quantum phases at 2D vdW interfaces. Using transitional metal dichalcogenide (TMDC) heterobilayers and 2D layered magnetic semiconductors (e.g., CrSBr), we probe the nature of the quantum phases and their coupling to different degrees of freedom. For TMDC moiré interfaces, we show the robustness of correlated electron phases and their coupling to excitons and phonons. In the layers magnetic semiconductors, we discover the coupling between interlayer electronic hybridization to magnetic order and, as a result, the strong coupling of excitons to coherent magnons. These time-domain views reveal not only the nature of the quantum phases, but also prospects of controlling these quantum phases by light.

Ultrafast Many-Body Interactions in Two-Dimensional Transition-Metal Dichalcogenides Suman KalyanPal and AshishSoni; IIT Mandi, India

Two-dimensional (2D) transition-metal dichalcogenides (TMDCs) have sparked tremendous interest because of their versatile application possibilities owing to exceptional optical, electrical, and mechanical properties. [1, 2] Strong Coulomb interaction and reduced screening make theme suitable candidates for investigating many-body interactions at room temperature. [3] In recent years, ultrafast optical techniques have been used to directly access many-body processes occurring in 2D TMDCs. [4] We investigated the charge carrier dynamics in chemical vapor deposition (CVD)-grown TMDC flakes using femtosecond transient absorption spectroscopy. In this talk, I will shed light on the interplay between exciton formation, relaxation, and trapping processes, providing insights into the dynamics of exciton annihilation in 2D TMDCs.
The first part of my talk is about the study of ultrafast carrier dynamics in monolayer WS_2. By monitoring the transient optical responses, we identified exciton trapping by defects, elucidating the impact of defect states on excitation-density dependent carrier decay dynamics. [5] Our findings shed light on the influence of defect states in CVD-grown TMDCs, thus paving the way for utilizing such TMDCs in optoelectronic devices. Next, I will demonstrate efficient multiple exciton generation (MEG) in monolayer MoS_2 by monitoring excitation photon-energy dependent carrier dynamics. We not only observed low threshold energy for MEG, but also high (86%) MEG efficiency. [6] The experimental findings obtained from this work will have greater implications in developing mechanically flexible and highly efficient next-generation solar cells and photodetectors.

Topological Resonace in Graphen-Like Materials KrishnaRana Magar and VadymApalkov; Georgia State University, United States

In topological materials, interacting with short and strong optical pulses, electrons can accumulate a topological phase during the pulse. Such phase can compensate the dynamic phase resulting in topological resonance, which is visible as a large inter-band transfer of electron population. We study theoretically the topological resonance in materials of the gapped multilayer graphene type. We show that the resonance can be observed only in the systems with finite bandgap. For monolayer graphene, the topological resonance can occur only in the field of an elliptically polarized pulse while for multilayer graphene, the resonance can also be realized in a linearly polarized pulse.

SESSION EL02.04/QT02.06: Joint Session: Time-Resolved Spectroscopies for Emergent Quantum Materials
Session Chairs: Burak Guzelturk and Yao Wang

New Physics in Driven Quantum Materials AndreaCavalleri[1,2]; [1]Max Planck Institute for the Structure and Dynamics of Matter, Germany; [2]University of Oxford, United Kingdom

I will discuss how coherent electromagnetic radiation at Tera-Hertz and mid-infrared frequencies can be used to manipulate complex solids. As collective excitations are driven coherently and nonlinearly, virtually uncoupled normal modes of the material are made to interact. Hence, these drives give rise to non-thermal states with unconventional properties, and sometimes with emergent order under a drive. Interesting examples involve the nonlinear control of the crystal lattice, used to induce magnetic order, ferroelectricity and non-equilibrium superconductivity at

high temperatures.

Unraveling Electron-Phonon and Phonon-Phonon Coupling in Momentum and Time with Ultrafast Electron Diffuse Scattering (UEDS) BradleySiwick; McGill University, Canada

The nature of the couplings within and between lattice and charge carrier degrees of freedom is central to condensed matter and materials physics. These interactions are essential to phenomena as diverse as superconductivity, charge density waves and carrier mobility in semiconductors and metals. Despite their fundamental importance, detailed momentum-dependent information on the strength of electron-phonon coupling (EPC) and phonon-phonon coupling (PPC) across the entire Brillouin zone has proved to be very difficult to obtain.

In this talk I will describe an emerging pump-probe technique, ultrafast electron diffuse scattering (UEDS), that provides such information from the perspective of the phonon system directly. Two recent examples of the application of UEDS to layered (2D) materials will be the focus. First, in the thermoelectric material SnSe – a strongly polar semiconductor – we directly observe the phonon dressing processes that yield carrier localization and polaron formation with UEDS. In SnSe these phonon dressing dynamics are profoundly bimodal, with the fast (300 fs) process associated with the formation of a quasi-1D lattice distortion and a relatively large polaron and the slower (4 ps, an order of magnitude slower timescale) process associated with small polaron formation. The observations in SnSe are consistent with electron and hole polarons being different sizes, or the process of polaron formation being instrincially bimodal for both carriers in a manner reminiscent of Lars Onsager's inverse snowball effect. Second, the extension of UEDS to a MoS_2 monolayer heterostructure will be demonstrated. These results reveal substrate dielectric screening of the electron-phonon interaction within the monolayer as well as the monomentum-dependent carrier-phonon equilibration. These results are compared directly against ab-initio simulations of these processes.
