Strategies for Improving The Microenvironment in Electrochemical CO_2 Reduction Using Nanostructured Catalysts Andrew B. Wong; National University of Singapore, Singapore

The electrochemical CO_2 reduction reaction (CO_2RR) represents a promising approach toward the carbon-neutral generation of hydrocarbons. However, despite intense research efforts, the need remains to increase selectivity and activity for electrocatalysts for CO_2RR. In order to accomplish these goals, there has been increasing interest in optimizing the microenvironment to boost the activity and selectivity of electrocatalytic sites for CO_2 conversion. However, the functional understanding of how to tune the microenvironment is still under development.

This presentation discusses several strategies that are being pursued in my research group to illustrate design principles to optimize the microenvironment for CO_2 conversion, which include:

(1) Nanostructured model systems to illustrate control of diffusion via engineering electrode structure at micro- and nano-length scales

(2) Nanostructured model systems to harness localization of tandem catalysts.

This talk will also share perspectives about harnessing nanoscale materials to control and enhance the microenvironment in order to enhance CO_2 conversion.

Transition Metal Doped Electrospun Fibers as Freestanding Electrodes for Carbon Dioxide Electroreduction Hattie Chisnall, Michael W. Thielke and Ana Jorge Sobrido; Queen Mary University of London, United Kingdom

The electrochemical carbon dioxide reduction reaction (CO_2RR) is a promising route to reducing excess atmospheric CO_2 emissions and producing valuable commodity chemicals. While there are upwards of 16 products accessible via the multi-electron, multi-step reduction, each pathway is required to proceed via an initial electron transfer from CO_2 to the anion radical, CO_2*−. This first electron transfer step, being the most energetically demanding, proves difficult in the absence of a catalyst due to the high overpotential (-1.9V vs SHE) required to reduce the thermodynamically stable, linear CO_2 molecule. The success of CO_2RR is therefore guided by efficient electrocatalysts which circumnavigate such high activation energies and promote favourable kinetics. The design of selective electrocatalysts which offer high faradaic efficiencies, reduced overpotentials, and provide high current densities has thus inspired an extensive area of research.

Transition metals have been consistently established as highly efficient electrocatalysts within this field. Within this reach, we have investigated two promising morphologies of active site: molecular-based catalysts with well defined active sites which demonstrate high selectivity for the 2-electron reduction of CO_2 into CO and in situ formed copper nanoparticles, which facilitate CO_2 conversion into C2+ products. The former has inspired investigation into the electrocatalytic behaviour of phthalocyanine complexes: aromatic, macrocyclic molecules consisting of four isoindole subunits with a central cavity which supports a metal atom. While distinct transition metal sites within the molecular cavity offer improved selectivity and work well to suppress the competing hydrogen evolution reaction (HER), they fail to offer pathways beyond C1 products. Attempts to access more energy dense products have been made via controlled in situ growth of copper nanoparticles during simultaneous carbonisation of the graphitic matrix. While an intermediate binding energy to *CO is responsible for the well-known propensity of copper to facilitate electrochemical CO_2 reduction to C2+ products, restraint of particle size and regulation of crystal facets via temperature control allow the user significant control over product selectivity and overall catalytic efficiency.

Freestanding electrocatalysts offer a significant advantage over commonly used catalytic inks as they provide a larger surface area. We have elected to synthesise freestanding nanofibrous mats via electrospinning polymer solutions followed by a carbonisation step. Polyacrylonitrile, a widely-available synthetic polymer, used as a precursor allows fabrication of conductive fibres with advantageous nitrogen doping. Likewise, electrospinning bio-mass derived lignin can introduce oxygen-functionalities with the added advantage of avoiding petrochemical-derived precursors. Heteroatom functionalities may act to both bolster performance of the overall catalyst through their inherent activity and also to anchor active sites to the surface of the support. The covalent binding of molecular catalysts via the central transition metal onto such supports has demonstrated improved charge transfer when compared to those which rely on isolated molecular catalysts or those bound through pi-pi stacking. In the case of freestanding carbon fibers with in situ deposition of copper nanoparticles, the distribution of uniformly sized catalytic particles is enabled throughout the graphitic fibres.

9:00 AM EN09.05.03
Comparison of Mono- and Multi-Layer MoS_2 within Non-Aqueous Reactive Carbon Capture and Conversion (RCC) Conditions Kingston Robinson[1], Rowan Brower[1], Jose L. Perez Gordillo[2,1] and Jesus M. Velazquez[1]; [1]University of California, Davis, United States; [2]University of Puerto Rico at Humacao, United States

With a need to reduce global emissions and scale up alternative energy sources to fossil fuels, RCC integrates CO_2 capture and conversion into a singular electrochemical, thermal, or biological process as a feedstock for value added chemicals. Despite significant progress in CO_2 electrocatalyst design to improve efficiency, reproducibility, and selectivity in aqueous media, achieving the same milestones within non-aqueous media under RCC conditions remains a challenge. However, preliminary results show that single crystal molybdenum disulfide (MoS_2) exhibits high efficiency (~65%) towards CO production under non-aqueous RCC with ionic liquids. The electrocatalytic behavior of MoS_2 can be controlled by exposing edge and terrace active sites through surface defects or by modulating its structure through compositions such as thin film monolayers and multi-layer nanosheets. It is hypothesized that by decreasing MoS_2 layers, further efficiency and selectivity of CO_2 reduction products under relevant non-aqueous RCC conditions will be observed due to increased surface area of active sites. Two different synthetic pathways are detailed in this work, shear exfoliation of bulk MoS_2 to yield dispersions of nanosheets and metal organic chemical vapor deposition (MOCVD) of monolayer MoS_2 thin films. The shear exfoliation process is a combination of mechanical and liquid-phase techniques, utilizing a homogenizer along with chemical exfoliation from different surfactants. Exfoliating agents such as sodium cholate resulted in MoS_2 nanosheets with large terraces while polyvinylpyrrolidone (PVP) resulted in small nanoparticle MoS_2 sheets. Therefore, size distribution of MoS_2 sheets may be controlled with the type of exfoliating agent. Our MOCVD process utilizes $Mo(CO_6)$ and diethyl sulfide (DES) as metal organic precursors flown in a vapor phase with Ar and H_2 gas for deposition onto Si/SiO_2 wafers. At optimal chamber pressure and temperature as well as precursor/gas flow rates, deposition of nucleation zones, monolayers, and few layered structures occur as a function of time. Shear exfoliated nanosheets and MOCVD deposited monolayers will be tested against single crystal MoS_2 under relevant non-aqueous RCC conditions with ionic liquids.

9:15 AM EN09.05.04
Regulating Spillover Effect in Cu-Ag via Zeolite Frameworks for Efficient CO_2 Electroreduction Dohun Kim[1], Joon Y. Kim[2], Woosuck Kwon[1], Taemin Lee[1], Uk Sim[2] and Dae-Hyun Nam[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Energy Technology (KENTECH), Korea (the Republic of)

Electrochemical CO_2 reduction reaction (CO_2RR) has been regarded as a promising green technology for lowering atmospheric CO_2 level and producing value-added products. For multi-carbon (C_{2+}) chemical production, Cu-based electrocatalysts have been developed by various strategies, such as defect engineering, alloying with other metals, and morphological engineering. Among these various strategies, the spillover effect between Cu and Ag has been considered as an effective avenue for modulating CO_2RR selectivity and activities. However, previous works about spillover effect have focused on controlling the Cu/Ag ratio rather than regulating the interface reaction between Cu and Ag.
Herein, we propose a novel strategy to optimize spillover effect on the Cu surface by modulating anion species in zeolite framework-augmented gas diffusion electrode (GDE). In CO_2RR, anions such as Cl, Br, and I can modulate the Cu surface oxidation states and create Cu (0)-Cu (I) mixed sites which facilitate C-C coupling by modifying *CO binding. However, these anions can easily migrate to the anodic side by crossover in anion exchange membrane under high current density conditions. Thus, we augmented AgX (X = Cl, Br, and I)-incorporated zeolite A (AgX-Zeolite A) on Cu electrocatalysts to modulate spillover effect by restricting anion migration. They showed lower hydrogen production and more efficient CO_2RR compared to bare Cu electrocatalysts in 1 M KOH electrolyte conditions. Especially, AgCl-, AgBr-, and AgI-Zeolite A on Cu electrocatalysts exhibited 586.3, 495.8, and 456.4

mA/cm^2 as maximum partial current densities for C_{2+} products. This trend is in inverse relationship with the electronegative force of anion species. With increasing electronegative force, the Cu (I) sites become more dominant rather than Cu (0)-Cu (I) mixed sites. However, AgCl-, AgBr-, and AgI-Zeolite A on Cu electrocatalysts showed the 0.89, 1.17, and 1.14 as Faradaic efficiency (FE) ratio of ethanol (C_2H_5OH)/ethylene (C_2H_4), respectively. These results verified that anion species stabilized by zeolite framework not only accelerate C_{2+} production but also steer the CO_2RR pathway to specific products *via* spillover effect. Our work provides an insight of zeolite framework-augmented GDEs for high rate and selective C_{2+} chemical production in CO_2RR.

9:30 AM EN09.05.05
Cation Exchange Ionomer-Based Microenvironment Control of Gas Diffusion Electrode for Efficient CO_2 Electroreduction Yujin Lee[1], Daewon Bae[1], Woosuck Kwon[1], Hansol Choi[2], Hyungju Ahn[3], Chang Hyuck Choi[2], Chanyeon Kim[1] and Dae-Hyun Nam[1]; [1]Daegu Gyeongbuk Institute of Science & Technology (DGIST), Korea (the Republic of); [2]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [3]Pohang Accelerator Laboratory (PAL), Korea (the Republic of)

Electrochemical CO_2 reduction reaction (CO_2RR) where CO_2 is converted into a high-value-added compound can be a great strategy for carbon neutrality. Gas diffusion electrode (GDE) which allows the formation of triple phase boundary (TPB) of catalyst, electrolyte, and CO_2 gas has been widely applied for CO_2RR. It results in overcoming the CO_2 solubility limitation in double phase boundary (DPB) of electrolyte and catalyst, and thus increases the CO_2 availability. However, the volume of TPB where the reaction occurs is much smaller than the volume of DPB. Therefore, it is important to increase the volume of TPB for CO_2RR activity. Cation exchange ionomer enables us to control the volume of TPB. The hydrophobic chains of ionomer that play a role as gas channel and hydrophilic ionic groups that form a water matrix increase the volume of TPB in GDE-based systems.
Here, we verify the effect of ionomer on CO_2RR performance in 1 M KOH electrolyte by controlling CO_2/H_2O ratio and CO_2 availability near GDE-based Cu catalyst surface. To distinguish the effect of each part of ionomer, we control the variables of ionomer; (1) Controlling the length of side chain with the application of Nafion as long side chain (LSC) ionomer and Aquivion as short side chain (SSC) ionomer, (2) Fixation of equivalent weight (EW). Compared to the maximum H_2 partial current density (J_{H2}) of 71.3 mA/cm^2 at bare Cu, Nafion decreases the maximum J_{H2} to 11.5 mA/cm^2 while Aquivion decreases it to 26.4 mA/cm^2. On the other hand, the maximum CO partial current density (J_{CO}) is 75.1 mA/cm^2 at Nafion whereas it is 24.1 mA/cm^2 at Aquivion. Nafion and Aquivion also improve the maximum C_2H_4 partial current density (J_{C2H4}) to 169.5 and 173.3 mA/cm^2, respectively. Based on the characterization of ionomers in GDE, we found that LSC ionomer can induce a higher CO_2/H_2O ratio than SSC ionomer and increase CO_2 availability near the active site. Also, we assume that it affects the CO_2RR selectivity by tuning the local OH^- concentration. Improved OH^- formation by high current density CO_2RR at ionomer-augmented catalysts affects the surface charge density that can enhance CO_2RR selectivity. Therefore, the key factor of ionomer effect on CO_2RR performance enhancement is regulation of the water concentration near the catalyst surface which impacts the CO_2 availability and ion conductivity through this water matrix. We expect that this work will suggest a more accurate understanding of the mechanism of ionomer effect on CO_2RR and strategy for optimizing the microenvironment of catalyst for efficient CO_2RR.

Cationic Cu Species Tracked via *Operando* X-Ray Microscopy during CO_2 Electrocatalysis and Their Role in Boosting C-C Coupling Activity Jongwoo Lim[1,2], Juwon Kim[1], Si Young Lee[3], Se-Jun Kim[4], Bonho Koo[1], Namdong Kim[5], Matthew Markus[6], David Shapiro[6], Shu-Chih Haw[2], Daan Hein Alsem[7], Norman Salmon[7], Hyungjun Kim[4] and Yun Jeong Hwang[1]; [1]Seoul National University, Korea (the Republic of); [2]National Synchrotron Radiation Research Center, Taiwan; [3]University of Michigan–Ann Arbor, United States; [4]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [5]Pohang Light Source, Korea (the Republic of); [6]Advanced Light Source, United States; [7]Hummingbird Sceintific, United States

Unraveling and guiding the dynamic evolution of active species in efficient electrochemical CO2 reduction (ECR) catalysts remains a challenge. Through observing the chemical and morphological changes of high-performance ECR catalysts in action, we pinpointed the essential intermediate species that lead to highly active surfaces and notably improved C–C coupling activity. Operando scanning transmission soft X-ray microscopy, a method that illustrates the nanoscale chemical composition distribution of Cu-based catalysts during ECR, showed that the emergence of partial Cu+ phases and surface Cu2+ phases are key to the dynamic dissolution-redeposition mechanism and heightened C–C coupling activity, respectively. We further established that this dissolution-redeposition process is electrochemical formation Cu^{2+} phases, even at elevated cathodic potentials. Our correlative microscopy and electrochemical analysis strengthen the substantial contribution of Cu2+ phases toward C-C coupling. In addition, DFT calculations corroborated that Cu2+ phases amplifies C–C coupling activity.

Vibrational Spectroscopy at Electrified Interfaces: Electrochemical CO_2 Reduction Reaction Heng-Liang Wu[1,2,1]; [1]National Taiwan University, Taiwan; [2]National Synchrotron Radiation Research Center, Taiwan

The solid-liquid interfacial reactions play a crucial role in controlling the performance and stability of electrocatalysts[1-4]. In situ vibrational spectroscopy techniques such as Raman and surface-enhanced infrared absorption spectroscopy (SEIRAS) are the powerful tools for examining the surface-adsorbed intermediates on the solid-liquid interfaces. In this talk, we report on our use of in situ SEIRAS, Raman, and X-ray absorption spectroscopy to investigate the electrochemical CO_2 reduction mechanism over the Cu-based electrocatalysts. The Cu-based electrodes with different oxidation states result in the formation of various CO intermediates such as CO_{atop} and CO_{bridge}. The co-existence of CO_{atop} and CO_{bridge} corresponds to the selectivity of CO_2-to-C_2H_4 reaction. Also, the bimetallic electrocatalysts are developed for efficient CO_2-to-HCOOH and CO_2-to-CO conversion processes. We found that the surface-adsorbed COO species with different binding structures play crucial role in the reduction process. The electronic structures of Cu-based electrocatalysts are associated with the formation of surface-adsorbed intermediates and electrocatalytic properties. The formation of surface-adsorbed intermediates and reaction mechanism associated with CO_2-to-HCOOH and CO_2-to-CO reactions over the bimetallic electrocatalysts will be discussed in detail.

Role of Reservoir and Diffusion for Electrocatalytic CO_2 Reduction to Ethylene on Cu Sydney H. Hemenway[1,2], Chansol Kim[1,3], Nitish Govindarajan[4], Junho Park[1,2], Anya Zoraster[1,2], Calton J. Kong[1,2], Rajiv R. Prabhakar[1], Joel Varley[4], Hee-Tae Jung[3], Christopher Hahn[4] and Joel W. Ager[1,2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [4]Lawrence Livermore National Laboratory, United States

Electrochemical CO_2 reduction (EC-CO_2R) on Cu is a promising approach to produce value-added-chemicals using renewable feedstocks. The ability of Cu to produce multi-carbon products during electrochemical CO_2 reduction is conventionally understood in terms of the binding energy of the crucial CO intermediate and the existence of active sites which facilitate C-C coupling. Yet the vast differences in activity and selectivity towards single and multi-carbon products produced by various Cu preparations suggest that this picture is incomplete. In this work, we find that the effective catalytic activity towards ethylene improves with a larger fraction of **less active** sites acting as reservoirs of *CO on the Cu surface. This surprising finding can be explained by the rapid supply of *CO from reservoir to active sites which increases the effective activity of active sites. Experimental evidence is provided by real-time measurements of mass flow exiting a gas diffusion electrode cell held at a fixed potential and subjected to different precursor feeds. When the precursor feed is switched from inert Ar to CO, CO reduction to C_2+ products begins promptly, as expected. However, when the precursor feed is switched from CO to Ar, CO reduction continues for several seconds (delay time) before transitioning to hydrogen evolution. Control experiments establish that some Cu preparations, most notably oxide-derived Cu, can maintain COR activity in the absence of the gas phase precursor due to reservoir sites on the Cu surface that bind CO but do not convert it. We introduce a microkinetic model which shows that the delay time originates from a less active *CO reservoir that exhibits fast diffusion to active sites on the surface of OD-Cu. Experiments find that delay time and *CO reservoir sizes are affected by the catalyst preparation, applied potential, and microenvironment. Notably, we associate large *CO reservoir surface coverages (maximally 86±5% at -1.52 V vs. SHE) with increased ethylene production. We also estimate that *CO can travel long distances (up to 10s of nm) prior to reaction. We propose a broader scope for EC-CO_2R catalyst design: in order to design high C_2+ activity, in addition to active sites, the role of less active sites in controlling the *CO availability must be considered.

11:15 AM EN09.05.09

Copper Silicophosphides: New Ternary Nanocrystals as Electrocatalysts for Carbon Monoxide Reduction Anissa Ghoridi[1,2], Ngoc-Huan Tran[3,1,2], Carlos V. Mendonça Inocêncio[1,2], Amandine Séné[1,2], Marzena Baron[1,2], Emile Defoy[1,2], Daniel Janisch[1,2], Fernando Igoa Saldana[1,2], Edouard De Rolland Dalon[1,2], Antoine Miche[1,2], Christel Gervais[1,2], Cristina Coelho-Diogo[1,2], Sandra Casale[1,2], Pierre-Olivier Autran[4], Andrea Zitolo[5], Isabelle Génois[1,2], Marc Fontecave[3,1,2] and David Portehault[1,2]; [1]CNRS, France; [2]Sorbonne Université, France; [3]Collège de France, France; [4]European Synchrotron Radiation Facility, France; [5]Synchrotron SOLEIL, France

Incorporating *p*-block elements into transition metals offers a mean to fine-tune their electrocatalytic properties through localized structural distortion, charge transfer, and hybridization [1]. Beyond simply doping, the design of compounds with specific compositions and crystal structures can significantly expand the range of accessible properties. Notably, copper phosphides and silicides have been explored for their efficiency as catalysts or pre-catalysts in electrochemical water splitting [2] and as anodes in Li-ion batteries [3,4]. However, the properties of ternary copper silicophosphides, which possess unique structures distinct from binary phases, have been little investigated. Currently, only three ternary copper phases are known ($CuSi_2P_3$, $CuSi_4P_3$, Cu_4SiP_8) [5,6], and have remained at the status of scientific oddities.

To boost catalytic activity and selectivity for the generation of high-value added products containing C-C bonds in the electrocatalysis of the CO_2 reduction reaction (CO_2RR) and of the CO reduction reaction (CORR), one approach is to create single metal active sites, which can deeply modify catalytic cycles compared to metal clusters or nanoparticles [7,8]. However, maintaining these single atom sites in an isolated state during electrocatalysis poses a significant challenge. Our strategy focuses on stabilizing these sites within crystallographic structures by seeking additional stabilization through the promotion of covalent bonding to establish a rigid crystal structure. It is also imperative to design nanostructures with a high surface-to-volume ratio, thereby amplifying catalytic activity. Copper silicophosphides present an ideal candidate for this purpose.

Here, we present the first synthesis of copper silicophosphide ($CuSi_2P_3$ and $CuSi_4P_3$) nanocrystals using molten salts as reaction media, promoting the nucleation of nanoparticles while limiting their growth [9]. *In situ* X-ray diffraction measurements conducted at the ESRF ID11 synchrotron beamline during the synthesis reveal the crystallization mechanism from the initial metal salts to the ternary phases. Following a comprehensive characterization of the nanomaterials, including their structure, composition, and morphology (TEM, HRTEM, STEM-EDX, EDS mapping, XPS), we will delve into the promising electrocatalytic properties of $CuSi_2P_3$ for CORR, studied via *in situ* X-ray absorption spectroscopy at the SOLEIL SAMBA synchrotron beamline.

Bimetallic Interface Control of Cu_2O Nanocrystals for Efficient CO_2-to-C_{2+} Chemical Conversion Seolha Lim, Woosuck Kwon and Dae-Hyun Nam; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Electrochemical carbon dioxide reduction reaction (CO_2RR) is promising in the pursuit of carbon neutrality, as it converts CO_2, the primary contributor to global warming, into valuable high-end fuels and chemical feedstocks. Copper (Cu) is the only metal that has an appropriate *CO binding energy for C-C coupling. Cu-based CO_2RR electrocatalysts can produce multi-carbon (C_{2+}) chemicals such as ethylene, ethanol, and acetic acid. Nonetheless, they suffer from low selectivity for producing specific products. Particularly, bimetallic systems including Cu with secondary metals such as Au and Ag for their weak *CO bonds, emerge as a promising strategy to enhance the production of C_{2+} chemicals. However, the focus of Cu-based bimetallic catalysts has primarily been optimizing the ratio of secondary metals, overlooking the significance of interface control for efficient CO_2RR.
In this study, we fabricated the facet-controlled Cu_2O nanocrystals (NCs) and studied the effect of bimetallic interface design on the CO_2RR. Cu_2O NCs includes cube with (100) facets, cuboctahedron (cubo) with (100) and (111) facets, and octahedron (octa) with (111) facets. We introduced Ag and Au as secondary metals to facet controlled Cu_2O NCs through galvanic replacement. Shape and size distributions of the secondary metal were affected by surface energy and the surface atomic diffusion rate. These factors proved to be pivotal in the fabrication of three distinct catalysts, each characterized by varying Cu-Ag, Cu-Au interfacial compositions. In general, Cu_2O cube with low-surface-energy exhibited segregation and agglomeration at the interfaces, whereas Cu_2O cubo and octa with high-surface-energy formed well-dispersed interfaces. Bare Cu_2O cube exhibited a 40% Faradaic efficiency (FE) for C_{2+} products and achieved H_2 FE of 19% at -0.73 V (vs RHE). Ag-augmented Cu_2O cube significantly improved selectivity by reaching 57% FE for C_{2+} and suppressing H_2 with a FE of 13% at -0.78 V (vs RHE). In contrast, the Au-augmented Cu_2O cube promoted H_2 with 25% FE and C_{2+} with 33% FE at -0.99 V (vs RHE), resulting in reduced performance. To gain deeper insights into the intermediate behavior of *CO, *in-situ* Raman spectroscopy was employed, highlighting

the critical importance of the metal effect in CO_2RR. Remarkably, it was observed that CO derived from Ag had a more pronounced impact on increasing *CO coverage on the Cu surface compared to that of Au. Furthermore, the relatively higher portion of high-frequency band (HFB) $*CO_{atop}$ represents efficient C-C coupling. This study sheds light on the bimetallic interface design of Cu-based active sites for efficient C_{2+} chemical production in CO_2RR.

Atomic Layer Deposition of Cu Electrocatalysts on Gas Diffusion Electrodes for CO_2 Reduction Julia D. Lenef[1], Si Young Lee[1], Kalyn M. Fuelling[1], Kevin E. Rivera Cruz[1], Aditya Prajapati[2], Daniel O. Delgado Cornejo[1], Tae Cho[1], Kai Sun[1], Eugenio Alvarado[1], Timothy S. Arthur[3], Charles A. Roberts[3], Christopher Hahn[2], Charles C. McCrory[1] and Neil P. Dasgupta[1]; [1]University of Michigan, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Toyota Research Institute of North America, United States

Electrochemical recycling of carbon dioxide into value-added products is a promising strategy to mitigate climate change as the CO_2 reduction reaction (CO_2RR) can be driven using renewable electricity (i.e. wind, solar). So far, copper metal is the only known single element catalyst to form multi-carbon products, such as ethylene and ethanol, from CO_2RR. Numerous synthesis strategies have been employed to deposit copper-based catalysts including sputtering, evaporation electrodeposition, and solution processing; however, they do not enable atomically precise control of film thickness and particle size and have limited conformality on 3-D substrates such as carbon gas diffusion electrodes. To address this knowledge gap, we fabricate Cu catalysts using plasma-enhanced atomic layer deposition (PE-ALD) with varied PE-ALD cycle numbers on 3D carbon electrodes to achieve precise control of catalyst loading. A polycrystalline Cu metal layer was confirmed by grazing incidence X-ray diffraction. The catalyst surface morphology was probed by scanning electron microscopy and atomic force microscopy, highlighting the island-growth mode of the metal catalyst.

We demonstrate that Cu surfaces prepared by PE-ALD can reduce CO_2, forming value-added products such as carbon monoxide, methane, and ethylene. Parasitic hydrogen evolution was minimized to Faradaic efficiencies of ~10%, as quantified using *in situ* gas chromatography measurements. We further demonstrate a selectivity over 40% Faradaic efficiency for ethylene production, which is among the highest values reported to date in an H-cell geometry. Compared to evaporated Cu catalysts, we show significant methane suppression for the PE-ALD Cu. Finally, we demonstrated stability for up to 15 h for CO_2 reduction products with minimum loss in the ethylene production rate. In summary, we demonstrate CO_2RR using PE-ALD of Cu catalysts with high selectivity and stability, which provides a pathway to conformal deposition on 3D substrates with precise control of particle size and catalyst loading.

SESSION EN09.06: Fuel Cells—Membranes

1:45 PM EN09.06.01
Pyrolysis of Conductive 2D Coordination Polymers for Use as Solid Acid Fuel Cell Electrode Materials James Ridenour[1], Bethany M. Hudak[1], Olga Baturina[1], Hannah Ashberry[2], William A. Maza[1], Brian Chaloux[1] and Albert Epshteyn[1]; [1]US Naval Research Laboratory, United States; [2]Former NRC Fellow - US Naval Research Laboratory, United States

The U.S. Department of Defense has shown great interest in the development of next-generation hydrogen-based energy systems that have long-term power-output, higher energy density, lower production and maintenance costs, and greater reliability [1]. In pursuit of those goals, solid acid fuel cells (SAFCs), which use solid acid electrolytic membranes (*e.g.* CsH_2PO_4) and operate at higher temperatures (150 – 300 C) compared to polymer electrolyte membranes (PEMs, <100 C), have shown great promise since their initial discovery two decades ago [2,3]. Yet, due to corrosive and reductive chemistries as well as the higher temperatures required, current electrode paradigms are ill-suited for direct translation from PEM fuel cells. SAFC electrodes need to be both thermally stable and chemically resistant to the corrosive environment of the solid acid electrolyte and fuel streams, porous to facilitate mass transport of fuels to the triple phase boundary, electrically conductive, and catalytic towards hydrogen oxidation or oxygen reduction. Metal-organic coordination polymers [4] are well suited for investigation as precursor compounds for SAFC electrode materials based on the requisite properties for SAFC electrodes. We have investigated several compounds as porous scaffold-like architectures suitable for pyrolysis in inert atmospheres to create metal-doped carbonized materials. These are highly electrically conductive and porous to facilitate nano-Pt catalyst impregnation and gas transport. Materials were characterized by powder X-ray diffraction and thermogravimetric analysis for bulk structure and stability and electrochemical impedance spectroscopy for electrical conductivity while pyrolysis was studied with TEM by *in situ* heating under vacuum. Pyrolysis of carbon-based coordination polymers generates carbonized materials with greater chemical stability and *in situ* TEM pyrolysis characterization was utilized to monitor thermally induced changes in the carbonized materials.

Investigation of Pt-Based Nanoparticle Degradation in Catalyst Layers through Automated Electron Tomography Lynda Amichi[1], Haoran Yu[1], Obaid Rahman[1], Amir Ziabari[1], Jose' D. Arregui-Mena[1], Laure Guetaz[2] and David Cullen[1]; [1]Oak Ridge National Laboratory, United States; [2]Commissariat à l'énergie atomique et aux énergies alternatives, France

Proton exchange membrane fuel cells (PEMFC) are promising devices for the deployment of hydrogen-powered heavy-duty vehicles, which provide higher efficiencies than internal combustion engine vehicles and similar driving ranges and fueling times. However, PEMFCs still encounter durability challenges, mainly due to catalyst degradation in the cathode. Mitigating these performance losses requires a better understanding of the degradation mechanisms under heavy-duty accelerated stress tests (ASTs) [1]. Electron tomography is a key tool for high-resolution three-dimensional analysis of Pt and PtCo nanoparticle spatial distribution to determine the rate and type of degradation as a function of position on the carbon support [2].

In this work, we developed an automated electron tomography workflow performed in scanning transmission electron microscopy (STEM) mode and utilizing SerialEM [3] for data acquisition. We applied a super-voxel model-based iterative reconstruction with adaptive regularization (MBIR-ARAR) for artifact reduction [4] and performed segmentation of the nanoparticles and carbon using the commercial software Avizo. This workflow allowed us to

differentiate Pt-based nanoparticles located on the exterior of the carbon support from those within the pore structure, which enabled assessment of the relative stability of interior versus exterior nanoparticles.

In this study, the catalyst powder was scraped from electrodes and drop-cast on tomography TEM grids. We compared Pt and PtCo catalyst particle size distributions at the beginning of test (BOT) and end of test (EOT). The findings indicated a noticeable increase in particle size, regardless of location, and a significant portion of particles remaining within the carbon pores. Simultaneously, there is evidence of an expanding size distribution of closed pores after the AST, possibly stemming from carbon corrosion. These observed degradation mechanisms challenge the assumption that Pt dissolving primarily on the carbon support interior and re-depositing on the surface is a major contributor to ECSA decline, suggesting that factors such as carbon corrosion, dissolution of exterior nanoparticles, and/or particle coalescence also contribute to ECSA loss. This shows the importance of automating the electron tomography workflow, i.e., acquisition, reconstruction, and visualization, for increasing sampling and determining statistical parameters for the measurements. The outlook for utilizing low-dose cryo-tomography for limiting damage to the catalyst, support, and especially proton-conducting ionomer will be discussed [5].

Strategies Towards Low-Ir-Catalysts for PEM Electrolysis: From Support Material and Morphology to Depositing Iridium Oxide Melisande Kost[1], Markus Döblinger[1], Dina Fatthakova-Rohlfing[2] and Thomas Bein[1]; [1]LMU Munich, Germany; [2]FZJ, Germany

The transition from fossil fuel based and CO_2-intensive energy production to a future sustainable energy-based economy requires solutions for efficient energy conversion and storage for later re-electrification of green energy such as solar or wind power. One possibility is to convert energy from sustainable sources into chemical energy in the form of hydrogen by electrolysis of water. To meet this challenge, Proton Exchange Membrane (PEM) electrolysis is a powerful state-of-the-art technology that uses scarce iridium-based catalysts to promote the oxygen evolution reaction (OER). To improve the sustainability and economics of the PEM process, it is necessary to minimize the use of rare and precious iridium to reduce the overall density of iridium-based catalysts for the OER.
Here we present different strategies for the synthesis of low overall iridium OER catalysts. In addition to the choice of support material and support morphology, we also consider the coating strategy to produce highly active and durable catalysts.
The coating of corrosion-resistant high surface area metal oxide supports of various morphologies with an ultrathin layer of amorphous iridium hydroxide by a simple wet chemical synthesis at low temperature and ambient pressure or by a hydrothermal approach leads to the formation of interconnected amorphous hydrous iridium oxide particles. In a subsequent step, the amorphous phase is oxidized at elevated temperatures using an Adams fusion salt melt. This process allows for a controllable phase transformation and crystallization to form a layer of interconnected partially crystalline IrO_x nanoparticles of ≈1.5 - 2 nm domain size on the surface of the supporting metal oxides, thus providing an electrical percolation path in the catalyst layer. The appropriate choice of support material in terms of crystal lattice parameters can modulate the crystal growth of the iridium oxide in terms of epitaxy and significantly increase the stability due to tight anchoring to the support. The final core-shell nanostructures comprise highly active iridium oxide with total Ir weight fractions as low as 7 at% on SnO_2 nanoparticles, compared to a state-of-the-art benchmark catalyst with 56 at% Ir supported on TiO_2 nanoparticles. Transmission electron microscopy (TEM) imaging was used to elucidate the impact of different core-shell designs, with a particular focus on iridium coating and crystallinity. Rotating disc electrode (RDE) measurements were also carried out to assess the electrochemical properties of each catalyst.

Use of X-Ray, Synchrotron and Neutron Diffraction for The Development of Metal Hydrides Jacques Huot; UQTR, Canada

Metal hydrides are attractive solutions for hydrogen storage in a wide range of applications going from fuel cell submarine down to smart phones. In metal hydrides hydrogen is chemically bonded to other elements to form an alloy. Therefore, knowledge of the crystal structure of the metal hydride in its hydride and dehydrided state is essential. Conventional X-ray diffraction gives important information such as crystal structure, crystallite size, microstrains, etc. However, in-situ investigation of fast kinetics is basically impossible with this technique. Synchrotron radiation provides a large flux of photons that enable the recording of phase change of very fast hydrogenation/dehydrogenation kinetics. Unfortunately, X-ray diffraction is not suitable to locate the hydrogen atom in the crystal lattice. Neutron diffraction is practically the only technique that could give the localization of the hydrogen in a metal hydride. However, another synchrotron technique, the Extended X-Ray Absorption Fine Structure (EXAFS) could probe the local environment of each type of atoms.
In this talk, we will briefly discuss each of these techniques and give the advantages and inconvenience of each of them. Examples on the utilization of X-

ray, synchrotron and neutron diffraction for the development and fundamental understanding of metal hydrides will be given.

4:00 PM EN09.07.02
Selective Water Oxidation to H_2O_2 on TiO_2 Surfaces with Sub-Surface Redox-Active Allosteric Sites Devan Solanki and Shu Hu; Yale, United States

Hydrogen peroxide H_2O_2, is a versatile chemical with applications ranging from industrial to household use such as pulp bleaching, wastewater treatment, and sterilization. In addition to these established uses, H_2O_2 is emerging as a green energy carrier which can release 96 kJ *mol^{-1} of energy via exothermic chemical decomposition with only water and oxygen as by-products. Currently, more than 95% of H_2O_2 produced globally originates from anthraquinone autoxidation. This process requires precious metal catalysts and expensive liquid-liquid extraction processes that are only feasible for large-scale chemical plants.
Electrochemical and photochemical syntheses are promising alternatives for distributed H_2O_2 production. H_2O_2 can be produced by $2e^-$ processes both via oxidatively, via water oxidation reaction (WOR) or reductively via oxygen reduction reaction (ORR). These approaches take advantage of abundant energy sources, i.e., renewable electrical or solar energy, and enables the storage of intermittent energy as the free energy of chemical bonds for distributed energy storage. In this work we focus on the water oxidation pathway.
Electrochemical Charge Transfer:
H_2O_2 can be (photo-)electrochemically synthesized via a two-electron (2e−) water oxidation pathway, as shown in equation 1.
$H_2O_2 \rightarrow H_2O + 2H^+ + 2e^-$, E = +1.77 V (1)
However, existing catalysts often exhibit low faradaic efficiency (FE) due to the competitive four-electron (4e) pathway of O_2 evolution reaction (OER) equation 2.
$H_2O_2 \rightarrow O_2 + 4H^+ + 4e^-$, E = +1.23 V (2)
The thermodynamic driving force for OER is always at least +0.54 V greater than that of the 2e H_2O_2 pathway which can allow the undesired O_2 evolution pathway to overcome any kinetic barriers and dominate. In addition, the produced H_2O_2 can be over-oxidized to O_2 at an excess potential of at least +1.09 V (equation 3).
$H_2O_2 \rightarrow O_2 + 2H^+ + 2e^-$, E = +0.68 V (3)
Thus, the partial oxidation of water to hydrogen peroxide presents a model system of a common challenge in catalysis where the desired product is kinetically feasible but thermodynamically unfavorable.
Conclusion:
In this work, we utilize X-ray Photoelectron Spectroscopy to quantify the presence of Mn(III) defect states within the TiO_2 band gap which are energetically aligned to peroxide generating reactive intermediates. During operation, the energy levels of CB and VB of TiO_2 are fixed, or “pinned”, at −0.05 and 3.29 VRHE, respectively, yet the empty states of the Mn defect states can precisely align with the energetics of H_2O_2 producing intermediates. Under a higher applied potential, i.e., +2.3 V , there would exist a moderate overpotential for the 2e water oxidation, but such a potential also enables the other pathways including 1e water oxidation to produce radicals, leading to an overall reduction in H_2O_2 production rates due to the reduced selectivity. Thus, this strategy of defect state tuning is best suited to low overpotentials, 90% at < 150 mV overpotentials was achieved for H_2O_2 production, accumulating 2.97 mM H_2O_2 after 8 hours. Nanoscale mixing of MnOx and TiOx resulted in a partially filled, highly conductive Mn intermediate band (IB) within the TiO_2 mid-gap to transport charge across the TiMnOx coating. This IB energetically matched that of H O -producing surface intermediates, turning a wide bandgap oxide into a selective electrocatalytic material that can operate in the dark.

Kinetic Mechanisms of M-N-C Electrocatalysts Saerom Yu, Zachary Levell and Yuanyue Liu; The University of Texas at Austin, United States

Single metal atoms embedded in nitrogen doped graphene (M-N-C) has attracted wide interest as electrocatalysts for various reactions. Although there have been many studies on the thermodynamic mechanisms (mostly based on computational hydrogen electrode model or its variants/derivations), the kinetic mechanisms are less understood partly due to the complexity of simulating reaction kinetics at electrochemistry interface. Using an advanced model developed recently in my group, I will show its application to elucidate the mechanisms of M-N-C for CO2 reduction and oxygen reduction.

4:30 PM EN09.07.04
Synchrotron Radiation Characterization to Understand The Nature of Catalysts during Operation Yan-Gu Lin; National Synchrotron Radiation Research Center, Taiwan

Catalysis has been tightly associated to X-ray spectroscopy from the very beginning, and this happy wedding is still holding and faithful. Catalysts studied at beamlines are quite a mirror of the needs of our society, reflecting current issues on global warming, oil shortage and economic struggles. In the recent years, the transition of dynamic atomic/electronic structure has been demonstrated to be induced by some external stimulus during catalysis, which enable one to potentially manipulate the unpaired electrons at the metal centers, thus directly influencing their dynamic structure as well as resulting nature. In this respect, the recent research trends have increasingly transferred from optimizing catalysts to making clear the real active species of the catalysts, especially understanding the underlying mechanisms behind these catalytic reactions. Abundant synchrotron-based X-ray spectroscopy methods, including in-situ/operando measurement have been developed and applicated, offering nonnegligible characterization assistance to researchers in the field of catalysis, material and chemistry. Regarding the advanced in situ/operando approaches, ongoing characterization efforts employing X-ray absorption spectroscopy (XAS) particularly have successfully unveiled the potential-induced or photo-driven changes in local geometry of the active sites. In this talk, I will illustrate a part of the activities of the NSRRC beamlines through examples to show the establishment of the correlation between atomic/electronic structure and the catalytic properties. The experimental results demonstrate that the operando X-ray characterization provides the unique information for understanding the real reaction mechanism.

Revealing The Roles of Oxygen Vacancies in Single Atoms to Sub-Nanometers Scaled Metal Oxide Clusters for The Oxygen Reduction and

Hydrogen Evolution Reactions via *In-Situ* X-Ray Absorption Spectroscopy Dinesh Bhalothia; National Tsing Hua University, India

Regardless of the well-explored role of oxygen vacancies in metal-oxide nanoparticles (NP)s, oxygen vacancies have rarely been correlated with the dimensions of NPs. In this context, we report a systematic study to uncover the fundamental mechanisms between dimension effects and the catalytic activity of oxygen vacancies enriched cobalt-oxide (CoOx) from a single atom to sub-nanometer scale clusters. To demonstrate such a concept, we report a nanocatalyst (NC) comprising CoOx-clusters decorated Pd NPs on the Co-oxide support (denoted as CPCo). For the optimum case, a single Co atom with oxygen atoms (denoted as CPCo-1) delivers an unprecedented high mass activity (MA) of 4394 $mAmgCo^{-1}$ at 0.85 V vs RHE and 426 $mAmgCo^{-1}$ at 0.90 V vs RHE in alkaline oxygen reduction reaction (ORR) (0.1 M KOH), which surpasses the commercial J.M.-Pt/C (20 wt%) catalyst by 65-times. On top of that, the CPCo-1 NC exhibits remarkable durability in an accelerated durability test (ADT) with a progressively increased MA by 40 % (6,140 $mAmgCo^{-1}$) as that of the initial condition after 20 k cycles. On the other hand, a sharp fall down in the catalytic performance is observed, when oxygen vacancies are created in CoOx species with increased dimensions. Through in-depth physical characterization, electrochemical analysis, and in-situ X-ray absorption spectroscopy (XAS), we demonstrated the conceptual framework of potential synergism between the oxygen vacancies enriched CoOx species and neighboring metallic Pd-sites. In this event, the surface-anchored CoOx species coupling with oxygen vacancies promotes the O_2 splitting, while the neighboring Pd-sites simultaneously trigger the O^{ads} relocation (i.e. OH^- desorption) step. In addition, the cobalt oxide support underneath assists the electron injection to surface Pd-sites.

5:00 PM EN09.08.01
Enhancing Energy Efficiency in Bicarbonate Electrolysis through The Development of an Au-NiO-CNT Catalyst for Glycerol Oxidation Dohee Kim[1], Hyeonuk Choi[1], Hojung Lee[2], Yoonyoung Kim[3], Eunui An[1], Youngkook Kwon[2] and Jihun Oh[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Korea Institute of Energy Research, Korea (the Republic of)

Reducing emitted CO_2 through direct air capture is crucial to mitigate climate change. Bicarbonate electrolysis is a method that facilitates CO_2 reduction by utilizing bicarbonate generated from aqueously captured CO_2, ultimately yielding syngas or CO as a product. However, the overall energy efficiency of bicarbonate electrolysis is impeded by the high theoretical voltage associated with the oxygen evolution reaction (OER) occurring at the anode. To enhance energy efficiency and bolster the economic viability of this process, it is important to design reactions and catalysts that can simultaneously produce valuable products at the anode while reducing operating voltage.
Here, we proposed a novel cell architecture that combines biomass upgrading, glycerol oxidation (GEOR) for glycolic acid (GCA) production with bicarbonate electrolysis. GCA serves as a monomer for bio-plastics, Poly(lactic-co-glycolic acid) (PLGA), but its current production relies on fossil fuels. In this work, to achieve sustainable GCA production via GEOR, we introduced Au catalyst design that incorporates NiO support and multi-walled carbon nanotubes (MWCNTs) to enhance the selectivity of GCA production through a synergy effect. We then successfully demonstrated that the addition of 4 wt% MWCNTs on Au-NiO catalyst leads to a remarkable achievement of 36% GCA selectivity and 28% glycerol conversion at 0.9 V (V vs. RHE) and 2 h in 0.1 M glycerol and 1 M KOH for GEOR. This showed that a 4.6-fold increase in glycerol conversion and a twofold increase in GCA production compared to the conventional Au-CB catalyst. Additionally, by controlling MWCNT ratio of Au-NiO catalyst, it showed that the amount of Au-NiO catalyst required to achieve 10% glycerol conversion at 0.9 V (V vs. RHE) was reduced by 20 wt%. We conducted operando raman analysis to gain mechanistic insights. Our findings suggested that during GEOR, the NiO support undergoes a transformation into $Ni(OH)_2$, and introduction of MWCNTs on NiO promotes formation of $Ni(OH)_2$. Additionally, our electrochemical impedance spectroscopy (EIS) indicated that MWCNTs improve the electrical conductivity of NiO, which could facilitate $Ni(OH)_2$ formation. Therefore, we demonstrated that the reaction between adsorbed glycerol on Au and Ni-OH transformed on the NiO support, resulting in enhanced conversion of glycerol to GCA. Finally, by combining bicarbonate electrolysis, we achieved an H_2/CO ratio of about 2.34 through bicarbonate electrolysis and a GCA selectivity of 26% through GEOR at 200 mA/cm^{-2}. This accomplishment confirms the successful development of an efficient system, proficiently yielding valuable compounds at both electrodes.

5:00 PM EN09.08.02
Zirconium Phosphate Layered Nanomaterials as Supports for Earth-Abundant Electrocatalysts for The Oxygen-Evolution Reaction Jorge L. Colón[1], Yannelly A. Serrano-Rosario[1], Sebastián Muñoz-Torres[1], Daniella M. Gibson-Colón[1], Biao Liu[1], Gabriella A. García-Machado[1], Antonio Torres-López[2], Louise M. Defebve[2] and Christopher J. Pollock[2]; [1]University of Puerto Rico at Río Piedras, United States; [2]Cornell University, United States

We are studying new applications of layered zirconium phosphate (ZrP) inorganic nanomaterials [1]. The θ phase of ZrP can be directly ion-exchanged with metal complexes and catalysts, producing intercalated phases useful for artificial photosynthesis schemes for water splitting, amperometric biosensors, and drug delivery applications. Recently, we have demonstrated improved electrocatalytic activity of ZrP nanomaterials loaded with metal ions suitable for the oxygen evolution reaction of water splitting. Electrocatalysts have been incorporated as intercalated species, surface bound, on exfoliated layers, and on nanoparticles of different morphologies (hexagonal platelets, cubes, rods, and spheres). Single and bimetallic electrocatalysts based on earth-abundant materials have been studied. Reduction in overpotentials and increases in mass activity have been achieved. Mixed metal NiFe-intercalated ZrP electrocatalysts at 90% Fe metal content proved to have superior OER electrocatalytic performance (decreased overpotentials, increased mass activities, reduced Tafel slopes) compared to adsorbed counterparts. We have recently prepared CoFe electrocatalysts systems and again the intercalated bimetallic system is more active than the surface-adsorbed one. We are starting to work also with Mn electrocatalysts. We are exploring OER activities of other mixed-metal catalysts on ZrP, bifunctional catalysts, and operando synchrotron X-ray absorption spectroscopy studies to elucidate the nature of the active species. We are also exploring efficient solar H_2 production using these supports.

Superior CO_2 Electroreduction Performance on Co-Ni-Nitrogen Bimetallic Sites Jianping Chen and Weining Wang; Virginia Commonwealth University, United States

The electrochemical reduction of carbon dioxide (CO_2 ECR) plays a crucial role in transitioning towards a sustainable energy and chemical industry. This process has the potential to not only address the rising CO_2 levels but also utilize it as a resource to produce valuable fuels and chemicals. Electrocatalysts are essential in CO_2 ECR, as their ability to selectively and efficiently convert CO_2 offers significant environmental and economic benefits. Our research, focusing on nanostructured electrocatalysts for energy applications, introduces an innovative nanostructured catalyst that represents a significant advancement in CO_2 ECR technology for energy generation and conversion.
Regarding CO_2 ECR, a wide range of catalysts including metals, alloys, metal oxides, functionalized carbons, and metal complexes have been studied for their effectiveness. Despite their remarkable CO_2 conversion capacity, challenges such as sub-optimal energy efficiency, varying activity levels, and undesired hydrogen evolution reactions (HER) present significant obstacles. Addressing these challenges, our study introduces a novel electrocatalyst featuring diatomic metal-nitrogen sites (Co-Ni-N-C). This catalyst is synthesized through a unique process involving ion exchange using a zeolitic imidazolate framework (ZIF) as a precursor, followed by pyrolysis. This method results in nitrogen-doped graphitic carbon, effectively anchoring the Co-Ni bimetallic active sites.
This work highlights the potential of nanostructured single-atom catalysts (SACs) and dual-active site catalysts (DASCs) in CO_2 ECR. Transition metal SACs, such as Ni-SAC on nitrogen-doped graphene, have previously shown promising results in CO_2 conversion efficiency. However, our Co-Ni-N-C catalyst takes a step forward by demonstrating a CO yield rate of 53.36 mA mg $cat.^{-1}$ and a CO Faradaic efficiency of 94.1% at an overpotential of -0.27 V. This performance showcases that Co-Ni-N_6 moiety plays a crucial synergistic role in promoting and sustaining these exceptional ECR activities Spectroscopic, microscopic, and density functional theory analyses collectively reveal the synergistic role played by the Co-Ni-N6 moiety in enhancing catalytic activity. This synergy is crucial in promoting and sustaining exceptional ECR activities. The findings not only emphasize the effectiveness of nanostructuring in electrocatalyst design but also shed light on the pathways for developing various advanced catalysts for sustainable energy conversion. Therefore, our study offers a novel perspective in the field of CO_2 ECR, opening new avenues for the development of efficient, nanostructured catalysts for energy applications.

5:00 PM EN09.08.05
High-Entropy Alloy Nanocrystals with Controlled Compositions and Surface Structures for Catalytic Applications Younan Xia; Georgia Institute of Technology, United States

We recently developed a robust method for the facet-controlled synthesis of nanocrystals with an ultrathin shell made of a nearly equimolar RuRhPdPt quaternary alloy. Our strategy involves the use of well-defined Rh cubic seeds, halide-free precursors, and a method for precisely controlling the reaction kinetics of different precursors. In the setting of dropwise addition, the precursors with different reactivities can be reduced at about the same pace for the generation of an alloy with a uniform and well-controlled composition. The core−shell nanocubes show greatly enhanced activity toward ethanol oxidation when benchmarked against Pd and Pt counterparts. Combining *in situ* and *ex situ* electron microscopy studies, we also demonstrate that the core−shell nanocubes possess good thermal and electrochemical stability in terms of both geometrical shape and elemental composition, with their cubic shape and alloy composition retained when annealing at 500 °C or after long-term electrochemical cycling. It is expected that the synthetic approach can be further extended to fabricate multi-metallic catalysts with enhanced activities toward a variety of thermal and electrochemical reactions.

Engineering Efficient Electrocatalysts: Non-Precious Bimetallic ZIF-Based Hybrid Nanocomposites for Oxygen Reduction Reaction Mahshid Mokhtarnejad, Erick Ribeiro, Dibyendu Mukherjee and Bamin Khomami; The University of Tennessee, United States

Synthesis of metal oxides/metal-organic frameworks (MOFs) into hybrid nanocomposites (HNCs), wherein transition metals combined with carbon (C) matrices, due to the excellent conductivity and high porosity present an attractive and cost-effective alternative for engineering electrocatalysts used for oxygen reduction reaction (ORR) in anion exchange membrane fuel cells (AEMFCs). To that end, improving the performance of these materials by adjusting their composition, structure, size, and morphology through an efficient synthesis process is of great technological importance. In this context, the Laser Ablation Synthesis in Solution in Tandem with Galvanic Replacement Reaction (LASiS-GRR) technique is employed as a fast, facile, and green approach for the synthesis, and precise control of complex hierarchical bimetallic Zeolitic Imidazolate Framework (ZIF) structures. Specifically, this novel one-pot, two-step LASiS-GRR process allows for the optimization and of the composition, structure, size, and morphology of Co-based MOFs encapsulated within Zn-based porous MOF crystals “dubbed” Co/ZIF-67@Zn/ZIF-8. The pyrolytic post-processing of these crystals leads to the development of HNCs exhibiting superior ORR electrocatalytic performance in AEMFCs. Overall, this research not only sheds light on the impact of two distinct salt precursors on particle size and morphology during LASiS but also showcases the exceptional performance and stability of post-pyrolytic (ZnO/ZIF@C) HNCs in AEMFC applications as non-precious ORR electrocatalysts when compared to state of art Pt- and platinum-group metals (PGM)-based electrocatalysts.

5:00 PM EN09.08.07
Biaxial Strained MoS_2 Nanoshells with Controllable Layers Boost Alkaline Hydrogen Evolution Tao Zhang; Nanyang Technological University, Singapore

Strain in layered transition-metal dichalcogenides (TMDs) is a type of effective approach to enhance the catalytic performance by activating their inert basal plane. However, compared with the traditional uniaxial strain, the influence of biaxial one and TMDs layer number on local electronic configuration remains unexplored. Herein, via a new *in situ* self-vulcanization strategy, we realize biaxial strained MoS_2 nanoshells in the form of single-crystalline Ni_3S_2@MoS_2 core-shell heterostructure, where the MoS_2 layer is precisely controlled between 1 to 5 layers. In particular, the electrode with bilayer MoS_2 nanoshells shows a remarkable hydrogen evolution reaction activity with a small overpotential of 78.1 mV at 10 mA cm^{-2}, and negligible activity degradation after durability test. Density Functional Theory calculations reveal the contribution of optimized biaxial strain together with the induced sulfur vacancies, and identify the origin of superior catalytic sites in these layer-resolved MoS_2 nanoshells. This work highlights the importance of the atomic-scale layer number and multiaxial strain in unlocking the potential of two-dimensional TMDs electrocatalysts.

5:00 PM EN09.08.08
Unleashing the Full Potential of Heterostructured Nickel–Cobalt Phosphate for Optically Active High-Performance Asymmetric Quasi-Solid-State Supercapacitor Devices Nageh K. Allam; American University in Cairo, Egypt

The rational design of hybrid systems that combine capacitor and battery merits is crucial to enable the fabrication of high-energy and power-density devices. However, the development of such systems remains a significant barrier to overcome. Herein, we report the design of a Ni-Co phosphate ($Ni_{3-x}Co_x(PO_4)_2.8H_2O$) nanoplatelet-based system via a facile coprecipitation method at ambient conditions. The nanoplatelets exhibit multicomponent synergy, exceptional charge storage capabilities, rich redox active sites (ameliorating the redox reaction activity), and high ionic diffusion rate/electron transfer kinetics. The designed $Ni_{3-x}Co_x(PO_4)_2.8H_2O$ offered a respectable gravimetric specific capacity and marvelous capability rate (966 and 595 C g^{-1} at 1 and

15 A g^{-1}) over the $Ni_3(PO_4)_2.8H_2O$ (327.3 C g^{-1}) and $Co_3(PO_4)_2.8H_2O$ (68 C g^{-1}) counterparts. Additionally, the nanoplatelets showed enhanced photoactive storage performance with a 9.7% increase in the recorded photocurrent density. Upon integration of $Ni_{3-x}Co_x(PO_4)_2.8H_2O$ as a positive pole and commercial activated carbon as a negative pole, the constructed hybrid supercapacitor device with PVA@KOH quasi-gel electrolyte exhibits great energy and power densities of 77.7 Wh kg^{-1} and 15998.54 W kg^{-1} with remarkable cycling stability of 6000 charging/discharging cycles and prominent Coulombic efficiency of 100%. Interestingly, two assembled devices are capable of glowing a red LED bulb for nearly 180 s. This research paves the way to design and fabricate electroactive species via a facile approach for boosting the design of a plethora of supercapattery devices.

5:00 PM EN09.08.09
Optimized V-Doped Defective TiO_2/α-$(Fe_2O_3)_{1-x}(Cr_2O_3)_x$ Heterojunctions for Photo-Assisted Supercapacitor Devices: Insights on the Materials Integrity and Dual Conversion-Storage Mechanism Nageh K. Allam; American University in Cairo, Egypt

Energy conversion and storage integrated power units suffer from multiple engineering issues. Replacing two devices (solar cell and supercapacitor assembly) with one device (photo-enhanced supercapacitor- PSC) requires materials with emerged dual solar-electrochemical storage attributes. Herein, a propitious approach is developed to fabricate all visible light-enhanced semisolid flexible PCS. Nanoflakes-based p-n junction α-$(Fe_2O_3)_{1-x}(Cr_2O_3)_x$ photocathode is synthesized directly on industrial waste stainless steel mesh (316L-SS). Alongside, three TiO_2-based electrodes are utilized as positive photoactive electrodes. Tuning the optical properties of TiO_2 is displayed via doping with mixed valence vanadium (V^{4+}/V^{5+}) together with thermal hydrogen annealing. This is revealed via the reduction of the bandgap energy from 2.89 to 2.15 eV, which can be ascribed to the induced oxygen vacancies. The device can sustain up to 1.6 V potential window with 91% stability after 350 successive charge/discharge cycles with the possibility of performance regeneration to its 100% retention. An illustration of the photo-storage mechanism is proposed based on the X-ray photoelectron spectroscopy, X-ray crystallography, and band position/alignment results. Quasi-reversible water splitting/formation is concluded as the main storage mechanism in the semisolid state electrolyte under illumination conditions.

5:00 PM EN09.08.10
Fe-Single-Atom Catalysts on Nitrogen-Doped Carbon Nanosheets for Electrochemical Conversion of Nitrogen to Ammonia Nageh K. Allam; American University in Cairo, Egypt

Electrochemical nitrogen reduction reaction (NRR) has been established as a promising and sustainable alternative to the Haber–Bosch process, which requires intensive energy to produce ammonia. Unfortunately, NRR is constrained by the high adsorption/activation of the N_2 energy barrier and the competing hydrogen evolution reaction, resulting in low faradic efficiency. Herein, a well-dispersed iron single-atom catalyst was successfully immobilized on nitrogen-doped carbon nanosheets (Fe_{SAC}-N-C) synthesized from pre-hydrothermally derived Fe-doped carbon quantum dots with an average particle size of 2.36 nm and used for efficient electrochemical N_2 fixation at ambient conditions. The as-synthesized Fe_{SAC}-N-C catalyst records an onset potential of 0.12 V_{RHE}, exhibiting a considerable faradic efficiency of 23.7% and an NH_3 yield rate of 3.47 μg h^{-1} cm^{-2} in aqueous 0.1 M KOH electrolyte at a potential of -0.1 V_{RHE} under continuous N_2 feeding conditions. The control experiments assert that the produced NH_3 molecules only emerge from the dissolved N_2-gas, reflecting the remarkable stability of the nitrogen–carbon framework during electrolysis. The DFT calculations showed the Fe_{SAC}-N-C catalyst to demonstrate a lower energy barrier during the rate-limiting step of the NRR process, consistent with the observed high activity of the catalyst. This study highlights the exceptional potential of single-atom catalysts for electrochemical NRR and offers a comprehensive understanding of the catalytic mechanisms involved. Ultimately, this work provides a facile synthesis strategy of Fe_{SAC}-N-C nano-sheets with high atomic dispersion, creating a novel design avenue of Fe_{SAC}-N-C that can vividly have potential applicability in the large spectrum of electrocatalytic applications.

5:00 PM EN09.08.11
3D Vertical Graphene Nanofibers with High Defect Density and Nitrogen Doping for Electrocatalytic Hydrogen Evolution Reaction TaeGyeong Lim[1], Sang Ho Shin[1] and Ji Won Suk[1,1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

The production of clean hydrogen using water electrolysis is a crucial element in achieving sustainable energy production and utilization systems.[1] A key challenge in attaining sustainable hydrogen production via water electrolysis lies in the development of suitable electrocatalyst materials for the hydrogen evolution reaction (HER), aiming to replace conventional noble-metal-based electrocatalysts with earth-abundant alternatives.[2] Graphene-based materials have emerged as promising candidates for metal-free electrocatalysts due to their exceptional electrical conductivity, high specific surface area, and chemical stability.[3] The electrocatalytic performance of graphene-based materials has notably advanced with the introduction of heteroatom doping or defects.[4,5]
In this study, we synthesized three-dimensional (3D) vertical graphene nanofibers (VGNFs) with unique 3D structures, serving as metal-free electrocatalyst for HER. The freestanding 3D VGNF sheets were synthesized via facile and scalable processes employing the electrospinning method combined with thermal chemical vapor deposition. The 3D VGNFs exhibited high defect density and nitrogen doping, which are favorable traits for enhancing electrocatalytic HER. In addition, they displayed hierarchical pore structures with high specific surface area. Therefore, the 3D VGNFs demonstrated outstanding HER performance, presenting a low overpotential and robust stability when evaluated in a 0.5 M H_2SO_4 acidic solution.

Impact of Surface Defects like Vacancies and Dopants on The Design of Energy-Efficient Ag Nanoparticle/Ligand-Based Catalysts for Electroreduction of CO_2 Asmita Jana, Jin Qian and Ethan Crumlin; Lawrence Berkeley National Laboratory, United States

Capture and subsequent conversion of CO_2 to value-added chemicals is a promising strategy to tackle the increase in CO_2 concentrations in the atmosphere. CO_2 electroreduction to CO is often the first step in such a conversion, necessitating the design of effective electrocatalysts that can not only produce CO with high selectivity but also do so energy-efficiently. The Ag-Nanoparticle/Ordered Ligand Interlayer (Ag-NOLI) catalyst produces CO at high selectivity. However, to achieve the catalytically active phase, the material needs to be biased to a large negative potential. Thus, any effort to create the catalytically active phase at lower magnitudes of negative potential can pave the way towards designing a more energy-efficient catalyst. We used density functional theory calculations to engineer the Ag surface by introducing vacancies, and Cu and Ag dopants, evaluated the relative energies of all the configurations, and computed the transition potentials needed to get to the catalytically active phase. We found that while introducing Ag vacancies and Cu dopants increase the magnitude of the transition potential, the opposite is seen with Au dopants, making Au dopants a suitable design modification.

Moreover, while Cu increases the stability of all the phases compared to Ag, Au decreases it. The source of this Cu < Ag < Au energy trend was evaluated and we found that the ligand-surface interaction was the most prominent contributor compared to other interactions in the system. Finally, we found that the trend in the ligand-surface interaction energy can be attributed partially to the intrinsic chemical interaction between the surface and ligand atoms, by investigating systems where the geometry of the topmost layer was kept fixed. Overall, this Cu < Ag < Au energy trend can be ascribed partially to the electronegativity differences with O, making it an important descriptor in the design of energy-efficient Ag-NOLI-based catalysts.

5:00 PM EN09.08.13
Thermodynamic Prediction of Gas-Solid Reactions for the Synthesis of Transition Metal Carbides Catalysts Sang-Ho Oh[1], Dohun Kim[2], Ji-Yong Kim[1], Geosan Kang[1], Jooyoung Jeon[1], Miyoung Kim[1], Young-Chang Joo[1] and Dae-Hyun Nam[2]; [1]Seoul National University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Transition metal carbides have garnered significant attention due to their extensively adjustable physicochemical characteristics based on their structure, phase, and polymorph, making them highly versatile in a broad spectrum of electrochemical applications owing to their unique d-band electronic structures. Nevertheless, the synthesis of metal carbides and the precise control of their phases and structures present formidable challenges. In comparison to other metal compounds like oxides, sulfides, and phosphides, metal carbides exhibit the highest Gibbs free energy of formation (ΔG^o), indicating the lowest inclination for synthesis. Additionally, the formation of metal carbides requires stringent processing conditions due to the preferential oxidation of metals in the presence of atmospheric oxygen. Typically, metal carbides are generated through carburization and carbothermic reduction using methane and graphite. However, the sluggish kinetics of carbon (C)-induced reactions demand elevated temperatures, leading to undesired sintering and aggregation. Moreover, an excessive supply of C sources inevitably results in coke encapsulation and precipitation.
In this work, we describe an approach for the predictive synthesis of nanostructured Mo carbides, achieved by steering the equilibrium reactions involving oxocarbons (carbon monoxide (CO) and carbon dioxide (CO_2)) during the calcination process. Oxocarbons engage in two equilibrium reactions: the Boudouard reaction ($2CO\ (g) \leftrightarrow CO_2\ (g) + C\ (s)$) and the CO/$CO_2$ redox reaction ($2CO_2\ (g) \leftrightarrow 2CO\ (g) + O_2\ (g)$). This phenomenon allows for concurrent C–O reactions (selective C combustion) and Mo–C interactions (Mo carbide formation) within the nanofibers, serving as a framework for the initiation and growth of Mo carbides. This process enables precise manipulation of the phases and structures of Mo compounds. Since inducing selective redox reactions in multi-atomic systems like Mo–C–O poses significant challenges, requiring considerable trial and error in experimentally determining process variables. Hence, the specific prediction of processing parameters becomes imperative.
We successfully established processing windows for nanoscale carbide synthesis by thermodynamically forecasting oxocarbon-mediated gas-solid reactions. By computing ΔG^o for Mo compound formation, we present a method for discovering specific processing windows to control the phases of diverse Mo compounds. Concurrently, the extent of selective C combustion is anticipated through pO_2 calculations to regulate the porosity of C nanofibers and diffusion behavior of Mo. By utilizing the thermodynamically predicted processing window, we not only controlled a wide range of Mo phases (MoO_2, α-MoC_{1-x}, and β-Mo_2C) but also manipulated various nanostructures (nanoparticle, spike, stain, and core–shell) by steering diffusion during the phase synthesis process in the Mo compounds/C nanofibers.
Moreover, to confirm the connections between material and properties in nanostructured Mo carbides, we examine their catalytic performance in the hydrogen evolution reaction (HER). Our results demonstrate a performance achievement, with an overpotential of 152 mV @ 10 mA cm^{-1}, accomplished through the formation of active nano-spikes of Mo_2C on C nanofibers. We expect that the predictions of element supply and spontaneous reactions will offer valuable insights to researchers involved in the synthesis and structural manipulation of diverse catalysts based on transition metal compounds.

5:00 PM EN09.08.15
Ammonia-Fueled Proton Ceramic Fuel Cells with Atomic Layer Desposited Palladium Catalysts Joon Hyung Shim; Korea University, Korea (the Republic of)

The study investigates the efficacy of protonic ceramic fuel cells (PCFCs) operating in an ammonia-fuel environment, focusing on enhancing their performance. PCFCs, known for lower operational temperatures, faced limitations in ammonia decomposition rates, which were remediated by introducing a catalyst. Specifically, treating the PCFC anode with a palladium (Pd) catalyst resulted in remarkable improvements. Compared to untreated counterparts, the treated PCFCs exhibited a substantial increase in performance, achieving a peak power density over 0.3 W/cm^2 at 500 °C, nearly doubling the output. The process involved depositing Pd catalysts via atomic layer deposition onto the anode surface, where a blend of nickel oxide and $BaZr_{0.2}Ce_{0.6}Y_{0.1}Yb_{0.1}O_{3-\delta}$ facilitated Pd penetration into the porous interior. This treatment significantly enhanced current collection and notably reduced polarization resistance, particularly evident at lower temperatures, ultimately bolstering overall performance. Importantly, impedance analysis confirmed the catalyst's role in augmenting the current flow and mitigating resistance, contributing to the observed improvements. Moreover, stability tests showcased the treated PCFCs' superior durability compared to untreated samples, suggesting the catalyst's role in enhancing long-term stability. These findings underscore the potential of this methodology as a promising avenue for achieving high-performance and resilient PCFCs in the context of ammonia injection environments. In summary, the study's approach of integrating a Pd catalyst into PCFCs operating under ammonia injection demonstrates substantial enhancements in performance, particularly at lower temperatures. The catalyst deposition technique enhances current collection, reduces resistance, and significantly improves durability, marking a significant stride toward realizing high-performing and stable PCFCs in ammonia-based energy systems.

5:00 PM EN09.08.16
Interplay of Oxygen and Sulphur Surface Sites in Controlling OER Kinetics on Cobalt Electrocatalyst supported on Porous 3-D Porous Hard Nanocarbons Subham Yadav and Chandramouli Subramaniam; Indian Institute of Technology Bombay, India

Hydrogen being a clean fuel has gained worldwide attention for improving its greener production pathways to meet energy demands. Electrocatalysis proven to be efficiently producing H_2 and O_2 via water splitting which has its own limiting step. Oxygen evolution reaction (OER) due to the involvement of $4e^-$ transfer in alkaline media. Transition metal oxides/oxyhydroxides are widely explored electrocatalysts for OER. Herein, we explored Cobalt sulphide nanoparticles with surface oxygen sites ($Co_xS_yO^*$) supported on nanocarbon floret (NCF) as electrocatalyst for OER. Interplay of these surface sulphur and oxygen sites in water splitting kinetics has been studied by comparing pristine and modifying the catalytic surface (by varying the ratio of oxygen ans sulfur sites) via electrochemical impedance spectroscopy, linear sweep voltammetry. The lowest overpotential ~ 350 mV and charge transfer resistance (R_{ct} ~ 21 Ω @ 1.6 V vs RHE) observed with using pristine $Co_xS_yO^*$@NCF catalysts. The results indicates significance of synergetic role of oxygen and sulphur sites for efficient water splitting.

5:00 PM EN09.08.17
Plasma-Treated 1D Transition Metal Dichalcogenides for Efficient Hydrogen Evolution Reaction Alex Laikhtman[1], Arie Borenstein[2], Alla Zak[1] and Asmita Dutta[2]; [1]Holon Institute of Technology (HIT), Israel; [2]Ariel University, Israel

Significant research endeavours have been dedicated to the search for highly efficient and cost-effective electrocatalysts for the Hydrogen Evolution Reaction (HER). Tungsten disulphide (WS_2) nanotubes were previously demonstrated for electrocatalysis performances owing to their unique chemical structure and physical properties. In this study, we report a new method of surface modification through cold radiofrequency (RF) plasma. The effect of

two plasmatic ions (D_2^+ and Ar^+) on WS_2 nanotubes has been investigated. The plasma-treated samples showed improved performances in HER electrocatalysis. Based on experimental results, both Ar and D_2 plasma treatments, when performed separately, show similar effects on electrocatalysis performances with improved HER overpotentials of 348 and 343 mV at -10mA/cm^2 compared to 567 mV of the pristine WS_2 nanotubes. On the other hand, combined treatment by Ar and then by D_2 radio frequency plasma notably decreases the overpotential to 264 mV.
Hydrogen is considered a promising alternative for energy production due to its high energy density, high calorific value, and zero environmental effect of combustion products. To avoid the risk of the continuous exploitation and increased consumption of fossil fuels, the efficient and sustainable electrocatalysts for HER is required.
Among all the known HER catalysts, Pt-group metals have been utilized as the most effective electrocatalysts for HER in an acidic medium. However, the low abundance and high cost considerably limit its large-scale application. The preferred electrocatalyst material should lower the activation energy so the process consumes less energy at fast reaction kinetics of the HER.
Two-dimensional transitional metal dichalcogenides (TMDs) are an emerging class of materials with advantageous properties for a wide range of applications such as nanoelectronics, nanophotonics, sensing, etc. Due to the very distinctive characteristics such as robustness, low cost, ease of intercalation, and accessibility to structural modification, this group of compounds exhibit excellent electrochemical characteristics. WS_2 is a representative member of the TMD family. One-dimensional (1D) WS_2 nanotubes are extensively studied for their unique structural and electronic properties. Among other applications, WS_2 nanotubes demonstrated efficient catalytic performance for HER. WS_2 nanotubes feature unique physical and chemical behavior originating from the lattice strain raised by the tubular curvature. Yet, this specific class of pristine inorganic nanotubes possesses fewer active sites and thus eventually suffers from the low affinity of WS_2 nanotubes for proton adsorption. Among different methods, plasma treatment was reported to modify the surface of WS_2 nanoparticles effectively. Low-power RF plasma treatment increases the number of disordered sites at the surface layer and produces atom vacancies, thus significantly enhancing energy conversion performance. Herein, we demonstrate the surface modification of WS_2 nanotubes by plasma treatment. This plasma modified WS_2 nanotubes used as catalyst reveal improved HER performance.
To summarise, we have successfully formed plasma-treated WS_2 nanotubes, which provides a high concentration of active catalytic sites for electrocatalytic reaction. As a result, the HER catalytic activity of all the treated samples significantly improved compared to pristine WS_2 nanotubes. Plasma treatment induces material modification by creating defects and disorders of the nanotube surface. Additionally, RF plasma treatment helps the incorporation of oxides hydrophilic groups inside the system, which promotes fast electron transfer. The effective lowering of overpotential for HER activity was achieved due to the simple, scalable, cost-effective, and less time-consuming plasma treatment on of the semiconductive WS_2 nanomaterial, demonstrates efficient and stable HER electrocatalytic performance.

5:00 PM EN09.08.18
An Improved Non-Enzymatic Glucose Sensor Using a Simple Metal Ion Tuning in Nickel-Aluminum Layered Double Hydroxides Sreejesh Moolayadukkam, Priyankan Datta, Dhrubajyoti Chowdhury and Ishwar K. Puri; University of Southern California, United States

Lifestyle diseases, such as Diabetic Mellitus where patients cannot process glucose effectively, are an increasing cause of human mortality. Glucose molecules in food and the human bloodstream are typically determined with relatively expensive enzyme-based sensors that are error prone due to enzyme degradation. Non-enzymatic sensors do not experience enzyme instability and offer an inexpensive alternative, but competing electrochemical reactions due to dissociation of water molecules at the electrode can lead to inaccurate measurements. Hence, new sensors must be designed with new materials that have accurate glucose adsorption and electrocatalytic performance. Layered double hydroxides (LDHs) with tunable skeletons and multiple metal ions are interesting candidates. We design and test non-enzymatic glucose sensors with nickel-aluminum LDHs, which are hydrothermally synthesized with Ni:Al ratios of 1:1, 3:1, and 4:1. X-ray diffraction (XRD) and scanning electron microscopy (SEM) morphological studies confirm the formation of pure LDH phases. The most robust glucose sensing occurs with the 3:1 metal ion ratio while the 1:1 ratio produces poorest sensing with the 4:1 ratio producing an intermediate result. Through chronoamperometry (CA), the sensor shows good sensitivity (31.206 $\mu A\ \mu M^{-1}\ cm^{-2}$) and selectivity against common interfering species, and a response time lower than 4s. We demonstrate that sensing capabilities can be enhanced using simple engineered materials to develop high-performing non-enzymatic glucose sensors.

5:00 PM EN09.08.19
Enhancing Ammonia Production Rate from Electrochemical Nitrogen Reduction by Modifying Cu Catalyst and Three-Phase Boundary Jeehye Kim[1,2], Ji Hee Jang[3], Mathieu Doucet[1], Hanyu Wang[1], Youn Jeong Jang[3] and Jae Sung Lee[2]; [1]Oak Ridge National Laboratory, United States; [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Hanyang University, Korea (the Republic of)

Ammonia (NH_3) is a critical component in fertilizer and other essential industrial chemical production, making it the second largest synthetic chemical worldwide (> 200 million tons). However, the traditional Haber-Bosch process requires massive energy input and results in the emission of a large amount of carbon dioxide [1,2].
The electrochemical nitrogen reduction reaction (eNRR) driven by renewable electricity under mild condition emerges as a sustainable method for NH_3 production to minimize carbon footprint [3,4]. We are focusing on the development of an effective eNRR system using Cu-based electrocatalysts in gas diffusion electrode (GDE) system with modification of three-phase interfaces. To overcome the low affinity of Cu for N_2, phosphorus activation was applied to create electron-deficient Cu sites for better N_2 adsorption and activation. Additionally, we address the limited solubility of nitrogen in aqueous electrolytes by incorporating a GDE coated with polytetrafluoroethylene (PTFE). This setup optimizes the three-phase interfaces among water, gaseous N_2, and the catalyst. Our innovative approach in a flow-type cell achieves a Faradaic efficiency of 13.15% and an ammonia production rate of 7.69 $\mu g\ h^{-1}\ cm^{-2}$ at -0.2 V_{RHE}. This represents a 59.2-fold increase in NH3 production rate compared to electrodeposited Cu electrodes, highlighting the potential of our strategies in practical systems [3].

5:00 PM EN09.08.20
Non-Noble Metal Oxide (WO_3), Sulfide (MoS_2) and Carbide (MoC) for Electro and Photoelectrocatalytic Hydrogen Evolution Reactions Jae-Jin Shim, Muhammed Shafi Parasseeri and Al Mahmud Abdullah; Yeungnam University, Korea (the Republic of)

Nonprecious transition metal electrocatalysts are cost-effective, possess catalytic solid performance, and are scalable for hydrogen generation via water splitting, which provides clean and sustainable energy. Developing an efficient catalyst for hydrogen evolution reaction (HER) based on metal oxide, sulfide, and carbide has been studied worldwide to replace the expensive noble metal PtC. In this work, selected oxide, sulfide, and carbide (WO_3, MoS_2, and MoC), together with other metal compounds, have been studied. The 2D molybdenum disulfide is a challenge because of the restacking of MoS2 layers, which leads to insufficient access to active sites. In this study, the drawbacks of 1T MoS_2 catalyst were overcome by employing carbon nano-onion

(CNO). This CNO-MoS_2 exhibited an excellent HER performance with an overpotential of 53 mV *vs.* RHE and a Tafel slope of 40.8 mV dec^{-1} for over 25 h, showing it one of the best HER catalysts next to platinum. 3D core-shell heterostructures of WO_3/Bi_2MoO_6/Co–Pi and $BiVO_4/MoS_2$ were also synthesized using hydrothermal synthesis/ electrodeposition and electrodeposition/plasma-enhanced atomic layer deposition (PECALD). The former hetero-photocatalyst exhibited significantly high photoelectrochemical activity, where its photocurrent efficiency was 4.6 times greater than that of the constituent WO_3. For the $BiVO_4/MoS_2$ photoelectrode, an optimal thickness of the MoS_2 layer was controlled by the number of PEALD cycles. The highest photocurrent (2.1 mA cm^{-2}) was produced from the electrode with a 6 nm layer-thickness, 2.4 times higher than the pristine $BiVO_4$. Thermal pyrolysis created a carbon-encased, nitrogen-rich γ-MoC/NiC composite that contains rGO. The overpotential at 10 mA cm^{-2}, of γ-MoC/NiC@rGO for HER is 185 mV, whereas it is 298 mV for OER. The Tafel slopes for HER and OER are relatively modest, at 78 and 80 mV dec^{-1}, respectively. This study highlights a new, highly stable, highly performing non-noble metal catalyst for electrochemical water splitting applications.

Organic Chemistry—A Tool for Improved Performance of Lithium Secondary Batteries Charlotte Mallet; Hydro Quebec, Canada

Hydro-Québec's Center of Excellence in Transportation Electrification and Energy Storage has been a world-class innovation hub in the field of battery materials for electric vehicles as well as other energy storage applications for more than 40 years. The Center's efforts are primarily focused on advanced lithium-ion batteries and solid-state batteries. Its know-how, extensive intellectual property portfolio and cutting-edge facilities draw interest from around the world and make it an essential partner for major industry players involved in the development of next generation battery materials and technologies.
This presentation will outline our major breakthroughs leveraging our strong expertise in organic chemistry. By dint of multidisciplinary team, our work is rooted in understanding degradation phenomena of battery systems and aims to provide solutions based on the structure-property relationships of materials, which resulted in 40 patents with new concepts since 2015.
To tackle the challenges related with high voltage cathodes like LMFP or NMC, we developed new additives to protect electrolyte-cathode interface and limit degradation phenomena such as transition metal dissolutions[1,2] or electrolyte side reactions.[3] In addition, we developed new binders or co-binders to improve low temperature applications, increase C-rate performance,[4] and polymers to eliminate different types of gas by in-situ trapping.[5] Our works include synthesis of new kind of salts for liquid and solid lithium batteries.[6] We also developed new organic cathode materials with high operation voltage up to 4.5V, and high specific capacity of 692 mAh/g. The cycle life was tested with polymer electrolyte system at 40˚C.[7] Finally, another major project is protection of lithium metal anode by different organic compound deposition method like spray-coating or solution casting. This protective organic layer stabilized Li metal interface providing enhanced performance with various electrolyte chemistries such as liquid, polymer, and sulfide electrolyte.[8]
The organic and polymer chemistry team of center of excellence has developed a lot of creative solutions to address a wide range of issues such as stability, efficiency, low temperature performance and low cost.

A Systematic Study of NiCo Layered Double Hydroxide Grown on Porous Carbon for Hybrid Supercapacitor Electrodes: Growth Method, Morphology and Composition Geonho Kim, Dongjun Kim and Jiwon Kim; Yonsei University, Korea (the Republic of)

Supercapacitors have drawn an extensive attention for their high power density and excellent cycling stability to meet a rapidly growing demand for high-capacity energy storage systems. Specifically, metal (e.g., Ni, Co, Fe, Al, Mn, and its combinations) layered double hydroxides (LDHs) have been integrated to supercapacitor electrodes owing to their seamless ion transport through interlayer. LDHs are often hybridized with conductive materials to facilitate charge transport since low conductivity of LDHs hinders the supercapacitors to reach their theoretical capacitance (e.g., ~3,000 F g^{-1} for pristine NiCo LDH). Although diverse forms of LDH hybridized carbon electrodes are designed, it has not yet been systematically studied how morphology and composition simultaneously affect the performance of supercapacitors.
Accordingly, we have systematically controlled the synthetic method/condition of growing metal LDHs on nitrogen doped porous carbons (NPCs) and studied their effects on electrical performance as hybrid electrodes of supercapacitors. In detail, various metals (i.e., Ni, Co, and NiCo) have been deposited on NPCs by both electrodeposition (i.e., 100, 300, 500, and 1000 mC) and solvothermal method. NPC was chosen as carbon electrodes since it can improve the rate performance as well as structural stability of electrodeposited LDHs owing to its higher conductivity, specific surface area, and hydrophilicity compared to other carbon-based materials with free-standing structure for electrodeposition compatibility. The supercapacitor with electrodeposited NiCo LDH@NPC electrodes exhibited higher specific capacitance than those of either Ni or Co LDH@NPC electrodes, since coexistence of metals shows a synergistic effect on storing higher energy via multiple reduction-oxidation (redox) reactions. Among NiCo LDH@NPC electrodes, the electrode with the total deposited charge of 500 mC (NiCo500 LDH@NPC) showed the highest capacitance of 3,155.52 F g^{-1}. These results might be ascribed to three main factors: (i) multiple redox reactions from Ni-Co coexistence, (ii) shortened hydroxide (OH^-) ion diffusion length due to the uniform distribution of LDH in nanomesh structure, and (iii) facilitated OH^- ion accessibility into active materials owing to broader interlayer of LDH. Furthermore, an asymmetric supercapacitor (NPC||NiCo500 LDH@NPC) achieved energy density of 39.22 Wh kg^{-1} at a power density of 913.87 W kg^{-1} and 80.00% retention after 20,000 cycles.

9:15 AM EN09.09.03

Microwave Synthesis for Trimetallic Needle Structures coupled with N-Doped Carbon for Highly Boosted Bifunctional Oxygen Catalysts for Zn–Air Batteries Hoyoung Jang, Youngsun Cha and Wonjoon Choi; Korea University, Korea (the Republic of)

Energy storage systems play a crucial role in expanding the capabilities of sustainable energy sources and addressing existing energy issues associated with environmental pollution concerns. While versatile renewable energy sources have been developed over the past decade, their large-scale implementation inherently requires the use of highly efficient yet robust energy storage solutions. Metal-air batteries have recently been attracting attention as a promising candidate for next-generation storage cells due to their high theoretical capacity and eco-friendly use of oxygen. Among various types of metal-air batteries, the Zn-air battery has notably demonstrated a high theoretical energy density of 1860 Wh/kg, while ensuring cost-effective production, safety, and environmental compatibility. The primary emphasis in the development of rechargeable Zn-air batteries has been on improving stability and energy efficiency. The challenge of achieving high energy efficiency lies in the substantial overpotential of the constituent materials, which impacts the effectiveness of both the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER). Noble metal-based electrocatalysts such as Pt/C and Ir/C exhibit remarkable electrochemical performances in ORR and OER. However, its widespread application is limited due to its high cost and stability issue.

In this work, we report a facile synthesis route of trimetallic bifunctional catalysts with N-doped carbon, with their low overpotential and high stability comparable to precious metals. The formulation of the precursor solution is conducted by precisely mixing 0.3 M iron nitrate hexahydrate ($Fe(NO_3)_36H_2O$), 0.3 M nickel nitrate hexahydrate ($Ni(NO_3)_36H_2O$), 0.3 M cobalt nitrate hexahydrate ($Co(NO_3)_26H_2O$), 1.2 M urea ($CO(NH_2)_2$), and 0.4 M ammonium fluoride (NH_4F) in 100 ml of deionized (DI) water. The melamine foam was soaked in this solution and it was subjected to heating in an oven at 130 degrees celsius for a duration of 5 h as an integral step in the synthesis process. Then, the catalyst is directly fabricated using microwave heating for 20 seconds at 1000 W power. Scanning electron microscopy images illustrate the morphology transition of the catalysts at each stage of the synthesis process. Optimizing the microwave heating exposure leads to the creation of uniform metal oxides, as validated through transmission electron microscopy analysis. The composition and chemical state of the elements constituting the catalyst surfaces are preciously examined using X-ray photoelectron spectroscopy and X-ray powder diffraction.

The electrochemical performance of the developed catalysts is examined using a potentiostat in a three-electrode electrochemical cell with a rotating ring disk. The optimized trimetallic (Fe-Ni-Co) catalysts exhibit a low overpotential (0.071 V), similar to that of Pt/C and Ir/C. Under the full cell test, the catalysts obtain stable performances for 300 h in repetitive charge/discharge cycles for an hour interval, and the specific capacitance reaches 769 mAh g^{-1} at 10 mA cm^{-2}. We believe that this rational synthesis strategy toward a facile fabrication process will contribute to developing novel active materials with mesoporous structure and large surface area, potentially useful for diverse electrochemical energy storage systems. Furthermore, the outcome of this work will inspire novel design of high performance electrocatalysts and other energy-related hybrid materials using transition metals.

Confining Highly Redox-Active Atoms in Stable Insertion-Type Anode Materials for Alkali Metal-Ion Batteries Dominic Bresser; Karlsruhe Institute of Technology, Germany

The unique combination of exceptional energy and power density along with the continuous decrease in cost have made lithium-ion batteries the electrochemical energy storage technology of choice for small-scale and large-scale applications.[1–3] However, the use of graphite as active material for the negative electrode is intrinsically limiting the possibility to rapidly charge these batteries.[4] Herein, a new class of active materials is presented that provides comparable charge storage capacities at much faster rates. This new class of materials is based on the introduction of highly redox-active atomic centers into stable metal oxide host structures. These host structures are well preserved upon continuous lithium cation insertion and deinsertion following a solid-solution-type mechanism, while the introduction of these highly redox-active atomic centers allows for the duplication and triplication of the charge storage capacity compared to the nanoparticulate metal oxide host structures alone. Remarkably, the redox centers are reversibly reduced to the metallic state at the atomic level without affecting the surrounding crystal structure. When replacing lithium cations by sodium or potassium cations, essentially the same mechanism is observed, apart from the expected “size effect”, highlighting the exceptional versatility of this new class of battery electrode materials.

Balancing Volmer Step by Dual-Active Domains for Electrocatalytic H_2 Formation Jinsong Zhou[1,2]; [1]City University of Hong Kong, China; [2]ETH Zürich, Switzerland

The reaction kinetics of hydrogen evolution reaction (HER) is primarily determined by balancing the Volmer step in alkaline/neutral media. The bifunctional effect as a proposed strategy divides the reaction process of water dissociation and intermediates ad-/de-sorption. However, sluggish OH^* desorption plagues water re-adsorption, leading to the active domain's poisoning effects. In addition, some active sites may even directly act as spectators and do not participate in the reaction. The activity comparison under approximate nanostructure between bifunctional effect and single-functional-domain is not fully understood.

We adopted a facile three-step strategy to successfully grow MoS_2 on cobalt-containing nitrogen-doped carbon nanotubes (Co-NCNTs), forming obvious dual-active domains. The active domains of Co-NCNTs and MoS_2, with the tuned electronic structure at the heterointerface, trigger the bifunctional effect

to balance the Volmer step and boost the catalytic activity. The HER driven by the bifunctional effect could significantly optimize the Gibbs free energy of water dissociation and hydrogen adsorption, resulting in fast reaction kinetics and superior catalytic performance.

The Effect of C_{60} Support on The Electrochemical Activity of Pd and Pt Particles Sergey Kozlov, Mohammed Aliasgar and Fernando Buendia; National University of Singapore, Singapore

Engineering nanoparticle-support interactions is a powerful strategy for improving the activity and stability of heterogeneous catalysts. In this contribution, we show how such interactions can also improve the electrocatalytic performance of Pd and Pt nanoparticles. First, we demonstrate how the interactions between Pt nanoparticles and C_{60} nanosheets lead to higher catalyst activity in alkaline hydrogen evolution reaction (HER) compared to unsupported Pt nanoparticles or Pt nanoparticles on graphene [1]. The nanoscale roughness of the C_{60}(110) support surface helps to stabilize ~2 nm large crystalline Pt particles between appropriately spaced rows of C_{60} molecules. Our density functional (DFT) simulations reveal the strong polarization of electron density on the interface between similarly sized Pt particles and the C_{60}(110) surface due to the transfer of ~2 electrons from each particle to the support. The polarized electron density on the Pt/C_{60} interface results in a significant variation of H binding energies, which are known to govern the HER activity of the catalyst. Curiously, our microkinetic modeling shows that such variation dramatically increases the rate of both Volmer, Heyrovsky, and Tafel steps by up to 100 times on the interface sites and decreases HER overpotential by almost 0.1 V at 10 mA/cm^2 under alkaline conditions, in line with experimental observations. The calculated simultaneous acceleration of both Volmer and Heyrovsky steps indicates that the introduced diversity of the active sites on the nanoparticle-support interface effectively allowed us to overcome the limitations of Sabatier activity volcano for hydrogen evolution reaction on transition metals. Moreover, the interactions between metal nanoparticles and fullerene support can also affect the phase transitions in the former. For example, we show how nanoparticle-support interactions alter the onset electrode potential for β-hydride formation in Pd nanoparticles, which notably changes their electronic structure and catalytic properties. As a result, the activities of Pd/C_{60} catalysts in HER and CO_2 reduction reactions significantly differ from those of unsupported Pd nanoparticles.

Bifunctional Nickel Cobalt Phosphorus Sulfide Electrocatalyst for Simultaneous Hydrogen Evolution and 5-Hydroxymethylfurfural Oxidation Kuan-Mei Hung and Jih-Jen Wu; National Cheng Kung Univeristy, Taiwan

The replacement of the O_2 evolution reaction of electrocatalytic water splitting with a thermodynamically more favorable reaction has attracted considerable attention for simultaneous value-added feedstock formation coupled with H_2 production. The electrocatalytic oxidation of renewable biomass platform chemical 5-hydroxymethyl furfural (HMF) to 2,5-furandicaroxylic acid (FDCA), a valuable bio-monomer of polyethylene furanoate (PEF), has emerged as a promising sustainable route for biomass valorization. In this work, bifunctional nickel cobalt phosphorous sulfide nanosheet arrays (NCPS) were constructed on Ni foams as the electrodes of a two-electrode electrolytic H cell for simultaneous electrocatalytic hydrogen evolution and HMF oxidation (HMFOR) to FDCA in 0.1 m KOH. With the addition of 5 mM HMF in the electrolyte, the cell voltage required to afford the current density of 10 mA cm^{-2} is less 153 mV than water electrolysis. It indicates the superior energy conversion efficiency of NCPS for electrocatalytic HER and HMFOR compared to water splitting. The amounts of H_2 and FDCA produced over NCPS in the two-electrode configuration were measured at a constant cell voltage of 2.12 V (the anode potential of 1.6 V vs. RHE) for 78 min to pass the charge of ~ 34.8 C. In the anodic chamber of the H cell, the HMF conversion is 95.01%, and the selectivity for forming FDCA is 89.06% with the Faradaic efficiency of FDCA is 86.83%. The generated H_2 in the cathodic chamber reaches a Faradaic efficiency of 96.07%. The XPS analyses indicate that the Ni^{2+}/Ni^{3+} and Co^{2+}/Co^{3+} ratios in the NCPS couples alter after the HER and HMFOR, suggesting that the Ni and Co cites play crucial roles in the electrocatalytic reactions. The influences of chemical and electronic structures on the electrocatalytic activity of NCPS will be discussed in this presentation.

11:30 AM EN09.10.04
Bimetallic Fe/Co Sites for Oxygen Reduction Reaction Xin Li[1,2,3] and Michael K. Leung[1]; [1]City University of Hong Kong, Hong Kong; [2]Tsinghua University, China; [3]University College London, United Kingdom

Double atom catalysts (DACs), featuring dual metal atoms dispersed on supports, provide innovative avenues for accelerating the sluggish kinetics of the oxygen reduction reaction (ORR). In this study, we have engineered a double-atom metal site consisting of iron (Fe) and cobalt (Co) anchored within a triazine-based covalent organic framework (Fe/Co-COF) with different Fe/Co ratios. This framework is derived from the assembly of 4,4′4″-(1,3,5-triazine-2,4,6-triyl) trianiline and ace-naphthenequinone monomers, resulting in a highly π–π conjugated structure. The COF structure incorporates two adjacent =N- groups, each featuring a lone pair that can coordinate with Fe and Co. We assessed the ORR performance in an O_2-saturated 0.1 M KOH electrolyte, where the Fe_2/Co_1-COF catalyst, with Fe at 1.27wt% and Co at 0.65wt%, exhibited a remarkable half-wave potential ($E_{1/2}$) of 0.95 V (vs RHE). Moreover, it displayed impressive durability, enduring 100,000 voltage cycles with only a 25 mV $E_{1/2}$ loss. This performance outstrips that of commercial Pt/C catalysts and virtually all other reported single atom-based catalysts. The improved activity is ascribed to the higher metal loading, a synergistic catalytic mechanism, and the presence of more intricate and adaptable active sites on the Fe/Co-COF surface.

Highlights:

In the realm of electrocatalysis, single atom catalysts (SACs) have garnered significant attention, particularly those with the metal-N-C structure. However, standard EXAFS fitting struggles to differentiate metal-C/N/O coordination, raising doubts about whether N truly coordinates with metal. In our work, ex-situ vtc-XES measurements were employed, confirming the coordination of Fe-N and Co-N.
We conducted *in-situ* X-ray Absorption Near Edge Structure (XANES) measurements to uncover the real active sites and determine the changes in metal electronic and coordination structures under the conditions of the oxygen reduction reaction. Our findings unveil the presence of synergistic Fe-N and Co-N active sites in Fe_2/Co_1-COF, demonstrating a mutually beneficial effect on overall ORR performance.

11:45 AM EN09.10.05
Photocatalysis and Photosensitization Using Atomically Precise Metal Nanoclusters for Solar Energy Harvesting and Conversion Nicola Pinna, Yu Wang and Ye Liu; Humboldt-Universitat Berlin, Germany

Metal nanoclusters (NCs) with atomic precision are a unique family of metal nanomaterials that are readily crystalized into single crystals, representing ideal models to unravel structure-property relationship at atomic level. By tuning the number of metal atoms in the core, the composition and the protecting ligand of metal NCs, their physicochemical properties can be precisely controlled. The strong, broad light absorption ability and the long-lived excited

states make metal NCs promising candidates as photosensitizer, and might replace traditional dyes. Their discrete energy levels allow them to prevent charge recombination at the semiconductor by efficiently separate the photoinduced charge carriers. Moreover, these metal NCs themselves can act as active catalysts. In the first part of the talk, we demonstrate the differences of working principle between metal NCs and their particle counterparts in photocatalytic system. The metal NC modified TiO_2 catalyst is found to exhibit a fiver times higher performance than TiO_2 modified with metal nanoparticles in the photocatalytic H_2 production reaction.[1] In the second part, we present the strategy to tune the charge transfer pathways of metal NCs sensitized semiconductors in photoelectrochemical system. While metal NCs serve as catalyst for oxidation reactions when loaded on n-type semiconductor, they serve as catalyst for reduction reactions when loaded on p-type semiconductor.[2] In the last part, we will use Au_{25} NC as an example to demonstrate how the protecting ligand and the composition of the metal NC influence the overall performance of a NC/semiconductor system in photocatalytic H_2 production.[3]

Interfacial Engineering of RuO_x on Rutile TiO_2 Supports to Boost the Acidic Oxygen Evolution Reaction Hyunseok Yoon and Dong-Wan Kim; Korea University, Korea (the Republic of)

As global concerns about crises such as climate change and fossil fuel depletion increase, the importance of hydrogen energy is being further emphasized. In particular, there is growing interest in the commercial feasibility of using polymer electrolyte membrane water electrolysis (PEMWE) for large-scale production of green hydrogen. However, there are significant obstacles to overcome, mainly related to the slow kinetics of the acidic oxygen evolution reaction (OER) that occurs at the anode. Ruthenium (Ru)-based materials (e.g. RuO_2), which are much more abundant and have relatively high OER activity, are very attractive alternatives to rare iridium (Ir)-based materials such as IrO_2, the most commercialized acidic OER catalyst. Nonetheless, Ru has a critical drawback in that it is easily over-oxidized and dissolved as a soluble species ($Ru^{>4}$) under acidic OER operating conditions. Therefore, additional research is required to find solutions to this issue. In this study, we tried to develop a highly efficient and durable Ru-based acidic OER electrocatalyst, employing interfacial engineering. Ruthenium oxide (RuO_x) nanoparticles were coated on the surface of one-dimensional (1D) rutile TiO_2 nanofibers using a facile hydrothermal method. Introducing rutile TiO_2 as a support is advantageous in enhancing the OER stability and promoting an interfacial affinity with the catalyst due to its excellent corrosion resistance and the common crystal structure sharing with RuO_x. Notably, the size, morphology, and crystallinity of Ru species crystal grains on the TiO_2 surface changed depending on the pH conditions during the reaction process. When RuO_2 was grown in the form of a large nanosheet with high crystallinity through alkaline pretreatment (RT-NSs), it was less affected by strain effect and showed OER performance with no significant difference from general RuO_2. On the other hand, in the case of a sample composed of a small nanoparticle film on a TiO_2 support synthesized in an acidic solution (RT-NPs), the interfacial synergy with TiO_2 was maximized, showing excellent OER activity. Finally, we achieved enhanced acidic OER performance by improving stability through a low-temperature post-annealing process.

Effective Catalysts Design for Selective OER in Seawater Sharafadeen Gbadamasi, Suraj Loomba, Muhammad Haris, Muhammad Waqas Khan and Nasir Mahmood; RMIT University, Australia

The oxygen evolution reaction (OER), a significant half-reaction in electrocatalytic water splitting to produce green hydrogen, has received considerable research attention. Currently, state-of-the-art water splitting technology utilises the expensive and scarce noble metal-based catalysts and freshwater, a limited resource, as it constitutes less than 1% of the world's total water. To this end, alternative feedstocks, such as seawater, need to be explored, which account for approximately 96.5% of the world's total water.
In recent years, research on developing efficient catalysts for seawater has been gaining significant attention. However, the complex nature of seawater and the presence of dissolved ions like chloride ions (Cl^-) have made seawater splitting more challenging. The Cl^- ions can induce electrode corrosion and have the capacity to engage in competing reactions with the oxygen evolution reaction (OER) at the anode. This necessitates developing highly active electrocatalysts that are exclusively selective towards OER and possess long-term stability. Based on this, I have developed a two-dimensional heterostructure catalyst that achieved 2 A before 2V, was stable for over 500 h and was exclusively OER selective in natural seawater. The catalyst benefits from the synergistic effects between the component 2D materials and strong electronic interactions between them.

2:00 PM *EN09.11.03
Electrochemical Activity of Iridium Oxides for OER: Porosity, Crystallinity and Nanocages Cédric Tard[1], Silvia Duran[1], Marine Elmaalouf[2], Andrea Zitolo[3], Benedikt Lassalle[3], Cédric Boissière[4], Marco Faustini[4], Marion Giraud[2] and Jennifer Peron[2]; [1]Ecole Polytechnique, France; [2]Université Paris-Cité, France; [3]Synchrotron Soleil, France; [4]Sorbonne Université, France

Iridium oxide is still considered the superior material for the oxygen evolution reaction (OER) in acidic environment, as it maintains both high activity and stability, making it the benchmark material for green hydrogen production.[1] Despite the numerous studies describing the activity of IrO_2 materials for the OER, it is crucial to have a thorough understanding of its functional principles in order to optimize and rationalize its utilization. Towards this objective, we have been able to produce porous iridium-based mixed oxides using aerosol chemistry via a sol-gel process,[2] to decouple the electronic processes from the structural transformations.[3] Indeed, the oxidation of iridium from IrO_2 occurs upon calcination, but is not related to the crystallization of the material itself. The measurements demonstrate that short-range ordering, corresponding to sub-2nm crystal size, is controlling the activity of the materials. This is the case regardless of the initial oxidation state and composition of the calcined iridium oxides, as evidenced by XAS, XRD and XPS measurements. Regarding other types of porous materials, we have also been able to prepare hierarchical structures of IrO_2 based on Pearson's hard and soft acid-base

theory and characterize their outstanding activity toward the OER.[4]

2:30 PM BREAK

3:00 PM EN09.11.04
Investigation of Active Factors for Oxygen Reduction Reaction by Titanium Oxide Model Electrode Takahiro Saida, Miyu Mashiyama and Takahiro Maruyama; Meijo University, Japan

Polymer electrolyte fuel cells (PEFCs) are one of the low-environmental-impact power sources. However, the broad commercialization of PEFCs has been slow. One reason for this is that the electrocatalyst of PEFCs is the high manufacturing cost and low durability. Titanium oxide-based catalysts have attracted attention as the candidate for low-cost and highly durable electrocatalysts. Titanium oxide-based catalysts need to address the drawback of poor catalytic activity.
Currently, introducing the oxygen vacancies and doping the other metal atoms are known to enhance the oxygen reduction-reaction (ORR) activity on titanium oxide. Generally, the catalytic reaction progresses at the low coordination site on the surface. Introducing oxygen vacancies leads to an increase in low-coordination sites, which means increasing the activity sites. As a result, the ORR activity of titanium oxide is improved by introducing oxygen vacancies. In addition, the oxygen vacancy changes the electron structure of titanium oxide and provides electron conductivity. From the results of the DFT calculation, it was reported that the low-coordination metal site, which was formed by oxygen vacancy, and the neighborhood structural oxygen played an important role in ORR. On the other hand, the structural analysis results using the pair distribution functions (PDFs) method using X-ray showed that the active site was related to the crystal distortion site and no confirmed oxygen vacancies. One of the problems in titanium oxide-based catalysts is that the active site and reaction mechanism are still unclear. For this reason, the design of new catalysts must rely on rules of thumb. Clarifying the active control factor for ORR on titanium oxide is one of the effective approaches to the high activity close to platinum-based catalysts.
In this study, a titanium oxide model electrode formed by a mono-layer of the titanium oxide nanosheets was used to separate the effects from the low coordination site and the crystal distortion. A titanium oxide nanosheet is composed of octahedrons centered on Ti atoms. Thus, the variation of Ti valence is linearly related to the number of low-coordination sites.
The crystal distortion was evaluated by in-plane XRD and grazing-incidence XAFS measurements in synchrotron radiation facilities. In particular, the local coordination structure of the titanium-oxide model electrode was investigated from pre-peak before the adsorption edge and EXAFS region in the obtained XAFS spectrum. The Ti valence was estimated from the energy of half value at the edge jump intensity in the XAFS spectrum. The number of oxygen vacancies on a titanium-oxide model electrode was roughly controlled by the calcination temperature with hydrogen flow conditions. Electrochemical measurements were performed in a three-electrode cell with 0.1 M $HClO_4$ electrolyte.
The structure of the titanium-oxide model electrode was changed from the lepidocrocytes structure to the anatase structure with increasing calcination temperature. The local coordinate structure was also transformed with increasing calcination temperature. At that time, the Ti valence was gradually elevated from 3.47 to 3.92. The ORR activity of the model electrode was enhanced by the calcination with hydrogen flowing until the beginning of the phase transition to the anatase structure. The distortion of the crystal structure was most significant after the phase transition. However, the ORR activity was low compared to before the phase transition. Introducing the oxygen vacancies to the titanium-oxide model electrode clearly enhanced the ORR activity and gave its structure a very slight crystal distortion. At this time, it is forecasted that the crystal distortion is more effective in ORR activity on titanium oxide rather than the number of oxygen vacancies. However, the permissible crystal distortion rate may be narrow, and the phase transition probably leads to the degradation of the ORR activity.

3:15 PM EN09.11.05
High-Performance Mo-N-C Electrocatalyst for Efficient Oxygen Reduction and Evolution Reaction Nadezda Kongi[1], Gulnara Yusibova[1] and Yevgen Karpichev[2]; [1]Institute of Chemistry, University of TartuUniversity of Tartu, Estonia; [2]Tallinn University of Technology, Estonia

Despite notable advancements in the development of catalysts for both the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER), there exists a persistent demand for materials that are more efficient and cost-effective. M-N-C (metal-nitrogen-carbon) materials have emerged as promising solutions that are efficient, low-cost, and sustainable. This study presents the synthesis of Mo-N-C catalysts through a novel metal-organic framework precursor, along with comprehensive characterizations involving X-ray diffraction, transmission electron microscopy, and X-ray photoelectron spectroscopy. These catalysts, owing to their highly porous structure and a high density of active sites, demonstrate remarkable performance and stability for both ORR and OER. Our findings underscore the potential of Mo-N-C catalysts as efficient and economical alternatives to noble-metal-based catalysts for ORR/OER.

3:30 PM EN09.11.06
MOF-Based Architectures towards Higher Activity Oxygen Reduction Reaction Catalysts Albert Epshteyn, William A. Maza, Benjamin L. Greenberg, James Ridenour, Bethany M. Hudak, Olga Baturina, Boris N. Feykelson and Brian Chaloux; U.S. Naval Research Laboratory, United States

The electrocatalyst responsible for carrying out the oxygen reduction reaction (ORR) at the hydrogen fuel cell (FC) cathode has a demanding task to perform in a highly acidic environment and under a corrosive potential. Despite its cost, platinum (Pt) has become the most common catalyst proven to have high activity and durability towards ORR catalysis. There is, therefore, a need to design and develop more cost-effective catalysts that can either replace or reduce Pt content. A key challenge in the design of ORR catalysts is maximizing the conduction and utilization of electrons, protons, and oxygen to the active sites on the electrode surface. For use in intermediate temperature hydrogen fuel cells, which operate above the boiling point of water, the ability to minimize transport barriers in the electrolyte material and optimizing the way it couples to the ORR catalyst is of great importance to maximize catalytic turnover and efficiency. To that end, we have set out to develop approaches toward using metal-organic frameworks (MOFs) as templates for high-surface-area platinum structures to develop high-performance ORR catalysts. As a proof-of-concept, we have chosen the highly robust and well-known UiO series, which among other benefits has the potential for pore-size tuning that should be conducive for effective gas transport. The MOF synthesis has been optimized to target well-defined, single crystalline MOF particles with shape control and narrow size distributions and scaled to multi-gram batches. Subsequently, we have explored different approaches to deposit Pt onto these MOF nanoparticles using methodologies that include colloid-derived methods, as well as solvothermal and atomic layer deposition (ALD) approaches. In this work we compare the different Pt deposition approaches by assessing the relative ORR activities and correlate the results to X-ray photoelectron spectroscopy (XPS) and the catalyst morphology as determined by high-resolution transmission electron microscopy (HR-TEM).

3:45 PM EN09.11.07

Current Density – Voltage (i-V) Dependence of Polymer Electrolyte Electrochemical Cells (PEEC) on The Cell Components of Gas Diffusion Layers (GDLs) and Cell Sealings Miyuki Nara, Katsushi Fujii, Takeharu Murakami, Takayo Ogawa and Satoshi Wada; RIKEN, RAP, Japan

Hydrogen production using water electrolysis in polymer electrolyte electrochemical cells (PEEC) is an attractive technique. The PEEC is known to be relatively strong for input energy fluctuation from a reliability point of view; thus, it is a suitable technique for fluctuating renewable energy storage.
The current density characteristics as a function of PEEC voltage are critical for improving the efficiency of hydrogen production from renewable energies. Research is continuing to improve an oxygen evolution catalyst whose overvoltage is relatively high compared to that of hydrogen evolution and using a thinner polymer electrolyte membrane to reduce the series resistance.
The PEEC cell structure consists of endplates, gas diffusion layers (GDLs), catalyst-coated membranes (CCM), and gas and supplied water-sealing materials. These components were not considered to improve PEEC performance. However, these structures affect electron, water, and gas electron flows. Thus, the effect of these components on the PEEC performance is discussed here.
The influence of the GDL thickness and porosity was evaluated by current density-voltage (i-V) characteristics and electrochemical impedance spectroscopy (EIS). A PEEC with a thicker and higher porosity GDL improved the i-V characteristics. It was also found that the thickness of the seal has an appropriate relationship with the internal parts. The series resistance evaluated by EIS decreased with an improvement in the i-V performance. From these results, the reason for this i-V characteristic change is estimated to be changing the flow of electrons and/or the flows of the source material of water and/or of the produced gas oxygen or hydrogen.

8:00 AM EN09.12.01
Modelling of Natural-Like Grain Generation of TiO2 and its effect on Band Structures Takuma Okamoto[1], Anastassia Sorkin[2], Keisuke Kameda[1], Wang v. Hao[2], Manabu Ihara[1] and Sergei Manzhos[1]; [1]Tokyo Institute of Technology, Japan; [2]National University of Singapore, Singapore

TiO2 is widely used in various electrochemical technologies including photosynthesis catalyst and optical applications such as dye sensitized solar cell, perovskite solar cells and batteries. Its polycrystal structure affects electronic properties, for example, introducing trap states into the band structure both in the bulk and at the interfaces and affects the ion and electron transport. It is difficult to understand these effects experimentally especially in bulk, therefore computational studies of effects of microstructural features are desired. These kinds of calculations have been done using models with a specific, postulated grain boundary. However, real materials have a distribution of grain boundaries. In monoelemental materials like Fe and Si, generation of grain structures have been reported using Molecular Dynamics (MD), but for ceramics containing several kinds of atoms, it is more difficult.
In this study, natural-like generation of grain boundaries is explored using MD at a million-atom scale. Different types of temperature schedules are explored, and different structures are obtained by different heat treatments. To facilitate the formation of grains, spherical seeds that are randomly located and oriented are introduced. Temperature dependence of the grain sizes of the obtained structures is investigated. Furthermore, the effects of the microstructural features on the band structure are computed using large-scale Density-Functional Tight-Binding calculations (DFTB). Differences in the electronic properties between ideal crystal and different grainy structures are compared.

8:15 AM EN09.12.02
Effects of Nanosizing of Zirconia and Bandstructure Modulation on Catalytic Activity: Insights from a Combined Density Functional Tight Binding – Order(N) Density Functional Theory Study Kexin Chen[1], William Dawson[2], Takahito Nakajima[2], Aulia S. Hutama[3], Keisuke Kameda[1], Sergei Manzhos[1] and Manabu Ihara[1]; [1]Tokyo Institute of Technology, Japan; [2]RIKEN Center for Computational Science, Japan; [3]Universitas Gadjah Mada, Indonesia

Zirconia based materials are widely utilized in the electrodes of solid oxide fuel cells and electrolysis cells. Interactions of small molecules with zirconia surfaces are of key importance in these applications. Numerous theoretical reports have focused on periodic models, while the properties of materials at the nanoparticle or cluster scales may differ markedly from their bulk counterparts. However, ab initio level understanding of gas adsorption behavior on Zirconia at this scale remains limited. We will present a comparative analysis based on first principles and semiempirical calculations of cubic ZrO_2 nanoparticles, varying in size from a few tens to a thousand atoms. This is achieved by combining density functional-based tight-binding (DFTB) and order-N DFT to balance computational cost and increase scalability. The band structure of the nanoparticles, which proves sensitive to oxygen deficiencies, exerts a significant influence on gas adsorption behavior. Notably, nanoparticles can exhibit intrinsic as well as p- and n-doped characteristics corresponding to O-rich or O-poor conditions. The n-type particles display heightened reactivity for the adsorption of CO and CO_2 gases on their surfaces with promoted electron transfer from zirconia adsorbents to the adsorbed molecules, which is useful for their catalysis, with the effect stronger due to nanosizing. Our results suggest good potential of nanosizing and bandstructure engineering in zirconia nanoparticles to achieve enhanced gas adsorption and catalytic performance, thus presenting promising utilization prospects in energy devices.

8:30 AM EN09.12.03
Chemical Vapor Deposition of Ru/$RuSe_2$ Catalyst for Electrolytic Hydrogen Evolution Reaction Daba D. Megersa[1], Gutema T. Gudena[1], Youngho Kim[2] and Hak K. Yu[1,3]; [1]Ajou Universiry, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Ajou University, Korea (the Republic of)

The current trend of synthesis in preparing catalysts for hydrogen evolution reaction (HER) is heavily dependent on solution processing which takes a great deal of time and is mostly not suitable to prepare supported structures. Solution processing has advantages to prepare controlled stoichiometry nano particles, while the prepared nano particles end up in another step of dispersing them into a solvent and coating onto desired substrate, which results in long process and sometimes poor adhesion of catalysts to the substrates. We believe chemical vapor deposition is less utilized in synthesis of supported catalysts for HER. In this regard the essence of this work was to provide a simple alternative synthesis route for catalysts used in HER. Therefore, this work demonstrates a one-step synthesis of highly stable Ru/$RuSe_2$ nanoparticles (NPs) on carbon paper using low temperature and pressure chemical vapor deposition (CVD), resulting in a heterointerface with multiple active sites for catalysis. The catalyst exhibited outstanding performance for the hydrogen evolution reaction (HER) in an alkaline solution, with low overpotentials and fast hydrogen adsorption and desorption kinetics. The Ru/$RuSe_2$/C nanoparticle structure has potential for large-scale production and can be used as an efficient catalyst for HER.

Transition Metal- Metal Carbide decorated N-Doped Carbon Framework as Efficient Dual Mott-Schottky Electrocatalysts for Water Splitting
Gokul Raj, Debanjan Das, Bidushi sarkar, Shauvik Biswas and Karuna K. Nanda; Indian Institute of Science, India

Transition metal carbides (TMCs) have garnered significant attention as effective electrocatalysts for the hydrogen evolution reaction (HER), offering a highly active and stable alternative to precious metals like platinum, because of their d-band electronic structure resembling that of platinum. In this study, we address the challenge of developing a top-tier bifunctional electrocatalyst for efficient water splitting by employing a dual transition metal approach to electronically modify bimetallic carbides. Here, we have designed a composite structure through an in-situ fabrication process, featuring N-doped carbon nanotubes (CNT) and graphene, which serve as anchors for Co/MoC, Co/WC, and Co/VC. This integrated pyrolysis technique promotes synergistic interactions among these components and creates dual Mott-Schottky junctions, resulting in a bifunctional catalyst capable of catalyzing both the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER) with exceptional activity in both acidic and basic environments. Furthermore, it demonstrates excellent performance in water splitting under basic conditions, requiring a relatively low cell voltage of approximately 1.686 V to generate a current of 10 mA/cm2 while maintaining good stability. This superior performance is attributed to the cooperative electron transfer between the Co and MoC moieties and the defects induced by nitrogen doping in the graphene/CNT-based conductive network, distinguishing it from other recently reported Mo-based carbide materials.

Dual-Function Electrochromic Smart Window based on PEDOT:PSS /Graphene and Cesium Tungsten Oxide for Transmittance Modulation and Near Infrared Shielding Lung-Hao Hu and Kai-Sheng Hsiao; National Sun Yat-Sen University, Taiwan

In this study, transparent conductive layers, which were made with the combination of few-layer graphene ink and poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT: PSS) by spin-coating method were utilized on an electrochromic device (ECD). Moreover, a dopant with excellent solar radiation shielding ability, cesium tungsten oxides, was added into the conductive layers, developing a cost-efficient electrochromic smart window with improved near inferred shielding feature. The present device was assembled with five primary layers, including two transparent conductive layers, two complementary electrochromic layers (Prussian blue as the cathode and PEDOT: PSS as the anode) and PC/$LiClO_4$ liquid electrolyte in the middle. The sheet resistance, electrochemical properties, optical performance, structure morphology and heat insulation ability of the devices were characterized by four-probe measurement with LCR meter, cyclic voltammetry (CV), vis-NIR spectrometer, field emission scanning electron microscopy (FE-SEM) and self-made heat insulative chamber test, respectively. The results shows that the sheet resistance of the PEDOT: PSS/graphene/$CsWO_3$ film with the thickness of 500nm to 600nm, is 0.77Ω/sq. And the films' visible light transmittance is 80.2% at 550nm wavelength. The transmittance of colored and bleached states at 700nm wavelength was 19.7% and 52.9%, respectively, having the maximum optical contrast about 33.2%. The coloration efficiency (CE) of the device was 435.04 cm^2C^{-1}. And the response time of the device switching between colored and bleached state is 1.7s and 0.7s, respectively. With the cesium tungsten oxides nanoparticles coated inside the transparent conductive layer, the transmittance of the NIR can be blocked by the ECD about 77.4% utmost, effectively isolating outdoor thermal radiation. In the insulating test with 100W Halogen lamp irradiating 10 cm from the heat insulative chamber for 1 hour, the simple coating layer of PEDOT: PSS/ graphene/ $CsWO_3$ film on glass substrate can achieve a lower indoor temperature difference, 4 °C compared to the normal glass window, performing good heat shielding ability with single film. In addition, the comparison of the ECD with/without$CsWO_3$ doping presents that the $CsWO_3$ doped ECD can significantly expand the indoor/outdoor temperature difference between colored and bleached states from 4.5 to 24.7°C. The outcomes indicate that the $CsWO_3$ doped ECD can improve the two-way heat insulative ability of the device, absorbing the heat coming from the outside and providing the heat leaking out from the inside.

High Catalyst Performance of 2D π–d Conjugated TM3B3N3S6 for Hydrogen Evolution Reaction Yongxiu Sun, Mengxuan Sun, Xiaohe Ren, Ziwei Gan and Zhijie Li; University of Electronic Science and Technology of China, China

Single-atom catalysts (SACs) for the hydrogen evolution reaction (HER) is an efficient electrochemical pathway to produce the green production. However, the development of HER process is hampered by the lack of high-performance electrocatalysts. In this work, we proposed a new π-d conjugated structure of the $Ti_3B_3N_3S_6$ monolayer as the single-atom catalysts for the HER process by using the density functional theory (DFT) calculations. The calculated results show that the Ti atom is active site of the $Ti_3B_3N_3S_6$ monolayer with the high catalytic activity (ΔG_H = –0.14 eV) for HER. The electronic properties of the $Ti_3B_3N_3S_6$ monolayer were explored by the electron localization function (ELF), Bader charge analysis and the polarized density of states (PDOS) density analysis. The $Ti_3B_3N_3S_6$ monolayer can promote the electronic transfer during the HER process, which indicates taht the $Ti_3B_3N_3S_6$ monolayer can is considered to investigate the catalytic activity for HER. The Gibbs free energy of H atoms adsorption on the $Ti_3B_3N_3S_6$ monolayer is –0.14 eV. Furthermore, the origin of high catalytic activity for the $Ti_3B_3N_3S_6$ monolayer was explored by the analysis the PDOS of the H adsorption on the $Ti_3B_3N_3S_6$ monolayer. Therefore, our work propose a new and high catalytic single-atom catalyst for the HER.

9:10 AM EN09.12.07
Development of Cs_xWO_3 Nanoparticles for Electrochemical Reduction of CO_2 to Formate Ramsha Saleem and Rana Rashad Mahmood Khan; Government College University Lahore, Pakistan

CO_2 is a greenhouse gas that mainly contributes to major environmental issues. Several strategies have been developed to alleviate the effects of the increased CO_2. Among all, converting CO_2 to valuable products is a bird-two-stone approach as it reduces the atmospheric concentration of CO2 and gives us the fuels to replace renewable energy sources. To commercialize these processes, highly efficient catalysts are required. In recent years, bimetallic nanoparticles have gained significant attention as the second metal influences the electronic properties of the first metal and, thus catalytic efficiency. We synthesized Cs_xWO_3 nanoparticles as a novel catalyst for electrochemical reduction of CO_2 to formate by hydrothermal method and WO_3 nanoparticles to compare the results. We characterized them by UV-visible, FTIR, SEM-EDX, and XRD. The bandgap of WO_3 was decreased from 2.67 eV to 1.87 eV when Cs was incorporated over them. SEM images revealed that Cs_xWO_3 nanoparticles were rougher and more porous than WO_3 nanoparticles. The WO_3 and Cs_xWO_3 nanoparticles were employed as working electrodes in H-type cells, and CV, LSV, and CA evaluated their electrochemical performance. LSV was used to calculate the onset potential, and the onset potential for Cs_xWO_3 was found to be -0.7 V *vs* Ag/AgCl. The electrochemical results showed that the maximum Faradaic efficiency and partial current density of formate over WO_3 nanoparticles were 50 % and -13.5 mA/cm^2, respectively. The FE and partial current density were increased to 76 % and -19 mA/cm^2, respectively, when Cs_xWO_3 was employed as a working electrode. Moreover, Cs_xWO_3 nanoparticles were stable at -1.33 V *vs* Ag/AgCl for 3 h. The high FE, low overpotential, and stable electrocatalysis proved that incorporating Cs over WO3 nanoparticles improved its efficiency, and Cs_xWO_3 nanoparticles can be used on a large scale in the future with little modifications.

9:25 AM EN09.12.08
Synthesis of Porous Bimetallic Nanocatalyst for Selective Formate Production by CO_2 Electroreduction Rana Rashad Mahmood Khan; Government College University Lahore, Pakistan

The emission of CO_2 into the air is causing a severe environmental problem because of the continuously increasing demand for fossil fuels. To fulfill these demands sustainably, the conversion of CO_2 into fuels has attracted profound research. The possible CO_2 conversion products are CO, hydrocarbons, and alcohols that are used as a chemical feedstock. Particularly, the electrocatalytic formation of formate is of great interest and have a potential for the development of an economically feasible process.
We prepared the Ag_2SnO_3 nanoparticles by a simple and cost-effective chemical reduction method. We conducted the electrochemical conversion of CO_2 to formate in aqueous electrolyte media at pH 6.8. The two-compartment cell (H type cell) was used for electrochemical measurements. The absorption maxima, the energy bandgap, surface morphology, catalytic composition, crystallinity, crystallite size, crystal facet, and electrochemical activity of the electrocatalyst were probed. The linear sweep voltammetry was used to record the polarization curve/current response. The catalyst shows porous/sponge-like morphology. The electrochemical results show higher current density (~26 mA/cm^2), long term stability, product selectivity, and higher faradaic efficiency (FE) on the bimetallic electrocatalyst electrode. The highest FE for the only liquid product (formate) was 89% at –1.3 V vs. Ag/AgCl with a Tafel slope of 174 mV/decade. The faradaic efficiency was found high as compared to the monometallic (Ag, Sn) nanoparticles. The high FE and product selectivity indicates the synergistic effect between these metals.

9:40 AM EN09.12.09
Stabilization of PtRu Alloy Nanocatalysts by Encapsulation with Niobium Oxide Annabelle M. Hadley[1], Frode Seland[2] and Byron D. Gates[1]; [1]Simon Fraser University, Canada; [2]NTNU, Norway

The threat of climate change motivates us to reduce our reliance on fossil fuels and transition to renewable energy infrastructure. Direct methanol fuel cells (DMFCs), in which electrocatalysts harness electricity from the reaction of methanol and oxygen, are an attractive clean energy technology because of the high energy density and ease of transport and storage of methanol compared to hydrogen. However, there remains much to improve upon in terms of the durability, and as a consequence the economic viability, of DMFCs. This project focuses on the durability of the anodic electrocatalysts which facilitate the methanol oxidation reaction. A platinum-ruthenium alloy is the most commonly used electrocatalyst towards the methanol oxidation reaction due to its high performance. The high activity and selectivity of the platinum is additionally imparted high tolerance for poisoning byproducts of methanol oxidation [carbon monoxide (CO)] by alloying with ruthenium. Unfortunately, the ruthenium is known to dissolve from the alloy and reduce the CO tolerance of the catalysts.
This project explored encapsulating the PtRu nanoparticle catalysts with porous niobium oxide to stabilize the PtRu alloy. Niobium oxide was chosen due to its high corrosion resistance and previous studies showing its stabilization of ruthenium. PtRu alloyed nanoparticles were synthesized *via* electrodeposition on a glassy carbon electrode substrate and subsequently encapsulated by an electrophoretic deposition method adapted from Penner *et al*.[1] The morphology and composition of the catalyst and encapsulating layer were characterized by scanning and transmission electron microscopy, energy dispersive X-ray spectroscopy, X-ray photoelectron spectroscopy, Raman spectroscopy, and optical microscopy. The activity and durability of pristine and encapsulated PtRu catalysts were evaluated by cyclic voltammetry, chronoamperometry, and electrochemical impedance spectroscopy. Carbon monoxide stripping and the double layer capacitance method was used to study changes in the electrochemically active surface area before and after deposition of the niobium oxide. Access to the electrocatalyst surfaces through the encapsulating layer was maximized by the addition of surfactants and the application of different potentials during the deposition of the niobium oxide to improve its porosity. The niobium oxide was shown to improve the stability of the PtRu alloy and maintain the CO tolerance of the alloy well beyond that of the un-encapsulated catalyst. The stabilization of PtRu imparted by the encapsulation of niobium oxide herein is promising for the stabilization of alloyed nanoparticle catalysts towards a wide range of electrocatalytic applications.

Novel Multifunctional Additives for Enhancing The Efficiency and Stability of Perovskite Solar Cells and Their Tandem Solar Cells with Organics Alex Jen; City University of Hong Kong, Hong Kong

Minimizing energy loss and increasing the quality of crystalline perovskite films are keys to improve the performance and long-term stability of perovskite solar cells. To address these challenges, we have developed several multifunctional, nonvolatile additives that can be used to modulate the kinetics of perovskite film growth to enable large-sized grains and coherent growth of perovskites from bottom to surface to be achieved. The improved film morphology resulted in significantly reduced non-radiative recombination, helping enhance the power conversion efficiency (PCE) of inverted (p-i-n) device to ~26% with low energy loss and good stability. In addition, these multifunctional additives can also be applied to address one of the most challenging problems involved in large bandgap perovskites and their derived devices for single junction and tandem solar cells. The commonly observed halide segregation critically limits the stability of mixed-halide perovskites under device operational conditions. There is a strong indication that halide movement/oxidation is the primary driving force behind halide de-mixing. To alleviate this problem, we have developed a series of multifunctional mediators that can suppress these factors while simultaneously passivate defects through tailored substitution. These effects enable wide-bandgap (1.81 eV) perovskite solar cells to achieve an outstanding PCE >20%, with 95% of its initial PCE retained after tracking at maximum power point for 500 h. Integrating this layer into a monolithic perovskite-organic tandem solar cell as a wide-bandgap subcell afforded a record-high PCE of 26.1% and impressive long-term operational stability.

1:45 PM EN10.01.01
Stress Relaxation in Metal Halide Perovskites and use of Controlling Film Stress to Improve Stability Nicholas Rolston[1], Muneeza Ahmad[1], Carsen Cartledge[1], Gabriel McAndrews[2], Antonella Giuri[3], Aurora Rizzo[3] and Michael D. McGehee[2]; [1]Arizona State University, United States; [2]University of Colorado Boulder, United States; [3]CNR Nanotec, Italy

Challenges to upscaling metal halide perovskites (MHPs) include mechanical film stresses which accelerate degradation, dominate at the module scale, and can lead to delamination or fracture. In this work, we demonstrate open-air blade coating of single-step coated perovskite as a scalable method to control residual film stress after processing and introduce beneficial compression in the thin film with the use of polymer additives such as gellan gum and corn starch.

Given the strong link between residual stress and degradation, we assessed the stability of perovskite films with different residual stress states. Perovskite films on silicon and glass were stress engineered using additives to either be tensile or compressive and aged under either high heat or humidity conditions (85°C vacuum or 85% relative humidity). A control $MAPbI_3$ film spin coated without additives was also added as a reference under 85% relative humidity. The samples were periodically removed, and the stress was remeasured in ambient conditions (22°C and 40% RH). The highly tensile samples experienced stress relaxation quickly in the humid environment due to moisture induced degradation. This effect was not observed for samples with compressive stress, which also did not experience visible degradation during the 100-hour exposure. We performed XRD measurements on these films to verify degradation and the tensile sample had PbI_2 peaks after the aging experiment, whereas the compressive sample had lower intensity PbI_2 peaks and still had $MAPbI_3$ in the film. This confirms that perovskites are more structurally stable when exposed to environmental conditions while in compression. Samples were reannealed to ensure that trapped moisture was not the cause of the relaxation, and there was no change observed in the stress. Therefore, residual moisture is not the explanation for stress reduction.
.
A similar experiment was conducted for thermal stability at 85°C under vacuum to monitor the changes in stress under thermal aging. Once again, stress relaxation was observed for the highly tensile sample with gum. The improvement in stability was visually apparent since the tensile films turned completely yellow after being aged for 100 hours while the compressive one remained largely in the black photoactive phase. The samples with additives took longer to visibly degrade, which also points towards their improved stability. The tensile stress was therefore relaxing as the film degraded due to the strained bonds likely enabled the methylammonium cation to diffuse out, whereas a compressive stress showed better stability and unchanging stress under heat, similar to the effect observed with aging in high humidity.
A thermal cycling experiment was also conducted for a tensile and compressive sample to monitor the perovskite films as the temperature changes between -40 to 85°C. The experiment ran for 200 cycles and the results supported what was observed under high heat and humidity conditions. The tensile sample relaxed by 180 MPa and turned completely yellow. However, the compressive sample was stable both in terms of its appearance and film stress. A spin coated $MAPbI_3$ film without additives (with tensile residual stress) was kept as the control sample. In all three aging conditions, films with residual tensile stress degraded significantly faster. The degradation also corresponded to stress relaxation in the perovskite film as the phase changed, marking the first time for which changes in stress have been directly mapped to stability. Stress relaxation has been observed in many other material systems (*i.e.*, polymers and metals) when exposed to tensile stress. Perovskites therefore act similarly, and despite their brittle nature, share in this property.

This discovery of a new mechanism underpinning MHP degradation shows that film stress can be used as a parameter to screen MHP devices and modules for quality control before deployment as a design for reliability criterion.

2:00 PM EN10.01.02
Interpreting Halide Perovskite Semiconductor Photoluminescence Kinetics Margherita Taddei[1], Sarthak Jariwala[2], Robert J. Westbrook[1], Shaun M. Gallagher[1], Aaron Weaver[1], Henry J. Snaith[3] and David S. Ginger[1]; [1]University of Washington, Italy; [2]Twelve, United States; [3]University of Oxford, United Kingdom

Drawing from both experimental data and simulation, we highlight best practices for fitting time-resolved photoluminescence (TRPL) decays on halide perovskite semiconductors now widely studied for applications in photovoltaics and light-emitting-diodes (LEDs). We focus on three key observations. First, at low excitation intensities, high-quality perovskites often show pseudo-first-order kinetics, consistent with classic minority carrier lifetimes. Second, non-single-exponential decays frequently observed at low excitation intensity often have significant contributions from spatial heterogeneity. We recommend fitting such decays by stretched exponentials, where the stretching factor (β) can be used to characterize the heterogeneity of the local lifetime distribution. Third, PL decay kinetics can depend on the excitation wavelength. We discuss how penetration depth, carrier diffusion, and surface recombination affect measurements, and make recommendations for choosing experimental parameters suited to the question at hand. Accounting for these factors will provide more reliable and physical interpretation of carrier recombination and better understanding of non-radiative losses in perovskite semiconductors.

2:15 PM EN10.01.03
Advancing Photovoltaic Performance and Stability of Perovskite Solar Cells Using a Solid-State Multi-Modal Electrochemical Approach Juan F. Tirado, Mriganka Singh, Michel De Keersmaecker and Erin L. Ratcliff; University of Arizona, United States

Analysis and characterization of buried interfaces in metal halide perovskite (MHP) devices has always been a major challenge in advancing device performance and stability, particularly under conditions of operation including light bias and charge transport. Recently, our group has developed a solid-state electrolyte “peel and stick” spectro-electrochemistry methodology in order to directly study the energy levels and charge extraction capabilities of the buried interface between ITO/MHP under *operando* conditions. Moreover, this tool allows including redox probes in the solid electrolyte in order to measure near-gap and mid-gap defect densities of MHP with quantification limits around ~10^{14} cm^{-3}, which is below the space-charge limited current methodology or conventional spectroscopic techniques.

Our approach overcomes a major challenge to industrial adaptation and manufacturing at scale of printable electronics. Generally, interface modifications at charge-selective-layer/MHP bottom contacts are speculated to improve performance through correlations with indirect measurements and a demonstration of a change in power conversion efficiency. For instance, photoelectron spectroscopies can only determine the chemical environment and energetics at the MHP surface, which is widely recognized to be dependent on buried interface chemistries that cannot be probed with subsequent layer deposition. Similarly, time-resolved photoluminescence spectroscopy is restricted to measuring the net total change in carrier lifetime but lacks exact information on charge extraction/injection at the buried interface with the MHP.

In this context, herein we extend the use of our “peel and stick” electrochemistry platform to assess the effect of partial device stacks comprised to transparent conductive oxide/hole-transporting-layer (HTL)/MHP interfaces, systematically modified using ionic liquids and phosphonic acids. Our approach is exquisitely sensitive to small changes in energetics, monitored through injection barriers, and charge extraction capabilities of HTL/MHP interface in a p-i-n Perovskite Solar Cells (PSCs) configuration. Remarkably, we demonstrate the correlation between interface charge extraction “quality” and photovoltaic response of p-i-n PSCs so that our solid-state electrochemical platform may advance the device performance by probing the buried interface.

Similarly, we take advantage of this powerful tool to explore MHP stability under thermal and illumination stress conditions and to measure the effect of HTL nature by quantifying the near-gap defect densities. Ultimately, by combining this approach with complementary spectroscopies, we are able to provide new insights into the degradation processes occurring in the MHP and corresponding devices. Thus, we highlight the potential of our solid-state electrochemistry methodology to become a very useful tool for advancing the behavior and stability of MHP and PSCs, which is necessary in order to find proper materials and interface treatments to increase PSCs stability to commercial level requirements.

2:30 PM EN10.01.04
***Operando* Trapped Carrier Dynamics in Perovskite Solar Cells Observed via Infrared Optical Activation Spectroscopy** Ziming Chen; Imperial College London, United Kingdom

Metal halide perovskites show promise for cost-effective and high-efficiency photovoltaics. Recent progress in perovskite solar cells (PeSCs) has achieved a certified power conversion efficiency (PCE) of approximately 26.0%. To push PeSCs closer to the Shockley-Queisser limit and enhance their performance, reducing non-radiative recombination caused by carrier 'traps' is crucial under standard sunlight conditions. Understanding these trap states and trapped carrier dynamics is vital to minimise performance losses.
To overcome the limitations of conventional spectroscopic techniques like time-resolved photoluminescence and transient absorption, which lack the necessary selectivity for detecting trapped carriers, we used a novel method called infrared optical activation spectroscopy, specifically optical pump-IR push-photocurrent (PPPc), to monitor trapped carriers in real-time during PeSC operation. PPPc involves generating band-edge carriers with a visible 'pump' beam, followed by carrier trapping. Subsequently, trapped carriers absorb IR 'push' beam photons, returning them to the band states. IR-detrapped carriers contribute to additional device photocurrent, allowing us to assess trapped carrier concentration and dynamics based on the amplitude and behaviour of IR-induced photocurrent.
Here, we employed PPPc (both its time-resolved and quasi-steady-state versions) to investigate how the surface passivation process and strain of perovskite make an impact on the trapped carrier dynamics, respectively:
1) To study surface passivation effects, we fabricated $FA_{0.99}Cs_{0.01}PbI_3$ PeSCs with and without surface passivation. Our device structure was ITO/SnO_2/$FA_{0.99}Cs_{0.01}PbI_3$/(OAI)/Spiro-OMeTAD/Au, where n-octylammonium iodide (OAI) served as a passivator for both cation and halide vacancies at the $FA_{0.99}Cs_{0.01}PbI_3$ surface.
We found that bulk traps filled rapidly (within 10 ns) due to nearby photocarrier trapping, while surface trap filling was slower (tens to hundreds of ns) and involved band-edge carrier drift/diffusion to the perovskite surface. The filling of surface trap states created an interfacial charge layer that screened the internal field and slowed carrier drift/diffusion. This process was also influenced by device temperature. The surface-passivated device exhibited faster saturation of trapped carrier concentration compared to the pristine device with higher trap density. Our kinetic model estimated a ~50 times reduction in trap states after surface passivation. Notably, the activation energy of trap state bands (~280 meV) remained nearly identical in both devices, indicating that surface passivation reduced trap numbers without changing trap types.
2) To investigate the impact of strain, we fabricated two perovskite films with varying strain levels: $MA_{0.95}GA_{0.05}PbI_3$ with tensile strain and $MA_{0.95}GA_{0.05}Pb(I_{0.95}Br_{0.05})_3$ with free strain due to Br (with smaller size) compensation in the lattice.
We found that non-radiative recombination loss was suppressed in the strain-free perovskite, which resulted in better emission properties and higher device performance. Considering trap-assisted recombination is the main process accounting for the non-radiative recombination loss, again, the combination of both quasi-steady-state and time-resolved PPPc measurements revealed that strain relaxation reduced trap density, shallowed trap depth, as well as prolonged trapped carrier lifetimes. Hence, this mitigated trap-assisted recombination losses in the strain-free device. This study represents the first explicit correlation between strain engineering and its effects on overall trap-assisted recombination processes.

2:45 PM EN10.01.05
Origin of Open-Circuit Voltage Losses from Energy-Level Misalignment between Metal Halide Perovskites and Hole Transport Layers Jae Eun Lee[1], Silvia G. Motti[1,2], Robert D. Oliver[1,3], Siyu Yan[1], Henry J. Snaith[1], Michael B. Johnston[1] and Laura Herz[1,4]; [1]University of Oxford, United Kingdom; [2]University of Southampton, United Kingdom; [3]The University of Sheffield, United Kingdom; [4]Technical University of Munich, Germany

Metal halide perovskites (MHPs) show great potential in multijunction photovoltaics applications due to their tunable bandgaps through compositional mixing on the halide site. However, wide-bandgap MHPs (>1.7 eV) typically suffer from greater open-circuit voltage (V_{OC}) losses compared to their narrow-bandgap counterparts (~1.6 eV) owing to energy-level misalignment with charge extraction layers. Herein, we investigate the origin of such losses, focusing on the energy level misalignment between the valence band maximum and the highest occupied molecular orbital (HOMO) for a commonly employed combination of perovskite with various halide compositions and hole transport layers.[1] Our research combines time-resolved photoluminescence spectroscopy and numerical modelling to reveal the origin of V_{OC} losses, which stem from the accumulation of holes in the HOMO of hole trasport layers, followed by subsequent non-radiative across-interfacial recombination via interfacial defects. By simulating an ideal choice of hole transport material to pair with a mixed-halide MHP whose 1.8-eV bandgap is optimized for tandem solar cells, we demonstrate a potential reduction in V_{OC} losses originating from energy level misalignment. Our findings underscore the pressing need for tailored charge-extraction materials with improved

energy level alignment to enhance the efficiency of solar cells based on wide-bandgap mixed halide MHPs.

Advancing Perovskite Solar Cell Development and Stability Using In-Line Electrochemical Methodologies Erin L. Ratcliff; University of Arizona, United States

This talk will discuss established (spectro)electrochemistry-based measurement science approaches to quantify the distribution and energetics of donor and acceptor defects in prototypical perovskite solar cell materials and partial device stacks.

We utilize a solid-state electrolyte top contact that equilibrates with the perovskite film to create “half-cells” of device-relevant material stacks and study them under solar cell-relevant electric fields. This allows us to spectroscopically assess onsets in valence and conduction bands under *operando* conditions, as well as quantify near-band edge defects using redox-active hole or electron capturing molecular probes. The combination of spectroscopy and electrochemistry characterizes the energetic distribution of donor defect states at an energy resolution of <10 meV in “stoichiometric” triple cation, mixed halide perovskite thin films (Cs0.05FA0.79 MA0.16)Pb(I0.87Br0.13)3) or CsFAMA. under device-relevant electric fields (i.e. electrochemical biasing). Limits of detection are at the 10^{14} defects/cm^3. Such detection limits are better than spectroscopic, electronic and photoemission protocols, with speciation (anion versus cation defects) not available in those other approaches.

The technique is exquisitely sensitive, allowing for detection of clear differences in buried perovskite/metal oxide interfaces to better understand photovoltaic performance. Ongoing efforts to characterize defects and distributions include both nickel oxide nanoparticles and sputtered nickel oxide hole-transport contacts, modified with molecular species. Advancements towards development of in-line characterization (i.e., roll-to-roll) and connections to stability will also be described and benchmarked with respect to photoluminescence and photoelectron spectroscopies.

4:00 PM EN10.02.02
Multifunctional Polymeric-Nanofiber Reinforcement of Perovskite Solar Cells for Improved Mechanical Stability without Performance Trade-Off Adam Printz, Anton Samoylov, Kenneth Lang, Patrick Lohr, Matthew Dailey, Yanan Li and Euan McLeod; University of Arizona, United States

Metal halide perovskites have been demonstrated to be extremely fragile materials that can fracture at low applied stresses. Previous efforts to mechanically reinforce perovskite films have focused on the extrinsic mechanical shielding such as polymer scaffolding, but these implementations demonstrated to date either have performance trade-offs or require complex manufacturing steps. I will discuss a perovskite-polymeric nanofiber composite that increases the mechanical toughness without an efficiency tradeoff. The fracture energy, G_c, of this nanocomposite is 500% higher (2.34 ± 1.67 J m^{-2}) than in pristine perovskite (0.40 ± 0.16 J m^{-2}). The nanocomposites were observed via scanning electron microscopy (SEM) and atomic force microscopy (AFM) to be homogeneous in the vertical direction, and x-ray diffraction (XRD) showed that the films were of similar quality to pristine perovskite (no lead iodide growth), but with a decrease in orientation. Furthermore, we show that there is no trade-off in device efficiency despite the integration of the insulating nanofibers, which we show is likely due to beneficial light scattering that increases current generation.

4:15 PM EN10.02.03
Increasing Halide Perovskite Scalability and Stability with Food Additives Carsen Cartledge, Muneeza Ahmad and Nicholas Rolston; Arizona State University, United States

In this work, we report on a polymeric additive endemic to the food industry, gellan gum, as a means of enabling scalable, open-air manufacturing of halide perovskites with improved stability characteristics under high heat and humidity conditions.
As the global demand for scalability escalates, traditional perovskite inks designed for small scale fabrication in inert environments like spin coating have been found to produce pinholed, incomplete, and shunted films when utilized in more scalable open-air processes like blade coating. Interestingly, gellan gum enables viable films through the critical transition of well-studied spin coating inks into solutions that are compatible with blade coating. By working as a non-toxic and efficient rheological modifier in combination with a pure dimethyl sulfoxide solvent system, gellan gum enables longer periods for crystallization which eliminates the formation of a patchy network of needle-shaped crystals attributed to the PbI_2 phase of perovskites in favor of larger spherulitic grains which results in smoother, more uniform films in a one-step coating method. In fact, the use of this additive reduces surface roughness of ambient blade coated films from 138nm using an unmodified ink to 35nm when gellan gum is incorporated.
Similarly, hyperspectral photoluminescence data reveals that gellan gum decreases the defect density between grains. In films with low gum concentration the intensity of the photon flux decreases when moving from the grain centers to the boundaries which could be explained by thinner coverage in those areas; however, the opposite trend is true for samples with higher gum concentration. This indicates the additive decreases the defect density through passivation and induces a corresponding reduction in non-radiative recombination centers. This reduction in defects, and therefore improvement in stability, is supported by XRD data demonstrating increased crystallinity through ordered texturing.
Additionally, open-air blade coated gellan gum samples feature an intrinsic compressive stress above 1wt% additive which contrasts with traditional tensile stress found in spin coated films. Not only does compressive stress indicate increased resistance to delamination and fracture under thermal and environmental conditions, but it is also associated with an increase in the activation energy for ion migration. For example, when aged under 85% relative humidity for 100 hours, a compressive film processed with gellan gum features very little change in compressive stress, from 50MPa to 75MPa, while a tensile sample can experience dramatic tensile relaxation from 450MPa to 200MPa. Under thermal aging at 85 degrees Celsius for 100 hours, a similar stress trend is observed, and the compressive film visually retains the black photoreactive phase while tensile samples turn completely yellow, indicative of degradation to PbI_2.
XRD data confirms that aged tensile control samples feature an increase of PbI_2 and a weakening of the perovskite peaks while aged compressive gum samples generate spectrums with markedly less prominent PbI_2 peaks and relatively unchanged perovskite peaks. Furthermore, when compared to a similar

polysaccharide biopolymer like cornstarch, gellan gum enables a reduction in additive concentration from 5wt% with an associated compressive stress of 35 MPa, to only 1wt% inducing compressive stresses of 75 MPa.
Overall, open-air blade coating of single-step gellan gum-halide perovskites reduces defect densities at grain boundaries and improves stability and manufacturability with compressive stresses that may limit ion migration leading to increased resiliency to heat, humidity, and illumination. In designing for reliability, this work mitigates some of the fundamental degradation mechanisms preventing halide perovskites from reaching service lifetimes comparable to incumbent PV technologies.

4:30 PM EN10.02.04
Ionic Self-Diffusion Approaches: Enhancing Stability and Efficiency in Perovskite Solar Cells through Ion Migration Suppression and Fermi Level Tuning Jihyun Kim[1], Ji-Sang Park[2], Gee Yeong Kim[3] and William Jo[1,1]; [1]Ewha Womans University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of)

Lead halide perovskites have garnered attention as potential energy-harvesting materials for optoelectronic devices due to their remarkable photovoltaic properties. Among these, the FA cation demonstrates the most promising performance and attributes to the formamidinium lead triiodide ($FAPbI_3$) perovskite, which has a narrow bandgap (E_g) and great thermal stability. Despite $FAPbI_3$ perovskite displaying great stability as an absorber layer for perovskite solar cells, issues of device instability persist due to absorbed Pb^{2+} or Iat the oxide surface which induced the ion migration of iodine vacancies. This phenomenon generates the hysteresis loop and accelerates degradation rate in photovoltaic performance. In this study, we customized the charge-selective interfaces, revealing the induced adjustment of the Fermi level at the $FAPI_3/SnO_2$ junction by ionic diffusion into the bulk. This adjustment enhances charge transport and mitigates ion migration. These findings were confirmed using computational simulations and ultraviolet photoelectron spectroscopy. To understand ion migration mechanism at the $FAPbI_3/SnO_2$ interface, we analyze the normalized ionic and electronic conductance as functions of film thickness through D.C polarization measurements. The space charge zone of cation and anion-treated SnO_2 (NH_4^+-SnO_2 and Cl^--SnO_2) [1], [2] was found to exhibit reduced zones under induced light. Based on our findings, it is evident that interfaces modified with cationic and anionic treatments lead to a decrease in Pb^{2+} and I absorption at the oxide surface. Additionally, these modifications enhance charge transport while significantly minimizing the occurrence of interfacial defects. As a result of this approach, the power conversion efficiency (PCE) increased to 24.38%, and the operational stability of perovskite solar cells (PSCs) was extended to 1600 hours.

A Bifunctional Organic Salt as *p*-Type Dopants of Spiro-OMeTAD for Perovskite Solar Cells with Enhanced Stability Sung-Kwang Jung and Jin-Wook Lee; Sungkyunkwan University, Korea (the Republic of)

2,2′,7,7′-tetrakis(N,N-di-p-methoxyphenyl-amine)9,9′-spirobifluorene (spiro-OMeTAD) has been a commonly employed in hole transport layer (HTL) for normal-structured perovskite solar cells (PSCs). Lithium bis(trifluoromethane)sulfonimide (Li-TFSI) is introduced into the spiro-OMeTAD as a *p*-type dopant to improve conductivity and band alignment to facilitate hole extraction. However, the lithium salt causes undesired side effects such as enhanced hygroscopicity, migration and accumulation of Li cations, and formation of by-products, which can lead to degradation of PSC performance and stability. Herein, we propose an alternative organic salt dopant, tetramethylammonium bis(trifluoro-methane)sulfonimide (TMA-TFSI). The TMA-TFSI reacts with the top surface of formamidinium lead iodide perovskite, forming a tetramethylammonium lead iodide film acting as a surface passivation layer of underlying perovskite thin film, contributing to an enhancement of open-circuit voltage of the devices. Furthermore, TMA-TFSI enhances resistance of the HTL against harsh environmental conditions, such as humidity and high temperature, owing to suppressed ion migration and hydrophobic nature. Resultingly, the TMA-TFSI-based devices demonstrate superior stability under high temperature (~85 degrees Celsius) and maximum-power-point tracking compared to those based on Li-TFSI.

Reduced Recombination via Tunable Surface Fields in Perovskite Solar Cells Dane W. DeQuilettes[1,2], Jason J. Yoo[1], Roberto Brenes[1], Felix U. Kosasih[3], Madeleine Laitz[1], Benjia Dou[1], Daniel Graham[4], Kevin Ho[4], Yangwei Shi[4], Seong Sik Shin[5,6], Caterina Ducati[3], Moungi G. Bawendi[1] and Vladimir Bulovic[1]; [1]Massachusetts Institute of Technology, United Kingdom; [2]Optigon Inc., United States; [3]University of Cambridge, United Kingdom; [4]University of Washington, United States; [5]Korea Institute of Science and Technology, Korea (the Republic of); [6]Sungkyunkwan University, Korea (the Republic of)

The ability to reduce energy loss at semiconductor surfaces through passivation or surface field engineering has become an essential step in the manufacturing of efficient photovoltaic (PV) and optoelectronic devices.[1] Similarly, surface modification of emerging halide perovskites with quasi-2D heterostructures is now ubiquitous to achieve PV power conversion efficiencies (PCEs) > 22% and has enabled single-junction PV devices to reach >26%, yet a fundamental understanding to how these treatments function is still generally lacking. This has established a bottleneck for maximizing beneficial improvements as no concrete selection and design rules currently exist. Here we uncover a new type of tunable passivation strategy and mechanism found in perovskite PV devices that were the first to reach the > 25% PCE milestone, which is enabled by surface treating a bulk perovskite layer with hexylammonium bromide (HABr). We uncover the simultaneous formation of an iodide-rich 2D layer along with a Br halide gradient achieved through partial halide exchange that extends from defective surfaces and grain boundaries into the bulk layer. We demonstrate and directly visualize the tunability of both the 2D layer thickness, halide gradient, and band structure using a unique combination of depth-sensitive nanoscale characterization techniques. We show that the optimization of this interface can extend the charge carrier lifetime to values > 30 μs, which is the longest value reported for a direct bandgap semiconductor (GaAs, InP, CdTe) over the past 50 years. Furthermore, we show that this heterostructure is well suited for a host of optoelectronic devices where we achieve a new benchmark for perovskite/charge transport layer surface recombination velocity with values < 7 cm s^{-1}. Importantly, this work reveals an entirely new strategy and knob for optimizing and tuning recombination and charge transport at semiconductor interfaces and will likely establish new frontiers in achieving the next set of perovskite device performance records.

5:15 PM EN10.02.07
Light Makes Right: Laser Polishing for Surface Modification of Perovskite Solar Cells Mayank Kedia[1,2] and Michael Saliba[1,2]; [1]University of Stuttgart, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Interface engineering is a common strategy for passivating surface defects to attain open circuit voltages (V_{oc}) in perovskite solar cells (PSCs). Although a large volume of reports highlights the potential of chemical passivation, an additional solvent-based processing step increases the challenges of upscaling

and reliability. Moreover, as the library of chemical passivators consistently expands, there is no consensus on the result risking that each perovskite composition needs its tailor-made solution. Hence, a solvent-free, up-scalable, and one-size-fits-all approach is desirable.

In this work, we introduce the concept of polishing a perovskite thin-film surface using a nanosecond (ns) pulsed ultraviolet laser to reduce surface defects, such as dangling bonds, undesirable phases, and suboptimal stoichiometry. Careful control of laser energy and scanning speed improves the photophysical properties of the surface without compromising the thickness. A detailed and complementary analysis of the perovskite top layer and the full device using photoluminescence imaging and Kelvin Probe Force Microscopy reveal the removal of *dark spots* that act as traps for photogenerated carriers, resulting in surface homogeneity and narrowing of the band gap. Using laser polishing, a record V_{oc} of 1.21 V is achieved for planar PSCs with a triple cation composition (E_g ~ 1.61 eV), showing an improved perovskite/hole transport interface by mitigating surface recombination losses. We measure an efficiency boost from 18.0% to 19.3% with an improved stability of up to 1000 h. The polishing effect on the $MAPbI_3$ perovskite is also studied to explore the versatility of this method.

Furthermore, the same laser is employed to fabricate ultra-thin perovskite films up to ~ 50 nm achieving a V_{oc} of 1.15 V, which is one of the highest reported so far for such semi-transparent PSCs. These results open the door to a new class of surface modification without any structural damage using lasers for interface passivation and semi-transparency in well-controllable, automated, scalable, and solvent-free surface treatments.

5:30 PM EN10.02.08
Highly Efficient Perovskite Blue Light-Emitting Diodes Jian Mao[1,2] and Samuel D. Stranks[1]; [1]University of Cambridge, United Kingdom; [2]Fudan University, China

Lead halide perovskite has attracted extensive attention during the past decade for applications in light-emitting diodes because of its wide emission tunability, high color purity, high quantum yield, and easy solution processibility. Despite the exciting progress of perovskite green, red, and near-infrared LEDs, fabrication of perovskite blue LEDs with high external quantum efficiency (EQE), high brightness, and high color purity remains a considerable challenge. Here, we report efficient perovskite blue LEDs with a world-record EQE of surpassing 22%, a peak luminance above 7000 cd/m^2, and a full width at half maximum of 15 nm. Besides, the devices exhibit a stable electroluminescence spectrum at constant elevated current injection. This performance is achieved by carefully manipulating the growth of perovskite into thin films with homogeneous isolated grains, which not only improve the light outcoupling efficiency but also enhance the spectrum stability.

5:45 PM EN10.02.09
Dual Strategies with Defect Suppression and Hole Transporting Bilayer for Inverted Perovskite Solar Cell (PCE ~24%) Hyunjung Shin, Hyoungmin Park, Hyeon Jun Jeong, Yongjae In and Urasawadee Amornkitbamrung; Sungkyunkwan University, Korea (the Republic of)

A growing interest in inverted structure perovskite solar cells (i-PSCs) is underway due to their higher stability and potential applications in tandem structures. Typical organic/polymeric hole-transporting layers (HTLs) often faced limitations in improving stability due to intrinsic hygroscopic nature, acidity, intrinsic instability, and non-uniform coating. On the other hand, self-assembled monolayers (SAMs) have demonstrated better stability and higher device performance. Nevertheless, challenges persist, such as non-uniform coating and the hydrophobicity, when perovskite's layers were fabricated on the top of SAMs. Inorganic hole transport layers like NiO can offer better stability and higher performance compared to organic HTLs, but surface defect-related undesirable reactions have been reported. In this study, an ultra-thin NiO (4nm) using atomic layer deposition (ALD) was applied, forming an ALD-NiO/SAMs bi-layer HTL. The use of ALD-NiO showed superior uniformity compared to traditional sol-gel and nano-particulate films' preparation methods, ensuring uniformly formed bi-layers with SAMs. Together with bi-layer strategy, perovskite composition engineering and defect suppression were also conducted. The molecules with both electron donating cation and pseudo halide anion, pyridinium tetrafluoroborate ($PyBF_4$), were added into perovskite precursor solution to suppress defects in perovskite layers. The suppressed defect was analyzed with thermal admittance spectroscopy. Finally, i-PSCs based on the bi-layer of ALD-NiO/SAMs with defects suppressed perovskite layers demonstrated high power conversion efficiency of 24.0%.

SESSION EN10.03: Stability II
Session Chairs: Marina Leite and Carolin Sutter-Fella
Tuesday Morning, April 23, 2024
Room 334, Level 3, Summit

10:30 AM *EN10.03.01
Facet Engineering for Stable and Efficient Perovskite Solar Cells Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Since the first report on 9.7 percent efficient solid state perovskite solar cell in 2012 by our group, the record power conversion efficiency of 26.1 percent was reported in 2023. In addition, more than 33 percent was demonstrated from a tandem structure with silicone bottom cell in 2023. This underlines that commercialization of perovskite solar cells is just around the corner. However, long-term stability is still challenging. To achieve highly stable perovskite solar cells, several approaches have been proposed and tried. Among them, we report here the facet engineering approach to improve stability of perovskite solar cells. Dependence of photocurrent generation, moisture stability and passivation on perovskite facets will be discussed in detail.

11:00 AM *EN10.03.02
High-Throughput Experiments and a Machine-Learning-Driven Analysis to Characterize the Stability of Halide Perovskites Marina S. Leite; University of California, Davis, United States

Machine learning (ML) is a powerful tool to accelerate the development of halide perovskite materials and devices. Because this burgeoning class of material for photovoltaics entails a colossal chemical composition space, ML is very suitable to replace the conventional trial-and-error approach used in their characterization. Thus, there has been a pressing need within the materials research community to identify ML models that can be implemented to inform the physical and chemical behavior of the perovskites. We apply ML models varying from echo state networks to statistical models to classify and predict physical properties such as hole transport layer electrical conductivity, halide perovskite photoluminescence response, the power conversion efficiency of photovoltaic devices, etc. Specifically, we use *in situ* environmental optical measurements to predict the optical behavior of Cs-FA perovskites for 50+ hours, upon materials' exposure to moisture. Here, we compare linear regression, echo state network, and seasonal auto-regressive integrated moving average with eXogenous regressor algorithms and attain accuracy of >90% for the latter. Our high-throughput measurements and ML-

supported analyses validate the potential of ML to detect and forecast hybrid perovskites' response with a variety of chemical compositions.

11:30 AM EN10.03.03
Improving Stability of Triple-Cation Perovskite Solar Cells under High-Temperature Operation Amy E. Louks[1,2], Robert Tirawat[1], Mengjin Yang[1], Severin N. Habisreutinger[1], Steven P. Harvey[1], Kelly Schutt[1], Kai Zhu[1], Joseph Berry[1,3,3] and Axel F. Palmstrom[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States; [3]University of Colorado Boulder, United States

Metal halide perovskite (MHP) photovoltaic performance required for commercial technology encompasses both efficiency and stability. Advances in both these parameters have recently been reported; however, these strategies are often difficult to directly compare due to differences in perovskite composition, device architecture, fabrication methods, and accelerated stressors applied in stability tests. Reported strategies to increase efficiency of perovskite photovoltaics include ink additives, pre- or post-treatments to the perovskite absorber, and choice of contact materials. While these methods may be effective for boosting the initial performance of MHPs, there is a distinct lack of standardized accelerated stability testing data showing the effects of these modifications on the operational stability. This work focuses on using individual and combinations of additive, post-treatment, and contact layer strategies from recent perovskite literature reports. A standardized accelerated testing protocol of light, heat (70 °C), and bias (modified ISOS-L-2) was applied throughout this study to evaluate overall performance impact across device architectures.

Initially, CsMAFA perovskites with an ink stoichiometry of $Cs_{0.05}MA_{0.16}FA_{0.79}Pb(I_{0.84}Br_{0.16})_3$ were investigated. Visible degradation was quickly observed across all devices tested with this composition. Time of flight secondary ion mass spectrometry (ToF-SIMS) analysis revealed lateral phase halide phase segregation under these elevated temperature test conditions, which was not induced at lower temperatures. Reduction of the bromine content on the X site to a composition of $Cs_{0.05}MA_{0.16}FA_{0.79}Pb(I_{0.92}Br_{0.08})_3$ mitigated this effect and provided a baseline platform for the broader study of additives, post-treatments, and alternative transport layers to determine the effect the interaction of each has on the stability of the device.

Through analysis of over 1000 devices, we identify the hole transport layer as the most significant factor toward improving performance at elevated temperature. Out of all the combinations tested, the four most stable architectures incorporated a NiOx contact. Post-treatment approaches targeting the perovskite/ETL interface showed positive effects on the initial performance of TC8Br devices but did not lead to significant stability improvements. This observation highlights that passivation approaches for perovskite solar cells should more regularly undergo accelerated aging tests that include exposure to light and heat to unambiguously establish whether the proposed passivation approach is worthwhile. Fundamentally, we observe that these p–i–n devices are stability limited by the HTL, consistent with recent trends in literature. This work therefore motivates the continued development of high-performance HTLs to realize stable and efficient perovskite solar cells.

SESSION EN10.04: Tandems and Wide Bandgaps

Vapor Phase Deposited Perovskite for Single Junction and Tandem Solar Cells Henk J. Bolink; University of Valencia, Spain

We will report on the progress on vapor phase deposited perovskites both for single junction and for Si tandems. Using substrate configuration we optimize the incoupling of sunlight which leads to current densities very close to the detailed balance limit. Impact of deposition speed will be commented upon.

2:15 PM EN10.04.02
Reverse-Bias Resilience of Monolithic Perovskite/Silicon Tandem Solar Cells Zhaojian Xu[1], Helen Bristow[2], Maxime Babics[2], Badri Vishal[2], Erkan Aydin[2], Randi Azmi[2], Esma Ugur[2], Bumin Yildirim[2], Jiang Liu[2], Ross Kerner[3], Stefaan De Wolf[2] and Barry P. Rand[1]; [1]Princeton University, United States; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]National Renewable Energy Laboratory, United States

Metal halide perovskites have rapidly enabled a range of high-performance photovoltaic technologies. However, catastrophic failure under reverse voltage bias hinders their commercialization. In this work, we demonstrate that by employing a monolithic perovskite/silicon tandem structure, the perovskite subcell can be effectively protected by the silicon subcell under reverse bias, owing to the low reverse-bias diode current of the silicon subcell. As a result, the tested perovskite/silicon tandem devices show superior reverse-bias resilience compared to perovskite single-junction devices in both long-term reverse voltage biasing tests at the single-cell level and partial shading tests at the module level. These results highlight that, compared to other perovskite technologies, monolithic perovskite/silicon tandems are at a higher technology readiness level in terms of tackling the reverse-bias and partial shading challenge, which is a considerable advantage towards commercialization.

2:30 PM EN10.04.03
Rational Design of Photoelectrochemical Perovskite-$BiVO_4$ Tandem Devices for Stable Fuel Production Virgil Andrei; University of Cambridge, United Kingdom

Metal halide perovskites have emerged as promising alternatives to commonly employed light absorbers for solar fuel synthesis, enabling unassisted photoelectrochemical (PEC) water splitting[1,3] and CO_2 reduction to syngas.[2,4] While the bare perovskite light absorber is rapidly degraded by moisture, recent developments in the device structure have led to substantial advances in the device stability. Here, we give an overview of the latest progress in perovskite PEC devices, introducing design principles to improve their performance and reliability. For this purpose, we will discuss the role of charge selective layers in increasing the device photocurrent and photovoltage, by fine-tuning the band alignment and enabling efficient charge separation. A further beneficial effect of hydrophobicity is revealed by comparing devices with different hole transport layers (HTLs).[1,3] On the manufacturing side, we will provide new insights into how appropriate encapsulation techniques can extend the device lifetime to a few days under operation in aqueous media.[1,2] To this end, we replace low melting alloys with graphite epoxy paste as a conductive, hydrophobic and low-cost encapsulant.[3,5] The combined advantages of these approaches are demonstrated in a perovskite-$BiVO_4$ tandem device archiving selective unassisted CO_2 reduction to syngas.[4] These design principles are successfully applied to an underexplored BiOI light absorber, increasing the photocathode stability towards hydrogen evolution from minutes to months.[6] Finally, we take a glance at the next steps required for scalable solar fuels production, showcasing our latest progress in terms of device manufacturing. A suitable choice of materials can decrease the device cost tenfold and expand the device functionality, resulting in flexible, floating artificial leaves.[7] Those materials are compatible with large-scale, automated fabrication processes, which present the most potential towards future real-

world applications.[8,9] Such PEC systems approaching a m^2 size can further take advantage of the modularity of artificial leaves.[10]

2:45 PM EN10.04.04
Unveiling Non-Fullerene Routes: Strategic Design of Wide Bandgap Inverted Perovskite Solar Cells with SnO2 Layers Sung Yong Kim[1] and Jun Hong Noh[1,2,3]; [1]Korea University, Korea (the Republic of); [2]KU-KIST Green School Graduate School of Energy and Environment, Korea University, Korea (the Republic of); [3]Department of Integrative Energy Engineering Korea University, Korea (the Republic of)

Recently, metal halide perovskites have garnered attention in photovoltaic research, experiencing a substantial increase in efficiency, achieving an impressive 26.1%. Within this realm, the inverted perovskite solar cell structure is notable for avoiding stability issues associated with the transport layer, such as Spiro-MeOTAD in regular perovskite solar cells. However, to date, the majority of high-efficiency inverted structures employ fullerene derivatives like C60 and PCBM as Electron Transport Layers (ETLs), posing difficulties in commercialization due to their long-term stability and cost-related challenges. Consequently, inorganic materials like SnO_2, TiO_2, and Nb_2O_5 have emerged as potential ETL candidates, with SnO2 being the most extensively used material in n-i-p structures due to its high electron mobility, wide bandgap, and low cost.

We report achieving a high efficiency of 18.3% at a 1.77eV bandgap, utilizing synthesized SnO2 nanoparticles, dispersed in a non-damaging solvent, as an Electron Transport Layer (ETL) in an inverted structure. This efficiency is the highest achieved using SnO2 in inverted structures, even without considering the bandgap. In order to mitigate defects originating from the expanded SnO2 surface area attributed to the small particles, ethylenediamine (EDA) was employed for passivation. Notably, EDA exhibited a bifunctional role between the perovskite and SnO2 layers. In order to validate this, observations of a reduction in defects and an enhancement in charge transportation between the perovskite/SnO2 interfaces will be conducted, utilizing Photoluminescence (PL) and X-ray Photoelectron Spectroscopy (XPS) analytical techniques.

3:30 PM *EN10.05.01
Advances in Materials and Process for Sustainable Perovskite Solar Cells Hyun Suk Jung[1,2]; [1]Sungkyunkwan University (SKKU), Korea (the Republic of); [2]SKKU Institute of Energy Science and Technology (SIEST), Korea (the Republic of)

All solid-state solar cells based on organometal trihalide perovskite absorbers have already achieved distinguished power conversion efficiency (PCE) to 26.1% and further improvements are expected up to 27%. Now, the research on perovskite solar cells (PSCs) has been moving toward commercialization. To facilitate commercialization of these great solar cells, some technical issues such as long-term stability, large scale fabrication process, Pb-related hazardous materials, and environmentally-burdened toxic solvent-based process need to be solved.
This talk is dealing with our recent efforts to facilitate commercialization of perovskite solar cells. For examples, we introduce a recycling technology of perovskite solar cells, which covers the regeneration process of Pb contained perovskite layer as well as recycling process of Au electrodes and transparent conducting oxide glass. Also, novel strategies for recycling toxic solvents such as DFM, used in fabricating PSCs are introduced, which is critical to realize close loop recycling process of PSCs. Finally, recent studies for achieving high efficiency PSC using ecofriendly solvent are demonstrated.

4:00 PM *EN10.05.02
Vacuum Processed Perovskites for Optoelectronic Devices Annalisa Bruno; Nanyang Technological University, Singapore

Metal-halide perovskites (MHP) are one of the most promising low-cost optoelectronic materials due to their excellent optoelectronic properties and fabrication versatility. The need to transfer the existing technology into large areas by industrial-compatible high throughput methods is becoming more urgent [1].
Thermal evaporation is a promising MHP fabrication technique to bring this technology closer to reliable and extended production by relying on excellent size scalability, fine composition control, surface adaptability, and enabling precision in layer thickness and fine control on composition [2-7]. On one hand, this annealing-free deposition process guarantees a strain-free perovskite and PSCs with remarkable thermal stability and structural robustness [4]. On the other, thermal evaporation of perovskite has expanded the horizons of thin film fabrication, proving the ability to produce ultrathin perovskite films as the base of multi-quantum well (MQW) structures.
Controlling the optoelectronic features of thin films and nanostructured materials, capitalizing on the quantum confinement effects, can open up a novel pathway for investigating cutting-edge phenomena and for new optoelectronic applications.

Sustainable Solvent Management for Viable Perovskite Solar Cell Recycling Process Hee Jung Kim[1], Oh Yeong Gong[1], Young Ju Kim[1], Geon Woo Yoon[1], Gill Sang Han[2], Hyunjung Shin[1,3] and Hyun Suk Jung[1,3]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]SKKU Institute of Energy Science and Technology, Korea (the Republic of)

Sustainable recycling technologies of perovskite solar cells (PSCs) at the end of life is inevitable for commercialization, which can reduce the environmental impacts as well as re-fabrication cost. Thus, several efforts have been made to recycle toxic Pb compounds and expensive components in PSCs. However, most recycling strategies included dissolving layers such as perovskite and charge transfer layer by using organic solvents, which can cause harmful effects on environmental, health, and safety. Nevertheless, studies related to these toxic solvents used in recycling processes have not yet been considered.
Here, we introduce a novel approach that recovers and reuses toxic solvents used in the recycling process. First, detailed evaluations were conducted to assess the effects of residual substances in PSC-dissolved solvents. Then, two-step dissolution process, which selectively dissolve spiro-OMeTAD and perovskite layer by layer, was introduced to minimize the factors affecting the efficiency reduction. PSCs were immersed in chlorobenzene and N,N′-dimethylformamide (DMF) solvents in sequence, and each solvent was recovered for reuse in the re-fabrication of PSCs. Especially, the recovered DMF was filtered by nano-absorbents for removing and managing toxic Pb ions. The recovered solvents were reused as precursor solvents to re-fabricate PSCs, and the dissolved spiro-OMeTAD also reused without any loss. Our results demonstrate the feasibility of a toxic solvent recycling process for PSC re-fabrication, which achieved a power conversion efficiency of 25.02%, comparable to that of the original PSCs (25.12%), as well as recycling of the dissolved hole conducting materials.

Open-Air Spray Deposition with Rapid Plasma Curing for High-Throughput Manufacturing of Low-Cost Perovskite Solar Modules Austin Flick, Justin P. Chen, Thomas W. Colburn, Abigail Carbone, Francisco Barrera, William Cai and Reinhold H. Dauskardt; Stanford University, United States

Successful commercialization of perovskite solar devices requires significant focus on scalable, low-cost manufacturing techniques. The solution processability of the perovskite layer yields a compelling candidate for low-cost solar energy production, though efforts to develop complementary low-cost transport layers, electrodes, and barrier layers are essential. Ultrasonic spray deposition provides a platform for high-throughput production, complemented with open-air plasma curing for rapid crystallization as previously demonstrated in rapid spray plasma processing (RSPP) of perovskite films.[1]-[3] Large-area spray deposition paired with ultrafast plasma-assisted crystallization enables processing speeds up to 20 cm/s, demonstrating the highest throughput and lowest cost perovskite manufacturing method. However, remaining vacuum-dependent transport layer and electrode depositions—including sputtering and thermal evaporation—create significant bottlenecks in production with elevated module costs.

In this work, open-air spray deposition with rapid plasma and near infrared curing sources are employed throughout the entire thin-film architecture for high-throughput production of low-cost additive-free inverted p-i-n perovskite devices. Ultrasonic spray deposition with rapid plasma curing is utilized for transparent conducting oxide (TCO) front electrode and perovskite layer production, meanwhile spray deposition with near infrared curing is employed across the transport layers and rear metal electrode. Validation of individual film morphologies and optoelectronic properties demonstrate large-area defect-free films deposited at linear throughputs of 10 – 20 cm/s. TCO front electrodes with >90% visible transmittance and Haack figure of merit ($T10/R_{SH}$) of 0.01 Ohm^{-1} are achieved with >80% fill factor compatible transport layers, enabling 20% device efficiencies and >18% module efficiencies across 25 cm^2.

Complementary technoeconomic analysis at 100 MW production scale demonstrates >50% cost reduction employing the developed open-air manufacturing techniques compared to conventional vacuum-based manufacturing. The high-throughput techniques enable reduced dependence on equipment, facilities, and labor costs, yielding considerable economies of scale beyond 1 GW production. The open-air spray deposition platform for perovskite module production provides a pathway towards reduced levelized cost of energy for photovoltaics below $0.02/kWhr.

Correlating Halide Segregation with Iodide Oxidation via *In-Situ* Opto-Gravimetric Analysis Zhaojian Xu and Barry P. Rand; Princeton University, United States

Halide oxidation plays an important role in halide segregation and degradation of metal halide perovskites. However, a direct and quantitative measurement of halide oxidation in solid-state perovskite samples is still required to fully understand and evaluate the effect of halide oxidation. In this work, we employed a quartz crystal microbalance to achieve an *in-situ* opto-gravimetric measurement of solid-state perovskite films and quantify the iodine loss rate under light excitation. Combining photoluminescence, X-ray photoelectron spectroscopy, X-ray diffraction, and *in-situ* opto-gravimetric measurements on a series of mixed-halide perovskite with different halide ratios, we are able to explain the degradation mechanism of mixed-halide perovskite under prolonged light illumination (photolysis of iodine), and demonstrate an identical compositional threshold for both light-induced halide segregation and iodide oxidation. These results not only reveal the correlation between light-indued halide segregation and iodide oxidation, which experimentally proves

the photoelectrochemical origin of light-induced halide segregation, but also provide a powerful tool to quantitatively study halogen loss and degradation kinetics of metal halide perovskites.

Utilizing Machine Learning and Diode Physics to Optimize Photovoltaic Performance in Sequentially Processed Perovskite Solar Cells Jeongbeom Cha and Min Kim; Jeonbuk National University, Korea (the Republic of)

Organic-inorganic lead halide perovskite photovoltaics are well-known for their exceptional solution processability. However, achieving uniformly crystalline perovskite films often requires complex deposition methods. To solve this challenge of the perovskite deposition method, several studies have been performed to utilize deposition parameters such as concentrations of the annealing temperatures, precursor solution, and spin-coating speeds. Unfortunately, most of these studies have been conducted on trial-and-error approaches, which are resource-intensive and time-consuming. Nowdays, machine learning techniques have considered as powerful tools for utilizing complex experimental parameters and predicting the device performance, making more efficient analysis of parameter spaces.
In our study, we combined Shockley diode-based numerical analysis with machine learning techniques to analyze the photovoltaic characteristics of the device and utilize their photovoltaic performance by considering experimental variables. The application of the Shockley diode equation allowed us to extract photovoltaic parameters and predict power conversion efficiencies, contributing to our understanding of charge recombination and device physics. Using machine learning techniques, we trained a machine learning model using current-voltage curves that are sensitive to changes in manufacturing conditions. This enabled us to identify the optimal settings for improved device performance.
Our harmonized approach not only reveals the relationship between experimental conditions and device performance, but also simplifies the optimization process, reducing the need for extensive trial-and-error experimentation. This methodology shows great promise in advancing the development and fine-tuning for next-generation perovskite solar cells.

5:00 PM EN10.06.03
Assembly-Coating through Marangoni and Capillary Convection Manipulation of Colloidal Droplets on a Substrate for Robust Luminescence Jin Young Kim, Byung Gi Kim, Woongsik Jang and Dong Hwan Wang; Chung-Ang University, Korea (the Republic of)

Recently, lighting and display technologies require high-resolution, and research into materials that produce vivid and natural colors is required [1,2]. In particular, semiconductor material selection and layering for key energy sensing components in industrial applications is important [3]. Quantum dots (QDs) are attracting attention as next-generation functional materials, but due to the nature of colloidal particles, it is difficult to deposit them evenly and uniformly on the substrate. Therefore, discussion is still needed to understand and solve the evaporation mechanism of drying a solution containing colloidal particles on a substrate. In general, when depositing a colloidal suspension on a solid substrate, non-uniform surfaces (coffee rings, multi-ring patterns, etc.) are mainly observed due to evaporation of the solvent [4,5]. At the evaporation location, the particles are circulated by the inward and outward flow of the droplets. As a result, colloidal particles move to the tri-contact line, resulting in irregular surface deposition, and many studies have been conducted to prevent this. However, a system that uniformly coats the entire surface of the substrate with a colloidal solution has not been studied. In this study, we focused on surface uniformity and luminescence efficiency by relating Marangoni flow and capillary flow to the inclination angle of the substrate. Perovskite QDs were used as colloidal particles, and the coating method was improved by tilting the substrate by manipulating the directions of the two main flows (Marangoni and capillary). Due to this, the internal flow circulation time of the droplet was different on the flat and inclined substrates, which extended the Marangoni flow and led to a uniform surface. In addition, lubrication theory was applied to the colloid applied to the inclined surface to analyze the correlation between the inclination angle of the substrate and the Marangoni and capillary numbers. It was found that the higher the Marangoni number, the more uniform the coating, and as the angle of the substrate increases, the shaded area increases, making the surface more non-uniform [6]. At an angle of 3°, the Marangoni and capillary flows circulated almost similarly, leading to a uniform surface, which was confirmed to not lose luminescence even in a thermal evaporation environment. In addition, as a result of manufacturing a diode device and evaluating the charge transport characteristics according to the quality of the QD thin film, improved hole carrier transport and extraction characteristics were observed. These results suggest that it may help improve the deposition quality of colloidal solutions that require uniform surfaces in applications.

5:00 PM EN10.06.04
Thermally Evaporated High-Performance Metal Halide Perovskite Transistors Youjin Reo[1], HuiHui Zhu[1,2], Ao Liu[1,2] and Yong-Young Noh[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Northwestern University, United States

Advances in metal halide perovskites for optoelectronic devices have resurrected the their potential as channel layer for transistors. Over the past several years, notable performances have been reported for solution-processed metal halide perovskite transistors through fine-tuning of material composition, crystallization and device structure.[1-3] However, their ionic nature allows the channel layer to be susceptible to common solvents used in lithography, which is challenging for complex circuit integration, large-area or micro-scale electronics. Here, we present thermally evaporated metal halide perovskite, caesium-tin-iodide, as a channel layer for high-performance p-channel thin-film transistor. While thermal evaporation is a mature fabrication technique, the low crystallinity of deposited thin-films, when compared with those from solution-process, was a fundamental bottleneck. The chemical reaction can take place by overcoming high energy barrier for diffusion and solid-solid interaction, unlike fast ionic reactions of the solution-process.[4,5] By incorporating chloride-based additives that accelerate the solid-state diffusion under high thermal energy and alkali metal iodide additives that modulate the formation of nucleation sites, we achieved a highly crystalline film and high-performance thin-film transistor with field-effect hole mobilities over 30 $cm^2V^{-1}s^{-1}$ and on/off current ratios exceeding 10^{10}. High reproducibility and operational stability were attained in large-area wafer-scale to micro-scale devices, accentuating the highly promising and industry-ready thermally evaporated metal halide perovskite thin-film transistors.

5:00 PM EN10.06.05

Down Layer Intercalation Control of Cesium Halides into $MAPbI_3$ Framework for High Stable Perovskite Solar Cells Yue Feng[1], Shahiduzzaman Md.[2], Munkhtuul Gantumur[1], Masahiro Nakano[3], Makoto Karakawa[1,2,3] and Tetsuya Taima[1,2,3]; [1]Graduate School of Frontier Science Initiative, Kanazawa University, Japan; [2]Nanomaterials Research Institute, Kanazawa University, Japan; [3]Graduate School of Natural Science and Technology, Kanazawa University, Japan

Perovskite solar cells (PSCs) have attracted considerable interest of the researchers and achieved the power conversion efficiency (PCE) of 26.1%. However, low stability is still the most challenging issue for PSCs that needs to be solved. Up to date, introduction of a small amount of cesium halides (CsX) particularly CsCl, CsBr and CsI into perovskite precursor solution showed improved device performance. However, this method leads to the formation of pinholes during the spin-coating and imperfect surface coverage of the perovskite due to the limited solubility of these materials and has difficulties to control Cs^+ concentration as well as thickness of the film. Previously, our group has successfully intercalated CsI into perovskite $MAPbI_3$ framework and achieved a PCE of 18.43% and remained above 80% of their initial output after 6000 h storage in open air (non-encapsulated) [1]. Precise intercalation of CsX technology has not yet studied widely. In this study, we introduced vacuum deposited CsX (CsCl, CsBr and CsI) thin layers into solution processed host perovskite $MAPbI_3$ film from down layer to promote precise intercalation, resulted in high-quality perovskite film for high stable PSCs. The use of CsX layer greatly altered the perovskite morphology to produce large grain sizes, as a result of the precise intercalation of the CsX molecules into the host $MAPbI_3$. We tested thermal stability of perovskite films and found that after heating at 85 °C on hot plate at relative humidity of 50% to 60% for more than 24 hours, Cs-containing perovskite films showed higher stability than pristine $MAPbI_3$ film. After that, PSCs were fabricated by using CsX intercalated perovskite films and evaluated device performance and stability. PSCs made with CsCl, CsBr, and CsI intercalation exhibited PCEs of 15.64%, 15.97% and 15.74%, respectively whereas the pristine $MAPbI_3$ based device showed PCE of 15.33%. Furthermore, the light-soaking of devices prepared with CsCl, CsBr and CsI intercalation remained 76.9%, 77.2% and 71.2%, respectively, of their initial efficiencies, while the pristine $MAPbI_3$ device showed only 4.3% of its initial efficiency after 120 minutes of light illumination (1 sun). More importantly, a similar trend with the CsCl, CsBr, and CsI-based PSCs were observed for the moisture stability for 3000 h storage at ambient with a relative humidity range of 50–60%. This CsX intercalation technology will enable a significant improvement in the device operational stability and processing reproducibility.

5:00 PM EN10.06.06

Process Optimization of Chemical Vapor Deposition of $MAPbBr_3$ for Optoelectronic Applications Jona Riedel[1], Franziska E. Muckel[2], Michael Heuken[1,3], Andrei Vescan[1] and Holger Kalisch[1]; [1]RWTH Aachen University, Germany; [2]Universität Duisburg-Essen, Germany; [3]AIXTRON SE, Germany

With growing commercial interest in halide perovskite (HP) thin-film applications, the question which deposition techniques can meet the requirements of industrial scalability and reproducibility becomes increasingly important. At the current time, solution-based methods which are prominent in research are limited to small areas, low reproducibility and are not able to meet special requirements such as deposition on structured substrates. Promising alternatives are vapor-based techniques like vacuum thermal evaporation (VTE) or chemical vapor deposition (CVD) which are well established in the field of semiconductor manufacturing.
At CST (RWTH Aachen University), we have designed and built a custom showerhead-based CVD tool for the deposition of HP thin films by thermal evaporation of halide salts into a heated carrier gas stream. The usage of an inert carrier gas such as N_2 at low vacuum around 5-10 hPa allows for the simultaneous or alternating evaporation of both metal-halide as well as organo-halide salts in a single process. The latter materials are typically difficult to use in high-vacuum techniques like VTE due to their large vapor pressures and low sticking coefficients. In addition, unlike quartz furnace CVD setups found in research literature, our tool features separate sources for different precursor salts. Temperature-controlled substrates are mounted in a heated showerhead-based reactor chamber allowing for uniform deposition on areas up to 100 cm^2.
While different HP materials have been successfully prepared in our tool, benchmarks for both LEDs and solar cells are lagging behind those of devices based on HP films prepared by spin coating. A typical feature of our CVD films is a reduction of photoluminescence (PL) intensity compared to spin-coated reference samples by 2-3 orders of magnitude. Times-resolved PL spectroscopy indicates the presence of a fast, non-radiative recombination channel in CVD samples absent in their solution-processed counterparts, which likely impedes efficient operation of both LEDs and solar cells. By sequential deposition of $PbBr_2$ and MABr to form $MAPbBr_3$ using combinations of CVD and solution deposition, we investigated the influence of both precursors and processes. We observed that spin-coated $PbBr_2$ layers can be easily converted to $MAPbBr_3$ layers with strong PL intensity using CVD-MABr, while simultaneously grown CVD-$MAPbBr_3$ as well as CVD-$PbBr_2$ films converted by either CVD-MABr or MABr solutions share a low PL intensity. This is in accordance with literature which comprises numerous reports on the conversion of lead-halide precursor films from solution or VTE via MABr-CVD, but lacks reports on the usage of lead halide salts as separate precursors under low vacuum. Unlike reports from high-vacuum evaporation, we observe strong evidence for the dissociation of thermally evaporated $PbBr_2$. Notably after prolonged evaporation of $PbBr_2$ precursor material, metallic residues can be found in the crucible. This indicates an at least partial dissociation of $PbBr_2$ into elemental Pb and volatile Br_2. Due to the high vapor pressure of Br_2, the deposition conditions inside our reactor can be expected to be Br-rich. This could facilitate the formation of intrinsic defects related to excess Br, like Br interstitials, and give a reason for the low PL intensity found when evaporated $PbBr_2$ is part of the process. Nevertheless, we were able to increase the PL intensity of $MAPbBr_3$ by 1-2 orders of magnitude by thermal annealing of $PbBr_2$ precursor layers for up to 3 h at 200-310 °C in N_2. A similar effect can be observed by increasing the substrate temperature during $PbBr_2$ deposition from 100 °C to above 200 °C, supporting the assumption of a volatile species like Br poisoning our HP. The combined results show a clear path to directly avoid the suspected negative impact of $PbBr_2$ dissociation in CVD of HPs.

5:00 PM EN10.06.07

Structure and Properties of Novel Mixed Organics Hybrid Lead-Halide Phase (1-NA)(1-MQ)Pb_2I_6 Yang Goh, Megan Cassingham, Peter Djurovich, Mark E. Thompson and Brent Melot; University of Southern California, United States

Low dimensional hybrid organic-inorganic lead-halide structures are gaining interest due to their structural flexibility and tunability compared their parent 3-D perovskite structure. By combining the tunability of organic chromophores and the desirable optical properties of perovskites, we aim to develop a new portfolio of hybrid organic-inorganic lead-halide materials. In order to achieve a mixed organics hybrid lead-halide phase, several 1-naphthylamine isomers were used to synthesize new 1-D hybrids to screen for similar crystal structures to the known 1-D hybrid, 1-naphthylammonium lead iodide (1-NA)PbI_3. 1-methylquinolinium iodide (1-MQ)PbI_3 has a similar structure, and a mixed organics hybrid phase, (1-NA)(1-MQ)Pb_2I_6 is successfully synthesized. (1-NA)(1-MQ)Pb_2I_6 shows clear ordering of the organics, which is the first we are aware of in these systems. We will discuss the optical and dielectric properties of the end members, (1-NA)PbI_3 and (1-MQ)PbI_3, as well as the mixed organics hybrid phase, (1-NA)(1-MQ)Pb_2I_6, and how that relates to their respective structures.

5:00 PM EN10.06.08

Direct Photo-Patterning of Perovskite Nanocrystals with Siloxane Resin Showing Highly Stable Luminescence Jinmin Park[1], Sang Woo Bae[1], Junho Jang[2], Hyukmin Kweon[1], Byeong-Soo Bae[2], Young-Hoon Kim[1] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Metal halide perovskite nanocrystals (PeNCs) are promising light emitting materials for color-converting light-emitting diodes (CC-LEDs) due to their

high absorption coefficient, narrow full width at half maximum (FWHM) and easily tunable bandgap. However, PeNCs face challenges, such as instability against chemicals and high humidity, as well as limited patternability without any additive, which limit their potential as color conversion layer (CCL) in CC-LEDs. Also, there are no reports regarding stable PeNCs patterns, despite the achievements of their high-resolution patterning using ligand crosslinkers.
Herein, we report highly stable PeNCs (green emitting $MAPbBr_3$/resin composites) patterns encapsulated in siloxane resin which is synthesized by the sol-gel reaction between methoxy groups of (3-methacryl oxypropyl) trimethoxysilane (MPTS) and hydroxyl groups of diphenylsilanediol (DPSD). The synthesized siloxane resin provides physical protection to core materials by crosslinking between methacrylate functionalized siloxane resin and unsaturated hydrocarbon of organic ligands (e.g., oleic amine or oleic acid) via UV-induced free radical reactions, resulting in direct optical patterning without ligand crosslinkers.
By introducing the siloxane resin, PeNCs patterns demonstrate high photoluminescence quantum yield (PLQY) in various harsh conditions: in DI water (> 100 days), ambient conditions (> 150 days) and under 40 °C/RH 70% (> 8 hours) without additional encapsulation process, since the siloxane resin suppresses hydrolysis of PeNCs and controls permeation of H_2O molecules moderately. Moreover, direct optical patterning with siloxane resin can be applied to various inorganic light emitting materials (red emitting CdSe QDs/resin composites).
We believe that our material design, which combines $MAPbBr_3$ and CdSe QDs with siloxane resin, will offer a universal solution, demonstrating high levels of pattern stability in harsh conditions while enabling direct optical patterning without the need for ligand crosslinkers, simultaneously.

Insights into Hybrid Perovskites Ink Reactivity and Evolution to Polytypes Silvia Colella[1,2]; [1]CNR-NANO, Italy; [2]University of Bari, Italy

Metal halide perovskite (MHP) semiconductors are excellent candidates for contemporary optoelectronics innovation, particularly for photovoltaics.[1] The advantages of this class of materials derive from their hybrid nature, allowing for straightforward fabrication processes, and from their unique optoelectronic properties. A typical 3D organic-inorganic perovskite has a chemical formula of ABX3, where A is an organic cation (such as MA [methylammonium] or FA [formamidinium]), B is a metal cation (such as Pb2+), and X is a halogen anion (such as I or Br).[2] However, recent advances have also explored more complex compositions embedding diverse cations/anions.[3] These materials are prepared by simple and straightforward solution processing, the material precursors dissolved in a solvent undergoes self assembly into a perovskite structure during spin-coating onto a substrate under mild thermal annealing. As the technology continues to mature, this still is a key advantage, allowing for affordable and scalable processing. Understanding perovskite ink properties is therefore a fundamental requirement towards industrialization, with special regards to their evolution over time. It has been demonstrated that even for the simplest system, the precursor solution is a complex – and dynamic – dispersion which contains not only solvated ions but also lead halide complexes, colloids and aggregates of different natures and dimensions. In these complex dispersions, multiple chemical species are present and can interact – or react – between each other or with the solvent. We have proved the existence of a reactivity between two of the perovskite components – MA and FA – in the precursors solutions, that leads to the formation of a novel condensation product, methylformamidinium (MFA). We have studied different parameters that affects such reactions kinetics, therefore modifying the ink composition over time, and proposed solutions to overcome these issues.[4] With the aim of correlating the solution chemistry with the film structural properties, through the synergic use of solution Nuclear Magnetic Resonance (NMR) spectroscopy, X-ray Diffraction and Density Functional Theory (DFT) calculations, we have recognized and explained for the first time a correlation between the aging of perovskite precursor solutions, the presence of MFA species in solution and the emergence of photoinactive hexagonal polytypes (6H and 4H) [5] Starting from the known reactivity of the chemical species present in ink solutions, we outline the directions towards which future research efforts should be directed.[6] References: [1] Jeong, J., Kim, M., Seo, J., Lu, H., Ahlawat, P., Mishra, A., Yang, Y., Hope, M.A., Eickemeyer, F.T., Kim, M., et al. Bi-Directional Simultaneous Cation/Anion Engineering of Formate Complex for Holistic Management of Perovskite Solar Cells Min Ju Jeong; Korea University, Korea (the Republic of)

Pseudo-halide anion formate ($HCOO^-$) has been widely recognized as crystallization agent to control the crystal growth without inducing any changes in the band-gap. However, there is a lack of understanding regarding the effect on perovskite films depending on the chemical bonding state of formate. In this work, we demonstrated the distinguishable crystallization behavior of $FAPbI_3$ film by comparing the formate complexes with different bonding state. In addition, we found that the distinct passivation mechanisms depending on the cations of formate complexes, which resulted in the differences in device performance. Notably, sodium formate (NaFo) showed bi-directional behavior of cation and anion, eliciting a distinction from other formate complexes. As a result, the NaFo device showed an enhanced power conversion efficiency (PCE) of 25.6% with a high open-circuit voltage (V_{oc}) of 1.18 V, achieving 95% of the Shockley-Qeuisser limit at the PV band-gap of 1.53 eV. This work provides insights of the effect of crystallization by the chemical bonding state of formate as well as different passivation mechanism depending on the cations of formate complexes.

8:45 AM EN10.07.03
Electrically Induced Directional Ion Migration in Two-Dimensional Perovskite Heterostructures Jee Yung Park, Yoonho Lee and Letian Dou; Purdue University, United States

Understanding ion migration in halide perovskite materials is key to enhancing both device performance and stability. The introduction of two-dimensional (2D) perovskites has improved stability, spurring increased interest in understanding ion migration in these materials. Hindered by the challenge in building

a reliable device platform, prior studies primarily focused on heat and light induced ion migration. Here, we construct a high-quality single crystal 2D perovskite heterostructure, free from grain boundaries and impurities. Using a device platform fabricated through a multi-step dry transfer process to realize near defect-free van der Waals contact, we achieve real-time visualization and imaging of directional ion migration. Notably, aside from the expected directional ion migration driven by the electric field, we discover the unique behavior of halide anions inter-diffusing against the field under strong and prolonged bias. Spatial confocal photoluminescence mapping reveals a halide migration channel that aligns with the crystal edge of high electrical conductivity, highlighting the role that electric current plays in ion migration. Finally, after a sustained mild bias, stable junction diodes exhibiting ~1000-fold forward to reverse current ratio are realized due to directional ion migration-induced asymmetricity. This study unveils important fundamental insights on halide migration under electrical bias, paving the way toward high-performance electronic and optoelectronic devices.

9:00 AM EN10.07.04
***In Situ* Polymerization of Cross-Linked Perovskite–Polymer Composites for Highly Stable and Efficient Perovskite Solar Cells** He Guo and Hyun Suk Jung; Sungkyunkwan University, Korea (the Republic of)

Mixed-halide perovskites have emerged as outstanding light absorbers that enable the fabrication of efficient solar cells; however, their instability hinders the commercialization of such systems. Grain-boundary defects and lattice tensile strain are critical intrinsic-instability factors in polycrystalline perovskite films. In this study, the light-induced cross-linking of acrylamide (Am) monomers with non-crystalline perovskite films was used to fabricate highly efficient and stable perovskite solar cells. The Am monomers induced the preferred crystal orientation in the polycrystalline perovskite films, enlarged the perovskite grain size, and cross-linked the perovskite grains. Additionally, the liquidity of Am effectively released lattice strain during perovskite-film crystallization. The cross-linked interfacial layer functioned as an airtight wall that protected the perovskite film from water corrosion. Devices fabricated using the proposed strategy showed an excellent power conversion efficiency (*PCE*) of 24.45% with an open-circuit voltage (V_{OC}) of 1.199 V, which, to date, is the highest V_{OC} reported for hybrid PSCs with electron transport layers comprising TiO_2. Large-area perovskite solar cell modules fabricated using the proposed strategy showed a *PCE* of 20.31% (with a high fill factor of 77.1%) over an active area of 33 cm^2, with excellent storage stability.

9:15 AM EN10.07.05
Metal-Organic Chemical Vapor Deposition of Hybrid Perovskites Alicia Bryan, Jonathan Meyers, Lorenzo Serafin and James Cahoon; University of North Carolina at Chapel Hill, United States

Hybrid perovskites (HPs) have become widely recognized in the chemistry and materials science communities as a promising candidate for the next generation of efficient optoelectronic and photovoltaic devices. Their unique hybrid organic-inorganic nature affords HPs an exciting blend of electronic and structural properties, and yields both advantages and challenges in fabrication. The vast majority of HP fabrication methods to date have focused on simple solution processing, while comparatively few vapor-phase HP deposition methods have been developed, and these broadly rely on single-source evaporation of solid HP perovskite crystals or dual-source coevaporation of precursor salts. However, these methods suffer from limited control over reactant vapor pressures and temperatures that in turn lead to limited control over final film composition and morphology. In light of this, we have developed a metal-organic chemical vapor deposition (MOCVD) method for HP fabrication to enable precise control of composition, stoichiometry, and film morphology. Using our custom-built reactor equipped with vapor precursors including methylamine, tetraethyllead, and hydrogen halide gasses, we have successfully deposited continuous thin films of phase-pure $CH_3NH_3PbI_3$ perovskites as confirmed using X-ray diffraction, UV-visible and photoluminescence spectroscopy, and scanning electron microscopy. We further probed deposition on a variety of substrates including FTO-glass, silicon oxide, and organic-functionalized materials to investigate the vital relationship between substrate identity and film nucleation and growth dynamics.

Revisiting Crystal Growth and Composition Engineering for Reproducible Fabrication of High-Performance Perovskite Solar Cells Jin-Wook Lee; Sungkyunkwan University, Korea (the Republic of)

Metal halide perovskite solar cells (PSCs) have been spotlighted as a promising next-generation photovoltaic technology. Recently, there has been a surge of efforts in the commercialization of PSCs in academia and industries worldwide with record power conversion efficiencies over 26% for both n-i-p and p-i-n structured devices. Nevertheless, their subpar operational durability, module scalability, and material toxicity are challenges often brought up as the major barriers hindering practical commercialization. The poor reproducibility of PSCs has been relatively overlooked, but negatively impacts institutional research laboratories, start-up companies, and large established corporations all alike. Reproducible fabrication of PSCs is a critical consideration for market viability and practical commercialization. In this work, I will discuss the critical functions of atmospheric humidity to regulate the crystallization and stabilization of formamidinium lead triiodide ($FAPbI_3$) perovskites. We demonstrate that the humidity content during processing underlies profound variations in perovskite stoichiometry, thermodynamic stability, optoelectronic quality and thus reproducibility of PSCs. In second part of the presentation, I will discuss the interplay between composition of perovskite, and performance and stability of inverted PSCs. We rationalize the difference in widely used perovskite compositions in n-i-p and p-i-n PSCs.

Unlocking Versatility: Innovative Crystallization Strategies for Metal Halide Perovskites and Their Application Potentials Pablo P. Boix; Instituto de Tecnología Química (UPV-CSIC), Spain

Metal halide perovskite crystals in the macro and nano scales can leverage the huge versatility of the perovskite family. They present exceptional optoelectronic properties that make them attractive for a variety of applications. However, these structures usually depend on complex synthesis processes, where the ligands play a dominating role, or are limited by growth form factor and surface losses.
We present crystallization insights that enable less demanding synthesis processes, such as a promising sol-gel approach [1] for humidity-triggered nanoparticle crystallization or a contactless surface passivation technique for large crystals. The particularity of these systems can be adapted to specific applications such as memristive devices or downconversion films with efficiencies >95%, which also serve as a platform to characterize the fundamental

working mechanisms of these materials.
The combination of the crystallization control with additive engineering also opens new routes for lead-free perovskite photovoltaics, improving their ambient and operational stabilities.

Light-Induced Halide Sublimation and Diffusion in 2D Halide Perovskites Yanqi Luo[1], Shuchen Zhang[2], Jia-Shiang Chen[1], Xuedan Ma[1], Ke Ma[2], Junjing Deng[1], Yi Jiang[1], Luxi Li[1], Barry Lai[1], Si Chen[1], Sarah Wieghold[1] and Letian Dou[2]; [1]Argonne National Laboratory, United States; [2]Purdue University, United States

To address stability challenges in two-dimensional (2D) perovskite semiconductor materials, an improved understanding of the degradation origins and pathways under external stimuli is needed. Here, we investigate the evolution of halide redistribution within various 2D halide perovskites (n = 1 to 3) lateral heterostructures using *in-situ synchrotron* nanoprobe X-ray fluorescence (nano-XRF) microscopy. The heterostructures comprise distinguishable iodine (I) and bromine (Br) regimes laterally. Continuous UV exposure leads to iodine sublimation in high-dimensional 2D perovskites and a visible amount of Br diffusion to the previously iodine-rich regime. In contrast, bromine is relatively more stable than iodine in n = 2 and 3 heterostructures, with no significant change in total Br concentration. Additionally, combining nano-XRF mapping and X-ray absorption spectroscopy, we found a reduction of dimensionality in the previously iodine-rich regime in crystals with $n > 1$ after UV exposure, indicating significant structural reconfiguration beyond ion migration. These findings provide new insights into the photo-induced ion migration and degradation mechanisms of 2D perovskite materials and shed light on future materials design.

11:00 AM EN10.08.04
3D Printing of Vertical Heterostructures of Two Dimensional Halide Perovskites Sixi Cao and Ji Tae Kim; The University of Hong Kong, Hong Kong

The integration of different materials into heterostructures allows for the manipulation of interfaces and electronic structures, playing a crucial role in various modern electronics and optoelectronics applications, such as solar cells, light-emitting diodes, lasers, self-powered photodetectors, transistors, and large-scale electronic circuits[1-3]. Two-dimensional (2D) halide perovskites have gained significant attention due to their superior optoelectronic properties and high stability, making them promising candidates for next-generation multifunctional devices[4,5]. The heterojunctions formed by 2D halide perovskites exhibit high tolerance to lattice mismatch and low intrinsic anionic diffusion at the interface, thanks to the presence of the organic layer in the 2D quantum well, which enhance their stability and performance in optoelectronic integrated device[6]. However, achieving controllable integration of 2D perovskites remains a challenge due to their mobile and fragile crystal lattices[7]. solution and gas-solid phase intercalation have been reported for fabricating 2D perovskite-based lateral and vertical heterostructures[8,9].Nevertheless, these methods suffer from limitations, including a lack of scalability and limited control over the morphology of the resulting heterostructures, which hinders large-scale production and integration of 2D perovskite nanowire heterostructures into practical devices. In this work, we propose a novel approach for fabricating freestanding layer perovskite nanowire heterostructures using a 3D printing method. This level of control ensures uniformity and reproducibility, facilitating the deterministic fabrication of arbitrary vertical heterostructures and multi-heterostructures using 2D perovskites. Our printed heterojunction nanowires showed an excellent stability with suppressed anionic diffusion at the interface.By offering greater structural degrees of freedom, our approach allows for the precise definition of the electronic structures of the heterojunctions.

Enhancing Crystallization Kinetics in Glass-Forming Halide Perovskites using Organic Cation Isomers Akash Singh, Yi Xie, Curtis Adams III and David B. Mitzi; Duke University, United States

The recent exploration of glass-forming hybrid metal halide perovskites (MHPs) has opened new possibilities to extend their applications beyond the well-established realm of optoelectronic research, which primarily focuses on their crystalline variants. In this regard, it is imperative to diversify the range of glass-forming MHP compositions and manipulate their crystallization kinetics through synthetic structural engineering. Herein, we conducted a comparative study involving two MHPs that possess subtly different structural characteristics, utilizing isomer organic cations while maintaining the same chemical composition. Our investigation sheds light on how these alterations in the position of functional groups profoundly influence the kinetics of both glass formation and cold crystallization. One of the MHPs, (S)-(−)-1-(1-naphthyl)ethylammonium lead bromide (S(1-1)NPB), exhibits a lower melting point (T_m) of 175 °C and readily transforms into a glassy state at a critical cooling rate (CCR) of 20 °C/min. In contrast, (S)-(−)-1-(2-naphthyl)ethylammonium lead bromide (S(1-2)NPB) displays a higher T_m of 193°C, and requires a CCR of 150,000°C/min, necessitating the use of ultrafast calorimetry for glass formation. The examination of the underlying crystallization kinetics, performed using iterative calorimetry and the Kissinger modeling technique, further indicates a small activation energy barrier (E_A) for crystallization in S(1-2)NPB.
We also investigate the interplay between structural and thermodynamic features that engenders distinct glass formation and crystallization behavior using a comprehensive analysis of the organic-inorganic hydrogen bonding interactions in the crystalline state and a careful examination of the enthalpy and entropy balance across the melting transition. These analyses highlight the strengthened hydrogen bonding in S(1-2)NPB and the reduced entropy of melting as the key factors contributing to the higher T_m and CCR, as well as a lower E_A, observed in comparison to S(1-1)NPB. The results presented in this

study establish a framework for evaluating the impact of structural elements on the kinetics of glass formation and crystallization, serving as a new material design strategy to diversify the family of glass-forming MHPs and extending their potential applications in areas demanding faster switching speeds such as memory, computing, metamaterials, and reconfigurable photonic devices.

A Templating Approach to Controlling the Growth of Co-Evaporated Halide Perovskites Siyu Yan[1], Jay Patel[1], Jae Eun Lee[1], Karim Elmestekawy[1], Sinclair R. Ratnasingham[1], Qimu Yuan[1], Laura Herz[1,2], Nakita K. Noel[1] and Michael B. Johnston[1]; [1]University of Oxford, United Kingdom; [2]Institute for Advanced Study, Technical University of Munich, Germany

Metal halide perovskite semiconductors have shown significant potential for use in photovoltaic devices. While fabrication of perovskite thin-films can be achieved through a variety of different techniques, thermal vapour deposition is particularly promising, allowing for high-throughput fabrication and large-scale production. However, the ability to control the nucleation and growth of these materials, particularly at the charge-transport layer (CTL)/perovskite interface, is critical to unlocking the full potential of vapour-deposited perovskite photovoltaics, since the surface of the substrate material exerts a substantial impact beyond the interface, leading to alterations in the morphology of the entire film. As a result, for vapor-deposited perovskites, it is crucial to choose the right CTLs to ensure uniform deposition of alkylammonium halides and appropriate crystallization of the perovskite material. This not only limits the range of available substrates, but also requires extensive experimentation to optimize the evaporation parameters for different types of substrates. This issue limits the economic feasibility of industrial applications, as the most attractive scale-up technique is to produce all device layers on the same vacuum fabrication lines. Therefore, the ability to decouple the nucleation and growth of coevaporated perovskite films from the influence of substrate materials is of the utmost importance.

We highlight our recent work [Yan et al., ACS Energy Lett. (2023)] wherein we explored the use of a templating layer to control the growth of co-evaporated perovskite films, and found that such templating reproducibly leads to highly oriented films with identical morphology, crystal structure, and optoelectronic properties, independent of the specific substrate on which the perovskite was deposited. When incorporated into solar cells, devices based on this approach showed reproducible improvements, yielding vapour-deposited $FA_{0.9}Cs_{0.1}PbI_{3-x}Cl_x$ solar cells with steady-state solar-to-electrical power conversion efficiencies over 19.8%. This report provides an effective and reproducible method for controlling the buried charge transport layer/perovskite interface in vapor-deposited perovskite solar cells, further increasing the competitiveness of this deposition technique, moving the field closer to large-scale fabrication of a wide-range of efficient perovskite optoelectronic devices.

Yan, S. et al., A Templating Approach to Controlling the Growth of Coevaporated Halide Perovskites, ACS Energy Lett. 2023, 8, 10, 4008–4015 DOI: 10.1021/acsenergylett.3c01368

11:45 AM EN10.08.07
Exploring The Relationship between The Local Structure of Lead Halide Perovskites and Their Macroscopic Properties Milos Dubajic; University of Cambridge, United Kingdom

Characterised by their exceptional optoelectronic characteristics, hybrid halide perovskites have gained prominence as a viable class of materials for energy conversion applications. Their marked impact is especially noticeable in the field of solar cell technology, where they have demonstrated substantial progress in efficiency. Despite these advancements, fully decoding their unique properties continues to pose a scientific enigma. Of particular interest is the local structure of these materials, which often diverges from their average configuration, and is hypothesised to be a significant determinant of their macroscopic properties.

We employed temperature-dependent diffuse X-ray scattering on a series of perovskite single crystals, enabling us to accurately characterise the local structure in real-space across all crystallographic phases of these perovskites. By developing a simple, computationally inexpensive model that accurately mirrors the experimental diffuse scattering, we were able to gain insights into how the local structure can be modulated through the substitution of A and X-site cations.

By employing a variety of optical microscopy techniques on identical compositions, we established a direct correlation with the emergence of ferroelastic properties in these materials.

Our study thereby underscores the critical role of compositional engineering in tailoring the local structure and, by extension, the macroscopic properties of hybrid halide perovskites.

Robustness and Versatility of CsPbBr3 Perovskite Detectors in Extreme Radiation Environments Mercouri G. Kanatzidis; Northwestern University, United States

The burgeoning field of radiation detection has witnessed a significant interest in semiconductors that can operate under harsh conditions and high photon fluxes. We present a comprehensive study on CsPbBr3, a perovskite-based semiconductor, showcasing its potential as a robust and cost-effective alternative to conventional Cd1-xZnxTe (CZT) detectors. Our research reveals that CsPbBr3 detectors demonstrate minimal degradation even after exposure to 1 Mrad of Co-60 gamma radiation, maintaining high energy resolution and hole mobility. Many of these detectors also continue to function after a 10 Mrad dose over 3 days, indicating that device failure is more likely related to electrode-material interactions rather than intrinsic material degradation. I will also present the behavior of these detectors under extreme x-ray flux conditions. Utilizing ultrahigh flux synchrotron x-rays and advanced pump-and-probe techniques, we examine the polarization effects and discover their correlation with deep defects generated by intense radiation. Importantly, we find that the polarization can be mitigated by stronger applied electric fields and reduced carrier traps. Additionally, we employ thermally stimulated current spectroscopy to identify trap states and their impact on performance. Our findings suggest that CsPbBr3 detectors fabricated with low defect concentrations (<1 x 10^14 cm^-3) show appreciable performance and stability. Another remarkable aspect of our research is the use of solution-

processed perovskites for hard X-ray and gamma-ray detection. These solution-grown CsPbBr3 detectors display excellent photocurrent linearity and sensitivity, even under ultrahigh x-ray fluxes, substantiating their wide applicability in high-flux environments. Comparisons between solution-grown and melt-grown crystals reveal comparable performance in terms of defect concentration and overall detector efficacy. There is a compelling case emerging for the use of CsPbBr3-based detectors in a variety of high-stress applications, ranging from industrial settings to space explorations while highlighting strategies for further optimizing these promising materials.

2:00 PM EN10.09.02
Multi-Energy X-Ray Imaging Technology for Security Check Tengyue He and Omar F Mohammed; KAUST, Saudi Arabia

Conventional grayscale single-energy X-ray imaging technology (SEXIT) often struggles to accomplish outstanding material-specific functions. While dual-energy X-ray imaging technology (DEXIT) partially compensates the limitation, its implementation typically demands dual detectors or twice X-ray exposures. Besides, valuable spectral photon information is abandoned by both SEXIT and DEXIT.[1,2] Herein, we have developed an inventive multi-energy X-ray imaging technique (MEXIT) designed by multiple scintillators with a ΔE-E telescope structure. Specifically, three distinct scintillators convert and assign X-rays from different energy bins into individual visible light information in an energy sequence. Emerging scintillation materials of metal halides were employed.[3] The carefully selected filters were inserted into them, enabling the combined radioluminescence (RL) to span the entire visible range (350 nm to 800 nm) devoid of any overlap. Consequently, substances with different CT numbers can be readily discriminated through their corresponding emission colors. Moreover, notable spatial imaging resolutions that exceeds 22 lp mm^{-1} across all X-ray energy were achieved by MEXIT. The conceptual demonstration was conducted in a scenario for the inspection of various substances with complicated composition, where the ΔE-E telescopic scintillator allows effective screening of different substances based on X-ray energy bins. Dirffrent ROIs (region of interests) are avaliable to be extracted by the orginal images. Our study presents a promising avenue for achieving MEXIT and extends it to trichromatic vision, introducing innovative perspectives for various scientific and practical fields. To the best of our knowledge, no prior reports exist of a similar design capable of translating X-ray energy into an ultrabroad RL spectra using three distinct scintillation materials to achieve multi-energy X-ray imaging.

2:15 PM EN10.09.03
Two-Dimensional Hybrid Halide Perovskite as Highly Efficient β-Ray Scintillator by Incorporation of Aromatic Cations Dongjun Kim, Seoyoung Yoon and Jiwon Kim; Yonsei University, Korea (the Republic of)

Scintillators are extensively employed in the fields of security inspection, industrial product analysis, and medical diagnosis, owing to their capability of converting high-energy ionizing radiation (e.g. α-, β-, γ-, X-, and neutron rays) into visible light. Specifically, organic scintillators – including single crystals, liquids, and plastics – are primarily utilized for detecting β-ray. However, organic single crystal scintillators, such as anthracene and naphthalene, encounter limitations associated with complexity in crystal growth and potential carcinogenicity resulting from the sublimation of substances. Liquid scintillators pose challenges in terms of manufacturing, transportation, storage, and handling due to their vulnerability to oxygen and flame. Meanwhile, plastic scintillators exhibit drawbacks owing to their low glass transition temperature of polymers and poor irradiation hardness.
Consequently, organic-inorganic hybrid halide perovskites have emerged as a promising alternative scintillator for high light yield, tunable emission wavelength, and low-temperature solution processability. To enhance the scintillation efficiency of perovskites, comprehensive investigations on their structure and composition have been preceded. Specifically, two-dimensional (2D) perovskites are known to exhibit higher light yield and faster scintillation decay compared to three-dimensional (3D) perovskite owing to higher exciton binding energy. Moreover, long aliphatic molecules were introduced as organic cations of 2D perovskite to enhance the capturing efficiency of β-rays. Nevertheless, 2D perovskite incorporating aromatic molecules, which are known to facilitate the absorption and release of energy, has not yet been developed as a scintillator.
Herein, we developed blue-emitting 2D hybrid halide perovskites and evaluated its scintillation properties under various types of radiation. More specifically, ammonium derivatives from organic scintillators (i.e. anthracene, naphthalene, or stilbene) were employed as cations, where aromatic rings effectively serve as centers for the absorption of radiation energy. The synthesized 2D perovskite exhibited a photoluminescence (PL) peak centered at 410 nm, along with a notably high PL quantum yield of 64.5%. Furthermore, it demonstrated highly efficient scintillation property under X-ray and β-ray (C-14, Ni-63). In this study, we proposed a new strategy to enhance scintillation efficiency by incorporating organic scintillator cations into 2D hybrid halide perovskites, thereby paving a way for applications in future nuclear radiation monitoring devices.

SESSION EN10.10: Light-Emitting Diodes
Session Chairs: Henk Bolink and Michael Saliba
Wednesday Afternoon, April 24, 2024
Room 334, Level 3, Summit

3:30 PM *EN10.10.01
Perovskite Light-Emitting Diodes for Next-Generation Data Communications Wei Zhang; University of Surrey, United Kingdom

Light-emitting diodes (LEDs) are ubiquitous in modern society. However, future applications of light-emitting diodes (LEDs) will not be limited to the fields of lighting and displays. As billions of Internet of Things (IoT) devices are already connected, the demand for data communication systems with low-cost and low-power consumption is dramatically increasing. It has been widely expected that LED-based links will act as key elements in the next-generation data communication systems[1]. The conventional III-nitride micro-LEDs have the potential to provide a modulation bandwidth of several hundred MHz, however, their complex fabrication process and high manufacturing costs pose significant challenges for their integration into next-generation communication systems where the considerations on costs and compatibility are sometimes prioritized over speed in current communication scenarios.

Metal halide perovskites are emerging classes of semiconductors that have recently showed great potentials in the optoelectronic devices such as high-

performance photovoltaics, photodetectors and LEDs[2]. Their widely tuneable properties such as bandgap and electronic energy levels can be tailored through synthesis and composition engineering[3,4]. Another distinct advantage is that these emerging materials can be solution-processed and deposited on different types of substrates under ambient conditions which are attractive for low-cost high-throughput industrial-scale fabrication. These fascinating features make metal halide perovskites promising materials for LED applications. Although prior research has progressed substantially in optimizing their external quantum efficiency for the applications in lighting and displays, the modulation characteristics of perovskite LEDs remain unclear.

In this talk, I will review the challenges that exist in developing practical high-speed LEDs, and highlight the most recent advance in the development of emerging LED materials—organic semiconductors, colloidal quantum dots and metal halide perovskites—for use in optical communications. I will then introduce a holistic approach that we developed most recently for realizing fast perovskite photonic sources on silicon based on tailoring alkylammonium cations in perovskite systems[5]. Under optimal conditions, we achieved device modulation bandwidths of 42.6 MHz and data rates above 50 Mbps, with further analysis suggesting that the bandwidth may exceed gigahertz levels. Finally, I will summarize the general principles that will support the future development of perovskite light sources for next-generation data-communication architectures, which might open up new possibility of integration with micro-electronics platforms.

4:00 PM *EN10.10.02
Molecular Interface Engineering and Optical Design for High-Efficiency Perovskite LEDs Hin-Lap Yip; City University of Hong Kong, Hong Kong

Metal halide perovskite light-emitting diodes (PeLEDs) have the potential to significantly impact next-generation lighting and display technology. However, their full promise has yet to be unlocked, particularly for blue and white PeLEDs. These devices face unique challenges such as maintaining stability, achieving high efficiency, and obtaining pure color emission, especially for blue light, due to the inherent material and device-related difficulties. Our research tackles these issues through a multifaceted strategy designed to optimize the performance and efficiency of PeLEDs. We commence with interfacial engineering, introducing a self-assembled monolayer (SAM) with functional hole injection properties between the NiOx and poly(9-vinylcarbazole) hole injection layers. This approach effectively mitigates common obstacles such as weak interfacial adhesion, high interfacial trap density, and mismatched energy levels. The introduction of the SAM has successfully led to blue PeLEDs with external quantum efficiencies (EQEs) exceeding 15% and green devices with EQEs of 26.0%. In addition to enhancing efficiency, the introduction of the SAM also augments the device response speed by reducing interfacial capacitance and resistance. These advancements together pave the way for the development of more efficient, brighter, and faster responding perovskite LEDs, thereby broadening their potential applications in various fields.
Furthermore, we have developed an advanced device structure that optically couples a blue PeLED with a red-emitting perovskite nanocrystal layer, leading to the creation of efficient white PeLEDs. This innovative strategy utilizes near-field effects to facilitate the extraction of trapped blue photons' optical modes to the red perovskite layer, resulting in white PeLEDs achieving EQEs over 12% - a significant advancement in white PeLED performance.

4:30 PM EN10.10.03
Semitransparent OLEDs with Ultrathin Light Emitting Layer and Extraordinarily Thick Perovskite Hole Transport Layer Michele Forzatti, Sang-Hyun Chin, Daniel Tordera and Henk J. Bolink; Universitat de Valencia, Spain

Organic light-emitting diodes (OLEDs) have had a huge gain in popularity by virtue of their simple fabrication process, thin structure and for the possibility to devise transparent devices. However, the production of stable, cheap and efficient devices remains a challenge. Ultrathin nondoped emitting layers have been investigated as a way to simplify fabrication process and lower material consumption, but the consequent reduction in thickness may decrease device stability. Overcoming this issue with thicker transport layers is alluring but tough, as organics have intrinsically low charge-carrier mobilities. On the other hand, metal halide perovskites (MHPs), promising materials in many fields of optoelectronics, have also been used as charge transport materials, where their transparency in the visible region and high hole conductivity make it possible to increase the thickness of the layer to the micrometer-scale without increasing the operation voltage or reducing luminous efficiency.

In light of this, we developed a semitransparent OLED having a thick cesium lead chloride all-inorganic perovskite hole transport layer, an ultrathin (<0.1 nm) $[Ir(ppy)_2acac]$ film as emitting layer and a semitransparent top indium-tin oxide contact deposited on top of a thin metallic layer. The resulting devices have a thickness exceeding 1 µm, a combined peak luminance of over 1000 cd m^{-2}, a current efficiency of 34 cd/A and a transparency in excess of 60% over the visible spectrum above 480 nm. The hole transporting $CsPbCl_3$ layer includes two thin (2 nm) CsCl layers at the interfaces, which have been demonstrated to be able to passivate interfacial halide vacancies, improving the photoluminescence and reducing exciton quenching in turn. The nature of the ultrathin layer was investigated by means of contact angle measurement, which confirmed that the molecules forming the LEL are not in the form of a neat layer. The metallic layer could be deposited with little damage to the underlying organic layers but despite its low thickness, essential to guarantee transparency, it still protected towards the final ITO sputtering deposition. The combination of transparent top electrode, thick perovskite HTL and ultrathin LEL, described herein for the first time, entails a reduction in material and fabrication costs and is promising towards future cheap and stable semitransparent OLEDs.

Overcome Charge Transfer Barrier via Electrostatically Stabilized $CsPbBr_3$ Nanocrystals for Efficient Perovskite Light-Emitting Diodes Min-Gi Jeon, Artavazd Kirakosyan, Kim Joonseok, Subin Yun and Jihoon Choi; Chungnam National University, Korea (the Republic of)

Electrically insulating organic ligands with long hydrocarbon chains cause bottlenecks, which hinder efficient charge injection and transportation in $CsPbBr_3$ nanocrystal (NC)-based light-emitting diodes (LEDs). Shorter ligand exchange with precise control of the surface ligand density through additional purification processes is a common strategy used to improve charge transport in optoelectronics. However, practical applications have been limited owing to poor structural integrity and colloidal stability associated with the low steric hindrance of short surface-capping ligands. Here, we report a post-synthesis treatment on $CsPbBr_3$ NCs using hydrazine monohydrobromide (N_2H_5Br; HZBr), and tetrafluoroborate derivatives (XBF4, X=Na^+, NO^+, NH_4^+, ...). Despite their short molecular structure, these inorganic ligands provide an excess amount of charged ions to the NC surface, enhancing the colloidal dispersion of the $CsPbBr_3$ NCs through electrostatic stabilization. Cryogenic photoluminescence spectroscopic analysis identified that the exciton-phonon coupling at the surface of $CsPbBr_3$ NCs is significantly reduced by the presence of short inorganic ligands, preventing the formation of both permanent and transient exciton traps. Furthermore, enhanced surface stabilization to improve the radiative recombination was accomplished by excess Br^- and F^- anions passivating Br^- ion vacancies at the $CsPbBr_3$ NC surfaces. LEDs based on the short inorganic ligands-treated $CsPbBr_3$ NCs showed improved

maximum current efficiency of 19.46 cd/A, and the external quantum efficiency of 6.04 % increased by a factor of 2.8. Additional electron and hole-only device measurements affirmed the enhanced hole-electron injection and transport into the $CsPbBr_3$ NCs.

PLD of Metal Halide Perovskites: From *In-Situ* Photoluminescence During Growth to Efficient Solar Cell Devices Monica Morales-Masis; University of Twente, Netherlands

The dominance of vapor phase deposition in semiconductor technology extends to various applications, such as commercial thin-film PV manufacturing. Physical vapor deposition (PVD) of thin film materials offers distinct advantages, including conformal deposition, precise thickness control, and scalability. An underexplored alternative within PVD for metal halide perovskites (MHP) is pulsed laser deposition (PLD). We have recently demonstrated that PLD facilitates single-source vapor phase growth and stoichiometry control of MHPs; and solar cell devices with PLD-perovskites exceeding 19% efficiency. Furthermore, the growth control afforded by PLD, encompassing thickness and deposition rate, allows the epitaxial formation of MAPbI3 on lattice-matched substrates. To delve into the growth mechanisms at different PLD deposition rates for halide perovskites (e.g., high rates for solar cell applications or low rates for epitaxy), we conduct in-situ photoluminescence measurements during film growth, complemented by an in-depth ex-situ analysis using PL, XRD, MAS ss-NMR, and XPS. We discuss the role of the deposition parameters, deposition rate and PLD target composition on final film quality. The role of the substrate or contact layers on the film morphology, optoelectronic quality, and final device performance will be furthermore discussed. Combining PLD-controlled growth with insights into structural-property relationships provide important insights into the vapor-phase growth of MHPs, which can be applied in more PVD beyond PLD. All these are important steps forward in the controlled growth and future scalability of optoelectronic materials for efficient devices, both single junction and tandem solar cells.

SESSION EN10.11: Poster Session II
Session Chairs: Henk Bolink and Michael Saliba
Wednesday Afternoon, April 24, 2024
Flex Hall C, Level 2, Summit

5:00 PM EN10.11.01
Effect of Interfacial Modification on Spray-Coated Lead-Free $Cs_2AgBiBr_6$ Double Perovskite Solar Cells Kun-Chin Wei[1], Hsin-Jung Wu[1] and Chih-Liang Wang[2]; [1]National Chung Hsing University, Taiwan; [2]National Tsing Hua University, Taiwan

The $Cs_2AgBiBr_6$-based double perovskites have recently been reported as alternatives to hybrid lead halide perovskites due to the improved stability and nontoxicity. However, the conversion efficiency of $Cs_2AgBiBr_6$ solar cell remains low due to inherent film-related defects. In this regard, the lead-free $Cs_2AgBiBr_6$ double perovskite solar cell was firstly studied by a spray coating to systemically understand the influence of spraying time, substrate temperature, and surrounding atmosphere on the spray-coated film. The interface between the spray-coated $Cs_2AgBiBr_6$ film and hole transport layer or electron transport layer was further modified by the dye layer, such as N719 and Z907. The result showed that the surrounding atmosphere from the solvent vapor during the spray deposition can play a key role in the growth of the high-quality $Cs_2AgBiBr_6$ resulting film. In addition, the insertion of the dye layer in $Cs_2AgBiBr_6$ solar cells showed a positive effect on the light absorption, charge carrier recombination, carrier extraction, and energy level alignment. The SEM, XRD, and UV-vis were carried out to understand the surface morphology, crystallization, phase purity and optical property of different spray-coated $Cs_2AgBiBr_6$ films. The electrochemical impedance spectroscopy was performed to figure out the electrical properties and the charge recombination of $Cs_2AgBiBr_6$ solar cell with and without the insertion of the dye layer. More details related to the stability and performance of the $Cs_2AgBiBr_6$ solar cells, influenced by the spray coating process and dye layer, will be reported in the presentation.

5:00 PM EN10.11.02
Understanding Nucleation and Film Growth of Perovskite in Confined Volume Printing Matthew Dailey and Adam Printz; University of Arizona, United States

Despite the promising characteristics of metal halide perovskites for optoelectronic applications, these materials are highly unstable to environmental factors such as moisture and heat. These instabilities stem predominantly from grain boundary defects, such as halide vacancies that allow more facile ion migration. One strategy to improve the stability of perovskites is to reduce the surface area of the grain boundaries within the film by increasing the grain size. A one-step pathway to increased grain size is limiting nucleation of crystallites followed by rapid growth, resulting in films with fewer, larger crystals. Batch processes have been developed to grow monocrystalline perovskite with confined volumes; however, these processes are slow and not scalable for manufacturing. Conversely, scalable printing techniques such as slot die coating or doctor blading provide limited control over nucleation and growth of crystallites. We have developed a printing process that bridges the gap between scalability and control over crystallization that we call Restricted Area Printing by Ink Drawing (RAPID). RAPID prints films from confined volumes (between a superstrate and substrate) in a continuous process.

Film growth with RAPID can be tuned by controlling the working parameters that dictate the nucleation and growth—confinement gap, residence time, and temperature. We will show the influence of the solvent evaporation rate, distance between substrate/superstrate, and surface chemistry on both the substrate and superstrate on the nucleation and growth of perovskite thin films. Finally, we will demonstrate RAPID-printed perovskite thin films with domains greater than 20 μm and no lead iodide can be achieved in ambient conditions without the need for post processing.

5:00 PM EN10.11.03
Elevating Perovskite Solar Cells: Advances in Scalable Thin Film Deposition and Degradation Insights Randall Headrick[1], Seid Yimer Abate[1,2], Pramod Baral[2], Gary E. Carver[1] and Richards G. Miller[2,1]; [1]University of Vermont, United States; [2]Verde Technologies Inc., United States

In the rapidly evolving landscape of perovskite solar cells (PSCs), two pivotal challenges take center stage: (i) pioneering scalable thin film deposition techniques and (ii) unraveling degradation mechanisms. This presentation converges groundbreaking research encompassing scalable thin film deposition, high-efficiency solar cells, in-situ synchrotron X-ray diffraction studies, spatially resolved photoluminescence analysis, and accelerated degradation investigations under maximum power point tracking conditions.

At the heart of this presentation lies the development of scalable thin film deposition techniques, with a special emphasis on the innovative Verde Slot Coater [Ref 1]. Engineered to bring perovskite solar cells closer to commercial viability, the Verde Slot Coater represents a significant leap forward. It addresses the challenges of achieving uniform coating and effectively bridges the gap between laboratory-scale experiments and large-scale production. Most notably, this innovation has resulted in achieving over 18% power conversion efficiency (PCE) for 1.25 cm^2 solar cells, underlining the potential of scalable manufacturing methods within the perovskite industry.

We have also embarked on a journey towards long-term stability, guided by cutting-edge research methodologies. Specifically, we have begun studies of Formamidinium Lead Iodide (FAPI) thin film devices. FAPI is slightly unstable with a Goldschmidt tolerance factor just above 1.0, making it susceptible to transforming into the undesirable hexagonal phase. Through in-situ synchrotron X-ray diffraction studies, we gain invaluable insights into the degradation processes that influence perovskite thin films over time. This research enables us to track the evolution of multiple phases over time, exploring responses to varying conditions such as temperature, light exposure, and humidity, across timescales from seconds to hours.

In the race to ensure PSCs can endure real-world challenges, accelerated degradation studies conducted under maximum power point tracking conditions provide indispensable insights. These studies simulate practical scenarios, enabling researchers to evaluate the resilience of perovskite solar cells and optimize their performance for long-term reliability. Furthermore, the use of spatially resolved photoluminescence studies (SRPL) during accelerated degradation investigations offers a microscopic understanding of degradation with a spatial resolution of 1 micron. By pinpointing specific regions of degradation and identifying potential mitigation strategies, this research substantially contributes to the long-term durability of perovskite solar cells.

The presentation will provide the latest results for each facet of the research outlined above. It encapsulates the spirit of innovation in perovskite solar cell research, emphasizing scalable manufacturing, high efficiency, and an in-depth exploration of degradation mechanisms. It invites us to closely scrutinize the path toward more robust and commercially viable perovskite solar cells.

Sn-Based Perovskite Solar Cells: Additive Engineering and Surface Modification to Improve Stability Ashraful Islam and Md. Emrul Kayesh; NIMS, Japan

Perovskite solar cells (PSCs) have attracted much attention because of the fast progress of their power conversion efficiency (PCE), from 3.8% to 25.7% in the past 14 years [1]. However, the toxicity of Pb effectively hinders the large-scale commercial production of PSCs. Therefore, researchers have turned their attention to Sn-based perovskite due to their similar or even superior optoelectronic properties, such as optimum band gap, higher charge carrier mobility, and low exciton binding energy [2–3]. However, the stability of the Sn-based PSCs is low compared to Pb-based PSCs, which limits the practical use of the solar cells. One of the reasons for this low stability is the rapid crystallization, which results in inhomogeneous films with a lot of pin holes. Another reason is the easy oxidation of Sn^{2+} to Sn^{4+}, which leads to high nonradiative recombination of carriers, low efficiency, and low stability. According to recent studies, Sn^{2+} oxidation is more dominant on the perovskite surface [2].
To enhance the quality of perovskite film, additive engineering is a well-known process for Sn-based PSCs to slow down the crystallization rate [3]. Recently, polydentate additives have shown effectiveness in modulating the growth of Sn-based perovskite films [4]. However, the stability of perovskite film is dependent on crystallinity and pin-hole-free large-grain compact films. The highly oriented crystal offers smooth charge transfer, whereas the larger grain reduces the grain boundaries, which are regarded as the recombination centers for the charges. In this work, we used a bifunctional additive in Sn precursor solution that acted as a modulator to dictate the growth of perovskite film and were able to fabricate highly crystalline and stable uniform perovskite film.
The additive-added $FASnI_3$ film showed large and compact grains without any pinholes. This is because the bifunctional additive had a strong interaction with SnI_2 through hydrogen bonding, which delayed the $FASnI_3$ crystal growth. At the same time, the bifunctional groups helped to create strong adherence between perovskite and PEODOT:PSS and dictated the growth of perovskite crystals in a preferred orientation. The XRD pattern of the modified FASnI3 film remains unchanged for up to 3h when exposed to air, which indicates that the addition of this bifunctional additive to the precursor solution significantly enhanced the environmental stability of the FASnI3 film.
With the addition of a bifunctional additive, the PCE jumped from 10.0% to 13.2%. It is important to state that the addition of the additive significantly improved the open circuit voltage (V_{OC}) from 0.85 V to 0.95 V as well as the short circuit current (J_{SC}) from 16.5 mA/cm^2 to 18.2 mA/cm^2. The enhancement of V_{OC} may be due to the suppression of leakage current with the addition of additives in the precursor solution, as we confirmed from our dark current measurement. This modification also reduced the charge recombination center, such as Sn^{4+} content in the film, as we observed from the XPS result. The PCE of the modified PSC retained its 90% initial PCE even after 100h. As a result, we achieved a certified (AIST, Japan) PCE of over 12% with superior device stability for Sn-based PSCs.

p-Type Doping of Cs_2SnI_6 Halide Perovskites Using Charge Transfer Dopants Alex Kratzer and Shubhra Bansal; Purdue University, United States

Perovskite solar cells (PSCs) have shown remarkable progress in recent years, surpassing the efficiency of conventional thin-film photovoltaic (PV) technologies such as CdTe and CIGS. The recent discoveries in organic-inorganic hybrid PSCs resulting from synergistic optimization of the perovskite absorber layer have generated remarkable development in device efficiency from 3.8% in 2009 to the present state-of-art 25.7%. Organic-inorganic halide perovskites have also shown 31.3% efficient tandem devices with Si bottom cells. Mixed-halide and mixed-cation systems have demonstrated high efficiency, improvement in stability and reduced hysteresis. The emergence of 2D perovskite passivation and 2D/3D heterojunctions, have shown promise by enhancing the long-term stability of Pb-based halide PSCs, however, addressing toxicity challenge is crucial for large scale adoption.
A2BX6 is a defect variant of the general perovskite structure ABX3 where half of the vacant B-cations results in corner-sharing octahedron of anions [BX6]2- and A-cation occupying the sites between the octahedron in 12-fold coordination. Alteration and substitution of B-cations and/or halogen anions (Cs2TeI6, Cs2PtI6, Cs2PbI6, Cs2TiBr6, Cs2AgBiBr6, Cs2AgBiCl6, etc.) offer a multitude of features in these double perovskite structures with enhanced thermal and moisture stability. Cs2SnI6 double perovskite has emerged as a promising light absorber, with a 4+ oxidation state of tin and shorter Sn-I bond length (2.85 Å vs. 3.11 Å in CsSnI3), making it oxidation resistant and air-stable. Cs2SnI6 has a direct bandgap of 1.3-1.6 eV, and the closed-packed halide

framework results in dispersed conduction and valence bands leading to low electron effective masses of 0.48m0 for electrons and 1.32m0 for holes. Cs2SnI6 exhibits electron and hole mobilities of 310 cm2V-1s-1 and 42 cm2V-1s-1, respectively, and is believed to be an ambipolar material due to formation of n-type iodide vacancies/tin interstitials or p-type cesium vacancies. Devices up to 5% PCE have been demonstrated with enhancements such as Cl, F, Rb, Ag, In doping; ZnO nanorod electron transport layer (ETL); ethylene diamine post-deposition treatments. However, state-of-art Cs2SnI6 devices show high bulk and interface recombination as indicated by low carrier lifetime and high dark saturation current. Power conversion efficiency of > 5% has been demonstrated for planar p-i-n Cs2SnI6 devices; however, to increase the device efficiency further robust methods of defect passivation and improved doping density are needed. Here we will present the results of a controlled study on charge transfer doping using molecules such as F4TCNQ for Cs2SnI6. When applied to $MAPb_{0.5}Sn_{0.5}I_3$, the electrical conductivity increased by 5 orders of magnitude, the hole density increased by 1 order of magnitude, and the passivation of charge carrier traps increased the carrier recombination lifetime. The molecular dopant F4TCNQ also fits the criteria to be an effective p-type dopant for Cs_2SnI_6, due to its lowest unoccupied molecular orbital (LUMO) value being less than the valence band maximum (VBM) value, so as to facilitate effective charge transfer for holes. Data on film processing, doping density and carrier lifetime will be presented for Cs2SnI6 processed by doctor blade method with and without molecular dopants. The effect of the dopants on phase stability, absorption bandgap will also be studied.

5:00 PM EN10.11.06
Optimal Interface Engineering through SAM Energy Alignment & Functionalization Hannah K. Contreras[1], Yangwei Shi[1], Fangyuan Jiang[1], Declan McCarthy[2], Aidan O'Brien[1], Seth R. Marder[2] and David S. Ginger[1]; [1]University of Washington, United States; [2]University of Colorado Boulder, United States

Open circuit voltage losses (V_{OC}) in the perovskite top cell remain a significant challenge for the commercialization of perovskite tandem solar cells. We show through simulations that common hole transport layers like PTAA and Me-4PACz are energetically mismatched with the perovskite active layer which lowers the quasi-Fermi level splitting and limits V_{OC}, particularly for wide bandgap compositions relevant to tandems ($E_g \geq 1.7$ eV). We identify the ideal energy offset between the hole extraction and the wide bandgap perovskite layers and modulate the anode work function to this ideal using novel halide self-assembled monolayers (SAMs) as interface modifiers. Mixing these SAMs allows for selective tunability of both wettability and work function. Using a two-step SAM-perovskite deposition, we have not found a clear correlation between improved alignment of the SAM-modified ITO-perovskite interface and improved V_{OC} in solar cell devices. However, we found that mixing the SAMs into the perovskite precursor solution using a one-step deposition method improves their solar cell performance. This suggests that interfacial chemistry, including SAM functionalization and SAM interactions with perovskite in solution, may supersede energy alignment as the primary factor currently limiting V_{OC}. Understanding their respective roles will enable the development of efficient wide gap perovskite devices for Si-tandem applications.

5:00 PM EN10.11.07
Efficient and Stable Perovskite Quantum Dot Photovoltaics enabled by Using Dopant-Free Hole Transport Materials with Rigid Segments Seyeong Lim, Sungryong Kim and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)

$CsPbI_3$ perovskite quantum dots (PQDs) with ideal optoelectronic properties offer high thermal stability for photovoltaics. In device fabrication, a ligand exchange process is required to enhance electrical coupling within PQDs. However, this dynamic ligand exchange is imperfectly performed, resulting in surface traps and inevitable exposure of PQDs to external conditions containing H_2O or O_2. So far, most PQD photovoltaics (PQDPVs) have adopted Spiro-OMeTAD as hole transport material (HTM), which requires deliquescent dopants to enhance its hole mobility, resulting in moisture that penetrates the perovskite crystal and greatly accelerates the decomposition of PQDs. In this point of view, hydrophobic HTMs on the PQD surface are crucial for achieving high device stability. Conjugated polymeric HTMs basically have strong molecular packing for efficient charge transport, but excessive intermolecular interactions degrade film-forming properties in perovskite, which causes interfacial nonradiative recombination. In this respect, side chain engineering (e.g., extended-, polar-, and asymmetric-side chains) is developed for optimizing the morphology. Nevertheless, these strategies reduce the charge hopping efficiency. Therefore, in this study, we propose a novel D-A conjugated polymeric HTM design employing unsubstituted rigid segments and fabricate three D-A conjugated polymeric HTMs: Asy-PDTS, Asy-PSDTS, and Asy-PSeDTS. Particularly, Asy-PSeDTS with a rigid segment locally induces strong intermolecular interactions, enhancing the charge hopping efficiency while exhibiting appropriate intermolecular interaction to maintain excellent film-forming properties. Owing to this synergy, Asy-PSeDTS-based PQDPVs achieved 15.2% power conversion efficiency (PCE) and maintained 80% of the initial PCE after 40 days, which is the highest PCE and stability among dopant-free HTM-based PQDPVs so far.

5:00 PM EN10.11.08
Electrochemical Impedance Spectroscopy on Perovskite Inks to Probe Ion Pairing in Solution Keenan W. Wyatt; University of Colorado Boulder, United States

Hybrid perovskite solar cells (PCS) are a disruptive technology with their rapid improvement in power conversion efficiencies over the last decade. At the laboratory scale, solution processed PCSs are studied to inform the eventual commercialization which is likely to use a slot dye coating process. Many steps in the PSC device fabrication process have been optimized, however there is still a lack of understanding of the solution chemistry and chemical species prior to the crystallization and annealing to perovskite phase. During the crystallization, solvent is expelled with the addition of anti-solvent or with a purge of nitrogen. Initially, the ratio of solvent molecules to ions is dominated by the solvent, especially in low concentration solutions. As solvent is driven off, the ratio of solvent molecules to ions begins to be dominated by ions until a solubility limit is reached and precipitate is formed then an eventual crystallization. In the interim, before any precipitation or crystallization, the solution will undergo concentration dependent regions of ion pairing which directly influence the kinetics of crystallization. Here, we use electrochemical impedance spectroscopy (EIS) to probe the ion pairing in different concentrations of perovskite inks and complement our results with pair distroputon function from the total scattering of x-rays.

5:00 PM EN10.11.09
Mechanism of the Anomalous Dependence between Spin–Orbit Coupling and Dimensionality in Lead Halide Perovskites Yeming Xian, Xiaoming Wang and Yanfa Yan; University of Toledo, United States

The spin–orbit coupling (SOC) effect of lead (Pb) atoms is a consequential attribute of the unique optoelectronic and defect properties of lead halide perovskites (LHPs). It has been found that the SOC effect varies significantly as the structural dimensionality changes with an anomalous dependence; i.e., while the SOC strength monotonically decreases as structural dimensionality decreases from three-dimensional (3D) to two-dimensional (2D) and then to one-dimensional (1D), the zero-dimensional (0D) SOC strength is greater than the 1D SOC strength. The underlying mechanism of such a SOC dimensionality dependence anomaly remains elusive. In this work, we show that Pb 6p energy splitting increases from 3D to 2D and to 1D LHPs due to the increased degree of distortion, leading to a reduced SOC strength. However, the degree of distortion decreases for the 1D to 0D transformation, resulting in reverse SOC enhancement. The mechanism described in this work can be employed to regulate the SOC effect in the design of perovskite materials.

5:00 PM EN10.11.10

Understanding the Structure-Property Relationship of Two-Dimensional Metal Halide Perovskites Yumeng Song and Philip Chow; The University of Hong Kong, Hong Kong

Yumeng Song, Philip C.Y. Chow*
Department of Mechanical Engineering, The University of Hong Kong,
Hong Kong SAR, China
pcyc@hku.hk

Two-dimensional (2D) metal halide perovskites have emerged as promising materials for next-generation solar cells and light-emitting diodes thanks to their outstanding optoelectronic properties, facile tunability, and superior stability over their 3D counterparts. However, the detailed structure-property relationship of 2D perovskites underlying their optoelectronic properties has remained unclear. In this project, we design and synthesize a variety of 2D perovskite single crystals, in both Ruddlesden-Popper and Dion-Jacobson phases. We then use a combination of steady-state and time-resolved optical spectroscopy methods to characterize the exciton properties and dynamics, specifically focusing on how they are affected by changes in structural properties. Our results will help us develop a fundamental understanding of 2D perovskites and enable rational material design and development.

SESSION EN10.12: Passivation and Interlayers I
Session Chairs: Virgil Andrei and Hin-Lap Yip
Thursday Morning, April 25, 2024

8:15 AM EN10.12.01
Mitigating Iodine Diffusion by a MoO_3-Organic Composite Hole Transport Layer for Stable Perovskite Solar Cells Jisu Hong[1], Zhaojian Xu[1], Dominique Lungwitz[1], Jonathan Scott[1], Holly Johnson[1], Yun-Hi Kim[2], Antoine Kahn[1] and Barry P. Rand[1]; [1]Princeton University, United States; [2]Gyeongsang National University, Korea (the Republic of)

Halide perovskite solar cells (PSCs) exhibit commercialization potential, but long-term stability still has to be addressed. Among various products of perovskite decomposition, iodine species are of considerable concern due to their high vapor pressure and corrosive nature. To address this, a small-molecule hole transport layer (HTL), 4,4',4"-tris[(3-methylphenyl)phenylamino]triphenylamine (m-MTDATA), is used, and *p*-doped using molybdenum trioxide (MoO_3) to prevent an alternative oxidation reaction with iodine species that are released from iodide perovskites upon degradation. The resulting m-MTDATA:MoO_3 composite HTL demonstrates high conductivity and suppressed iodine permeation. We demonstrate that m-MTDATA:MoO_3 HTLs employed in PSCs improve stability under both thermal and voltage bias stress compared to devices with a conventional doped 2,2',7,7'-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobifluorene (spiro-OMeTAD) HTL.

8:30 AM EN10.12.02
Time-Resolved Electrostatic Force Microscopy Measures Effect of Phosphonic Acid Hole Transport Layers on Lead Halide Perovskite Carrier Dynamics on the Nanoscale Madeleine Breshears, Rajiv Giridharagopal, Justin Pothoof and David S. Ginger; University of Washington, United States

Phosphonic acids hole transport layers (HTLs) demonstrate great promise in improving lead halide perovskite device performance metrics such as open circuit voltage and radiative recombination lifetime. As perovskite thin films exhibit morphological features on the scale of hundreds of nanometers, and carrier dynamic processes on the order of microseconds and below, it is important to investigate the effects of these HTLs at sub-diffraction limited lengthscales with high temporal resolution. Time-resolved electrostatic force microscopy (trEFM) is an atomic force microscopy method that measures photoinduced charging in samples under realistic intensities with sub-microsecond time resolution and nanometer-scale spatial resolution. Here, we use trEFM to investigate the effect of two phosphonic acid HTLs, MeO2PACz and Me4PACz, on carrier dynamics at grains and grain boundaries. We find that phosphonic acid HTLs promote slower dynamics as captured by trEFM, which agrees with bulk carrier lifetime measurements and provides a nanoscale view of charging dynamics. Furthermore, we observe variation in those dynamics across grain boundaries, with grain boundaries exhibiting slower charging compared to grain centers. The microsecond timescales suggest that trEFM measures fast capacitive charging, which may be convolved with carrier trapping, non-radiative recombination, and ion motion. These experiments indicate that trEFM is a powerful tool for probing dynamic processes in perovskites at the nanoscale.

8:45 AM EN10.12.03
Halide Choice is Critical for The Formation of 2D/3D Perovskites and Their Performance in Solar Cells Raphael F. Moral[1,2], Carlo Andrea Riccardo Perini[3], Tim Kodalle[1], Ahyoung Kim[1], Finn Babbe[1], Nao Harada[4], Philip Schulz[5], Naomi S. Ginsberg[6], Ruipeng Li[7], Shaul Aloni[1], Craig Schwartz[2], Juan-Pablo Correa-Baena[3] and Carolin M. Sutter-Fella[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Nevada, Las Vegas, United States; [3]Georgia Institute of Technology, United States; [4]L'Institut Photovoltaïque d'Île-de-France, France; [5]Centre National de la Recherche Scientifique, France; [6]University of California, Berkeley, United States; [7]Brookhaven National Laboratory, United States

2D/3D perovskite solar cells (PSCs) hold great promise for photovoltaics applications.[1] The key to the development of stable and efficient devices is the synergy between the higher ambient stability of 2D phases and the outstanding electrical and optical properties of 3D halide perovskites. These materials also have high versatility in terms of composition, allowing for different material design and engineering strategies.
The vast list of molecules (spacers cations) that can be used for the synthesis of the 2D phases also poses a challenge to the development of these materials.[2] Each of these spacer cation presents a different reactivity with the underlying 3D perovskite, encouraging trial-and-error approaches rather than a rational design of stable 2D/3D interfaces.[3] For example, the choice of the halide anion, both in the spacer cation and in the 3D perovskite, greatly influences materials' photovoltaic and device properties.[4] To provide more insights into the formation and ionic dynamics of these complex interfaces, we examined the impact of halide choice (I and Br) in 3D perovskites treated with phenylethylammonium salts (PEAI and PEABr, respectively).
We evaluated the formation of layered perovskites using PEAI and PEABr salts on top of 3D perovskites with pure iodine and mixed halides, $Cs_{0.17}FA_{0.83}PbI_3$ and $Cs_{0.17}FA_{0.83}PbI_{2.5}Br_{0.5}$, respectively, before, during, and after annealing at 65 °C for 30 minutes. Through various spectroscopic techniques, we revealed that PEABr reacts less readily with the 3D film compared to PEAI to form the 2D phases. As a consequence of this lower reactivity, PEABr can diffuse through the grain boundaries as an ionic pair, and this behavior was revealed by X-ray photoelectron spectroscopy (XPS). Also, the mixed-halide 3D perovskite is less reactive than its pure-iodine counterpart. The lower reactivity of PEABr may be attributed to the higher lattice energy of ammonium bromides in comparison to ammonium iodides,[5] and similar reasoning applies to the mixed-halide 3D perovskite. Consequently, PEAI presents higher passivation ability than PEABr, and the best device performance and reproducibility were achieved with PEAI-treated

$Cs_{0.17}FA_{0.83}PbI_3$. Our work provides valuable insights into the fundamental properties and formation mechanisms of 2D/3D perovskites, which is crucial for advancing these photovoltaic devices.

9:00 AM EN10.12.04
Preventing Metal Shunting in Perovskite Solar Cells during Reverse Bias Daniel A. Morales and Michael McGehee; University of Colorado Boulder, United States

Perovskite solar cells (PSCs) are emerging as promising materials for photovoltaic energy conversion due to their rapidly increasing power conversion efficiencies and cost-effective fabrication procedures. Many research efforts are currently dedicated to investigating external stressors that perovskite solar cells experience in the field – oxygen, elevated temperatures, and moisture/humidity. However, there remains a knowledge gap concerning the behavior of this technology when subjected to another real-world external stressor for solar panels – reverse bias.

PSCs typically exhibit low breakdown voltages in reverse bias (<5V), making the integration of traditional bypass diodes used in Si arrays difficult due to the increased production costs [1] [2]. Therefore, numerous efforts have been made to identify and address the root causes of reverse bias-induced degradation of PSCs. These breakdown mechanisms of PSCs have been directly correlated with voltage-induced ion migration and the formation of hotspots when using metal electrodes [2] [3]. The diffusion of metallic species in PSCs has been recorded during regular operation, but is accelerated under reverse bias conditions as elevated electric fields facilitate ion migration and initiate interactions between mobile ions and metal species at the contacts.

We have studied a wide variety of strategically chosen perovskite solar cells under reverse bias, and we observe the formation of these metallic shunts in PIN architectures with metal electrodes. We employed metals with various electrochemical reactivities (Ag, Au, Cu, & Al) and found that metal shunting is most prominent in silver metal electrodes, one of the most popular contact materials used in perovskite solar cells. Metal diffusion/shunting most-often results in catastrophic failure of the device when returned to normal operating conditions. We attribute this metal shunting behavior to the preferred oxidation state of the metals and the increased activation energy for these metal ions to diffuse through the perovskite device architecture. We show that metal shunting/diffusion in our inverted perovskites can be prevented by simply using higher oxidation-state metals (Au, Cu, & Al). We also investigate the application of interlayer additives, including barrier layers deposited via atomic layer deposition (ALD), chromium (Cr), benzotriazole (BTA), and other chelating agents commonly employed in water treatment facilities to address metal accumulation.

All Inorganic Layer Perovskite Solar Cells Based on Oxide/Halide/Oxide Architecture Soo Woong Jeon, Min Ju Jeong and Jun Hong Noh; Korea University, Korea (the Republic of)

Inorganic $CsPbI_2Br$ perovskite has outstanding thermal stability and substantial potential for semi-transparent solar cells. However, Cesium-based perovskite solar cells (PSCs) exhibit phase instability due to the perovskite film's moisture penetration. Therefore, 2,2′,7,7′-tetrakis(N,N-di-p-methoxyphenylamine)-9,9′-spirobifluorene (spiro-OMeTAD) which has been commonly used as hole transporting layers (HTLs) in high-performance PSCs is not suitable for $CsPbI_2Br$-based PSCs. Herein, we report all inorganic layer PSCs based on oxide/halide/oxide architecture for the high stability and performance of PSCs. We introduced nickel oxide (NiOx) nanoparticles overlayer on the perovskite layer as HTLs. As a result, the all-inorganic layer device shows an improved thermal stability and power conversion efficiency (PCE) of 16.67%. In addition, we fabricated the semi-transparent devices by sputtering the tin-doped indium oxide (ITO) as an electrode, which achieved an average visible transmittance higher than 20%. All inorganic layer PSCs with oxide/halide/oxide also showed superior storage stability without encapsulation under 10% relative humidity, retaining over 85% of initial PCE for 1000 h. We believe that this architecture with n-type oxide/inorganic perovskite/p-type oxide represents a cornerstone for the high stability of PSCs.

9:30 AM EN10.12.06
Irreversible Performance Degradation Driven by Lithium-Ion Migration in $FAPbI_3$ Perovskite Solar Cells Seung-Gu Choi and Jin-Wook Lee; Sungkyunkwan University, Korea (the Republic of)

The typical n-i-p structured perovskite solar cells (PSCs) incorporate 2,2′,7,7′-Tetrakis (N, N-di-p-methoxyphenylamine)-9,9′-spirobifluorene (Spiro-OMeTAD) as a hole transporting material. The chemical doping process of the spiro-OMeTAD involves a redox reaction with bis(trifluoromethane) sulfonimide lithium salt (Li-TFSI) accompanying complex side reactions of which impact on device performance is not fully understood. Here, we investigate correlation between aging dependent device performance of widely used formamidinium lead tri-iodides ($FAPbI_3$) based PSCs and migration of lithium-ion (Li^+) generated from Li-TFSI. The cross-sectional Kelvin probe force microscopy unraveled aging time dependent change in hetero-interface energetics in PSCs, which was correlated with progressive migration of Li^+ ions generated from Li-TFSI confirmed by Time-of-flight secondary ion mass spectroscopy. Comprehensive analysis revealed that the Li^+ migrate from spiro-OMeTAD to perovskite, SnO_2, and their carrier extraction interfaces to induce phase back conversion of α-$FAPbI_3$ to δ-$FAPbI_3$ with local microstrain, and consequent generation and migration of iodine defects and dedoping of the spiro-OMeTAD. The rapid performance drop of PSCs even aging under dark conditions was attributed to a series of these processes. Our work unraveled the hidden side effect of Li^+ ion migration in $FAPbI_3$ based PSCs that can guide further work to maximize the operational stability of the PSCs.

Effective Addition of Cation and halides in $FAPbI_3$ Perovskite Solar Cells by Multiple Thermal Co-EvaporatioH Ha Kyung Park and William Jo; Ewha Womans University, Korea (the Republic of)

Metal halide perovskite solar cells (PSCs) have rapidly advanced as a next-generation solar cells with high efficiency over 25%. Among the various fabrication methods for the perovskite, thermal evaporation stands out as a suitable option for scaling up commercialization. However, achieving precise stoichiometry with multiple sources is challenging when using a co-evaporation method due to their varying volatility. In this study, multiple co-evaporation method was designed to fabricate the stoichiometrically mixed cation and halides PSCs using two sources. Formamidinium iodide (FAI) and lead iodide (PbI_2) were co-evaporated followed by the co-evaporation of methylammonium iodide (MAI) and PbI_2 or methylammonium bromide (MABr) and lead bromide ($PbBr_2$). The deposition rates and thickness of secondly co-evaporated layer were controlled to achieve stoichiometry of mixed cations and halides precursors. After that, samples were annealed to form $FAPbI_3$, $(FA,MA)PbI_3$, and $(FA,MA)Pb(I,Br)_3$ films. The completed PSCs were semi fully-vacuum-deposited, except for the hole transport layer. Among the samples, $(FA,MA)Pb(I,Br)_3$ solar cells showed the highest performance of 11.38% efficiency with improved open-circuit voltage of 25 mV and current-voltage hysteresis. Herein, band gap of MA and Br added $FAPbI_3$ slightly increased indicating only small amount of $MAPbI_3$ and $MAPbBr_3$ phases formed. Still, mixed cations samples showed improved absorbance compared to FA cation only sample. In conclusion, multiple co-evaporation is effective method for mixing cations and halides in PSCs.

10:30 AM EN10.13.01
High Mobility Anthracene-Based Perovskites: Tunable Phase Morphology via GIWAXS Damara G. Dayton[1], Pattarawadee Therdkatanyuphong[1], Junxiang Zhang[1], Yifan Dong[2], Keith P. White[1], Tatiana Temofeeva[3], Kathryn Bairley[1], Michael Toney[1], Seth R. Marder[1] and Matthew C. Beard[2]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States; [3]New Mexico Highlands University, United States

Exploiting the inherent stability of two-dimensional metal halide perovskites (2D MHPs) is a desirable approach to enable scaled production of perovskite solar cells. The addition of a light-absorbing 2D MHP passivation layer promises to address the poor stability plaguing 3D MHPS- degradation induced by ambient moisture, oxygen, and light.[1] Despite recent achievements in this area, the community lacks a consensus of thin film processing controls towards preferential orientation for high photoconductivity in 2D MHPs, nor an understanding of how 2D MHP polymorphism influences charge transport and device efficiency. In this work, an anthracene-based family of spacer cations were used to synthesize two-dimensional MHPs with record-breaking carrier mobility values in the n=1 2D MHP class of materials. The band structures of the anthracene-based family of organic cations are compatible with that of the lead-iodide octahedra, and thus offer desirable charge transport properties due to electronic coupling and wavefunction hybridization.
The position and length of the alkylamine on the anthracene cation greatly influence the film's morphological response when solution processed across a binary solvent system compositional loading series. The polar aprotic solvents NMP and DMF were selected for this study due to their similar properties and common use in the perovskite community. Characteristic trends in photoconductivity and morphology are apparently correlated, unique to each cation. The photoconductivity of these anthracene-based Ruddleston-Popper 2D Lead Iodide MHPs was interrogated with time-resolved Microwave Conductivity (TRMC) and Terahertz Spectroscopy (TRTS). TRTS provides picosecond resolution of charge carrier mobility and diffusion lengths, complementary to the longer nanosecond timescales of carrier lifetimes probed by TRMC. TRMC measures the change in microwave power reflection coefficient from the sample cell relative to a control, from which the conductivity of the sample can be calculated. [2]
From this work, we present record values for mobility and demonstrate correlations between alkylamine local chemistry and solvent interactions, and the photoconductivity of these films to the equilibrium polymorphic phase distribution and degree of orientation of the 2D MHP lamella parallel to the substrate. Grazing Incidence Wide Angle X-ray Scattering (GIWAXS) is an incredibly powerful technique enabling a comprehensive analysis of phase behavior- including octahedral tilting, degree of orientation, phase distribution, crystallinity, strain, static disorder and stacking faults.[3] In addition to this analysis via internally developed programs, we show GIWAXS simulations in agreement with the experimental data utilizing solved single crystal structures for two of the cations. Additionally, the crystallographic space group was determined for a particular cation which was unable to yield a single crystal. Herein, this analysis is used to propose generally applicable processing and design rules for high mobility 2D MHP passivation layers for use in MHP device applications.

10:45 AM EN10.13.02
How The Dynamics of Attachment to The Substrate Influence Stress in Metal Halide Perovskites Gabriel McAndrews[1,2], Boyu Guo[3], Daniel Morales[1], Aram Amassian[3] and Michael D. McGehee[1,1,1]; [1]University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States; [3]North Carolina State University, United States

Metal halide perovskites, hereon referred to perovskites for simplicity, are a promising class of semiconductors eagerly researched for their use in photovoltaic and optoelectronic applications. Despite low fabrication cost and superb initial efficiencies, improvements to the operational stability of perovskites would aid extensive deployment in both terrestrial and space applications. Mechanical stress is an important, but often misunderstood factor impacting chemical and structural degradation as well as reliability during extreme temperature cycling. Tension has been linked to accelerated formation of undesirable PbI_2 which has been attributed to decreased activation energy for ion migration.[1,2] In addition, the brittle nature of polycrystalline metal halide perovskite films leaves them susceptible to fracture and delamination.[3] Therefore, it is crucial to accurately identify and reduce sources of tension that arise from film formation processes and in response to environmental exposure.

The formation of perovskite thin films using solution processing methods usually includes a thermal annealing step to fully convert the film from intermediate to perovskite phases. The field has primarily focused on thermal strain originating from an order of magnitude difference in coefficient of thermal expansion (CTE) between perovskite and substrates used for photovoltaic applications, such as silicon and glass.[2] Consequently, tensile stress is predicted to develop in the perovskite layer while cooling back to room temperature due to the film's constraint to the substrate and inability to fully contract.

Here, we show that a simple application of the CTE mismatch equation inaccurately predicts residual stress in perovskite films. For example, despite similar CTEs, there is a 60 MPa stress difference between narrow bandgap "SnPb Perovskite" ($Cs_{0.25}FA_{0.75}Sn_{0.5}Pb_{0.5}I_3$) and popularized "Triple Cation Perovskite" ($Cs_{0.05}MA_{0.16}FA_{0.79}Pb(I_{0.83}Br_{0.17})_3$). We probe the cause of residual stress variation in metal halide perovskite with a combination of *in situ* absorbance and substrate curvature measurements during the spin coating, anneal, and cooldown procedures. This reveals that the degree of partial attachment prior to the anneal can reduce residual tension following cooldown. Additionally, we demonstrate the dynamic nature of stress in perovskite with evidence of tensile stress relaxation which is accelerated by the presence of moisture and oxygen. In turn, we propose a new framework to understand the relationship between stress and degradation as films with tension are driven to uptake moisture and oxygen to release stress. Finally, we present a critical perspective on stress engineering strategies based on high CTE buffer or interlayers which are claimed to modify thermal stress in the perovskite.[4] We show that these strategies are not grounded in thin-film mechanics as the stress in the perovskite in response to temperature changes is dominated by the thickest, stiffest layer, such as glass.

Suppressing Trap-Assisted Recombination in Perovskite Solar Cells via Strain Relaxation Beier Hu; Imperial College London, United Kingdom

Intraband trap states can be formed unavoidably during the solution-processed fabrication of perovskite solar cells (PeSCs). Their existence contributes to non-radiative recombination loss via trap-assisted recombination pathways in PeSCs, leading to insufficient power conversion as well as a higherIntraband trap states can be formed unavoidably during the solution-processed fabrication of perovskite solar cells (PeSCs). Their existence contributes to non-radiative recombination loss via trap-assisted recombination pathways in PeSCs, leading to insufficient power conversion as well as a higher probability of lattice decomposition. Particularly, regarding the soft nature of perovskites, one should consider the impact of local lattice strain on the properties of trap states. However, the relationship between strain and trap-assisted recombination has not been disclosed systematically and comprehensively.

Herein, we fabricated two perovskite films with different strain levels, i.e., $MA_{0.95}GA_{0.05}PbI_3$ with tensile strain and $MA_{0.95}GA_{0.05}Pb(I_{0.95}Br_{0.05})_3$ with free strain due to the compensation of the smaller-size Br towards the expanded lattice. To access the critical factors that affect the trap-assisted recombination including the number of traps, depth of traps, and lifetime of trapped carriers, we employed the advanced visible-pump-IR-push photocurrent spectroscopy (PPPc) on devices based on the aforementioned perovskite films with and without strain. PPPc is a highly selective technique for observing localized state behaviours of PeSCs under operational conditions, to display a full scenario of the regulated trapped carrier dynamics after strain manipulation. Steady-state and time-resolved PPPc measurements evidenced that the strain relaxation was able to reduce the density of traps, shallow the depth of traps, and prolong the lifetime of trapped carriers, alleviating the trap-assisted recombination loss in the strain-free device. To the best of our knowledge, this is the first report which provides an explicit correlation between strain engineering and its impacts on the overall trap-assisted recombination processes.

11:15 AM EN10.13.04
Lattice Volume Anchoring Attenuates Natural Performance Loss in Perovskite Solar Cells during Day/Night Cycling Tiankai Zhang and Feng Gao; Linköping University, Sweden

It is commonly believed that perovskite solar cells (pero-SCs) show enhanced stability under day/night cycling due to reported self-healing effect in the dark. However, it is discovered that the operational lifetime of highly efficient FAPbI3 pero-SCs is in fact much shorter under day/night cycling mode, being into question the widely accepted approach to estimate the pero-SCs' operational lifetime based on continuous mode testing. We reveal the key factor to be the lattice volume change during the operation, an effect which gradually relaxes under the continuous illumination mode but cycles synchronously under the cycling mode. The cycled lattice volume change results in plastic deformation and deep trap accumulation during operation, decreasing the ion migration potential and hence the lifetime under the cycling mode. To address the challenges induced by the synchronously cycled lattice volume, we introduce Ph-Se-Cl to stabilize the perovskite lattice during day/night cycling. As a result, the pero-SCs achieved the certified efficiency of 25.6% and a 10-time improved T80 lifetime under the cycling mode (ISOS-LC-2 suggested protocol) after the modification. Our results uncover the unique degradation mechanism caused by the cycling mode and highlight the necessity of lattice volume fixing to prolong the real working lifetime of pero-SCs.

11:30 AM EN10.13.05
Advancing Perovskite Single Crystal Fabrication: Enhanced Crystallinity and Reproducibility through Feedback Control of Linear Growth Rate Yuki Haruta, Antoine Pavesic Junior and Makhsud Saidaminov; University of Victoria, Canada

Lead halide perovskites have gained significant attention in recent years thanks to their excellent photon absorption capabilities and charge transport properties, raising high expectations for diverse device applications such as solar cells and X-ray detectors. However, their instability presents a major challenge that demands resolution. Notably, perovskite single crystals are known to exhibit substantially higher durability compared to polycrystalline films, with an even higher degree of crystallinity suggesting enhanced stability. Nevertheless, conventional methods for synthesizing perovskite single crystals have often been relatively straightforward, yet challenging to consistently produce high-quality single crystals.
In light of this, our research focused on controlling the linear growth rate of the single crystals which has been likely overlooked in the conventional methods. Methylammonium lead tribromide ($MAPbBr_3$) single crystals are fabricated as a case study. Our novel approach combines in-situ imaging techniques to monitor crystal growth rates with a conventional solvent evaporation method. When the crystal growth deviates from the desired rate, our system provides feedback to adjust growth conditions accordingly. Through this approach, we successfully maintain a constant linear growth rate for over 60 hours, leading to the reproducible synthesis of single crystals with enhanced crystallinity.
The degree of crystallinity is quantified by measuring the rocking curves of the (100) plane of the obtained $MAPbBr_3$ single crystals. This work uncovers the critical role of controlling the linear growth rate, rather than the mass growth rate, in achieving superior crystallinity and reproducibility. $MAPbBr_3$ single crystals grown with a linear growth rate of less than 0.3 mm h^{-1} exhibit narrow rocking curves, with a full width at half maximum (FWHM) of 19.0±2.7 arcsecs (n=17), while growth rates exceeding 0.3 mm h^{-1} results in a FWHM of 27.9±10.0 arcsecs (n=15). The best crystal achieves a remarkable FWHM of 15.3 arcsecs, the narrowest reported for $MAPbBr_3$ single crystals, comparable to a commercial silicon wafer. Note that these excellent FWHM are achieved with centimeter-scale single crystals. This research emphasizes the pivotal importance of linear growth rate control in single crystal growth.

11:45 AM EN10.13.06
Slow Spontaneous Enhancement in Efficiencies of Single-Crystal Metal Halide Perovskite Solar Cells Vishal Yeddu[1], Parinaz Moazzezi[1], Bekir Turedi[2,2], Muhammad N. Lintangpradipto[2,2], Dongyang Zhang[1], Soumya Kundu[1], Deepak Thrithamarassery Gangadharan[1], Reuven Gordon[1], Osman M. Bakr[2,2] and Makhsud Saidaminov[1,1,1]; [1]University of Victoria, Canada; [2]King Abdullah University of Science and Technology, Saudi Arabia

Perovskite solar cells exhibit an interesting phenomenon known as spontaneous efficiency enhancement (SEE), where their efficiencies gradually improves over a few days. Numerous mechanisms have been proposed to explain this behavior in polycrystalline perovskite solar cells. However, investigations into such phenomena have not been extended to single-crystal perovskite solar cells (SC-PSCs). In this presentation, we present our findings of a relatively slow (approximately 20 days) SEE in single crystal methylammonium lead iodide perovskite solar cells. We show that the average PCE of SC-PSCs increases by at least 50% upon storage in an inert atmosphere for two weeks.
Our studies have revealed that SEE in SC-PSCs can be attributed to the slow escape of solvent trapped by the perovskite single-crystal thin films. We have demonstrated that SEE can be significantly accelerated through a heat treatment of at 40 °C. This work provides a ground for fast-tracking the progress of single-crystal perovskite solar cells.

1:30 PM EN10.14.01
Perovskite Nanocrystals for Down Conversion Displays and AR/VR Application Tae-Woo Lee[1,2]; [1]SN Display, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Colloidal perovskites nanocrystals (PeNCs) have been proven to possess high color purity (FWHM ~ 20 nm), high photoluminescence quantum yield (PLQY) and low-cost solution processability, making them promising candidates for the next generation light emitters. However, poor stability and the potential toxicity issues arising from lead leakage have hindered the commercialization of PeNCs. Furthermore, light-induced halide segregation limits the spectral stability of red and blue perovskite nano crystals, restricting their spectral tunability.
Here, first of all, we have developed ultra-stable and bright PeNCs by constructing a multi-layer structure. The multi-layer structure improved aging stability under 60 oC and 90% relative humidity condition and the photostability. Furthermore, this structure successfully prevents the leakage of lead, significantly reducing the toxicity of the nanocrystal film. Secondly, we have developed polymer matrix to improve stability of PeNC film. The polymer matrix successfully prevents degradation of PeNC by external condition and halide, leading to stable PeNC down conversion films with long lifetime under 60 oC and 90% relative humidity condition and under high flux (100 mW/cm2). With efficient and stable PeNC down conversion film, we successfully demonstrated a 28-inch monitor and a 10.1-inch tablet that surpasses existing products in terms of vivid images, achieving Rec. 2020 over 95%. Our work sheds great light on the potential that PeNCs can be commercialized in the near future.

1:45 PM EN10.14.02
Trap-Free Field Effect Transistors based on Epitaxial Single-Crystal Perovskites Vladimir V. Bruevich and Vitaly Podzorov; Rutgers University Physics Department, United States

Lead-halide perovskites have emerged as important semiconducting materials suitable for a variety of optoelectronic applications. Further advances in the field will rely on establishing the basic properties of these materials. We report the first experimental realization of the *intrinsic* (not dominated by defects) charge conduction regime in metal-halide perovskite field-effect transistors (FETs). The advance has been enabled by: i) a new vapor-phase epitaxy technique that results in large-area single crystalline all-inorganic cesium lead bromide ($CsPbBr_3$) films with excellent structural and surface properties, including atomically-flat surface morphology, essentially free from defects and traps at the level relevant to device operation; ii) an extensive materials analysis of these films using a variety of thin film and surface probes certifying the chemical and structural quality of the material; iii) the fabrication of nearly ideal (trap-free) FETs with textbook FET characteristics superior to any reported to date. These devices have allowed the investigation of the intrinsic carrier mobility as a function of temperature via both FET and gated Hall-effect measurements. The intrinsic mobility of our $CsPbBr_3$ FETs was found to increase on cooling from ~ 30 $cm^2V^{-1}s^{-1}$ at room temperature to ~ 250 $cm^2V^{-1}s^{-1}$ at 50 K. The combination of photo-Hall, gated Hall, and FET measurements reveal the intrinsic band transport occurring in these devices, with the mobility limited only by phonon scattering. The outstanding quality of these devices is largely due to the atomically flat, single crystalline morphology of the epitaxial $CsPbBr_3$ films achieved over macroscopic length scales, as confirmed by comprehensive structural, morphological and surface analysis.
The epitaxial $CsPbBr_3$ FETs exhibit no degradation over a long-term storage in air (as tested for up to several months) or during extended electric measurements (that sometimes run for several weeks on end), with the exceptions of driving the FETs into a saturation regime or micro crack formation at low temperatures. While the encapsulation of the perovskite in parylene may have contributed to the excellent operational stability of our FETs, our as-grown uncoated perovskite films did not exhibit noticeable degradation during a prolonged storage in the regular laboratory air (ranging in duration from days to weeks).
Establishing the intrinsic (phonon-scattering limited) mobility can not only serve as a rigorous test for theoretical models of carrier transport but can also reveal the ultimate fundamental limits of mobility in these materials, as well as point to a path for future innovation to still newer and improved perovskite systems. Additionally, our findings suggest that epitaxial perovskites offer an ideal platform for fundamental studies on charge transport in this class of materials. The robust, simple, and effective method for fabricating perovskite FETs that exhibit stable and ultimately efficient intrinsic charge transport paves a way for a plethora of new perovskite-based devices, such as light emitting FETs, electrically pumped injection lasers, better radiation detectors, sensors and memories.

2:00 PM EN10.14.03
High-Resolution Multicolor Transfer Printing of Perovskite Nanocrystals for Ultrathin Skin-Attachable Displays. Gwang Heon Lee[1], Jong Ik Kwon[1], Gyuri Park[2], Jae Hong Jang[1], Jiwoong Yang[2] and Moon Kee Choi[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Over the past decade, the development of wearable displays with ultrahigh definition has garnered considerable attention in the information technology. Wearable displays exhibit mechanical deformability, allowing them to conformally attach to various objects with curvilinear surfaces. Technological advances to achieve deformable form factors enable mechanical changes such as bending, rolling, and twisting. In parallel to the advanced at form factors, high-definition red/green/blue (RGB) subpixels are crucial for visualizing diverse information on the compact screens of wearable displays. Despite the recent advancements in display technology, the development of high-definition full-color wearable light-emitting diodes (LEDs) remain an unresolved problem.
Metal halide perovskite have gained attention as promising light-emitting substances due to their narrow full-width half-maximum, high photoluminescence, and color tunability. Furthermore, the extremely thin construction of perovskite light-emitting diode (PeLEDs) (<1 μm, excluding the thickness of the substrate) make them highly promising for candidates for application to ultrathin and deformable displays. With recent advances in synthesis and device engineering, progress in this field has led to impressive external quantum efficiency (EQE) values, with red, green, and blue PeLEDs achieving 25.8%, 28.9%, and 18%, respectively. Most previous studies predominantly centered on optimizing PeLED performance via monochromatic perovskite nanocrystal (PeNC) films produced by spin-coating techniques. However, manufacturing full-color displays on the commercial scale requires the development of patterning methods to ensure the seamless integration of RGB subpixels within electroluminescent (EL) devices.
Conceptually, the RGB patterning of PeNCs have several requirements : 1) Preservation of device layer integrity and no contamination during the patterning process 2) high reproducibility and 3) high-resolution patterning capabilities, particularly at the sub-micrometer scale. Unfortunately, conventional patterning methods (e.g., photolithography and inkjet printing) of perovskite materials are unsuitable for the fabrication of highly efficient PeLEDs. Photolithography suffer from the degradation of perovskite materials by ultraviolet(UV) light , moisture and polar solvents, owing to their ionic

bonding nature. Ink jet printing is applicable to multicolor pixelation of PeNCs through additive patterning. However, the additives (i.e., polymer matrix, surfactant, and viscosity modifier) suppress the EL device performance. Dry transfer printing employing a viscoelastic stamp represents a strategic choice for producing high-definition PeNC pixels for EL devices. This method circumvents the use of wet chemicals, mitigating concerns about solvent compatibility and cross-contamination between different colored pixels. Nonetheless, this approach has seen limited application in the case of PeNCs. The low interaction energy among PeNCs can lead to internal film cracking during the transfer process
Here, we demonstrate high-resolution dry transfer printing for ultrathin wearable displays. Specifically, we employ a simple and effective double-layer transfer printing method with an additional organic layer between PeNCs and a poly(dimethylsiloxane) (PDMS) stamp. The organic layer serves to prevent internal cracks in the transferred PeNCs layer. Furthermore, the pressure applied during the transfer printing process reduces the interparticle distance in the transfer-printed PeNCs layer, enabling the highly efficient PeLEDs, which exhibit peak EQE of 15.3%, 14.8%, and 2.5% for red, green, and blue PeLEDs, respectively. Finally, we demonstrate ultrathin, skin-attachable PeLEDs based on this patterning method. The realization of high-resolution RGB patterns using double-layer transfer printing may open up unique opportunities for wearable displays with various form factors.

Halide Perovskites as Thermoelectric Materials Oliver Fenwick; Queen Mary University of London, United Kingdom

Halide perovskites are well known as promising candidates for photovoltaics and light-emitting diodes. Additionally, promising thermoelectric performance has been reported for a small number a halide perovskites, with this class of materials offering ultralow thermal conductivity, good Seebeck coefficients and potential advantages in processing and sustainability. However, there is not yet a good understanding of how thermoelectric performance of halide perovskites can be optimised. This talk will cover the origins of ultralow thermal conductivity and quanitfy both the Lorenz number and the thermal boundary resistance [3] in polycrystalline films. Extrinsic doping and self-doping will be discussed as methods to optimise the thermoelectric figure of merit zT, with values of zT reaching 0.14 in $CsSnI_3$ [2] The case of self-doping by Sn-oxidation in $CsSnI_3$ will be examined in detail and strategies to improve performance and control the rate of oxidation by modification of deposition procedures, or by using mixed halide and mixed metal stoichiometries will be presented. Thin-film vapour deposition, single crystal growth [1] and solid-state synthesis of pellets will be discussed, along with doping techniques to improve stability and conductivity.

A Molecular Clamp Approach to Layered Halide Perovskite Nanowires Wenhao Shao, Jeong Hui Kim and Letian Dou; Purdue University, United States

Layered materials can be exfoliated into atomically thin 2D sheets or further fragmented into quantum dots, forming the foundation of numerous technology breakthroughs since the discovery of graphene. However, achieving 1D nanostructures from these materials with inherent in-plane symmetry remains a demanding yet rewarding endeavor. To date, only a few material-specific top-down methods exist, such as creating 1D nanoribbons of graphene and transition metal dichalcogenides through physical or chemical etching and unzipping from carbon nanotubes. The pursuit for a simpler and more universal bottom-up approaches with superior tunability, scalability, and capabilities to create precise and complex epitaxial structures therefore continues, necessitating a fundamental redesign of the crystal growth mechanism.

Here, we addressed this demand using organic-inorganic hybrid layered perovskites as a model system. Distinct from inorganic layered materials, hybrid semiconductors allow the incorporation of tailor-designed organic spacers with directional supramolecular synthons that communicate beyond single-molecule level. In this regard, a new “molecular clamp” approach is proposed to restrict crystal growth along all crystallographic directions except for [110] and thus to regulate 1D nanowire growth. Our approach is widely applicable to synthesize a range of high-quality 2D perovskite nanowires with large aspect ratios and tunable chemical compositions. These nanowires form exceptionally well-defined and flexible cavities that exhibit versatile unusual optical properties beyond conventional perovskite nanowires including anisotropic emission polarization, low-loss waveguiding (below 3 dB/mm), and efficient low-threshold light-amplification (below 20 $\mu J/cm^2$). Our approach highlights the unique structural tunability of organic-inorganic hybrid semiconducting materials by synergizing the merits of each, which also brings unprecedented morphological control to layered materials.

2:45 PM EN10.14.06
Degradation Mechanism of Colloidal Perovskite Nanocrystals and its Stabilization Strategy Qingsen Zeng, Huanyu Zhou and Tae-Woo Lee; Seoul National University, Korea (the Republic of)

The commercialization of colloidal perovskite nanocrystals (PeNCs) has been impeded by their rapid degradation in response to environmental factors and potential toxicity concerns due to lead leakage. Furthermore, the spectral stability of red-emitting and blue-emitting PeNCs is limited by light-induced halide segregation, restricting their spectral tunability.
Herein, we present a novel approach to address these issues. We have developed a facile and versatile method based on hierarchical confinement, involving the construction of a multi-layered structure. This technique facilitates the fabrication of CsPbBr3 PeNC films with a photoluminescence quantum yield (PLQY) exceeding 84%. Importantly, the hierarchical confinement method significantly enhances the aging stability of $CsPbBr_3$ PeNCs, extending their operational lifetime at 60°C and 90% relative humidity and under blue light irradiation to 3400 hours and over 6000 hours, respectively. Moreover, this hierarchical confinement strategy proves to be versatile, effectively stabilizing mixed halide perovskite lattices, thereby suppressing halide segregation in mixed halide red-emitting PeNC films (QY: 83%) and blue-emitting PeNC films (QY: 40%) for 800 hours and 500 hours, respectively.
Most importantly, the hierarchical confined structure successfully prevents the leakage of lead ions, mitigating the toxicity concerns associated with the PeNC film material. Consequently, these findings render the PeNCs biocompatible, paving the way for their utilization in wearable devices and virtual/augmented reality display applications in the future.

Light Emission from Localization in Halide Perovskites – Composition, Doping, Dimensionality Sascha Feldmann; Harvard University, United States

Halide perovskites are fascinating semiconductors for light-emitting applications. Compared to conventional inorganic covalent semiconductors like silicon or GaAs, perovskites are structurally soft and often more disordered. Understanding the consequences of this remains a key challenge for commercialization.
Here I will present our recent mechanistic insights from spectroscopy on the role of composition, doping and dimensionality to control light emission through localization in these materials, including the introduction of a new method of doping halide perovskites at room temperature and its impact on excitation dynamics.

4:00 PM EN10.15.02
Tailoring The Optoelectronic Properties of Tin-Based Perovskite Light-Emitting Diodes Ece Aktas; University of Naples Federico II, Italy

Two-dimensional perovskite thin films have shown tremendous potential as active materials for light-emitting diode (LED) applications, thanks to their remarkable optoelectronic properties and high environmental stability compared to their three-dimensional counterparts. However, achieving precise control over their composition and morphology remains a significant challenge. To overcome these issues, a strong coordinating agent, several functionalized bulky cations, and an increasing number of precursor materials have been applied. In this study, we investigate the influence of additives on the growth and performance of 2D tin-based perovskite thin films in nonoxidative solvent. We employed advanced characterization techniques such as UV-Vis absorption spectroscopy, X-ray diffraction, scanning electron microscopy, and photoluminescence spectroscopy to understand its effect. By systematically varying the processing parameters, including the amount of additive and the deposition conditions, we gain insights into the underlying mechanisms governing the film formation and properties. As a result, the 2D tin-based perovskite LED device had a low turn-on voltage of 1.75 V, and a maximum external quantum efficiency of ~2.2% in a nonoxidative solvent. The optimized thin film compositions and processing conditions from this research will facilitate the development of good-performance tin-based perovskite LEDs with enhanced external quantum efficiency, stability, and color purity. Furthermore, this work will contribute to the advancement of additive engineering strategies for the scalable fabrication of perovskite-based LEDs, fostering their integration into next-generation solid-state lighting technologies.

4:15 PM EN10.15.03
How Pinholes in Perovskite Films Create Stealthy ETL-HTL Diodes that Slightly Reduce Efficiency and Dramatically Enhance Reverse Bias Shunting Samuel A. Johnson and Michael D. McGehee; University of Colorado, Boulder, United States

Solution processing metal halide perovskites has advantages for scaling up manufacturing, but reproducibility and reliability are complicated by physics dictating coating (e.g. surface tension and dewetting). Void defects and pinholes form via tension created by volume reduction during the drying phase. We systematically investigate the origin and impacts of ‘void defects’ and reveal five common defect formation mechanisms that can result in points where the intrinsic perovskite absorber is missing. At most of these sites, metal- electron transport material (ETM) -hole transport material (HTM)- metal diodes exist. We determined how much current can pass through these defect diodes by making diodes without the perovskite layer and measuring the current-voltage curve. We found that the current turned on between 0.4 and 0.8 V depending on which contact layers we used. Dark Lock-in Thermography (DLIT) of a perovskite solar cell shows localized regions begin to heat under forward bias, but only above the turn-on voltage of transport-layer diodes indicating diode-like defect response in real devices. An important consequence of this behavior is that the defect diodes do not pass current near 0 V where the shunt resistance is typically measured by taking the slope of the current-voltage curve. They do, however, pass significant current at the maximum power point and the open circuit voltage. Consequently, they have a more detrimental effect on device performance than most people realize. These defects have even more important consequences when the cells are operated in reverse bias, which can happen when a panel is partially shaded. These defects enable break down at lower voltages and shunt current, resulting in local ohmic heating, followed by the melting and propagation of burning metal shunts across the surface. This effect produces catastrophic degradation of the solar module. It is therefore critical to mitigate such defects for widespread implementation of perovskite PV. We demonstrate optical profilometry and PL-mapping as high-throughput detection methods for these defects as well as improved particle control and solution wetting as possible preventative measures. Elimination or passivation of these defects will prevent localized loss and enhance long-term reliability of perovskite solar cells, paving the way for successful commercial perovskite solar cell production.

4:30 PM EN10.15.04
Bismuth: An Infrared-Emitting, Deep-Level Trap in $CsPbBr_3$ Kyle Sendgikoski[1], Brendon T. Jones[2], Michael H. Stewart[1], Barbara A. Marcheschi[1], Todd H. Brintlinger[1], John Lyons[1] and Sarah Brittman[1]; [1]U. S. Naval Research Laboratory, United States; [2]Florida State University, United States

Halide perovskites have already demonstrated impressive optoelectronic performance in applications ranging from photovoltaics, to light-emitting diodes and lasers, to X-ray and gamma-ray detectors and scintillators. Understanding how extrinsic dopants behave in this class of materials is a critical next step to gaining greater control over the stability and performance of this versatile class of materials.

While Bi^{3+} was originally proposed as a potential n-type dopant in lead halide perovskites, experiments and theory clearly demonstrate that it is a deep-level trap that gives rise to broad near-infrared emission. We synthesized a series of crystals of $CsPbBr_3$ doped with Bi content ranging from 0.01 to 0.32 atomic percent, as quantified by inductively coupled plasma optical emission spectroscopy (ICP-OES). The absorption edge shifts redder with Bi incorporation, but density function theory (DFT) calculations show that this increased absorption comes from the electronic structure of Bi as a deep-level trap, not from a shift in the $CsPbBr_3$ band edge. Indeed, all doped crystals emit both narrow band-edge (2.37 eV) and broad defect-level (1.12 eV) photoluminescence at room temperature, consistent with our theoretical prediction. We also apply STEM-EDS to the most heavily doped samples to characterize the spatial uniformity of the Bi incorporation within the $CsPbBr_3$ crystals. Our combined results demonstrate the power of current theoretical approaches to predict defect behavior in halide perovskites, which will be invaluable in guiding the development of these materials.

4:45 PM EN10.15.05
Photoluminescence Enhancement of Perovskite Quantum Dot@Polymer Nanocomposite via Silver Epoxy Paste Treatment for Time-And Environment-Dependent Optical Encryption Jaehyeok Ryu, Jiyeon Lee, Dongjun Kim and Jiwon Kim; Yonsei University, Korea (the Republic of)

In an increasingly digital and interconnected world, advanced information encryption techniques became imperative for ensuring the confidentiality,

integrity, and availability of data. The integration of perovskite quantum dots (PQDs) with polymers has garnered considerable attention in the field of optical encryption for their eminent photoluminescence (PL) property and improved stability. Herein, we have designed a time- and environment-dependent optical encryption/decryption method based on the PL enhancement of $CsPbBr_3$ QD/polydimethylsiloxane (PDMS) nanocomposite film using a conductive Ag epoxy paste. Ag epoxy paste treatment was conducted by a thermal treatment subsequent to applying the Ag epoxy paste on the surface of nanocomposite film, followed by the removal of cured paste with ease. The Ag^+ ions from the Ag epoxy paste diffuse into the PDMS matrix and passivate the surface defects of $CsPbBr_3$ QDs, resulting in enhanced PL properties (*e.g.*, intensity, lifetime, PL quantum yield (PLQY)) of the nanocomposite film. In order to enhance the image contrast for an optical encryption, surface defects have further been generated by ligand purification of $CsPbBr_3$ QDs during the synthesis of nanocomposite film. By controlling the treatment duration and external environment, Ag epoxy paste treatment was utilized as a time-dependent information encryption/decryption method via regulation of the PL intensity. Specifically, an encrypted information was initially concealed under daylight and disguised by a fake information under UV light, which was decrypted over time owing to the differences in the degradation rates of PQDs. Once the information had been confirmed by an intended receiver, the leakage of information was further avoided with a subsequent water immersion, in which the decrypted information permanently reverts to the initial fake information via PL intensity inversion between treated and untreated region. In this work, we propose novel applications of commercially available Ag epoxy paste as a method for surface defects passivation in PQDs embedded in polymer matrix and as a strategy for optical encryption/decryption, providing a high level of security with multiple encryption states and a straightforward decryption.

Beginner's Guide to Visual Analysis of Perovskite and Organic Solar Cell Current Density-Voltage Characteristics Albert These[1,2]; [1]Institute Materials for Electronics and Energy Technology, Germany; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The current density-voltage characteristic (JV) is a critical tool for understanding the behaviour of solar cells. In this poster, I will present an overview of the key aspects of JV analysis and introduce a user-friendly flowchart that facilitates the swift identification of the most probable limiting process in a solar cell, based mainly on the outcomes of light-intensity-dependent JV measurements. The flowchart was developed through extensive drift-diffusion simulations and a rigorous review of the literature, with a specific focus on perovskite and organic solar cells. Moreover, the flowchart proposes supplementary experiments that can be conducted to obtain a more precise prediction of the primary performance losses. It therefore serves as an optimal starting point to analyse performance losses of solar cells.

5:00 PM EN10.16.02
Grain-Boundary Grooves in Perovskite Solar Cells Mingwei Hao[1] and Yuanyuan Zhou[2]; [1]Hong Kong Baptist University, Hong Kong; [2]The Hong Kong University of Science and Technology, Hong Kong

Metal halide perovskites (MHPs) have shown great potential as light absorbers in solar cells, achieving high power conversion efficiencies and approaching industrialization standards. In order to fully harness the capabilities of MHPs, it is imperative to delve deeper into the understanding of their microstructural characteristics and provide valuable insights into the properties, performance, and stability of MHPs, paving the way for advancements in material design, device engineering, and fabrication techniques. Here, we introduce a typical microstructure referred to as the grain boundary groove. We provide a detailed examination of its formation, the influence of it, and various approaches for its control. By studying this microstructural characteristic, we aim to offer a fresh perspective and contribute to the understanding of perovskite microstructures and their influences.

5:00 PM EN10.16.03
Investigation of Interface Engineering for High-Performance All-Inorganic Cs-Based Perovskite Solar Cells Gaukhar Nigmetova[1], Gulzhan Zhumadil[1], Menghua Cao[2], Yu Han[2], Zhuldyz Yelzhanova[1], Vladimir Pavlenko[1], Hryhorii Parkhomenko[1], Marat Kaikanov[1], Mannix Balanay[1], Askhat J.[1], Gang Li[2], Zhiwei Ren[2] and Annie Ng[1]; [1]Nazarbayev University, Kazakhstan; [2]The Hong Kong Polytechnic University, Hong Kong

The halide perovskite solar cells (PSCs) have emerged as a promising photovoltaic technology for the generation of cost-effective renewable energy. Over the past decade, a significant progress has been made in improving the power conversion efficiency (PCE) and stability of PSCs. Among the various types of PSCs, all-inorganic $CsPbI_2Br$ PSCs have recently garnered increasing attention due to their excellent thermal stability and promising photovoltaic properties, with a bandgap size suitable for efficient light harvesting, particularly in short-wavelength portion for tandem device applications.

This work focuses on investigating interface engineering techniques to further enhance the performance of all-inorganic cesium-based PSCs in ambient and protonated irradiation condition. The first technique involves the growth of two-dimensional (2D) Ruddlesden-Popper mixed halide perovskite nanostructures on the surface of $CsPbI_2Br$. The deposition of Cs_2PbX_4 (where X=I and Br) requires precise processing conditions, allowing for good control of the Cs_2PbX_4 morphology. This controlled growth of 2D nanostrucutres improves the interface quality between the perovskite layer and the hole transport layer, thereby enhancing charge transport properties. Consequently, a significant enhancement in the PCE and device stability can be achieved. The impact of incorporating an ionic liquid (IL) in the bulk of $CsPbI_2Br$ perovskite is also investigated. Experimental results demonstrate that the use of [EMIM+][PF6-] IL promotes the formation of highly crystalline perovskite thin films, leading to a reduction in the defect density of the perovskite material. This reduction in defects improves carrier recombination processes, resulting in enhanced PCE and stability of the devices under harsh ambient conditions.

Through systematic optimization processes of interface engineering, a PCE above 17% can be achieved, accompanied by a significant improvement in the device lifetime. To understand the underlying mechanisms of these interface engineering techniques, comprehensive experimental characterizations were conducted. These characterizations include analyzing the morphology, crystal structure, carrier transport dynamics, and recombination processes etc. The results obtained from this work provide valuable insights into the effectiveness of interface engineering strategies for all-inorganic Cs-based perovskite materials, contributing to the advancement of this type of PSCs in the community.

5:00 PM EN10.16.04
Trap Density and Energy States in Organic-Inorganic Halide Perovskite Thin Films: A Study of Thickness Variations Using Drive Level

Capacitance Profiling and Admittance Spectroscopy JaeGwan Sin[1], Jaeho Kim[1], Gisung Kim[1], Mijung Kim[1], Moonhoe Kim[1], Hyojung Kim[1,2] and Jung Yup Yang[1]; [1]Kunsan National University, Korea (the Republic of); [2]The Institute of Basic Science, Korea (the Republic of)

Recently, organic-inorganic halide perovskite (OIHP) materials have gained significant prominence in various applications, especially in renewable energy and semiconductor technology, such as photovoltaic and thin film transistor (TFT) devices. Thickness of the OIHP film is an important factor in determining device characteristics. For example, an OHIP thin film thickness of approximately 30 nm must be achieved in order to achieve optimal on/off ratios and high mobility for TFT devices. Despite its critical importance, the relationship between halide perovskite film thickness and trap density has not been comprehensively explored. In this research, drive-level capacitance profiling (DLCP) and temperature derivative admittance spectroscopy (TAS) were used to investigate changes in trap energy and density depending on the thickness of the OHIP film. The DLCP and TAS methods were employed to explore the intricate relationship between OHIP film thickness and trap characteristics, providing insights into their effects on charge transfer dynamics and overall stability. From the DLCP and TAS analysis, it was observed that as the OHIP film thickness decreases, the trap density rapidly increases from $10^{15}/cm^3$ to $10^{17}/cm^3$ at the 0.35 eV trap energy level, due to the increasing influence of the interface caused by the reduction in OHIP film thickness. The defect energy level of 0.35 eV appears as an iodine interstitial defect, and we were able to improve device performances by applying an interface passivation process to remove iodine interstitial defects. We believe that this study provides a detailed analysis of the complex relationship between OHIP film thickness and trap states and can provide key research directions for OHIP-based photovoltaic and semiconductor devices and provide guidance for device optimization.

5:00 PM EN10.16.05
Damage-Free Process of Metal Electrode Using Plasma-Assisted Vapor Deposition for Halide Perovskite Devices Gisung Kim[1,2], Mijung Kim[2], JaeGwan Sin[2], Hyojung Kim[3], Kang-il Lee[1], Yongsup Choi[1] and Jung Yup Yang[2,3]; [1]Korea Institute of Fusion Energy, Korea (the Republic of); [2]Kunsan National University, Korea (the Republic of); [3]The Institute of Basic Science, Korea (the Republic of)

In response to fossil fuel depletion and global warming, research and development of new and renewable energy are recognized as crucial tasks worldwide. Solar cells, which utilize unlimited solar energy to generate electricity in an environmentally friendly manner, are at the forefront of new renewable energy technologies. Next-generation perovskite solar cells have emerged as promising candidates, owing to their cost-effectiveness and simplified low-temperature processes. The structure of a perovskite solar cell typically consists of glass/transparent electrode/electron transport layer/perovskite (light absorption layer)/hole transport layer (HTL)/metal electrode. The HTL, predominantly composed of organic materials like Spiro-OMeTAD, PTAA, and P3HT, etc. is susceptible to plasma damage when metal electrodes are formed using the commonly employed vacuum physical vapor deposition (PVD) method, limiting its utility. Although the thermal evaporation method is employed in the metallization process, it also carries the disadvantage of uneven metal particle deposition, resulting in reduced transparency and conductivity of the thin film. To overcome these challenges, this research focuses on fabricating perovskite solar cells with high-quality and damage-free metal electrode deposition on organic materials using plasma-assisted vapor deposition (PAVD). Unlike conventional methods, PAVD technology does not require heating the substrate to enhance the thin film. Instead, it converts the interior of the thermal evaporation source into a plasma state, thereby transforming the metal particles into a high-energy state. As a result, the metal particles firmly bond to the substrate without the need for additional energy, like heat. This process results in the formation of high-quality and low-resistance metal thin films. The morphology, structure, and electrical characteristics of the metal thin film formed using PAVD were compared with those obtained using the thermal evaporation method. Furthermore, the relationship between the deposition method and the device characteristics was investigated. Given the critical importance of metal electrode quality and resistance in large-area perovskite monolithic modules, this research also concentrated on their application in large-area modules. The large-area perovskite modules fabricated with the PAVD metal electrode show over a 1% improvement in efficiency compared to those using the evaporation method. In addition, improvements in long-term stability characteristics were observed. In the future, the PAVD technology is expected to be highly utilized as a damage-free electrode deposition process for electronic devices using organic thin film layers due to its high quality and low resistance.

5:00 PM EN10.16.06
Controllable Synthesis of 0D/3D Perovskite Heterostructure for High-Performance and Stable X-Ray Detection Devices Thanh Hai Le; Los Alamos National Laboratory, United States

Despite the impressive optoelectronic performance, perovskite-based detectors are poorly stable under operation, failing by far the market requirements. Various technological approaches have been proposed to overcome the instability problem caused by the migration of halide ions, which, while delivering appreciable incremental improvements, are still far from a market-proof solution. Here, We demonstrate that a zero-dimensional PEA_2ZnI_4 induces more robust surface passivation on 2D perovskite single crystal and stronger n–N isotype two-dimensional/zero-dimensional heterojunctions than its lead-based counterpart. The 0D/2D forms an exceptional gradually-organized multi-dimensional interface that yields up to 30% external quantum efficiency which 8 % higher than 2D perovskite device. Our device maintains 100 % initial efficiency after 1000 on-off cycles and after >70 hours under continuous illumination of 178.7 μGy/s and an applied voltage of 10V. In addition, the unencapsulated device exhibited zero performance loss under normal measured and storage conditions (temperature: 25 ºC, humidity: 20 to 60%) in 2 months. Our findings expand the material library for low-dimensional interface engineering and open an opportunity for the timely commercialization of perovskite x-ray detectors.

5:00 PM EN10.16.07
Conductivity Analysis of a Polycaprolactone/Carbon Nanotube Composite for use in Electrospun Photovoltaics and Flexible Electronics Luke J. Suttey[1], Dennis J. Moritz[2], John Borkowski[2], Jessica M. Andriolo[1] and Jack L. Skinner[1]; [1]Montana Technological University, United States; [2]Montana State University, United States

In recent years, conductive electrospun (ES) microfibers have gained traction for use in flexible electronics and perovskite photovoltaics. ES fibers are attractive for their large surface-area-to-volume ratio and relative strength. Conductivity in ES nanofibers has been accomplished using conductive or semiconducting polymers. Alternatively, conductivity in polymer thin films can be accomplished through addition of carbon nanotubes (CNTs) or graphene.

Previously, we formed hybrid perovskite crystals encased in ES fibers *in situ* that demonstrated improved stability in humid conditions. In other work, we used melt electrospinning to produce conductive graphene-doped polymer fibers. Additionally, we have utilized the previously established method of multiwalled CNT (MWCNT) dispersion by combined use of a hydroxy-functionalized and unfunctionalized MWCNT blend in polycaprolactone (PCL) matrix to fabricate a conductive PCL/MWCNT composite. Thin films of the composite were measured using a four-point probe and demonstrated a maximum conductivity of 0.3765 S/cm. In the present work, the hydroxy-functionalized and unfunctionalized MWCNTs will be replaced with hydroxy functionalized and unfunctionalized metallic single-wall carbon nanotubes (MSWCNTs) to achieve larger conductivity values in the composite material in preparation for electrospinning of a multi-layer solar cell structure.

Triaxial ES will be used to form the multi-layer solar cell structure described. In the design, a conductive PCL core will be coated with the previously

established perovskite-polymer composite. The exterior layer of the solar cell fiber structure will consist of a polymeric electron transport layer (ETL). In this work, each layer of the device will be characterized. Conductivity of a PCL thin-film doped with a mixture of functionalized and unfunctionalized MSWCNTs will be evaluated for conductivity via a non-destructive four-point probe method. Conductivity characterization will be used to determine the percolation threshold and preferable ratios for the MSWCNT-doped PCL composite used as the core of the functional fibers proposed. MSWCNT dispersion in the composite as a function of sonication time will be characterized through crystallinity analysis via Raman spectroscopy and electron microscopy.

Presented work will include conductivity characterization of the PCL/MSWCNT composite material and fabrication methods of a four-layer thin film photovoltaic system consisting of the conductive MSWCNT/PCL composite, a polymer-encapsulated hybrid perovskite layer, a polymeric ETL, and a transparent conductor. This work will provide the foundational preliminary data for future fabrication of an ES perovskite solar cell. The design is achieved without a hole transport layer, which has previously been established as non-consequential to perovskite solar cell performance. After adequate conductivity is achieved, the conductive ES nanofibers will be used as a central electrode in a concentric, triaxial ES photovoltaic cell.

5:00 PM EN10.16.08
Electronic Coupling in Low Dimensional Hetero-Metallic Halide Hybrids Janardan Kundu; Indian Institute of Science Education and Research, India

Low dimensional metal halide hybrids (2D, 1D, 0D) incorporating hetero-metal halide units is of fundamental importance to understanding electronic coupling between distinct excitons of the constituent metal halide units. However, synthesis of such multicomponent one phase systems is challenging. In this talk, I will highlight our current efforts on exploiting various synthetic strategies towards phase pure multi-metallic halide hybrids. I will present the photo-physical properties of such multi-metallic halide hybrids that manifest emissive properties arising due to electronic cross-talk/coupling between the multiple metal halide centers. I will discuss the relevant mechanism/pathway of the observed electronic coupling highlighting energy transfer interaction that are mediated through the structural components of the low dimensional metal halide hybrids. I will conclude my talk by emphasizing the need of robust theoretical calculations and ultra-fast spectroscopy to provide insight to the observed electronic coupling effects in low D hybrids.

5:00 PM EN10.16.09
High-Performance Photodetector and Angular-Dependent Random Lasing from Long-Chain Organic Diammonium Sandwiched 2D Hybrid Perovskite Non-Linear Optical Single Crystal Rajesh Kumar Ulaganathan[1], Pradip Kumar Roy[2], Raghavan Chinnambedu Murugesan[3], Ambika Subramanian[4], Chang-Yu Lin[4], Chi-Te Liang[2] and Raman Sankar[1]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]Aston University, United Kingdom; [4]Chung Yuan Christian University, Taiwan

3D organic-inorganic metal halide perovskites are excellent materials for optoelectronic applications due to their exceptional properties, solution processability, and cost-effectiveness. However, the lack of environmental stability highly restricts them from practical applications. Herein, a stable centimeter-long 2D hybrid perovskite (N-MPDA)[$PbBr_4$] single crystal using divalent N1-methylpropane-1,3-diammonium (N-MPDA) cation as an organic spacer, is reported. The as-grown single crystal exhibits stable optoelectronic performance, low threshold random lasing, and multi-photon luminescence/multi-harmonic generation. A photoconductive device fabricated using (N-MPDA)[$PbBr_4$] single crystal exhibits an excellent photoresponsivity (≈124 AW^{-1} at 405 nm) that is ≈4 orders of magnitudes higher than that of monovalent organic spacer-assisted 2D perovskites, such as $(BA)_2PbBr_4$ and $(PEA)_2PbBr_4$, and large specific detectivity (≈10^{12} Jones). As an optical gain media, the (N-MPDA)[$PbBr_4$] single crystal exhibits a low threshold random lasing (≈6.5 μJ cm^{-2}) with angular dependent narrow linewidth (≈0.1 nm) and high-quality factor ($Q \approx 2673$). Based on these results, the outstanding optoelectronic merits of (N-MPDA)[$PbBr_4$] single crystal will offer a high-performance device and act as a dynamic material to construct stable future electronics and optoelectronic-based applications.

5:00 PM EN10.16.10
Co-Deposition of Hole-Selective Contact and Absorber for Improving The Processability of Perovskite Solar Cells Xiaopeng Zheng[1] and Joseph Luther[2]; [1]University of Chinese Academy of Sciences, China; [2]National Renewable Energy Laboratory, United States

Simplifying the manufacturing processes of renewable energy technologies is crucial to lowering the barriers to commercialization. In this context, to improve the manufacturability of perovskite solar cells (PSCs), we have developed a one-step solution-coating procedure in which the hole-selective contact and perovskite light absorber spontaneously form, resulting in efficient inverted PSCs. We observed that phosphonic or carboxylic acids, incorporated into perovskite precursor solutions, self-assemble on the indium tin oxide substrate during perovskite film processing. They form a robust self-assembled monolayer as an excellent hole-selective contact while the perovskite crystallizes. Our approach solves wettability issues and simplifies device fabrication, advancing the manufacturability of PSCs. Our PSC devices with positive–intrinsic–negative (p-i-n) geometry show a power conversion efficiency of 24.5% and retain >90% of their initial efficiency after 1200 h of operating at the maximum power point under continuous illumination. The approach shows good generality as it is compatible with different self-assembled monolayer molecular systems, perovskites, solvents and processing methods.

5:00 PM EN10.16.11
Advancing Operational Stability of Inverted Perovskite Solar Cells Utilizing Parylene-C Encapsulation Techniques Elnaz Ghahremani Rad, Abraha Tadese Gidey, Towhid H. Chowdhury and Alexander R. Uhl; The University of British Columbia, Canada

Following advancements to increase the efficiency of perovskite solar cells, the current emphasis is mainly on enhancing their operational stability. Various methods of encapsulation have been employed to safeguard perovskite solar cells from environmental factors and preserve their efficiency. Recent research studies have primarily focused on using organic/inorganic multilayers to create a more robust barrier against the degradation of perovskite solar cells. However, the commercial feasibility of employing inorganic materials might be limited due to their high-cost fabrication process and low flexibility. The encapsulation techniques using polymers stand out for their versatility in material selection and functionality, making them suitable for manufacturing flexible devices. Polymers efficiently act as encapsulants, preventing the infiltration of water and oxygen into the perovskite layer while also inhibiting the release of perovskite composition. One such polymer, parylene-C, offers cost-effective extrinsic protection against environmental harm, mainly humidity and oxygen, to uphold the performance and reliability of perovskite solar cells. In our study, we utilized a multilayer deposition of parylene-C with a high light and low water vapor transmission rate, uniformly applied across the surface of the perovskite solar cells. To assess the operational stability of these devices, we employed ISOS-D1 and D2 protocols including conditions such as ambient/ambient and 85 /ambient, pertaining to temperature/relative humidity. The obtained results underscore the durability of parylene-C coated perovskite solar cells compared to their unencapsulated counterparts.

Novel 3D Cubic Topology in Hybrid Lead Halides with a Symmetric Aromatic Triammonium Exhibiting Water Stability Eugenia S. Vasileiadou[1], Imra S. Tajuddin[1], Michael C. De Siena[1], Vladislav V. Klepov[1], Mikaël Kepenekian[2], George Volonakis[2], Jacky Even[2], Lukasz Wojtas[3], Ioannis Spanopoulos[3], Xiuquan Zhou[1], Abishek Iyer[1], Julie L Fenton[4], William Dichtel[1] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States;

[2]Univ. Rennes, France; [3]University of South Florida, United States; [4]The Pennsylvania State University, United States

The limitations of three-dimensional (3D) perovskites are related to their narrow structural tunability of the organic cations and their moisture sensitivity. Herein, we report a new family of 3D cubic hybrid metal halides $(T\text{-}Et_6)_3Pb_{11}X_{31}$ (X = I, Br), where T is 1,3,5-tris-(4-aminophenyl)benzene. The materials are synthesized through an *in situ* N-alkylation of T and an efficient one-step solvothermal reaction containing ethanol, initiating a tunable synthetic avenue for the acquisition of structurally complex hybrid halides with luminophores. $(T\text{-}Et_6)_3Pb_{11}X_{31}$ consist of an unprecedented *Ia*3 framework of $[Pb_{11}X_{31}]^{9-}$ one-dimensional (1D) chains embedded with $(T\text{-}Et_6)^{3+}$ cations, affording an overall 3D topology. The constituent $[Pb_{11}X_{31}]^{9-}$ chains include exclusively octahedral lead halide units with clusters of face- and edge-sharing connectivity, giving rise to weak broad emission centered at ~660 nm observed at 78 K. $(T\text{-}Et_6)_3Pb_{11}I_{31}$ demonstrates water stability for at least 7 days. Synthesis through ambient pressure results in tunable structural variations of zero-dimensional (0D) structures rendering $T_7Pb_3Br_{27}DMF$ and $T_2Sn_3Br_{18}4H_2O0.5Br_2$, both of which feature blue PL emission at room temperature.

Anisotropy and Exciton Self-Trapping in the 1D Perovskite $C_4N_2H_{14}PbBr_4$ from First Principles Rijan Karkee and David A. Strubbe; University of California, Merced, United States

Low-dimensional organic-inorganic metal halide hybrids have remarkable optical and electronic properties and better stability against heat and moisture. We study a 1D perovskite of formula $C_4N_2H_{14}PbBr_4$, consisting of PbBr chains separated by organic cations. Experiments showed a large Stokes shift (0.83 eV) with broadband emission [Nat. Commun. 8, 14051 (2017)] which hints at interesting photo-physics involving self-trapped excitons. We calculate the highly anisotropic optical, bandstructure, vibrational, and transport properties of this 1D perovskite, which could be used for polarized photodetectors and LEDs. The bands are highly dispersive along Pb-Br chains and nearly flat along other directions, leading to a factor of 100 in conductivity as calculated by Boltzmann transport. We find an indirect gap and a direct gap which is just slightly higher in energy. Our GW/Bethe-Salpeter equation calculations using BerkeleyGW show strong anisotropy in absorption, especially in the lowest exciton which has a binding energy of 0.83 eV [Small Struc. 4, 2200378 (2023)]. We calculate excited-state forces based on these results and our vibrational calculations to find the coupling of excitons and phonons, from which we can predict exciton self-trapping and get insight into mechanisms of broadband emission.

Unravelling Rashba Effect through Spin Texture Evolution in Uni-Dimensional Confined Halide Perovskite under Compression Jagjit Kaur and Sudip Chakraborty; Harish-Chandra Research Institute, India

The pursuit of uni-dimensional hybrid halide perovskites holds significant importance in the field of spin-optoelectronics due to quantum confinement effect. Moreover, such confined systems with constituent heavy elements (Pb,Bi, etc) could be prone to Rashba effect considering relativistic spin-orbit coupling (SOC) and inversion symmetry breaking. The repercussion of Rashba splitting could be very well reflected in charge carrier recombination rate, which is significant for manifesting efficient photovoltaic devices. One way to manipulate such recombination rate is through tuning the Rashba splitting corresponding to the spin texture of such materials under the external pressure or structural compression. In this work, we have envisaged such evolution paradigm in one of the promising non-centrosymmetric hybrid halide perovskite through rigorous electronic structure calculations. The electronic and optical properties along with the Rashba splitting and spin texture are being systematically observed within the thermodynamic limit of under compression equivalent to 9.6 GPa in this promising halide perovskite. Our study successfully reveals the intriguing transition of electronic band structure from indirect to a direct bandgap phenomena under compression in addition to an interesting red shift in the optical absorption spectra. To accurately describe the spin polarization both in-plane and out-of-plane, we have explored a three-dimensional Rashba model. The in-plane spin-texture has been found to arise from the octahedral distortion along the b-direction. The fundamental interplay between structural distortions and the Rashba-splitting in the considered one-dimensional system under the influence of compression along with the evolution of spin texture could very much hold potential for the pursuit of sustainable energy.

8:30 AM EN10.17.03
Intrinsic Limits of Charge Carrier Mobilities in Halide Perovskites: From 3D to Layered Materials Bruno Cucco[1,2], Joshua Leveillee[2], Jacky Even[3], Mikaël Kepenekian[1], Feliciano Giustino[2] and George Volonakis[1]; [1]Univ Rennes, ENSCR, INSA Rennes, CNRS, ISCR (Institut des Sciences Chimiques de Rennes), UMR 6226, France; [2]Department of Physics, Oden Institute for Computational Engineering and Sciences, The University of Texas at Austin, United States; [3]Univ Rennes, INSA Rennes, CNRS, Institut FOTON, UMR 6082, France

Over the past decade, we have witnessed the emergence of metal halide perovskites as a most formidable building block for emergent solar cells with record-breaking performances. Recently, 2D/3D materials that combine these ABX_3 (3D) metal halide perovskites with their layered (or 2D) counterparts, have enabled the fabrication of photovoltaic devices that are both stable and highly efficient. [1] Yet, it is well-known that layered perovskites exhibit poor charge carrier transport in comparison with 3D perovskites. [2] To date, the underlying mechanisms behind the reported reduced mobilities remain elusive. In this work, we employ a combination of state-of-the-art ab initio approaches [3] and symmetry analysis to explore the electron-phonon coupling mechanisms in layered halide perovskites. We start from the three-dimensional perovskite $CsPbBr_3$ and model the cases of layered n = 1 (Cs_2PbBr_4) and n = 2 ($Cs_3Pb_2Br_7$). We show that the diminished charge carrier mobilities in layered systems primarily originate from differences in the carrier's lifetimes. We identify the vibrational modes contributing to charge carrier scattering and associate them with polar-phonon scattering mechanisms arising from long-range Fröhlich coupling and non-polar optical deformation potential scattering processes. Furthermore, we show that the charge carrier mobilities are not only reduced by the increased polar-phonon interactions but also by an abrupt increase in the electronic density of states near the band edges. Our findings uncover the electron-phonon coupling mechanisms that intrinsically limit the charge carrier transport of layered metal halide perovskites, which is critical for their application in any optoelectronic device, such as solar cells.

Combining First-Principles Simulations and Combinatorial Synthesis: Effects of Exciton Binding Energy Halide Perovskite-Based Optoelectronic Devices SangMyeong Lee, Hee Jung Kim, Young Ju Kim, Geon Woo Yoon, Oh Yeong Gong and Hyun Suk Jung; Sungkyunkwan University, Korea (the Republic of)

Halide perovskites (HPs) have garnered significant attention in optoelectronics due to their excellent optoelectronic properties. The performance of HP optoelectronics is affected by the exciton binding energy, which represents the combined energy of electron-hole pairs. Therefore, a method that can comprehensively and rapidly explore and measure changes in exciton binding energy based on HP composition is highly valuable. In this study, we report the effects of HP optoelectronic properties depending on the HP compositions using a combination of first-principles simulations and combinatorial synthesis. The first-principles simulations confirm that an increase in the concentration of halide ions leads to an increased band gap, strengthening the Coulomb interactions. We demonstrate that an increase in the band gap corresponds to a decrease in relative permittivity when fabricating HP thin films with a halide compositional gradient using combinatorial synthesis. Furthermore, we measured the photoelectric conversion efficiency and responsivity of HP-based optoelectronics depending on exciton binding energy, including time-resolved photoluminescence. The results indicate that the dissociation of electron-hole pairs increases with a reduction in exciton binding energy, thereby improving device properties. Thus, this study suggests a high-throughput screening method that combines first-principles simulations and combinatorial synthesis to explore the effects of HP properties on optoelectronics.

9:00 AM *EN10.18.01
Towards Semi-Opaque Perovskite Solar Cells via Molecular Templates Jacek Jasieniak; Monash University, Australia

Metal halide perovskite semi-transparent perovskite solar cells (ST-PSC) have drawn great interest for applications in building integrated photovoltaics (BIPV), such as solar windows. Conventionally, ST-PSC are realised by thinning the perovskite absorber layer to allow partial light transmission, while also replacing the opaque back electrode with one that is transparent. This approach has been shown to produce efficient and stable cells, with window-grade levels of transparency (>30%). However, their main drawback is the unavoidable perceived colour (typically red to yellow) due the optical bandgap laying within the visible range, which lowers the colour-rendering index (CRI) and therefore impedes their application in BIPV. A possible path to overcome this hurdle is by patterning the solar cell in a way that selected regions are entirely transmissive, while others remain fully absorbing. Such semi-opaque configurations can support greater efficiencies and color purity levels than ST-PSC. Towards this technological evolution, here, we explore a low-cost and efficient method for patterning metal-halide perovskites via stamping of a hydrophobic template on substrates. The facile approach is demonstrated to be scalable and suitable for both flexible and rigid substrates. It further removes the need for post-processing, thus minimizing potential lithographic steps, and the burden they pose. The use of such patterned perovskite films are considered within semi-opaque solar cell configurations, highlighting the challenges and the major opportunities that such patterned films and this form of solar cell architecture present.

9:30 AM EN10.18.02
Multi-Spectral Optical Platform of Luminescent Patterns by Single-Shot Optical Lithography Hyewon Shim, Geonwoong Park, Hyunsuk Yun, Sunmin Ryu, Yong-Young Noh and Cheol-Joo Kim; Pohang University of Science and Technology, Korea (the Republic of)

Integration of numerous optical materials with different band gaps forms the basis of a multispectral technology. While step-by-step integrations are the prevailing manufacturing approach, realizations of complex patterns with increasing numbers of material units by high definition and reproducibility remain challenging, preventing the wide implications of the multispectral platform. Here, we report optical lithography to spatially control the optical band gaps of semiconductor alloys by composition modulations with a single-shot expose. Luminescent patterns with intrinsic emission wavelengths, spanning the entire visible-spectral range are designed to realize functional multispectral films. With programmed correlations between spatial and spectral information, we fabricate multivariate optical filters for dispersive optics-free spectroscopy with a high spectral resolution and wavelength-selective encoding patterns for encryptions with precise spectral programming. The fabrication is at room temperature, and compatible with various device platforms for monolithic integrations.

9:45 AM EN10.18.03
Photon Management for Efficient and Stable Large-Area Perovskite Solar Cells via Luminescent Thin Films of Platinum(II) Complex Eunhye Hwang[1], Hak-Beom Kim[2], Dong Suk Kim[1] and Tae-Hyuk Kwon[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of)

As a representative photon management strategy converting high-energy photons into low-energy ones, photon downshifting in photovoltaic applications can be realized by introducing strongly luminescent materials that are properly designed to have spectral overlap with the corresponding light absorbers. Especially for perovskite solar cells (PSCs), photon downshifting has been suggested as an effective way to overcome UV-related problems such as exciton loss, thermalization, and catalytic decomposition of the photoactive layers. However, it is still challenging to achieve thin-film photon downshifting layers (PDLs) with high photoluminescence quantum yields (PLQYs) and versatility for fabrication, considering upcoming high-performance and large-area PSCs.
Herein, to enhance UV stability without any loss in photocurrent generation, a highly blue-emissive Pt(II) complex is developed for effective photon management in high-performance PSCs. Thin PDLs based on the Pt(II) complex are fabricated on glass substrates of PSCs using ultrasonic spray deposition, leading to significant improvement in PLQY and facile production of large-area PDLs. By introducing the PDLs, a maximum device performance of 22.03% is achieved for large-area PSCs with an active area of 25 cm^2. Owing to their long-range photon downshifting effect, in which absorbed UV photons are converted into visible emission, remarkable improvements in UV stability of PSCs are realized with the PDL coating. In terms of

efficient photon management, luminescent thin films of UV-to-visible converting Pt(II) complex suggest wide ranging applicability that can further improve the performance and stability of other optoelectronic devices.

Material and Device Stability of Lead-Tin Perovskite Solar Cells Florine Rombach and Henry J. Snaith; University of Oxford, United Kingdom

Narrow bandgap perovskite solar cells based on mixed lead-tin perovskites tend to suffer from poor stability under operating conditions. This impedes the successful development of all-perovskite tandems. We explore the causes of this instability under extended periods of combined 65°C thermal and 1 sun illumination stressing, using a range of structural, optical, and electronic characterization techniques on lead-tin perovskite films, half-stacks and devices.

We show that the phase, absorbance, morphology and mobility of lead-tin perovskite films are stable on timescales that exceed those of device degradation, although we reveal an interesting pattern of phase segregation after stressing for much longer amounts of time. Additionally, we observe only a slight increase in background carrier density and a moderate decrease in charge carrier lifetime during the first few hundred hours of stressing. We simulate the impact of these properties on device performance using SCAPS, and argue that these changes can only partially account for the observed device degradation.

A close investigation of the EQE and J-V characteristics of devices reveals the formation of a charge extraction barrier in aged devices. We find that the impact of this barrier is hugely decreased in very fast J-V scans, suggesting that mobile ions contribute significantly to device degradation. We quantify the increasing impact of mobile ions on device performance during aging, and furthermore reveal that the extent of this impact is strongly related to the hole transport layer used in devices.

Ultimately, we identify a rapidly worsening impact of mobile ions during aging as the major cause of the observed device performance degradation. The segregation of a non-perovskite $CsSnI_3$ degradation phase and an increasing defect density are also expected to limit the stability of lead-tin perovskite solar cells over longer timescales. Finally, we propose solutions related to both bulk perovskite composition and device architecture to overcome these challenges.

10:45 AM EN10.19.02
Highly Efficient and Stable Thermal Evaporated Lead-Tin Perovskites Heon Jin and Henry J. Snaith; University of Oxford, United Kingdom

Multi-junction tandem solar cells, utilizing complementary bandgaps, offer the potential to surpass the detailed balance limit for single-junction perovskite solar cells (PSCs). Through the tunability of perovskite bandgaps and recent advancements in mixed lead-tin (Pb:Sn) narrow bandgap PSCs, it is now possible to create highly efficient multi-junction solar cells solely using perovskites, achieving certified PCEs of up to 26.4% in all-perovskite tandem solar cells.
However, there are two main challenges when using Pb:Sn perovskites. Firstly, methylammonium (MA) has been traditionally used in the most efficient Pb:Sn PSCs, but its thermal and chemical stability concerns prompt the search for MA-free alternatives. Second, conventional solution processing methods remain prevalent in lab-scale Pb:Sn PSCs fabrication. There were many attempts to thermal evaporate Pb:Sn as this method presents significant advantages, including high-quality thin film fabrication, precise thickness control, elimination of toxic solvents, large-scale compatibility, and reproducibility. Vacuum evaporation can also be applied to the fabrication of all-perovskite tandem solar cells without damaging underlying layers. Although vacuum deposition has proven successful in achieving high-efficiency and large-area PSCs for Pb-based perovskites, its application to Pb:Sn perovskites is less unexplored. Ball et al. and Igual-Munoz et al. are among the few to report Pb:Sn PSCs using vacuum evaporation.
In this work, we demonstrate that through careful control of the environment and some fine-tuning, it is possible to deposit Pb:Sn perovskite films of high quality through thermal evaporation. We compare devices made using this method to those made from similar state-of-the-art solution processed methods. Our work demonstrates that it is possible to approach the performance of solution processed devices within a workable processing window using vacuum evaporation. Our champion devices reach PCEs of 17%, surpassing previously set records of 14% for thermally coevaporated Pb:Sn devices. This was done without requiring additional passivation or bulk additive, which are used in the previous reports.

11:00 AM EN10.19.03
Local Background Hole Density Drives Non-Radiative Recombination in Tin Halide Perovskites Robert J. Westbrook[1], Margherita Taddei[1], Rajiv Giridharagopal[1], Meihuizi Jiang[2], Shaun Gallagher[1], Kathryn Guye[1,3], Aaron Warga[1], Saif Haque[2] and David S. Ginger[1,3]; [1]University of Washington, United Kingdom; [2]Imperial College London, United Kingdom; [3]Pacific Northwest National Laboratory, United States

Tin halide perovskites, with the general formula ABX_3 [A = Formamidinium (FA), B = Sn, X = Br, I], offer a narrower bandgap (~1.3 eV) than their lead counterparts, making them suitable candidates for the light-absorbing semiconductor in single-junction photovoltaic devices. Moreover, this attribute makes tin halide perovskites integral to all-perovskite tandems, with the best-performing cells incorporating a 50-50 Sn-Pb composition in the low bandgap component. Nevertheless, record-breaking pure-Sn devices still exhibit severe losses in both open-circuit voltage (V_{OC}) and short-circuit current (J_{SC}), keeping power conversion efficiencies well below theoretical limits.
Non-radiative voltage loss is directly linked to decreases in the photoluminescence quantum yield (PLQY), and thus the prevalence of non-radiative recombination.[1] This picture is complicated in Sn perovskites given that the presence of Sn^{4+} impurities in the precursor solution leads to both the introduction of background hole dopants (serving to *increase* the PLQY) and non-radiative recombination centers (serving to *decrease* the PLQY). [2]
We use the observation of pseudo-first order photoluminescence (PL) decay kinetics in Sn perovskite films to establish a method for characterizing the hole dopant level and non-radiative recombination rate constant with combined time-correlated single photon counting (TCSPC) and photoluminescence quantum yield (PLQY) measurements. We find that untreated $FASnI_3$ films exhibit large hole doping concentrations of $p_0 > 8.8 \times 10^{18}$ cm^{-3}, which is reduced to $p_0 \sim 10^{16}$ cm^{-3} after precursor sublimation and SnF_2 treatments. While it is well known that the radiative recombination rates are increased with p_0, we reveal that the non-radiative rate is also increased. Employing hyperspectral photoluminescence microscopy, we find that microscale *p*-type regions

in untreated $FASnI_3$ films are centers for non-radiative recombination, which are diminished in films with $p_0 \sim 10^{16}$ cm^{-3}. We find significant PL heterogeneity even in $FASnI_3$ films with moderate dopant levels, suggesting that new strategies to eliminate deleterious defects in $FASnI_3$ should be developed. [3]

Quantifying Spatiotemporal Signal in Photothermal Heterodyne Imaging of Metal-Halide Perovskites Lauren Cisneros and Matthew Crane; Colorado School of Mines, United States

Resonant pump-probe spectroscopies like photothermal heterodyne imaging have emerged as promising approaches to selectively measure the distribution of chemical species with high spatial and temporal resolution. In photothermal heterodyne imaging, a pump resonant with an electronic or vibrational transition of the species of interest heats the sample, and a higher energy probe measures differential reflectance (or transmittance) due to heating. For materials research, pump-probe photothermal spectroscopies thus offer an attractive and unique tool to evaluate the spatial distribution of "dark" species including, *e.g.* defects or molecules without significant radiative transitions. However, the conditions under which signal is optimized in thin films, including metal-halide perovskites, is not well understood, and approximations are frequently used to describe to differential reflectance or transmittance signal. Here, we develop a multiphysics simulation implemented with a finite-difference method to quantify transient photothermal heating and the resulting differential reflectance signal. Using this approach, we investigate the conditions that optimize spatiotemporal resolution in alloyed methylammonium and formamidinium metal-halide perovskite thin films and evaluate these simulations experimentally. Combining these results, we identify key figures of merit to optimize spatiotemporal resolution in thin films and find that significant information about spatial distribution is buried within the temporal signal.

11:30 AM EN10.19.05
3D Lead-Organoselenide-Halide Perovskites and Their Mixed-Chalcogenide and -Halide Alloys Jiayi Li[1], Yang Wang[2], Santanu Saha[3], Zhihengyu Chen[4], Jason Misleh[1], Karena Chapman[4], Jeffrey Reimer[2], Marina R. Filip[3] and Hemamala Karunadasa[1]; [1]Stanford University, United States; [2]University of California, Berkeley, United States; [3]University of Oxford, United Kingdom; [4]Stony Brook University, The State University of New York, United States

Following our previous report of organosulfide-halide perovskites (RS)PbX_2 (X = Cl, Br; RS = organosulfide ligand), we present the first examples of organoselenide-halide perovskites (RSe)PbX_2 (RSe = organoselenide ligand) using organoselenide zwitterionic ligands, occupying both the X and A sites in the prototypical ABX_3 perovskite lattice. We applied X-ray diffraction/scattering measurements to study the average structures of the organochalcogenide-halide perovskites, with disordered organic components and anion sites. Considering the heteroanionic nature of these materials, we collected solid-state ^{77}Se and ^{207}Pb NMR to probe the local coordination environments at Pb centers and anion (X/Se) distributions, complemented by theoretical simulations. The experimental results support the fully disorder distribution of organochalcogenide in (L)PbX_2. The band structures calculated by density functional theory (DFT) of (SeCYS)PbX_2 closely resemble those of (CYS)PbX_2 with chalcogenide dominating the valence band maximum (VBM). Due to the higher energy of Se 4p orbitals compared to the S 3p orbitals, (SeCYS)PbX_2 exhibit considerable bandgap (E_g) decrease, with E_gs = 2.07 and 1.86 eV for X = Cl and Br, respectively. We further demonstrate different methods to alloy the halides (Cl/Br) and chalcogenides (S/Se) to obtain a continuous bandgap tuning. Overall, the expansion of this novel family of organochalcogenide-halide perovskites can provide new handles to tune the band structures of halide perovskites, and the comprehensive understanding of both average and local structures sets the foundation to further optimize the optoelectronic properties.

11:45 AM EN10.19.06
Structure and Stability of Multi-Component B-Site Mixed $CsBX_3$ Metal Halide Perovskites Riley W. Hooper, Brian Phan, Trinanjan Dey, Cole Butler, Jonathan Veinot and Vladimir Michaelis; University of Alberta, Canada

ABX_3 [A = Cs, FA, MA; B = Pb, Sn, Ge; X = Cl, Br, I] metal halide perovskites have dominated the research landscape since the first demonstration of $MAPbI_3$ as an absorber layer for dye-sensitized solar cells.[1] Since then, developments in this space have realized perovskites for widespread applications in LEDs, photovoltaics, sensing, radiation detection, lasing, and more.[2,3] The ubiquity of perovskites today is partly due to their facile synthesis via multiple routes, their tolerance to high defect concentrations, and highly tunable composition whereby properties can be defined. Of late, low-dimensional perovskite-based materials, alloys, or high entropy systems (with multiple elements at the same site) have brought renewed interest.[4]

Widespread deployment of ABX_3 perovskites has been slowed by the inclusion of the toxic heavy metal Pb, and material instability to heat and moisture. An attractive method for promoting the formation of the desired phase(s) while limiting degradation involves site-mixing. A- and X-site mixing is currently applied to materials in state-of-the-art compositions for the current best-performing prototype solar cells. Only limited examples showing mixing at the B-site have appeared and most involve Pb-Sn derivatives that only reduce Pb content in the material, without completely eliminating it. Sn-Ge mixed perovskites have received some attention, and exhibit improved stability and solar cell performance than previous Ge-based perovskites.[5,6] A detailed understanding of the phenomena leading to such improvements using a suite of bulk spectroscopic and diffraction methods can provide insight into the mechanisms at play. Specifically, NMR spectroscopy offers atomic-level precision of the local chemical environment and has been used with much success for studying challenging and interesting perovskite materials.[7-10] Together, this toolkit can provide the means for rational design of new materials for advanced solar absorbers.

Our work explores new systems of mixed B-site perovskites, starting with lead-free Sn-Ge solid solutions of the formula $CsSn_xGe_{1-x}Br_3$. Their optical properties and structure were explored using optical band gap measurements, XRD, SEM/EDX, and ^{133}Cs NMR spectroscopy. We then investigate the impact of halide identity on the mixed Sn-Ge system, and explore the possibility of a triple B-site mixed Pb-Sn-Ge perovskite.

Halide Perovskites based Indoor Photovoltaics: Role of Composition Tuning and Interfacial Layers Shaoyang Wang[1], Paul Edwards[2], Maged Abdelsamie[3], Peter Brown[1], David Webster[1], Arvydas Ruseckas[1], Robert W. Martin[2], Carolin M. Sutter-Fella[3], Graham Turnbull[1], Ifor Samuel[1] and Lethy Krishnan Jagadamma[1]; [1]University of St Andrews, United Kingdom; [2]University of Strathclyde, United Kingdom; [3]Lawrence Berkeley National Laboratory, United States

With the explosive development of the Internet of Things (IoT) technology, indoor photovoltaics (IPVs) are becoming a promising candidate to sustainably power billions of wireless sensors for secured and smart buildings. Among the various photovoltaics technologies available today, halide perovskite-based IPVs are most promising for integration with IoT because of their excellent optoelectronic properties, easy and cost-effective processability using solution-based methods such as roll-to-roll printing, high specific power, and earth-abundance. The low intensity of the indoor light sources means the absence of beneficial light-induced trap filling of the perovskite photoactive layer. This demands stringent defect minimisation approaches at every functional layer to maximize the power conversion efficiency of IPVs and thereby reduce the efficiency gap (more than 20 % now) between the theoretically predicted and experimentally observed power conversion efficiency of IPVs. In this talk, I will discuss the effect of active layer composition tuning and the role of interfacial layers in maximizing efficiency and suppressing the hysteresis effects under indoor lighting. While tuning the composition of the halide perovskites we observed that the fast processing of the triple anion perovskite composition enables the retention of Chlorine and enhances the photovoltaic device performance under indoor lighting. The kinetics of chlorine incorporation/escape was investigated by in situ grazing incidence wide-angle X-ray scattering and correlated the Cl content with the photovoltaic device performance. The selection of organic vs oxide-based transport layers and the effect of light soaking and J-V hysteresis under indoor lighting will also be discussed in detail.

2:00 PM EN10.20.02
ALD-SnOx as a Top Layer and Hole Transport Layer to Improve The Thermal Stability of Lead-Free Tin Perovskite Solar Cells Takeshi Kitamura and Shuzi Hayase; The University of Electro-Communications, Japan

Lead perovskite solar cells (Pb-PSCs) have attracted significant worldwide attention due to their rapid increase in power conversion efficiency (PCE) from 3.8% to 25.8%.However, lead toxicity is a concern for their commercialization.
Among lead-free alternatives, tin perovskite solar cells (Sn-PSCs) have the highest PCE (>14%) due to their narrow band gap (1.4 eV), low exciton binding energy, and high carrier mobility.
Despite the vigorous efforts to improve the efficiency of Sn-PSCs, thermal stability is still a critical issue that has not been solved.Inverse structure devices using poly(3,4-ethylenedioxythiophene) poly(styrenesulfonic acid) (PEDOT:PSS) as the hole transport layer (HTL) are commonly used for highly efficient Sn-PSCs.However, the PEDOT:PSS layer has hygroscopic and acidic properties that reduce the stability of the solar cell.Therefore, Sn-PSCs without PEDOT:PSS is an important research item in terms of stability.In addition, the diffusion of iodine ions within the tin perovskite layer reduces device stability. Therefore, preventing iodine ion diffusion is also important to improve the stability of Sn-PSCs.
Previous studies have reported that ALD-SnOx (x = 1.7-1.8) can serve as HTLs in tin-lead alloy perovskite solar cells. Furthermore, our previous study demonstrated that SnOx (x = 1.7-1.8), obtained by plasma oxidation of metallic Sn, can serve as HTLs in Sn-PVK-PV with PCEs exceeding 14%. We have also found that tin oxide nanoparticle layers, which are commonly used as electron transport layers (ETLs) in Pb-PSCs, can operate as HTLs in Sn-PSCs.These SnOx layers are partially composed of Sn^{2+} rather than Sn^{4+} and exhibit bipolar carrier transport.Sn-PSCs with tin oxide nanoparticle HTLs exhibit higher stability than PEDOT:PSS HTL devices.Therefore, tin oxide HTLs may be effective to enhance the stability of Sn-PSCs.
ALD-SnOx in the top layer has been reported to improve stability in Pb-PSCs by preventing the diffusion of iodine ions.
In this report, we first replaced HTL with ALD-SnOx to improve the thermal stability of Sn-PSCs. In addition, ALD-SnOx was also introduced in the top layer.
In the presentation, the mechanism of thermal stability improvement by ALD-SnOx will be discussed.

2:15 PM EN10.20.03
Synergistic Effect of Charge-Modulated Molecular Passivation in MA/Br-Free Perovskite Solar Cells Dhruba B. Khadka, Yasuhiro Shirai, Masatoshi Yanagida, Hitoshi Ota and Kenjiro Miyano; National Institute for Materials Science (NIMS), Japan

Molecular passivation represents a promising avenue for enhancing both the efficiency and operational stability of perovskite solar cells. This work reports on the effect of diammonium iodide functional molecules featuring aryl or alkyl cores onto 3D-perovskite surfaces. Our findings reveal the remarkable efficacy of piperazine dihydriodide, characterized by an alkyl core and electron-rich -NH terminal, in mitigating surface and bulk defects while modifying surface chemistry and improving carrier extraction efficiency. This results in an impressive efficiency of 23.17% (1 cm^2 area) with superior long-term stability. Device analysis substantiates that these robust bonding interactions reduce defect densities in the perovskite film and suppress ion migration. This report will shed light on the synergetic effect of bifunctional molecules in defect mitigation, opening avenues for design strategies centered on bonding-regulated molecular passivation to enhance solar cell performance and stability.

Taming Phase Transitions in Two-Dimensional Hybrid Perovskites Connor G. Bischak; The University of Utah, United States

Metal halide perovskites often exhibit phase transitions that occur near room temperature. Typically, efforts have focused on suppressing phase transitions for optimal device stability. Yet, strategies to control these phase transitions could lead to new applications in memory storage, thermal energy storage, and switchable optoelectronic devices. We demonstrate that we can control the temperature of the order-to-disorder phase transition of two-dimensional Ruddlesden Popper perovskites through alkyl cation alloying. We also connect structural transformations to changes in photophysical properties and show that changes in photoluminescence wavelength and intensity are tied to octahedral distortions in the perovskite crystal lattice. Last, using photoluminescence imaging, we image the dynamics of the phase transition and show that the nature of these dynamics depends on the alkyl cation length.

3:15 PM EN10.21.02
The Role of Mobile Ions in The Early Performance Degradation of Perovskite Solar Cells Jarla Thiesbrummel[1,2], Sahil Shah[2], Vincent Le Corre[3], Henry J. Snaith[1] and Martin Stolterfoht[2,4]; [1]University of Oxford, United Kingdom; [2]University of Potsdam, Germany; [3]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [4]The Chinese University of Hong Kong, Hong Kong

In the last decade, perovskite semiconductors have triggered a revolution in solar cell research. However, there remain some critical issues concerning the stability of metal-halide perovskites, which need to be overcome to enable a large scale commercialisation of perovskite photovoltaics. While the rather poor environmental stability of these perovskites is usually attributed to their ionic nature rendering them sensitive to moisture and oxygen, the actual contribution of mobile ions to the total degradation loss under different environmental conditions is poorly understood. Here, we reveal that the initial degradation of perovskite semiconductors is largely the result of mobile ion-induced internal field screening - a phenomenon that has not been previously discussed in relation to the degradation of perovskite solar cells. The increased field screening leads to a decrease in the steady-state power conversion efficiency mainly due to a large reduction in current density, while the efficiency at high scan speeds (>1000 V/s) where the ions are immobilized is much less affected. We also show that interfacial recombination does not increase upon ageing, yet the open-circuit voltage decreases as the result of an increase in the mobile ion density upon ageing. Furthermore, similar ionic losses appear under different external stressors, in particular when there are free charges present in the absorber layer. Finally, we generalize these findings beyond triple cation solar cells by showing the same degradation mechanisms take place in perovskites with a range of different compositions, including methylammonium leadiodide ('MAPI'), formamidinium cesium leadiodide ('FACs'), and several mixed-halide perovskites with different bandgaps. This work reveals a key degradation mechanism, providing new insights into initial device degradation before chemical or extrinsic mechanical device degradation effects manifest, and it highlights the critical role mobile ions play therein. It highlights the importance of efficiently managing mobile ions and their effects to enable long term stability in perovskite-based photovoltaics and move towards commercialization.

3:30 PM EN10.21.03
Potential of Perovskite Doping Unlocked: Shaping The Future of Energy and Electronics Zuzanna Molenda[1], Dario Bassani[2] and Lionel Hirsch[1]; [1]IMS-Bordeaux, France; [2]ISM, France

Doping of metal halide perovskites (MPHs) is the next, essential step towards the implementation of perovskite semiconductor technology for electronic devices. Nonetheless, only a limited number of successful doping instances have been documented, and it is frequently mistaken for additives, grain passivation, or surface functionalization, none of which affect the semiconductor's charge carrier density. Due to the ionic character of the perovskite crystal, the introduction of heterovalent ions is accompanied by the counter ions that balance out the potential doping effect. Here we present a use of homovalent yet metastable ions, in particular Sm^{2+}, to substitute Pb^{2+} in $MAPbI_3$ (MA = methylammonium). Sm^{2+} ions spontaneously oxidize to Sm^{3+}, once incorporated into the crystal lattice and each of them releases one electron to the conduction band. The oxidation of samarium ions is confirmed by the analysis of the Sm 3d core level in the X-ray photoelectron spectrum (XPS). Residual content of the oxidized form of Sm^{3+} present in the doping solution allows to observe a slight shift of the Sm 3d peak towards higher binding energy, suggesting the environment change of the Sm^{3+} ion, once introduced inside the perovskite film. Together with the shift of the XRD pattern upon doping, this supports the hypothesis that the dopant ion is incorporated and stabilized in the crystal lattice. At the same time, the crystal structure of the doped perovskite layer is conserved and no phase separation is observed from the XRD patterns. Ultraviolet photoelectron spectroscopy (UPS) shows a shift of the Fermi level (E_F) by around 0.5 eV towards the conduction band, proving the doping to be n-type. The increase of the free electron density in the conduction band is the direct reason for the conductivity increase for the doped films by 3 orders of magnitude. Using the Mott-Schottky method, the ionized charge carrier density is estimated to be 10^{17} cm^{-3} for the sample showing the highest conductivity increase, which suggests the ionized dopant concentration in the doped perovskite film to be around 0.01% (Pb density in $MAPbI_3 \approx 20^{21}$ cm^{-3}). The discrepancy between this result and the doping concentration stemming from the XPS measurement, which is calculated to be around 20%, leads to two possible explanations. Either the majority of the Sm^{2+} introduced to the perovskite polycrystalline film resides at grain boundaries and therefore does not act as a dopant or the dopant is only partially oxidized in normal conditions, exhibiting the freeze-out effect. The dopant activation energy (the energy necessary to oxidize all the Sm^{2+} ions to Sm^{3+}) of around 350 meV seems to support the latter hypothesis and is in agreement with the energy between the E_F and conduction energy (E_C). The presented method allows to reach the highest to-date conductivity increase for the n-type and may become a protocol for the efficient n-type doping of MHPs. To illustrate one of its applications, we fabricated perovskite solar cells (PSC) with poly(triaryl amine) (PTAA) as a hole transporting layer (HTL) (p-side) and Sm-doped $MAPbI_3$ (n-side), without the electron transporting layer (ETL). Additionally, we used gold as an electron collecting electrode (WF_{Au} = 5.22 eV). The strain-induced ohmic contact between highly doped perovskite and Au allows to minimize the series resistance at this interface and an efficient electron collection. This shows the potential of flexible electrode selection for the doped PSC. Therefore, the ETL-free n-doped PSC retains the same PCE as the reference sample (with PCBM as an ETL), in spite of the simplified architecture that decreases the fabrication cost and the number of interfaces.

3:45 PM EN10.21.04
Spatially Resolved Parameter Mapping and Degradation of Perovskite Solar Cells Akash Dasgupta and Henry J. Snaith; University of Oxford, United Kingdom

Perovskite solar cells have made significant strides towards maturity; however, two major challenges persist: stability and up-scalability. Achieving uniform deposition methods is crucial for ensuring the suitability of devices for large-scale production. Furthermore, a comprehensive understanding of degradation mechanisms is essential for mitigating these effects and improving stability. In this study, we introduce a novel approach that integrates photoluminescence imaging with drift diffusion simulations which incorporate the effects of mobile ions. By employing machine learning techniques, we

generate inferred maps of various material parameters. These maps are then tracked throughout the aging process to analyse their spatially resolved temporal evolution during degradation, enabling us to distinguish between bulk. Our findings reveal that macroscopic-scale spatial defects propagate outward, ultimately resulting in device degradation across the entire area. By distinguishing between bulk and surface degradation, our technique provides an additional dimension of insight into the heterogeneous nature of degradation in perovskite solar cells. This enables meaningful comparisons and enhanced comprehension of different treatments and processes. We expect analysis using our approach to enable the field to target sources of inhomogeneity and degradation more precisely, paving the way towards commercialisation.

4:00 PM EN10.21.05
***In-Situ* Spatially-Resolved Analysis of Degradation in Perovskite Solar Cells** Dana Kern, Jack Schall, Goutam Paul, Steve Johnston, Andrew Norman, Harvey Guthrey, Nikita S. Dutta, Chun-Sheng Jiang and Andrew Glaws; National Renewable Energy Laboratory, United States

Long-term durability of metal halide perovskite solar cells (PSCs) can be impacted by both the intrinsic nature of the as-designed device stack as well as unintentional local nonuniformities. Here, we present methods for spatially-resolved in-situ degradation analysis during perovskite stress testing. We use repeated bias/rest cycles from timescales of minutes up to 100 hours to separately assess metastability in comparison to irreversible degradation. We visualize device evolution in-situ under light or electrical bias, either in surface view using electro-optical imaging or in cross-section using kelvin probe force microscopy. We further demonstrate multi-scale investigation of defects, from rapid electro-optical screening of the full device area down to nanoscale microscopic characterization to reveal the underlying chemical or structural nature of defects. Our results inform methods to screen for defects in PSCs, as well as further development of accelerated stress testing and degradation analysis which will become essential for perovskite devices to improve their durability and enter the commercial market.

4:15 PM EN10.21.06
From Electrically Assisted Amplified Spontaneous Emission to Injection Lasing with Metal Halide Perovskites Iakov Goldberg, Karim Elkhouly, Xin Zhang, Nirav Annavarapu, Sarah Hamdad, Guillaume Croes, Cedric Rolin, Jan Genoe, Weiming Qiu, Robert Gehlhaar and Paul Heremans; IMEC, Belgium

Metal halide perovskites have emerged as promising gain media for thin-film laser diodes. However, achieving electrically excited amplified spontaneous emission (ASE) and lasing in perovskite light-emitting diodes (PeLEDs) is challenged by the conflicting requirements of high conductivity and high net modal gain of the device stack. We break this trade-off by developing a transparent PeLED architecture that combines excellent current-injection properties with low optical losses [1]. The device is operated at 77 K and delivers current densities above 3 kA cm^{-2} with irradiance values above 40 W cm^{-2}, whilst displaying an ASE threshold of 9.1 μJ cm^{-2} using 2.3 ns optical laser pulses. By co-exciting the PeLED with optical pulses that are synchronized with the leading edge of an intense electrical pulse, we achieve a reduction of the ASE threshold by 1.2 μJ cm^{-2}, showing that electrically injected carriers contribute to optical gain. This breakthrough addresses the first essential pre-condition for perovskite laser diodes. A perovskite gain layer with a three-dimensional morphology has been used in this work, showing that there is potential for the reduction of the amplification threshold through elaborate quantum confinement engineering.

Integration of an optical cavity, which does not compromise PeLED performance, is a critical next step in transitioning from optical amplifier structures to laser diodes. It is noteworthy that reaching injection lasing might turn out to be more accessible than cavity-free electrically stimulated ASE. Specifically, when studying standalone perovskite films deposited over distributed feedback structures, we have achieved an optically pumped lasing threshold that is a factor of ~2 lower than the ASE threshold of neat films [2]. Consequently, we propose an integration route where the resonators are embedded into the substrate with a planarized arrangement of alternating materials with differing refractive indices. This approach eliminates challenges associated with the thin-film deposition atop corrugated surfaces, such as increased leakage currents, strong local electric fields, and nonuniform current distribution. Finally, we show that such a planarized grating can be married with the proposed transparent PeLED architecture, where efficient mode coupling is facilitated by the use of a thin bottom transparent electrode [3]. We believe that this alternative integrating scheme will accelerate the development of thin-film perovskite injection lasers.

Facile and Composition-Flexible Alternate Route to Perovskites Dean G. Grier, Tapan K. Jena, Yuvraj Patil and Philip Boudjouk; North Dakota State University, United States

Halide perovskites have emerged as promising candidates for a variety of applications, including solar cells and light emitting diodes. In the field of photovoltaics, power conversion efficiencies have risen rapidly and competitively over the past several years, although environmental stability remains a focus of study. Herein we report a method for synthesizing a variety of phase pure perovskites through a simple solution method followed by mild thermolysis. Our group has previously successfully demonstrated synthesis of metal chalcogenide semiconductors as well as nanocomposites of polymers with metal chalcogenide semiconductor quantum dots, through the use of organometallic single source precursors. The approach allows access to compositions across the periodic table, including those from Groups 13-15, 14-16, and 12-16. Following on from this work, we turned our approach to perovskite materials. In this study, we demonstrate synthesis of the all-inorganic lead-free perovskites A_2SnX_6, with A=Cs, Rb, K, and X=Cl, Br, I.

Less Defect and Stable Perovskite Nanocrystals: Optical Property and Photoexcited Carrier Dynamics Qing Shen, Yusheng Li and Hua Li; The University of Electro-Communications, Japan

Perovskite nanocrystlas (PNCs) have gained significant attention for both fundamental research and applications of optoelectronic devices owing to their appealing optoelectronic properties and excellent chemical processability. For their wide range of potential applications, synthesizing PNCs with high crystal quality and stability is of crucial importance. Recently, we have suceeded in synthesis of phase stable and less defect PNCs, including $APbX_3$ NCs (A: FA, MA, Cs; X: I, Br, Cl), Sn-Pb alloyed NCs and Sn-based PNCs [1-7]. We have demonstrated that a high room-temperature photoluminescence quantum yield (PL QY) of close to 100% can be obtained in the Pb-based PNCs, signifying the achievement of ignorable less trapping defects in the PNCs. Ultrafast kinetic analysis with time-resolved transient absorption spectroscopy evidences the negligible electron or hole trapping pathways in our PNCs, which explains such a high quantum efficiency. In addtion, photoexcited hot and cold carrier dynamics as well as charge transfer were systematically investigated [4,8,9]. Solar cells based on these high-quality PNCs exhibit power conversion efficiency of over 15%, showing great promise for practical application. In addition, through metal doping and Sn (IV) control [5-7,10] , we found that Sn(IV)-induced defects and distortions could be reduced greatly in Sn and Sn-Pb PNCs. As a result, stable Sn and Sn-Pb PNCs with ultra long carrier lifetimes (> 180 ns) were realized. Our findings provide new insights into the materials design strategies for improved optoelectronic properties of Sn-containing perovskites [10].

High Stability of Sn-Based Perovskite by Adding Reducing Agents for Perovskite Solar Cells Teresa S. Ripolles; University of Valencia, Spain

Tin-based (Sn) halide perovskites have become one of the most prospective photovoltaic materials due to their optoelectronic properties, high photoconversion efficiency and relatively low toxicity.[1][2] Nevertheless, the rapid crystallization of tin-based perovskite and the easy oxidation of Sn^{2+} to Sn^{4+} under ambient conditions increases the interest of the scientific community.[3] To avoid these undesirable processes, we will address by two different methods, for instance, (i) organic cations engineering in Sn-based halide perovskite microcrystals, and (ii) adding reducing agents in three dimensional perovskite thin film.
On the one hand, Sn-based halide perovskite microcrystals have been synthetized by hot-injection method to control the dimensionality by changes the concentration of reactants. The physical properties suggest high photoluminescence quantum yield (PLQY) of 75% and 25% for chloride-based and bromide-based, respectively, and almost negligible for 2D Sn-based microcrystals.
On the other hand, increasing the perovskite dimensionality, we suggest adding a variety of additives that act as reducing agents with different nature in thin film. The addition of these novel materials into the $FASnI_3$ (FA is formamidinium) perovskite solution controlled the oxidation reaction and improved the surface morphology. An inverted perovskite solar cell was prepared and characterized. Due to the Sn^{4+} concentration is reduced in the Sn-based perovskite layer, the power conversion efficiency in a solar cell and the cell stability under ambient conditions are improved notably in comparison with the pure $FASnI_3$.

Investigating The Influence of Multivalent Transition Metal Dopants on Copper Antimony Sulphide Thin Films for Enhanced Photovoltaic and Electrochemical Properties Kimberly A. Weston and Richard A. Taylor; The University of The West Indies, Trinidad and Tobago

Undoped non-stoichiometric semiconducting copper antimony sulphide (CAS) thin films were deposited at 500, 550 and 600 °C onto glass substrates by aerosol-assisted chemical vapour deposition (AACVD) at different flow rates and copper concentrations using metal diethyldithiocarbamate precursors. For thin films deposited at an optimal flow rate, data from powder X-ray diffraction (p-XRD), X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, and scanning electron microscopy-energy dispersive X-ray spectroscopy (SEM-EDS) suggest a correlation of composition of the non-stoichiometric sulphur-deficient tetrahedrite phase (cubic structure) microcrystalline CAS ($Cu_{12}Sb_4S_{13}$) thin films with particle sizes ranging from 0.1 to 4 µm. For undoped thin films, visible optical absorption and cyclic voltammograms (CV) show a bandgap of ~2.1 eV is likely associated with compositional variations involving intrinsic lattice defects, including shallow electronic states such as copper interstitials ($Cu_i^{\bullet/\bullet\bullet}$) and vacancies of sulphur ($V_s^{\bullet\bullet}$) as deep-lying donors, and copper-antimony anti-sites ($Cu_{Sb}^{\prime/\prime\prime}$) and antimony vacancies ($V_{Sb}^{\prime\prime\prime}$) as deep-lying acceptors. Additionally, upper first row transition metal divalent (M^{2+}) ions such as Mn^{2+}, Co^{2+}, Ni^{2+} and Zn^{2+} were incorporated into tetrahedrite phase CAS (*t*CAS) thin films at optimal temperature, 550 °C and flow rate, 150 sccm. M^{2+} ions incorporated (M_x-*t*CAS) exhibit tunable composition-driven electronic structure for small M^{2+} content influencing narrower bandgaps between 1.7 and 1.9 eV. The Raman data suggest that the phase purity is affected by small fractions of the famatinite (tetragonal) phase. Additionally, *t*CAS and M_x-*t*CAS thin films were deposited on conducting substrates (ITO/FTO) and were found to be efficient as a novel catalyst for the hydrogen and oxygen evolution reactions in water splitting. Overall, the thin films display broad emission of fast dual radiative recombination, and an additional recombination pathway exhibited for M_x-*t*CAS associated with divalent ion-related point defects. These results show the utility of AACVD in tuning compositional and optical and electrochemical properties of undoped *t*CAS and M_x-*t*CAS thin films for possible applications in photovoltaics and electrochemical conversion.

9:00 AM EN10/EN11.04
Lead-free Perovskites: Toward an Opto-Electronics based on Abundant Elements and Low Temperature Synthesis Ilhem Elgargouri[1,2], Hind Kadiri[1], Akram Alhussein[1], Rached Ben Hassen[2] and Gilles Lerondel[1]; [1]Université de Technologie de Troyes, France; [2]University of Tunis El Manar, Tunisia

The depletion of natural resources today necessitates a reevaluation of technological development, considering both material abundance and energy-efficient processes while maintaining device efficiency. This research presents a comprehensive investigation into the design and synthesis of advanced thin films materials for improved optoelectronic applications. By exploring the unique properties of lead-free perovskites oxides, we aimed at engineering materials with enhanced electrical conductivity, stability, and optical properties.
For this work, we chose two types of perovskites oxides: $SrSnO_3$ and $LaVO_3$. The reason behind this choice is the combination of abundancy, non-toxicity, and low-cost production of these materials along with the tunable bandgap, the stability and durability.
In this study, we will detail the tailored synthesis process with sol-gel method using different percentages of doping. We discuss the systematic characterization of the resulting thin films through various analytical tools.
Nontoxic, relatively cheap precursors, and solvents were used without generating waste materials. The viscosities were controlled, and the resulting resins were spin-coated on Silicon and Quartz. The wet films were then annealed at 673 K to remove organic material and crystallized at 1173 K for 1h in air**.**
Using scanning electron microscopy, the film thickness was found to be around 200nm with a highly uniform and homogeneous surface, X-ray diffraction confirmed the perovskite phase with an intense peak at 32°, and optical measurements proved the transparency of 80% in the visible range with an absorption in the UV range around 300nm.
The results reveal a clear correlation between the synthesis parameters and the optoelectronic performance of the materials, demonstrating the feasibility of optimizing these materials characteristics through precise control of the synthesis process.
The objective of this work is the realization of optoelectronic components (pn junction) based on doped perovskite oxide semiconductors ($SrSnO_3$: Sb@$SrSnO_3$: Al on ITO and $LaVO_3$) synthesized using an ecofriendly environmental synthesis (sol-gel process). Application as light absorbers or barrier layers in highly efficient solar cells are foreseen. Other applications are also possible (e.g., LEDs).
This work contributes to the ongoing efforts to develop sustainable and efficient materials for optoelectronic devices and underscores the pivotal role of advanced material synthesis techniques in achieving this goal.

Computational Workflows for an Accelerated Design of Novel Materials and Interfaces Ivano Eligio Castelli; Technical University of Denmark, Denmark

The development of automated computational tools is required to accelerate the discovery of new functional materials, to speed up the transition to a sustainable future. Here, I address this topic by designing new electrodes with controlled interfaces for different applications which accelerate the transition to a sustainable future. These workflows are implemented in the framework of Density Functional Theory (DFT), using MyQueue and the Atomistic Simulation Environment (ASE). In the first part of my talk, starting from our recent work on a fully autonomous workflow, which identifies materials to be used as intercalation electrodes in batteries, based on thermodynamic and kinetic descriptors like adsorption energies and diffusion barriers,[1] I will describe a new modular approach to estimate electronic and ionic mobility in energy materials useful for a variety of applications, from batteries and fuel cells and solar energy conversion and storage. A substantial acceleration for the calculations of the kinetic properties has been obtained due to a recent implementation of the Nudged Elastic Bands (NEB) method, which takes into consideration the symmetries of the system to reduce the number of images to calculate. Moreover, we have established a surrogate model to identify the transition states, which can further reduce the computational cost to at least one order of magnitude.[2,3] In the second part of my talk, I discuss how engineering the interface can positively impact surface properties for electrochemical water splitting: I apply strain engineering and external stimuli to switch material's polarization to decrease the reaction overpotential in oxynitride materials for the oxygen evolution reaction.[5,6] In the last part of my talk, I will describe my vision for autonomous computational workflows, namely the creation of workflows for interface and their integration with experimental workflows.

SESSION EN11.01: Phosphide PV I
Session Chairs: Andrea Crovetto and Xiaojing Hao
Wednesday Afternoon, April 24, 2024
Room 335, Level 3, Summit

1:30 PM *EN11.01.01
Experiments toward High-Performance Zintl Phosphide Solar Absorbers Sage Bauers[1], Obadiah Reid[1], David Fenning[2], Andriy Zakutayev[1], Jifeng Liu[3], Kirill Kovnir[4] and Geoffroy Hautier[3]; [1]National Renewable Energy Laboratory, United States; [2]University of California, San Diego, United States; [3]Dartmouth College, United States; [4]Iowa State University of Science and Technology, United States

Most photovoltaic absorber materials development is done on materials with known or slightly modified structural prototypes; for example, kesterite, chalcopyrite, and zincblende are all derived from mutations to the diamond crystal structure. It is rare and sometimes transformative—such as in halide perovskites—when new structural classes of absorber materials are discovered. The AM_2P_2 (A = alkaline earth cation such as Ba, Ca, Sr and M = 2+ cation such as Zn, Cd) compounds have previously been described as semiconducting zintl phases and are structurally distinct to widely studied PV materials. However, these have attracted recent interest from theory as materials with solar-spectrum matched band gaps and tolerance to intrinsic point defects. $BaCd_2P_2$ is particularly compelling with a direct 1.45 eV band gap and mostly comprising inexpensive elements already used in solar absorber applications, thus having high-grade feedstocks already available. Here, we report on the synthesis and properties of $BaCd_2P_2$ and related AM_2P_2 materials. $BaCd_2P_2$ can be synthesized in powder form from elemental precursors using conventional solid-state reaction methods. The material forms in a P-3m1 crystal structure ($CaAl_2Si_2$ prototype) and is stable in open air heating up to 300 °C as well as in acids, bases, and at even higher temperatures in inert environments. $BaCd_2P_2$ powder shows strong band-to-band photoluminescence that is stable at elevated temperature and time-resolved microwave conductivity shows long photoexcited carrier lifetimes of around 30 ns, which is already longer than observed in some much more mature absorber technologies. Since the direct-gap AM_2P_2 materials will be most compelling as thin film absorbers, we also discuss several ongoing efforts to realize these compounds in thin film format.

2:00 PM *EN11.01.02
Emerging Cu-Based Phosphides as Contacts and Absorbers for Solar Energy Conversion Andrea Crovetto[1,2,3] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Technical University of Denmark, Denmark; [3]Helmholtz-Zentrum Berlin, Germany

Many new contact and absorber materials have been studied in the past decade for solar energy conversion applications. For example, research into emerging chalcogenides expanded from zincblende-derived CdTe, $CuInSe_2$ and Cu_2ZnSnS_4 to include non-tetrahedrally bonded compounds like 1D-bonded Sb_2S_3, layered $CuSbS_2$ chalcostybites, or $BaZrS_3$ perovksites.

There are much fewer known phosphide solar materials, besides II-IV-P_2 derivatives of GaP (e.g. $ZnSnP_2$, $ZnSiP_2$) and their binary constituents (e.g. Zn_3P_2) studied as absorbers, or wide band gap bipolar dopable BP that has been considered for contact applications. Nevertheless, the reported semiconductor properties and initial device performances of phosphide materials are quite promising and deserve further research attention.

This presentation will highlight a few emerging phosphide materials based on Cu, as potential transparent contact and light absorber layers in solar energy conversion devices. The first example is experimental demonstration of high electrical conductivity and measurement optical transparency in theoretically predicted CaCuP sputtered thin film material [1]. The second example is two-step synthesis and semiconductor property measurements of CuP_2 – one of the first known phosphorus-rich semiconductors in thin film form [2].

General synthesis and characterization challenges associated with doing experiments on the phosphide class of materials will be also discussed.

Biased Photoreflectance Spectroscopy for Characterization of Band Bending in Compound Solar Cells Isshin Sumiyoshi and Yoshitaro Nose; Kyoto University, Japan

Introductions
The optimization of pn junctions is an inevitable subject to realize high performance of emerging solar cells. Junction capacitance, derived from overall capacitance of a solar cell through an equivalent circuit, widely used to evaluate band bending in a pn junction. However, in emerging solar cells, the electrical properties and band structures of layers or junctions other than the target are often unknown, thereby introducing various unknown factors into the evaluation of specific physical properties.
In this study, we present a characterization technique of pn junctions through Franz-Keldysh oscillations (FKOs). FKOs can be observed in spectra of modulation spectroscopy, such as photoreflectance (PR) and electroreflectance (ER). Analyzing the oscillation periods in spectra provides the internal electric field applied to the pn junctions, offering a means to estimate band bending. Furthermore, we propose applying a bias voltage to solar cells during

PR measurement, denoted as biased PR (B-PR) measurement. Through this method, we attempted to evaluate the interface states within pn junction.
Experimental methods
We performed PR measurements on pn junction solar cells using $ZnSnP_2$ (ZTP) bulk crystals and GaInP thin film as absorbing layers, representing emerging and highly efficient solar cells, respectively.
The PR and B-PR measurement was conducted at room temperature using a PR measurement system (Seishin Trading Co. Ltd). A YAG laser (λ=532 nm) was used as a pump beam and its modulation frequency was set at 711 Hz. The probe beam was a monochromatized light from Xenon lamp. In the B-PR measurement, a bias voltage ranging from -5 to +1.4 V was applied to the solar cells using a source meter (Keithly 2400) and Au probes.
Results and discussions
In the PR spectra of the ZTP solar cell measured without bias voltage and any contacts, FKOs with up to the 5th extrema were observed at photon energies higher than the bandgap of ZTP (1.64 eV). The internal electric field in ZTP layer around the pn junction was determined to be 87 ± 8 kV cm^{-1}, derived from the FKOs period following the theory proposed by Aspnes and Studna [2]. Assuming an uniform acceptor concentration of 5.5×10^{16} cm^{-3} in the ZTP layer, we estimated the charge distribution around the pn junction using the Poisson's equation. As the results, we determined the depletion layer width and the surface potential at the pn junction in ZTP side as 83 nm and +0.47 eV from the valence band maximum (VBM) of ZTP, respectively. It is here emphasized that the above results were obtained with contactless.
FKOs were observed over a bias voltage range from -5 to + 1.4 V also in the B-PR spectra. Following the above-mentioned analysis, we obtained the bias voltage dependence of the surface potential. In the absence of interface states at a pn junction, the surface potential is expected to monotonically increase with rising reverse bias. This behavior is theoretically expressed through the Poisson's equation. However, the experimental results deviate from the theoretical curve, exhibiting plateau regions around bias voltage of 0 and -4 V. The applying of bias voltage to a solar cell corresponds to the control of the Fermi level. The deviation in the bias dependence of the surface potential from the theoretical curve may be attributed to the occupation (emission) of electrons at interface states. Such transitions of electrons are facilitated by approach of the Fermi level to the interface level. In the ZTP solar cells, the levels of the plateau regions were +0.45 eV and +1.3~+1.5 eV from the VBM of ZTP. In the presentation, we will discuss the consistency between the B-PR measurement and conventional capacitance measurement, using GaInP III-V solar cells together with ZTP solar cells.

Recent Progress on The Application of Spectroscopic Ellipsometry for a Multilayer Analysis of CdTe-Based Solar Cell Structures Incorporating Magnesium–Zinc Oxide Transparent Layers Mohammed Alaani[1], Prakash Koirala[1], Balaji Ramanujam[1], Ambalanath Shan[1], Adam Phillips[1], Nikolas Podraza[1], Stephen K. O'Leary[2] and Robert Collins[1]; [1]The University of Toledo, United States; [2]University of British Columbia, Canada

We present some recent progress that has been made on the application of an optical function parameterization of polycrystalline Mg*x*Zn1-*x*O (MZO) thin films on the bandgap that has been used for the metrology of CdTe-based solar cell structures that incorporate MZO thin films as high resistivity transparent (HRT) layers. The acquired parametric expressions are applied to facilitate the mapping spectroscopic ellipsometry (M-SE) of device structures consisting of glass/SnO2:F/MZO. M-SE is shown to provide maps in the MZO effective thickness and bandgap within confidence limits of ± 1 nm and ± 0.003 eV, respectively. As a second application of this parameterization, performed on an as-deposited glass/SnO2:F/MZO/CdS/ CdTe device structure, has been made using through-the-glass spectroscopic ellipsometry (TG-SE). Such an analysis is also shown to provide the MZO effective thickness and bandgap. The outcome of the TG-SE analysis for this device structure enables simulations of the external quantum efficiency (EQE) spectrum of the resulting solar cell assuming different recombination losses within the individual layers of the structure. A comparison of these simulations with the experimental EQE spectrum reveals improved current collection from the front of the device incorporating an MZO HRT layer.

A Detailed Investigation on The Photothermal Properties of $SnFe_2O_4$ as a Photocatalyst for Wastewater Treatment Lei Liu and Chunli Liu; Hankuk University of Foreign Studies, Korea (the Republic of)

$SnFe_2O_4$ is a magnetic semiconductor with a spinel crystal structure. Due to its relatively narrow bandgap of less than 2.0 *e*V, $SnFe_2O_4$ holds promising potential for achieving a full spectral response to the solar radiation with enhanced energy utilization. However, research on its photothermal effects has been limited so far. In this study, we successfully synthesized narrow-bandgap $SnFe_2O_4$ (1.62 *e*V) via hydrothermal synthesis. Using Chlorotetracycline (CTC) as a model antibiotic pollutant, we investigate the photothermal properties of $SnFe_2O_4$ in various catalytic modes. Thermal catalytic experiments at different temperatures, photocatalytic experiments with various light wavelengths, and photothermal catalytic experiments under simulated solar light were conducted to evaluate the photoexcitation and thermal excitation properties.
Our findings reveal that $SnFe_2O_4$ efficiently utilizes different spectral regions of sunlight: photothermally activated under UV and visible light and mainly thermally excited under near-infrared light. Furthermore, CTC degradation experiments have shown that SnFe2O4 can degrade CTC effectively under real outdoor sunlight. Even under cloudy weather conditions, $SnFe_2O_4$ retains catalytic activity if the ambient temperature can be kept at higher than 35°C. Therefore, this narrow-bandgap catalyst possesses the remarkable capability to enhance solar energy utilization significantly. Thus, it is believed to promise the design of a full solar spectrum photocatalyst for wastewater treatment.

Efficient Photocatalytic Degradation of Pharmaceutical Residues with Ni-TiO2/gC3N4 Heterojunction Yiting Xiao, Yang Tian and Jun Zhu; University of Arkansas, Fayetteville, United States

The proliferation of pharmaceutical residues in natural water systems has emerged as a significant environmental concern over the past decades. In response to these contaminants of emerging concern (CECs), our study introduces an innovative photocatalytic system, comprising Nickel (Ni)-doped Titanium Dioxide (TiO2) synergized with graphitic carbon nitride (gC3N4). This system demonstrated a notable 82.3% degradation efficiency of sodium salicylate, a precursor and active component of one of the most widely used medications (aspirin) in the world, within 4.5 hours. Utilizing the Central Composite Design and Response Surface Methodology (CCD/RSM), we optimized the Ni to TiO2 ratio, the gC3N4 to Ni-TiO2 proportion, and catalyst dosage. Detailed characterizations, including SEM, XRD, XPS, UV-VIS spectrophotometry, and electrochemical studies, revealed the catalyst's superior properties. Beyond sodium salicylate degradation, this system exhibits potential for broader organic pollutant remediation, presenting a promising avenue in wastewater treatment and environmental cleanup strategies.

5:00 PM EN11.03.05
Breaking Barriers in Chalcogenide Perovskite Synthesis Kiruba Catherine Vincent, Shubhanshu Agarwal, Jonathan Turnley and Rakesh Agrawal; Purdue University, United States

Chalcogenide perovskites are emerging semiconductor materials with attractive optoelectronic properties. These materials have been shown

computationally and experimentally to possess high absorption coefficient, tunable bandgap, and high dielectric constant. In contrast to their lead halide counterparts, they are known to be stable, and earth-abundant with nontoxic constituents, making them potential candidates for a variety of electronic applications.
However, the existing rudimentary synthesis techniques have limited the growth of these materials. Traditional solid-state and vacuum processing methods demand temperatures in excess of 800-1000 °C, which bring about difficulties in identifying suitable substrates and subsequent device fabrication.
To address these issues, we have identified the key barriers in the synthesis of these materials and succeeded in reducing the synthesis conditions to moderate temperatures (<600 °C) and time periods of 1-2hrs. Our work also identifies a potential liquid flux that enables to overcome the diffusional limitations between precursors.

5:00 PM EN11.03.06
Structure and Phase Transition Study of Emerging Sb and Bi Chalcohalides by X-Ray Diffraction Ivan Caño Prades[1], Alejandro Navarro[1], Mykhailo Kolstov[2], Maria Del Barrio[1], Marcel Placidi[1], Josep Lluís Tamarit[1], Xavier Alcobé[3], Nicolae Spalatu[2], Joaquim Puigdollers[1] and Edgardo Saucedo[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Tallinn University of Technology, Estonia; [3]Universitat de Barcelona, Spain

Sb and Bi-based Van der Waals chalcohalides with formula MChX (M=Sb or Bi, Ch=S or Se and X=Br or I) are constituted by relatively earth-abundant and non-toxic elements, they have bandgaps in the 1.5-2.0 eV range, and they can be synthesized at low temperatures. In addition, their low-dimensional structure leads to enhanced transport properties, which make these largely overlooked materials very attractive for advanced energy applications, including photovoltaics. Furthermore, chalcohalides have been reported to possess ferroelectric properties, whereby a small displacement along their *c*-axis switches between centrosymmetric and non-centrosymmetric structures.[1] However, despite previous studies and theoretical calculations, there is a general lack of information on their structural properties regarding the impact of elemental substitution and temperature on the cell parameters, phase stability, and ferroelectricity.

In this work, the eight materials obtained from MChX permutations have been synthesized as thin films by physical vapor routes. Then, they have been characterized by X-ray diffraction (XRD), and Le Bail and Rietveld refinement techniques have been performed to acquire the cell parameters and volume, phase composition, texture characteristics, and other structural features. Various trends and correlations have been observed, revealing the impact that the metal, chalcogenide and halogen have on the structure of the material respectively. For example, it is shown that the halogens have a bigger impact on the cell volume and parameter *a* but the chalcogenide has the strongest effect on parameter *c* (covalently-bonded ribbons). On the other hand, changing the metal (M), the unit cell is compressed in direction *a*, but expands in the other crystallographic directions. Also, it has been observed that the volume and cell parameters are highly correlated with the ionic radii, and that compounds with larger electronegativities have lower cell volumes. Overall, it is demonstrated that halogens have the biggest impact on all the structural properties.

Secondly, thermal characterization and temperature-dependent X-ray diffraction experiments have been performed on selected samples, aiming at studying phase stability and transitions. For instance, SbSI powders have been analyzed by differential scanning calorimetry and XRD, identifying the phase transition between paraelectric and ferroelectric structures with Curie point at room temperature. Thin films have also been characterized using temperature-dependent XRD, giving bigger insight on the stability of chalcohalide phases and the effect of temperature on their structure.

A Figure of Merit to Quantify The Efficiency Potential of your Favorite Emerging PV Material Andrea Crovetto; Technical University of Denmark, Denmark

The pace of exploration of new photovoltaic (PV) materials has accelerated in recent years, but we are still lacking methods to (i) quantify their efficiency potential during early development stages, (ii) guide their optimization, and (iii) help researchers make rational decisions on which materials are worth investigating.

To help achieve these goals, I propose a human-derived figure of merit for PV materials based on 30,000 drift-diffusion simulations. The applicability of the figure of merit is demonstrated on a sample of 25 PV materials of current research interest, but the method can immediately be applied to experimentally synthesized or computationally examined materials at any development level, as long as seven of their bulk material properties have been determined by experiment of first-principles calculations.

This figure-of-merit approach helps understand whether imperfect PV performance is intrinsic to the material (inadequate bulk properties at the current stage of development), or if it "only" requires a different device structure, contact layers, or improved interface properties. For example, the reasons for the lack of and $NaBiS_2$ and $BaZrS_3$ solar cells with notable PV efficiencies are completely different for the two materials.

Using a local version of the proposed figure of merit, a material-specific optimization strategy can be laid out for any experimentally synthesized PV absorber, by specifying the bulk properties that should most urgently be improved to increase their PV efficiency.

Come by my poster and estimate the maximum efficiency of your favorite emerging PV material!

5:00 PM EN11.03.08
Photoluminescence of $BaCd_2P_2$ as a New Defect-Insensitive Solar Material Gideon Kassa[1], Smitakshi Goswami[1], Zhenkun Yuan[1], Muhammad R. Hasan[2], Andrew Pike[1], Shaham Quadir[3], Yihuang Xiong[1], Victoria Kyveryga[2], Diana F. Dahliah[4], Gian-Marco Rignanese[4], Romain Claes[4], Andriy Zakutayev[3], David Fenning[5], Obadiah Reid[6], Sage Bauers[3], Kirill Kovnir[2], Geoffroy Hautier[1] and Jifeng Liu[1]; [1]Dartmouth College, United States; [2]Iowa State University of Science and Technology, United States; [3]National Renewable Energy Laboratory, United States; [4]Université Catholique de Louvain, Belgium; [5]University of California, San Diego, United States; [6]University of Colorado Boulder, United States

Searching for earth-abundant, defect-insensitive solar materials can play a significant role in future photovoltaics. Here we experimentally verify $BaCd_2P_2$ as a promising candidate for low-cost, high-efficiency photovoltaic material, as predicted by high-throughput screening of nearly 40,000 semiconductors. Its optimal band gap of 1.45 eV and properties such as temperature stability and long carrier lifetime make $BaCd_2P_2$ a strong photovoltaic candidate. We were able to experimentally demonstrate the optical performance of $BaCd_2P_2$ by comparing its photoluminescence (PL) intensity with that of GaAs. The relatively low-purity (99.9%) $BaCd_2P_2$ powder had direct gap PL intensity in the same order as GaAs powder obtained from a prime single crystalline wafer, suggesting that it is insensitive to impurities and defects. We further present an in-depth investigation of the PL spectrum of this promising material

by studying the impact of temperature, excitation laser power, and composition variations. Nearly all our experimental data have agreed with our theoretically calculated properties of $BaCd_2P_2$. The calculated band structure suggested a direct gap of 1.45 eV and an indirect gap of 1.48 eV. The PL spectrum of $BaCd_2P_2$ at 298 K, had a peak at 847 nm (1.46 eV), aligning well with the predicted band structure, and another, broader, peak at 980 nm. At 78 K we observed a separate peak on the lower wavelength side of the 847 nm peak resulting from the indirect gap transition, further validating our computed band structure. This material also showed great temperature stability, increasing the temperature to 368 K had only a slight decrease in the PL emission by ~5%, which fully recovered when going back to 298 K. Our work on excitation power dependence of PL intensity has enabled us to confirm the nature of 847 nm peak and gain a better understanding of the 980 nm peak. We did this by modifying the well-known equation $I_{PL} = C * (P_{laser})^{\alpha}$ (meant to model the change in PL peak intensity with power) to account for competing nonradiative processes such as Auger recombination at higher excitation powers and consider the potential saturation of available states. We developed a more generalized equation that treats PL intensity as a function of thermal excitation, laser excitation, and nonradiative recombination. For the 847 nm peak, we repeatedly got a value of the α parameter that was strongly indicative of a band-to-band transition. We saw that the 980 nm peak does not blueshift with decreasing temperature and that it had a strikingly similar response to PL laser excitation power variations as the radiative defect of Si-doped GaAs, appearing at 950 nm, leading us to hypothesize that the 980 nm peak of $BaCd_2P_2$ is due to a shallow radiative defect. We conducted an evaluation of the change in the 950 nm defect PL peak when using off-stoichiometric $BaCd_2P_2$ samples. We observed that the peak intensifies and is slightly redshifted in Ba-poor samples. We further used the data from our studies of PL intensity change with temperature to calculate the activation energy of the prominent nonradiative defects.

Enhancing Photocatalytic Hydrogen Production with Nanocone-Structured Z-Scheme Photocatalysts Jihun Kim, Ryun Na Kim, Sungwan Kwon, HyungYong Ji, Jeongyeol Kim and Whi Dong Kim; Korea Institute of Industrial Technology (KITECH, Korea (the Republic of)

Z-scheme photocatalysts have emerged as a promising solution to address the efficiency challenges in solar-assisted water splitting, thanks to their capability to efficiently absorb visible light and maintain the essential charge potential required for overall water splitting. To ensure the successful operation of Z-scheme photocatalysts, it is crucial that the two constituent photocatalysts and the charge recombination layer are precisely arranged in a specific sequential order. However, previous research has predominantly utilized Z-scheme photocatalysts in a randomly mixed configuration, thereby preventing the full exploitation of the unique attributes inherent to Z-scheme photocatalysts.

This study demonstrates fabrication of a nanocone-structured BiVO4/SrTiO3 Z-scheme photocatalytic thin film, enabling effective Z-scheme charge transfer. The fabrication process involves the preparation of a nanocone BiVO4 structure on a glass substrate, the formation of a BiVO4/reduced graphene oxide (RGO) composite nanocone structure, and the deposition of SrTiO3 nanoparticles to form BiVO4-RGO-SrTiO3 Z-scheme photocatalyst. The resulting structure comprises BiVO4, RGO, and SrTiO3 arranged sequentially. A comparative analysis between randomly mixed Z-scheme photocatalysts and the arranged Z-scheme photocatalyst demonstrates a significant enhancement in hydrogen production efficiency for the latter, underscoring the pivotal role of precise arrangement in Z-scheme photocatalysis.

Additionally, the study investigates how the superhydrophobic surface properties of the nanocone structure influence the capture of hydrogen and oxygen gas bubbles generated during the water splitting reaction in photocatalyst module. The nanocone-structured Z-scheme thin film efficiently captures gas bubbles due to its superhydrophobic surface characteristics, while the randomly mixed Z-scheme photocatalyst experiences reduced gas bubble detachment, resulting in decreased photocatalyst production efficiency.

This study underscores the importance of meticulous Z-scheme photocatalyst arrangement and highlights the advantages of the nanocone structure in improving gas bubble capture during the water splitting process, thus contributing to the advancement of photocatalytic hydrogen production.

5:00 PM EN11.03.10
Enhancing Photocatalyst Efficiency through Type-II Core/Crown Nanoplatelets for Improved Charge Separation Ryun Na Kim, Jihun Kim, Sungwan Kwon, HyungYong Ji and Whi Dong Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Semiconductor nanocrystal-based photocatalysts have garnered significant attention for their potential applications in diverse fields, including hydrogen production, CO2 conversion, and pollutant removal. However, a major hurdle to improving their efficiency arises from the fact that the radiative recombination rate of semiconductor nanoparticles (~hundreds of nanoseconds) is much faster than the rates of photocatalytic reactions (~microseconds to ~milliseconds). This leads to the loss of the majority of charges before they can actively participate in the desired photocatalytic reactions, resulting in low efficiency. Therefore, it is crucial to develop structures that facilitate efficient charge separation to address this efficiency issue in photocatalysts. The most common approach to tackle this challenge involves utilizing core/shell structures to create a type-II band alignment structure. However, this approach has a drawback: while it enhances charge separation, it tends to trap electrons or holes within the core, limiting their participation in photocatalytic reactions.

In this research, we explore the influence of type-II core/crown nanoplatelets (NPLs) on photocatalytic reactions. These NPLs possess a type-II band alignment structure while exposing both the core and crown regions externally, enabling active participation of both electrons and holes in photocatalytic reactions. To maximize the efficiency of charge separation in this open structure, we prepared core/crown nanoplatelets with various compositions, including CdS, CdSe, and CdTe, while carefully controlling the surface area of both the core and crown regions.

We conducted femtosecond laser-based time-resolved photoluminescence measurements and transient absorption measurements to analyze the carrier dynamics of the prepared NPLs. Then, we performed water-splitting experiments under light irradiation to clarify the relationship between charge separation and photocatalytic activity. The results revealed that as the carrier lifetime of the photocatalyst increased, the hydrogen generation rate also significantly increased. This highlights the significance of the charge carrier lifetime as a pivotal parameter impacting photocatalytic activity.

Furthermore, to validate tthe significance of an open structure, such as the core/crown configuration, we prepared type-II core/shell quantum dots with the equivalent composition and similar lifetimes to the core/crown nanoplatelets. Surprisingly, despite the efficient charge separation structure of the type-II core/shell quantum dots, their photocatalytic efficiency decreased. These findings underscore the importance of an open structure that facilitates the active participation of both electrons and holes in photocatalytic reactions while concurrently prolonging the carrier lifetime, ultimately resulting in enhanced photocatalyst efficiency.

5:00 PM EN11.03.12
Aspects Relevant to Developing Solar Cells of Tin Sulfide-Selenide of Cubic Crystalline Structure produced by Vacuum Thermal Evaporation Fabiola De Bray Sanchez, M.T. Santhamma Nair and P. K. Nair; Universidad Nacional Autonoma de Mexico, Mexico

In recent work (2023), thin films of tin sulfide selenide of cubic crystalline structure were prepared at a substrate temperature of 450 °C at a low deposition rate of 3 nm/s by vacuum thermal evaporation (TE) of SnS-SnSe/Se powder sources. This opens up methodologies for preparing novel photovoltaic

absorber materials of a cubic crystalline structure with optical bandgap (E_g) 1.45 – 1.65 eV, which permits to achieve a light generated current density of 25 – 35 mA cm^{-2} and a relatively high open circuit voltage, unlike in the more commonly known orthorhombic polymorph of SnS or SnSe with E_g of 1.1 or 1 eV, respectively. The development of SnS or SnSe of cubic crystalline structure by TE eluded until recently because of a deposition rate of > 10 nm/s typical in vacuum deposition techniques resulting in films of orthorhombic structure. The relatively higher content of Se in a SnS-Se-CUB helps to modify the E_g of the films toward 1.5 eV. It also helps to increase its p-type conductivity from 10^{-6} to nearly 10^{-3} Ω^{-1} cm^{-1}. With less than 1% of Se in the SnS-CUB film, the vacancies at the S-sites are compensated, while maintaining the E_g of 1.7 eV (inherent in a SnS-CUB film) along with an increased electrical conductivity of 10^{-3} Ω^{-1} cm^{-1}, which is higher by three orders of magnitude than that of the SnS cubic film. These results offer many options for solar cell configurations. Basically, they help to improve the proof-of-concept solar cell of FTO/CdS/SnS-CUB (TE)/C with V_{oc} of 0.478 V, but with la ow conversion efficiency of < 1% by providing a back surface field p-type layer of SnS-Se-CUB:Se. The use of an $SnS_{0.45}Se_{0.55}$-CUB layer of thickness 120 nm with E_g, 1.57 eV of σ_p, 0.02 Ω^{-1} cm^{-1} produced by vacuum thermal evaporation in the FTO/CdS/SnS-CUB (TE)/SnS-Se-CUB:Se (TE)/C cell illustrates such prospects.

First Principles Thermodynamic Model of $BaZrS_3$ Synthesis Prakriti Kayastha, Giulia Longo and Lucy Whalley; Northumbria University, United Kingdom

The $BaZrS_3$ chalcogenide perovskite shows strong light absorption, high chemical stability, is nontoxic, and is made from earth-abundant elements. These properties make it a promising candidate material for application in optoelectronic technologies, including next-generation photovoltaic absorber materials [1]. It has been proposed as a more chemically stable alternative to the widely studied lead-based metal halide perovskite family [2]. Although the chemical and physical properties of this perovskite are favorable, a scalable synthesis technique remains an open challenge. Standard solid-state synthesis requires temperatures that are not suitable for device integration (>900°C).

Several studies have now established that the perovskite forms at moderate temperatures (500-600°C) through liquid-flux assisted synthesis [3]. This method is based on the formation of BaS_3 in a sulfur-rich environment. Other methods based on molecular precursors or nanoparticles have also been proposed, but no good quality crystalline thin films have been formed to date [4,5]. Progress is hindered by our limited understanding of the underlying reaction thermodynamics.

In our work, we use density functional theory and lattice dynamics to calculate the thermodynamic and vibrational properties of $BaZrS_3$ and its competing ternary, binary, and elemental phases. We consider the experimentally reported BaS_x, ZrS_x (x = 1, 2, 3) and $BaZrS_3$ phases. Using our open-source code ThemoPot [6] we calculate the temperature and pressure-dependent Gibbs free energy of formation with reference to competing ternary, binary, and elemental phases.

We find that to promote the formation of $BaZrS_3$ through liquid-flux there is a “goldilocks” zone for temperature and sulfur partial pressure. This is driven by the high sensitivity of Gibbs formation energy to the sulfur gas allotrope. At intermediate temperatures (500°C) and higher pressures (>10^3 Pa) the S_8 allotrope dominates [7] and suppresses the formation of BaS_3. At lower pressures (<10^2 Pa) the S_2 allotrope dominates and BaS_2 forms. At intermediate pressures, the S_2 allotrope dominates and forms BaS_3 (10^2-10^3 Pa). We find good agreement between our results and those reported in the experimental literature [5]. Our work provides insights into the reaction thermodynamics of this promising material and suggests the experimental regimes to target for future synthesis.

Investigating Light-Induced Metastabilities in Kesterite Solar Cells: Implications and Applications Axel Gon Medaille[1], Alex Jimenez Arguijo[1], Romain Scaffidi[2], Yuancai Gong[1], Kunal Tiwari[1], Sergio Giraldo[1], Marcel Placidi[1], Edgardo Saucedo[1] and Zacharie Jehl Li-Kao[1]; [1]Polytechnic University of Catalonia, Spain; [2]Interuniversity Microelectronics Centre, Belgium

Kesterite solar cells have recently achieved a significant efficiency milestone, now **at the edge of the 15% threshold**, thanks to the innovative solution-based approach developed by Gong et al [1]. While thin-film chalcogenides are renowned for their **stability** in comparison to organic or perovskite counterparts, the phenomenon of **light soaking has persisted as a recurring characteristic in solar cell devices**. Light soaking refers to the alteration of a solar cell's characteristics after being exposed to illumination for a specific duration. Importantly, this property, whether enhancing or diminishing efficiency, often exhibits reversibility, highlighting **a fundamental metastability** within the system. Typically, light soaking is conducted under AM1.5g illumination for several minutes, in order to reach a stable state before assessing the performance of the device.
In this study, we aim at offering a comprehensive exploration of these instabilities by manipulating the **illumination power density and varying the wavelength** during the light soaking process, done both in short circuit and open circuit conditions. We systematically monitor the resultant dark current-voltage (JV) curve and observe noteworthy, reversible changes. These changes can be attributed to **interface defects**, which are investigated using wavelengths that are minimally absorbed by the absorber. Our approach is supported through optical modelling, utilizing a self-developed code to validate the optical characteristics.
Leveraging numerical electrical modelling via SCAPS1D, we propose a physical interpretation based in the **bandgap position of interface defects and their charge states**. This comprehensive analysis combines theoretical insights with practical observations, to analyze the complex mechanisms at play during light soaking. Additionally, the results and hypotheses derived from our results are rigorously tested against materials characterizations, including Raman spectroscopy and Photothermal Deflection Spectroscopy.
Beyond the implications for solar cells, these instabilities offer promising possibilities for applications extending **beyond the energy sector.** One such application is the potential for creating **optically controlled memristors**, a novel development with significant ramifications in the field of neuromorphic computing and beyond. This research offers a new perspective on light-induced metastabilities in Kesterite solar cells, shedding light on their potential for controlled applications in emerging technologies.

Unlocking The Potential of Silicon Clathrate films for Photovoltaics and Beyond Anil K. Bharwal[1], Romain Vollondat[1], Daniel Stoeffler[1], Céline

Chevalier[2], Stéphane Roques[1], Aziz Dinia[1], Abdelilah Slaoui[1] and Thomas Fix[1]; [1]University of Strasbourg and CNRS, France; [2]University of Lyon and CNRS, France

Silicon materials in various forms, including mono-, poly-, and amorphous, have been actively studied since their use in solar technology seven decades ago. Exotic, low-density silicon forms, namely silicon clathrates, have recently received attention for their attractive semiconducting and optical capabilities, which are equivalent to normal silicon materials [1–3]. The type II clathrate (Na_xSi_{136}), an open cage polymorph of silicon with unusual structural properties capable of accepting or releasing Na atoms, was discovered in powder form in 1965 [4]. However, type II clathrate investigation in films is relatively new, which is of great significance to thin-film technologies. Specifically, commercial solar cells employing d-Si with an indirect bandgap may see a large increase in energy conversion efficiency when using Si clathrate with a direct bandgap. Interestingly, inserting or removing Na from these cages can significantly alter their electrical characteristics, making them suitable for a wide range of applications in optoelectronics and energy conversion devices [5]. The removal of Na from the cages allows the guest-free clathrates to be used for various applications such as electrodes in Li-ion battery [6,7] and has great potential in H_2-storage [8]. Nevertheless, further work needs to be done to understand the precise mechanism of Na insertion or removal within the empty Si_{136} cages.
The present research focuses on investigating, in premiere the electronic properties resulting from the insertion and removal of Na atoms in type II clathrate films using Kelvin Probe-Ambient pressure photoemission spectroscopy (KP-APS) characterization and density functional theory (DFT) calculations. The films were prepared using three different types of silicon substrates: intrinsic, n-type, and p-doped wafers and are characterized thoroughly. By manipulating the Na composition parameter x from 0 to 23 within Na_xSi_{136} films, a transition from the semiconducting to a metallic state is achieved [5]. We investigated the energy levels and precisely drew the band diagram for each of the studied clathrate systems using KP-APS and optical measurements. This communication also highlights the use of clathrate film preparation and doping strategies for achieving efficient photovoltaic devices with a unique and novel heterojunction configuration, as well as great potential in maximizing their employment in LEDs, H_2-gas storage, and lithium-ion batteries.

Acknowledgement

Improved Photovoltaic Performance and Robustness of Inverted $AgBiS_2$ Nanocrystal Solar Cells by Sodium Doping Bosen Zou and Jonathan E. Halpert; Hong Kong University of Science and Technology, China

Silver bismuth sulfide ($AgBiS_2$) is a third-generation photovoltaic material used in solution-processed solar cells. The material's high absorption coefficient enables it to generate a theoretical current density of over 28 mA/cm^2 with an ultra-thin active layer of approximately 30 nm. However, the innate traps from $AgBiS_2$ nanocrystals cause a non-negligible loss in open-circuit voltage (V_{OC}) and operating lifetime. To address this issue, we employed a sodium doping strategy in $AgBiS_2$ nanocrystals (NCs). Our findings suggest that sodium doping is particularly effective in improving solar cell performance by trap filling and by obtaining larger-sized NCs. Partial substitution between Na and Ag provides a reduced-trap density surface that can bind with a higher density of oleate ligands after purification, resulting in higher power conversion efficiency (PCE) and operational stability. The champion device achieved a PCE over 4.6% and light-soaking stability over 200 hours, making it one of the best-performing $AgBiS_2$ solar cells based on an inverted, p-i-n structure. Our metal-doping strategy offers an alternative approach to enhance the performance of $AgBiS_2$-based solar cells.

Using Inorganic Chemistry to Design New Functional Semiconductors with a Computer Joseph W. Bennett; University of Maryland Baltimore County, United States

The design and discovery of new inorganic semiconductors to be used as platforms for functional properties can be expedited by investigating already synthesized and characterized compounds whose merits may have been previously overlooked. Here we use data-enabled methods that combine searchable crystallographic databases, group theory, and first-principles density functional theory calculations to create new semiconductors to function over a wide range of chemical environments. We investigate a family of known A_2BX_3 compounds as solid-state materials for applications such as solar harvesting and energy storage, and then use inorganic chemistry and group theory to explain how distortions in the 1D chains present in the structure types can lead to the microscopic mechanisms of ferroelectricity and antiferroelectricity that we predict. We then use compositional tuning to determine the optimal chemical formulas and ground state properties of a new class of inorganic semiconductors to be used for solar energy harvesting and storage. Ultimately, we would like to create a family of materials whose compositions span a wide set of cations and anions, specifically oxide and chalcogenides, to complement well-established semiconductors like the ABX_3 perovskites, Dion-Jacobson, and Ruddlesden-Popper phases.

Direct Solar Energy Storage with Doped Metal Oxides Nanocrystals Luca Rebecchi[1,2], Andrea Rubino[1], Irene Martin[1,3] and Ilka Kriegel[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Genova, Italy; [3]Politecnico di Torino, Italy

The profound impacts of the ongoing energy and climate crises are escalating the need for sustainable energy solutions within our society. To counteract these challenges, scientific research has directed its focus towards the investigation of novel technologies for the direct storage of solar energy. Notably, the utilization of doped metal oxide nanocrystals (MO NCs) has emerged as a promising avenue. Recent research has shown that different materials, such as Zinc Iron Oxide (ZIO) and Indium Tin Oxide (ITO) NCs can undergo photodoping[1,2], a process in which multiple photo-generated electrons after illumination beyond the bandgap accumulate in the NCs and remain stored within the NCs for a prolonged time in inert atmosphere[1]. These properties make these materials attractive as prospective solution for the photon energy conversion and storage. However, to date this process has been observed only in solution, while for application in energy storage, it is mandatory to develop solid-state electrodes based on these nanomaterials.
In this contribution, we present our results obtained on thin film photo-electrodes made from ITO NCs. We show that these electrodes display typical supercapacitor behaviour in the dark with capacitance values in the order of mF. When excited with UV light, beyond the bandgap of ITO, we see with respect to dark conditions an increase in the time required to discharge the electrodes, while charging time decreases. This behaviour is typical of the

generation of an external photo-current, induced by light absorption. Finally, in this contribution we will show the first attempts to broaden the spectral range that the system can harvest by sensitizing the electrode with a visible absorber. We then characterized the electrodes photo-electrochemically to investigate how interaction with different wavelength ranges influences their behaviour.

The Defect Chemistry of Emerging, Wide-Bandgap Absorber BiOI Adair Nicolson[1], Seán R. Kavanagh[2], Alex M. Ganose[2] and David O. Scanlon[3]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]University of Birmingham, United Kingdom

Wide bandgap solar absorbers are seeing significant interest for a variety emerging photovoltaic technologies, from top-layers in tandem cells to single junction devices for indoor applications. V-VI-VII materials have been studied for photocatalysis, but have recently gained interest as “perovskite-inspired” materials (PIMs) for solar absorber applications.[1] These are materials which stray from the perovskite structure, but share an elemental space, thus keeping the strong antibonding character at the band edges and large dielectric constant, which are associated with the defect tolerance observed in lead halide perovskites.

From the family of bismuth-based absorbers, BiOI has emerged as a leading candidate due to its improved air stability and lack of ultrafast charge-carrier localization, which can pose a challenge for many Bi containing PIMs originating from the reduction in dimensionality.[1,2,3] However, large concentrations of electron traps have been measured in BiOI thin films, the potential source of poor device performance.[4]

Therefore, in this project we perform the first, complete investigation into all intrinsic point defect in BiOI at the hybrid DFT level, using the shakenbreak method to thoroughly search the complex defect potential energy surface.[5] This will allow the identification of harmful defects and guide the development of fabrication processes to reduce their impact.

Air-Stable Bismuth Sulfobromide (BiSBr) Visible-Light Absorbers: Optoelectronic Properties and Potential for Energy Harvesting Xiaoyu Guo[1], Yi-Teng Huang[1], Hugh Lohan[1,2], Junzhi Ye[1], Yuanbao Lin[1], Juhwan Lim[3], Nicolas Gauriot[3], Szymon Zelewski[3], Daniel Darvill[2], Aron Walsh[2], Huimin Zhu[4,1], Akshay Rao[3], Iain McCulloch[1] and Robert L. Hoye[1]; [1]University of Oxford, United Kingdom; [2]Imperial College London, United Kingdom; [3]University of Cambridge, United Kingdom; [4]University of Strathclyde, United Kingdom

ns^2 compounds have recently attracted considerable interest due to their potential to replicate the defect tolerance of lead-halide perovskites and overcome their toxicity and stability limitations. However, only a handful of compounds beyond the perovskite family have been explored thus far. Herein, we investigate bismuth sulfobromide (BiSBr), which is a quasi-one-dimensional semiconductor, but very little is known about its optoelectronic properties or how it can be processed as thin films. We develop a solution processing route to achieve phase-pure, stoichiometric BiSBr films (*ca.* 240 nm thick), which we show to be stable in ambient air for over two weeks without encapsulation. The bandgap (1.91 ± 0.06 eV) is ideal for harvesting visible light from common indoor light sources, and we calculate the optical limit in efficiency (i.e., spectroscopic limited maximum efficiency, SLME) to be 43.6% under 1000 lux white light emitting diode illumination. The photoluminescence lifetime is also found to exceed the 1 ns threshold for photovoltaic absorber materials worth further development. Through X-ray photoemission spectroscopy and Kelvin probe measurements, we find the BiSBr films grown to be n-type, with an electron affinity of 4.1±0.1 eV and ionization potential of 6.0±0.1 eV, which are compatible with a wide range of established charge transport layer materials. This work shows BiSBr to hold promise for indoor photovoltaics, as well as other visible-light harvesting applications, such as photoelectrochemical cells, or top-cells for tandem photovoltaics.

9:00 AM EN11.04.03
Photoanodes and Thin-Film Solar Cells Based on SbSBr, SbSeI and BiSeI Absorbers Edoardo Maggi[1,2], Ivan Caño Prades[1], Alejandro Navarro[1], Cibrán López Álvarez[1], Oriol Segura Blanch[1], Hao Zhe Chun[2], Joaquim Puigdollers[1], Jordi Llorca Pique[1], Lluis Soler Turu[1], Lydia H. Wong[2] and Edgardo Saucedo[1]; [1]Universitat Politecnica de Catalunya, Spain; [2]Nanyang Technological University, Singapore

Emerging quasi-1D (Q1-D) van der Waals materials, (Sb,Bi)(S,Se)(Br,I), hold the potential to be a breakthrough in photovoltaic (PV), photocatalytic (PC), and photoelectrocatalytic (PEC) applications, aiming to address some of the main issues affecting even the more mature PV, PC, and PEC technologies. Although this materials family has rarely been explored for these applications, mixed chalco-halides fulfill the urgent need for innovative and renewable energy sources based on earth-abundant, low-toxicity, thermally stable, and defect-tolerant compounds.

This materials class has the peculiarity of possessing a crystallographic structure in which the atoms are held together by strong covalent bonds along one of their crystallographic directions and weak van der Waals bonds along the other two directions. When properly oriented, it results in a highly anisotropic material composed of nano/micro-ribbons with unique conductive properties. The high tunability of these materials and the results obtained in the present

work place these semiconductors in the spotlight for a wide range of applications, including next-generation PV tandem and transparent applications, photocatalytic hydrogen production, and oxygen and hydrogen evolution reactions (OER, HER) among others.

The nano/micro-ribbon structure, coupled with the extremely uniform single-crystal phases, leads to an increased number of photons that reach the space charge region, and the light-trapping effect reduces reflection. This morphology enhances the optoelectronic properties of SbSBr and BiSeI-based solar cells, the OER of Q1-D van der Waals-based photoanodes, and the photocatalytic activity of such-based photocatalysts. The dense coverage of properly oriented nano/micro-ribbons increases the surface area, a key parameter for improving photons and reactant absorption, enabling the synthesis of efficient, photoactive, photostable, and nontoxic photoanodes and photocatalysts. Furthermore, the band gaps of the obtained materials range between 1.25 and 2 eV, making them active to visible light and allowing an optimal usage of the solar spectrum.

The above-mentioned reasons are indicative of what can be achieved with this relatively unexplored technology. To date, no mixed chalco-halide compounds have been synthesized using physical vapor deposition (PVD) techniques, primarily due to the complexity of the material and the varying vapor pressures involved. This work marks the very first successful attempt to synthesize and investigate Q1-D van der Waals-based semiconductors using an innovative methodology that involves the co-evaporation of chalcogenides followed by high-pressure annealing under a halogen atmosphere. Various characterization techniques (XRD, XRF, SEM, EDX, PDS, UV-Vis, Raman spectroscopy, and DFT calculations) have demonstrated the high tunability of the morphology of this compound family by modifying the annealing conditions, confirming the possibility of synthesizing high-quality single-phase material with PVD techniques for the first time.

The versatility of the system allows for the optimal distribution of nano/micro-ribbons in terms of height, thickness, density, and orientation, according to the final device's use. An array of operational Q1-D van der Waals-based solar cells and photoanodes, each derived from distinct stack combinations, will be showcased and thoroughly examined, together with some preliminary results about photocatalytic hydrogen production under visible light. Notably, solar cells have exhibited open-circuit voltages reaching up to 600 mV, and photoanodes, even when utilizing non-protected absorbers, have achieved a photoanode current of nearly 2 mA/cm-2. This study demonstrates how these novel compounds represent a promising development in advanced energy conversion applications.

9:15 AM EN11.04.04
Exploring The Impact of Physical Vapor Synthesis Regime on The Properties of Pnictogen Chalco-Halides for Solar Cell Applications Alejandro Navarro[1], Mykhailo Kolstov[2], Ivan Caño Prades[1], Nicolae Spalatu[2], Ilona Oja Acik[2], Atanas Katerski[2] and Edgardo Saucedo[1]; [1]Polytechnic University of Catalunya, Spain; [2]Tallinn University of Technology, Estonia

Recent advances in the study of van der Waals (vdW) materials have led to an increase in the effort devoted to their development for energy applications. In particular, the photoconversion efficiencies of $Sb_2(S_{1-x}Se_x)_3$ compounds highlight the potential of vdW semiconductors as photovoltaic absorbers. Significantly, their unique structure based on covalently-linked chains in the z-direction (low-dimensional structure) gives rise to anisotropic optoelectronic properties, which can result in enhanced charge carrier transport when the material is correctly oriented in the (00l) crystallographic direction. Sb-chalcogenides also have high absorption coefficients, optimal bandgap for solar energy conversion, and they are constituted by earth-abundant low-toxic elements. Similarly, pnictogen chalcohalides are recently gaining a lot of attention, showing great potential as PV candidates. In addition to the aforementioned properties originating from vdW structure, the antibonding character of their valence band together with the conduction band consisting of an extension of p-states, results in a highly dispersive character for both bands, which can lead to defect tolerant properties, similar to those of Pb-halide perovskites. However, the particular vdW structure also leads to a complicated morphology consisting of randomly oriented needle-shaped crystals, which is clearly inadequate for the design of conventional thin film solar cells. Therefore, it is necessary to explore new alternatives to obtain more compact and uniform morphologies.
In this work, the formation dynamics of SbSI and SbSeI compounds from the selective halogenation of precursors Sb_2S_3 and Sb_2Se_3 has been investigated. In particular, the effects of different reaction pathways are analyzed in detail. These reactions are divided into convection-controlled and diffusion-controlled processes. For the first case, a series of experiments are carried out in high pressure and large volume tubular furnaces, where the effects of pressure and temperature as well as duration have been studied. In this case, high pressures are necessary to prevent the decomposition of the resulting compound at high temperatures. In the second case, the same reactions are carried out in the reduced volume of a close-space sublimation (CSS) reactor. A thin film deposition system is innovatively used as a reaction medium. In this case, the control of the decomposition is facilitated by the saturation of the atmosphere with the halide source (i.e., SbI_3). In addition to the effect of convection or diffusion-controlled processing, other synthesis routes have been investigated, including the reaction of previously deposited chalcogen and halide layers (solid-solid or solid-liquid reaction), which offers interesting possibilities for very high-pressure systems where evaporation is disabled and a fully diffusive solid-state reaction is favored.
The differences between the two reaction pathways are clear, confirming that the diffusion-controlled process has much slower kinetics. Indeed, it has been observed that for processes of the same duration, the reaction is not complete in the diffusion-controlled case, suggesting that longer processes are necessary. The study is supported by microscopy and energy-dispersive X-ray spectroscopy analyses, which demonstrate the formation of large and compact micro-columns. The evolution of the reaction has been studied by X-ray diffraction in order to evaluate the reaction kinetics. In addition, photovoltaic devices have been developed using both methodologies. Temperature-dependent current-voltage and external quantum efficiency measurements have been performed.

Theoretical and Experimental Characterization of Highly Anharmonic Chalcohalide Anti-Perovskites for Energy Applications Pol Benítez Colominas[1], Ivan Caño Prades[1], Cong Liu[1], Cibrán López Álvarez[1], Jonathan Turnley[2], Rakesh Agrawal[2], Edgardo Saucedo[1] and Claudio Cazorla[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Purdue University, United States

Silver chalcohalide antiperovskites (AH) are a family of materials with chemical formula Ag3BC where B=S, Se and C=Cl, Br, I. These are interesting energy materials that present suitable thermal stability and optoelectronic properties for applications in photovoltaics, solid-state batteries and fuel cells [1, 2]. Few experimental works have already reported the structural and ionic transport properties of Ag3sBr and Ag3SI [3], and recently a facile synthesis method has been proposed for them [4]. Nevertheless, a detailed description and understanding of the phase competition and thermodynamic properties of AH is still lacking, both at the experimental and theoretical levels, hence their thermodynamic and structural properties remain relatively unknown to date. Here, we present a comprehensive computational and characterization study of this family of materials, based on first principle calculations (DFT), as well as structural and optoelectronic measurements, which endorse the validity of the employed simulation approaches. Ag3SBr and Ag3SI polycrystalline thin films have been synthesized by a low-temperature solution-based methodology using thiol-amine molecular precursor inks. Then, structural and optical properties have been investigated by X-ray diffraction, microscopy and photothermal deflection spectroscopy experiments, demonstrating cubic anti-perovskite structure for both Ag3SBr and Ag3SI (Pm-3m and Im-3m respectively), and measured bandgaps in the 0 9-1.0 eV range. Interestingly, Ag3S(Br1-x Ix) solid solutions have been successfully synthesized, showing a bandgap bowing effect (bandgap increases, saturates after a certain value of x, and then decreases again). Thin film prototype solar cells have been prepared using Ag3SBr and Ag3SI absorbers (FTO/TiO2/AH/P3HT/Au superstrate device structure), showing photo-active response and Voc values up to 150 mV. For theoretical calculations, we performed a thorough exploration of the

zero-temperature polymorphism of AH by using advanced crystal structure prediction and DFT methods. Several previously overlooked stable phases were thus predicted and studied for the six analysed parent compounds; for example, a cubic phase with space group P2_13 for Ag3SBr and an orthorhombic phase with space group P2_12_12_1 for Ag3SeBr. Ab initio molecular dynamics (AIMD) simulations were also performed at different temperatures to take into account the effects of anharmonicity (i.e., electron-phonon coupling) and ionic diffusivity on the optoelectronic properties of AH. Remarkably, it was found that temperature-renormalization effects on the band gap of AH are giant (i.e., decrease it around 40% decreasing for Ag3SBr) and necessary to provide good agreement with the experiments. Thus, these materials could be exploited for applications in which materials with strongly temperature-dependent electronic properties are required.

Photovoltaic Cu_3PS_4 Films via a Combinatorial Synthesis Platform Dedicated to Multi-Anion Semiconductors Lena A. Mittmann, Javier Sanz Rodrigo and Andrea Crovetto; Technical University of Denmark, Denmark

Inorganic phosphosulfides – materials containing phosphorus, sulfur, and at least one metal – are a vast and chemically-versatile family of materials. Since metal phosphides and metal sulfides are among the highest-performing optoelectronic semiconductors, it seems reasonable to consider the phosphosulfide family as a potential pool of materials for solar cells, photoelectrochemical cells, and light-emitting diodes. Nevertheless, phosphosulfide semiconductors have very rarely been characterized with these applications in mind.
Only 258 out of over 320,000 chemically plausible phosphosulfides (up to quaternaries) have been synthesized in some form, and just a handful of them have been optoelectronically characterized. Thus, there is significant opportunity for new discoveries, but conventional synthesis approaches would be inefficient and tedious.
In the first part of this contribution, we will present our unique suite of high-throughput thin-film deposition tools dedicated to phosphosulfides and other sulfur-containing multi-anion semiconductors. The main high-throughput synthesis method we use for this project is based on reactive sputtering to generate combinatorial material libraries with two perpendicular gradients. The first gradient goes from sulfur rich to phosphorus rich while the second gradient goes from metal A rich to metal B rich, resulting in a variety of different stoichiometries for, e.g., quaternary phosphosulfides. The deposition suite also includes a rapid thermal annealing furnace with access to reactive sources of sulfur and phosphorus, as well as a separate evaporator for incorporating volatile metals. The whole system is glove-box integrated.
In the second part of this contribution, we will show the first experimental results on Cu_3PS_4 films, the first directly deposited phosphosulfide film specifically intended as a PV or PEC absorber.[1–4] The experimental results are complemented by computational studies carried out within our group. The computational track has been of crucial importance for obtaining properties that are difficult to measure experimentally, and for interpreting experimental results. Importantly, we show that the photoluminescence decay time of unoptimized Cu_3PS_4 films is already above 100 ns, demonstrating that phosphosulfides deserve close attention by the PV and PEC research community.

Computational Approaches for Clean Energy Materials: Defect Graph Neural Networks, Equilibria with Interacting Defects and Interface Structure Prediction Stephan Lany; National Renewable Energy Laboratory, United States

Currently, 80% of the global final energy consumption occurs in form of fuels and only 20% as electricity. On the other hand, renewable energy additions come almost exclusively in the form of electricity (dominantly photovoltaics and wind). Thus, a successful energy transition will require enormous growth in renewables, sufficient to convert excess electricity into fuels, as well as the development of non-electricity based solar fuel technologies. As much as photovoltaic capacities have grown over the past 20 years, it is far from clear that current technologies and materials are up to the task to grow from here by yet another factor 100 until 2050. Therefore, sustained research efforts on emerging inorganic semiconductors for solar electricity and fuels are essential for facing the double challenge of climate change and energy security. Computational materials science can make important contributions, guiding and supporting research activities through both materials search and discovery and through detailed studies that help to develop a mechanistic understanding of materials performance and bottlenecks. This presentation will highlight three recent computational projects with relevance for photovoltaics and solar fuels (1) Defect graph neural networks (dGNN) for materials discovery in solar thermochemical hydrogen (STCH) [1]. The dGNN approach facilitates broad and fast materials screening for defect properties. (2) Modeling highly off-stoichiometric systems by evaluating the free energy of defect interaction [2]. This approach allows quantitative prediction of H_2 production in complex STCH oxides. (3) First-principles atomic structure prediction for interfaces [3]. This work showed how an atomically thin $CdCl_2$ interlayer phase enables in principle ideal electron transport across the incommensurate SnO_2/CdTe interface.

Statistics of Crystal Defects from Dilute Limit to Alloys, Excluded Volume Exchange Interaction and Effective Energetics of Defect Ensembles
Mike Scarpulla; University of Utah, United States

Point defects determine the properties of otherwise-perfect semiconductors and insulators, thus computing their concentrations accurately is of prime importance. Typically, the dilute limit is assumed leading to Boltzmann statistics, however it is obvious that multiple defects or defect complexes cannot occupy the same site at the same time. Herein, we present closed-form expressions for point defect statistics applicable for all concentrations; thus unifying defect and alloy theories. These expressions prevent unphysical prediction of more defects than available sites when either a) any defect of type j in chargestate q has zero or negative formation energy ΔE_j^q (e.g. charged defects at certain Fermi energies) or more interestingly b) when multiple defects and/or chargestates have small ΔE_j^q compared to the thermal energy k_BT. An important insight is that different statistics arise if 1) host atom or 2) site conservation is assumed: Case 1 corresponds to a finite crystal with N_o sites and moving displaced host-crystal atoms to extra unit cells on the surface, while Case 2 corresponds to an infinite crystal with N_o sites per volume and moving displaced host-crystal atoms into external reservoirs (e.g. the case corresponding to modern DFT supercell calculations).
Analogously to quantum Fermions but classical in origin, the mutual exclusion between defects of any type can be conceptualized as an exchange interaction energy. Additionally, we demonstrate that multiple chargestates of a defect, multiple configurations of a chargestate, or other arbitrary subgroups of defects and complexes can be gathered together into objects having effective formation energy. This allows, for example, plotting the finite-temperature formation enthalpy of a defect having multiple chargestates as a continuous function of Fermi level or using an effective chemical potential to enforce constraints on subgroups of defects, amongst other applications.
These fundamental tools add flexibility and accuracy to quantitative defect calculations and join smoothly to thermodynamics of solutions and alloys while adding only minor computational costs.

***Doped*: A Python Package for Solid-State Defect and Dopant Calculations** Seán R. Kavanagh[1], David O. Scanlon[2] and Aron Walsh[3]; [1]Harvard University, United States; [2]University of Birmingham, United Kingdom; [3]Imperial College London, United Kingdom

Defect-induced non-radiative recombination typically represents the dominant limiting factor in the efficiencies of emerging inorganic solar cells / photocatalysts.[1,2] Computational methods are widely used to predict defect behavior in solar materials, before combining and comparing theoretical predictions with experimental measurements. However, there are many critical stages in the computational workflow for defects, which, when performed manually, not only leave room for human error but also consume significant researcher time and effort. Moreover, there are growing efforts to perform high-throughput defect investigations,[3–5] necessitating robust, user-friendly and efficient software implementing this calculation workflow.
Here we report *doped*, our python package for the full generation, calculation setup, post-processing and analysis of defect supercell calculations.[2,6–9] The generation and thermodynamic analysis (i.e. defect formation energy diagrams, chemical potentials, doping analysis etc.) are agnostic to the underlying first-principles software, while input file generation is supported for several of the most widely-used DFT codes, including VASP, FHI-aims, CP2k, Quantum Espresso and CASTEP. A defect charge state prediction algorithm is implemented, which is shown to significantly outperform previous oxidation-state approaches in terms of both efficiency and completeness. Moreover, *doped* is built to be compatible with other computational toolkits for advanced defect characterisation, including *ShakeNBreak*[10] for defect structure-searching, *py-sc-fermi*[11] for in-depth concentration, doping and Fermi level analysis, and *CarrierCapture.jl*[12]*/nonrad*[13] for non-radiative recombination calculations. Its object-oriented python framework make it readily-usable in high-throughput architectures such as *atomate(2)* or *AiiDA*, with examples included in the documentation.
We will discuss the key features of *doped* for computational defect workflows, exemplified with relevant solar cell materials (CdTe, Sb_2Se_3, *t*-Se). We anticipate that *doped* will serve as a highly useful tool for computational defect researchers, being an efficient platform for conducting reproducible calculations of solid-state defect properties.

High-Throughput Virtual Screening of Novel Ternary Phosphosulfides for Photovoltaic Applications Javier Sanz Rodrigo, Andrea Crovetto, Lena A. Mittmann and Ivano Eligio Castelli; DTU, Denmark

In order to improve the efficiency of solar cells, stable materials with suitable optoelectronic properties must be found. For this purpose, phosphosulfides offer a large and varied range of semiconductors with very diverse compositions, structures, and therefore, optoelectronic properties. This is mainly due to the wide range of oxidations states that phosphorus can take in this class of materials (from -3 to +5). We are currently studying phosphosulfides for solar energy by a multi-faceted approach, including first-principles calculations, high-throughput experiments, and machine learning.
It is estimated that the number of chemically-plausible ternary phosphosulfides is close to 1800, yet just around 100 have been synthesized, and only a handful have been investigated for PV or PEC applications. A high-throughput screening is reported here for over 800 of these materials, obtained from metal substitution in 67 structural prototypes reported in the Materials Project, resulting in some completely unknown potential candidates as wide-gap solar cell absorbers in tandem solar cells. On top of these simple elemental substitutions, we have also explored some previously unreported phosphosulfide stoichiometries, based on analogy with other pnictogens (N, As, Sb) and chalcogens (Se, Te). Unlike the case of most of the already-known phosphosulfides, these structures have phosphorus-rich stoichiometries, which appears to be correlated with favorable optoelectronic properties.

The initial criteria for the screening process are thermodynamic stability, intermediate band gaps and low effective masses. As a result, around 100 new phosphosulfide materials potentially suitable for solar cell applications are obtained from this virtual screening. Most of these compounds are not present in computational materials databases and have never been synthesized. More detailed calculations on a selected subset of these new materials suggest that a few of them deserve experimental investigation as PV absorbers.
The large volume of materials screened gives us a unique opportunity to identify composition-structure-property trends in phosphosulfides with special emphasis on optoelectronic energy conversion applications. We will show how these trends can be used to design new optoelectronic phosphosulfides beyond ternary systems.

11:45 AM EN11.05.05
First-Principles Studies of The Role of Cation Disorder on The Electronic and Optical Properties of Photoactive $ZnTiN_2$ Sijia Ke[1,2], John Mangum[3], Andriy Zakutayev[3], Annie Greenaway[3] and Jeffrey B. Neaton[1,2,4]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]National Renewable Energy Laboratory, United States; [4]Kavli Energy NanoScience Institute, United States

The recently synthesized wurtzite-derived nitride semiconductor $ZnTiN_2$ exhibits promising properties for photoelectrochemical (PEC) applications, including an optically measured band gap appropriate for PEC reactions, high potential for integration with high-performing semiconductors, and the formation of self-passivating surface layers under operating conditions. Similar to other heterovalent ternary nitrides, experimentally synthesized $ZnTiN_2$ thin film features a large concentration of antisite defects, or cation disorder, which can have significant effects on its electronic and optoelectronic properties, and which has been used to rationalize the large difference between experimental absorption onset around 2 eV and theoretical fundamental band gap of cation-ordered $ZnTiN_2$ of 3.4 eV. Using state-of-the-art first-principles density functional theory calculations with non-empirical optimally-tuned hybrid functionals on nearly one hundred large supercells, we compute the energetics, electronic structure, and optoelectronic properties of cation-disordered $ZnTiN_2$. Energetically preferable and undesirable local atomic arrangements are identified. We also demonstrate that cation disorder-induced local charge imbalance broadens the valence and conduction bands near band edges, leading to a reduction in band gap relative to the cation-ordered phase, a mechanism that can be extended to the family of multivalent ternary nitrides. Accounting for cation disorder, our calculated optical absorptions agree well with experiments. Our work reveals the nature of cation disorder and its influence in $ZnTiN_2$ in light of possible solar energy applications.

This work is supported by the Liquid Sunlight Alliance, a DOE Energy Innovation Hub; computational resources provided by NERSC.

Accelerating The Search of New Solar Absorbers for Thin-Film Photovoltaic Using High-Throughput Computational Screening Geoffroy Hautier; Dartmouth College, United States

Thin film photovoltaic technology has advantages to single-crystal silicon in terms of flexibility, lower energy manufacturing needs or potential for tandem cells. However, the high efficiency technologies available (e.g., CIGS, CdTe or halide perovksites) have all issues in terms of cost, abundance or long-term stability. Finding new solar absorber is a cumbersome process involving complex synthesis and characterization. First principles computations on the other hand offers an attractive way to speed up this process. Here, we will report on a large scale high-throughput computational search for new solar absorbers among known inorganic materials. Importantly, the need for high carrier lifetime is taken into account by considering in the screening intrinsic defects and their role as potential Shockley-Read-Hall recombination centers. Screening 30,000 known inorganic compounds, we identify a handful very promising solar absorbers combing large optical absorption in the visible, good transport properties and high carrier lifetime. I will discuss the chemistries that we found and highlight a few interesting new materials. I will especially focus on BaCd2P2, a new phosphide where our experimental follow-up work confirms the promising properties including adequate band gap but also long carrier lifetime. We also show that this new material is extremely stable even in harsh conditions. I will finish my talk by discussing how large data sets of defect computations can also be used to test and develop design principles for solar absorbers with “defect-tolerance”.

First Principles Phase Diagram and Electronic Structure Properties of Potassium-Based Copper Chalcogenide Alloys for Photocathode Applications Arini Kar, Balasubramaniam Kavaipatti and Dayadeep S. Monder; Indian Institute of Technology Bombay, India

A recent high throughput study of copper-based semiconductors has identified potassium-based copper chalcogenides as optimal light absorbers in PV/PEC devices. In this work, we investigate the applicability of $KCuTe_{1-x}Se_x$ and $KCuSe_{1-x}S_x$ as photocathode materials. We first calculate the temperature-composition phase diagram of $KCuTe_{1-x}Se_x$ and $KCuSe_{1-x}S_x$ via solid solution model and cluster expansion-based Monte Carlo simulations. Our calculations predict a miscibility gap up to a maximum critical temperature of 243 K beyond which the alloy forms a solid solution in the hexagonal structure over the entire composition range. Similarly, $KCuSe_{1-x}S_x$ forms a solid solution in orthorhombic structure, although ordered ground states at x = 0.25, 0.333, 0.5, 0.667, 0.75 and 0.833 are present at low temperatures. Based on the stable structure of the alloys we calculate the electronic structure properties via DFT. Unlike the bandgap bowing typical of highly mismatched alloys, predicted by band-anticrossing (BAC) model the electronic band gap of potassium-based copper chalcogenide alloys obeys Vegard’s law. The conduction band of these alloys is appropriately aligned with respect to the hydrogen reduction reaction and suggests the utility of these alloys as a photocathode.

Discovering efficient and scalable photocatalysts for water splitting is a major challenge for the sustainable production of carbon-free hydrogen. In this presentation, we tackle that challenge and expand the list of known water-splitting photocatalysts using data-intensive screening based on accurate first-principles calculations of band gaps, band edges, and free energies of electrochemical decomposition. Building on previous studies [1,2] which show that

inserting pre-transition (*s*-block) metals in binary metal oxides can improve redox activity while preserving solar absorption, we specifically target the family of post-transition (*p*-block) metal oxides. We analyze the influence of adding *s*-block cations on the band gaps and band edges of these materials and on their photocatalytic efficiency. Based on this analysis, we screen 109 ternary metal oxides and identify nine candidates, among which two appear to not have been previously proposed as water-splitting photocatalysts [3]. We then extend these results to the family of ternary *s*- and *p*-block metal sulfides, leading to the discovery of additional photoactive compounds, which warrants further studies [4].

Navigating The Vast Materials Landscape for Photovoltaics with NOMAD Jose Marquez Prieto; Humboldt University of Berlin, Germany

Accelerating the development of innovative solar materials demands a fundamental transformation in lab methods, particularly in enhancing efficiency in production, characterization, and device integration. Numerous research labs are beginning to adopt more efficient methods to achieve the necessary acceleration, including high throughput computation and experimentation, and the emergence of some autonomous labs. All these efforts generate a massive volume of data that needs to be organized, automated and made ready for AI analyses and programmatic access.
This talk offers insight into how NOMAD (https://nomad-lab.eu), an open-source platform developed by the NFDI (Germany's National Research Data Infrastructure) consortium FAIRmat (https://fairmat-nfdi.eu), can help individuals and labs in this task. NOMAD is designed to tackle these challenges by enhancing the accessibility and usefulness of materials science data following the FAIR principles - making data Findable, Accessible, Interoperable, and Reusable. I will overview the dynamic improvements within the NOMAD infrastructure beyond computational materials science, specifically tailored for experimental solar cell research, and highlight an application created for detailed visualization and investigation of a broad, AI-ready solar cell dataset. As an illustration, I will examine the historical advancement of charge transport layers for perovskite solar cells using network analysis, demonstrating how it is possible to navigate effectively this extensive materials space.
To provide a digitization platform for experimental developments, the NOMAD platform incorporates a flexible electronic lab notebook (ELN), configured for customization to meet the specific needs of individual research laboratories, thereby facilitating the efficient capture, transfer, and processing of AI-ready data and metadata within a well-organized FAIR database framework.
Ultimately, this presentation aims to illuminate the path forward in the realm of semiconductor materials for solar applications, guided by data-centric methodologies and collaborative infrastructures like NOMAD, which are indispensable in accelerating the journey toward efficient and sustainable solar energy solutions.

Accelerating The Development of Semiconductor Thin Films through Advanced Automated Characterization. Sebastian Siol; Empa-Swiss Federal Institute of Materials Science and Technology, Switzerland

The discovery of new functional materials remains a key challenge in the development of next-generation sustainable technologies. Fueled by advances in high-throughput computation, new exciting materials are being predicted at an ever-increasing rate. Combinatorial high-throughput materials science techniques hold the promise to match this rate by facilitating the rapid exploration of complex phase spaces. Today, combinatorial materials science workflows are employed in many laboratories around the world. While gradient deposition of combinatorial thin-film libraries can be implemented in most standard deposition equipment, a comprehensive tool box for rapid materials characterization which is just as crucial is often harder to realize. In this presentation, it will be shown how accelerated thin-film materials development is performed in the Coating Technologies group at Empa. We employ a workflow consisting of reactive combinatorial physical vapor deposition, automated characterization and semi-automated data analysis which covers most common thin-film characterization techniques as well as functional property mapping. In recent years, we extended this infrastructure to include high-throughput surface analysis, but also optical measurement setups for accelerated aging studies. This extension not only complements the existing workflows, but provides additional insights that were previously much harder to obtain. It will be shown how surface analysis mapping can facilitate the discovery of new semiconductor materials in complex phase spaces, such as the wide band gap nitride semiconductors Zn_2VN_3[1,2] or Zn_2TaN_3[3]. In addition, it will be shown how accelerated optical aging studies combined with machine-learning assisted data analysis can generate insights into the operational stability and degradation kinetics of more volatile materials.[4] The results presented here showcase the potential of integrating advanced characterization techniques into high-throughput materials science workflows for the rapid development of new energy materials.

Co-Design of Zinc Titanium Nitride Semiconductor towards Durable Photoelectrochemical Applications John Mangum[1], Sijia Ke[2,3], Andriy Zakutayev[1], Jeffrey B. Neaton[2,3,2] and Annie Greenaway[1]; [1]National Renewable Energy Laboratory, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

Development of photoelectrochemical (PEC) systems requires, among other advances, photoelectrode materials that are both photocatalytically active and stable in harsh electrochemical environments. We have intentionally searched for a candidate photoabsorber based on co-design principles, wherein design for photoactivity is based on the ability to integrate the new material with established semiconductors and design for stability is based on the propensity for

the photoabsorber to self-passivate during operation. This has led to the first synthesis and substantial development of wurtzite $ZnTiN_2$ as a photoabsorber. Initially, high-throughput combinatorial synthesis was used to identify the radio-frequency co-sputtering parameter space for $ZnTiN_2$.[1] Cation disorder in these films reduced the bandgap to ~2.0 eV, appropriate for solar fuel generation, and the $ZnTiN_2$ surface was found to transform to stable oxides under CO_2R-relevant electrochemical conditions. Together, these characteristics indicate that $ZnTiN_2$ could be used as a photoelectrode, but the optoelectronic and crystalline properties of the material would require substantial improvement before operation in PEC applications. Next, experimental integration of $ZnTiN_2$ with established semiconductor systems allowed us to rapidly improve the crystalline and optoelectronic properties of the sputtered $ZnTiN_2$ films, paving the way for high photocatalytic activity for PEC to be demonstrated using this semiconductor. We will report on materials quality advances in $ZnTiN_2$ thin films as well as progress toward demonstration of this material as a photoelectrode. Future work will focus on developing PEC device structures based on the improved $ZnTiN_2$ photoelectrode films by optimizing semiconductor properties (e.g. doping) and interfaces with surrounding device layers.

Defect Engineering of Ta_3N_5 Photoanodes: Enhancing Charge Transport and Photoconversion Efficiencies via Ti Doping Laura I. Wagner[1,2], Elise I. Sirotti[1,2], Oliver Brune[1,2], Gabriel Groetzner[1,2], Johanna Eichhorn[1,2], Saswati Santra[1,2], Frans Munnik[3], Simone Pollastri[4], Luca Olivi[4], Dennis Friedrich[5], Verena Streibel[1,2] and Ian D. Sharp[1,2]; [1]Walter Schottky Institute, Germany; [2]TU Munich, Germany; [3]HZDR, Germany; [4]Elettra, Italy; [5]HZB, Germany

Ta_3N_5 shows great potential as a semiconductor photoanode for solar fuel applications. However, its performance is hindered by poor charge carrier transport and trapping due to a high density of defects that introduce electronic states deep within its bandgap. Here, we demonstrate that controlled Ti-doping of Ta_3N_5 can dramatically reduce the concentration of deep-level defects and enhance its photoelectrochemical performance, yielding a seven-fold increase in photocurrent density and a 300 mV cathodic shift in onset potential compared to undoped material.[1] Comprehensive characterization, including structural, compositional, optical, electrical, and photoelectrochemical methods, reveals that Ti^{4+} ions substitute Ta^{5+} lattice sites, thereby introducing compensating acceptor states, reducing concentrations of nitrogen vacancies, and reduced Ta^{3+} states, and suppressing trapping and recombination. Importantly, Ti doping offers distinct advantages compared to Zr, an intensively investigated dopant in the same group. Specifically, Ti^{4+} and Ta^{5+} have more similar atomic radii, allowing for substitution without introducing lattice strain, and Ti exhibits a lower affinity for oxygen than Zr, enabling its incorporation without increasing the oxygen donor content. Consequently, we demonstrate that Ti doping decreases the conductivity immensely by lowering the charge carrier density but simultaneously increases the mobility of free charge carriers due to reduced recombination at nitrogen vacancies. Thus, these findings provide a powerful basis for precisely engineering the optoelectronic characteristics of Ta_3N_5 and to substantially improve its functional characteristics as an advanced photoelectrode for solar fuel applications.

4:30 PM EN11.07.04
Transition Metal Coated Single Crystalline $BiVO_4$ Photoanode for Photoelectrochemical Chlorine Generation Zhaoyi Xi[1,2], Chenyu Zhou[1], Kim Kisslinger[1], Xiao Tong[1] and Mingzhao Liu[1]; [1]Brookhaven National Laboratory, United States; [2]Stony Brook University, The State University of New York, United States

Bismuth vanadate ($BiVO_4$) is an outstanding photoanode material for photoelectrochemical water splitting. In this work, a series of single crystalline $BiVO_4$ photoanodes are synthesized by pulsed laser deposition (PLD). Once coated with a thin layer of cobalt oxides (CoO_x) co-catalyst, also by PLD, the photoanodes support efficient photoelectrochemical generation of chlorine (Cl_2) from brine under simulated solar light. Activity of the chlorine generation reaction (ClER) is optimized when the thickness of CoO_x is about 3 nm, with the faradic efficiency of ClER exceeding 60%. Detailed studies show that the CoO_x co-catalyst layer is amorphous, uniform in thickness, and chemically robust. As such, the co-catalyst also effectively protects the underlaying $BiVO_4$ photoanodes against chlorine corrosion. The other metal oxides cocatalysts are also compared, detailed mechanism on how the cocatalyst layers influence the performance of $BiVO_4$ photoanode is revealed. This work provides insights on using artificial photosynthesis for by-products that carries significant economic value while avoiding the energetically expensive oxygen evolution reactions.

4:45 PM EN11.07.05
Heterostructured Hematite Photoanodes featuring C_3N_4 with *In-Situ* Grown Ni-CoP_x for Boosted Photoelectrochemical Water Oxidation Mengya Yang, Anna Hankin and Salvador Eslava; Imperial College London, United Kingdom

The high demand for renewable and clean energy resources has led to the rapid development of cutting-edge materials for photoelectrochemical (PEC) water splitting. However, the question of how to enhance solar conversion efficiency remains a persistent challenge. In line with this, we present a novel constructive strategy for a ternary-material-system photoanode, aimed at simultaneously improving charge separation and transfer, as well as water oxidation efficiency. Specifically, we demonstrate the PEC efficiency of composite Ti-Fe_2O_3/CN/NCP photoanodes obtained by loading hierarchical C_3N_4 (CN) nanosheets anchored with in-situ grown Ni-doped CoP_x (NCP) onto porous Ti-doped hematite (Ti-Fe_2O_3) photoanodes. The resulting Ti-Fe_2O_3/CN/NCP photoanodes exhibit a remarkable enhancement of photocurrent density (2.01 mA cm^{-2} at +1.23 V_{RHE}) compared to Ti-Fe_2O_3 photoanodes (0.28 mA cm^{-2} at +1.23 V_{RHE}). It is noteworthy that CN and NCP serve to deplete photogenerated electrons and remove photogenerated holes directionally from the surface of Ti-Fe_2O_3. This leads to the facile transfer and separation of electron-hole pairs necessary for exceptional catalytic performance. Moreover, we undertake a systematic analysis of the role of CN and NCP to gain deeper insights into the underlying mechanisms for the superior PEC water oxidation process.

SESSION EN11.08: Poster Session II
Session Chairs: Andrea Crovetto and Xiaojing Hao

Stress-Induced Charge Redistribution at Grain Boundaries in Various Alkali Treated Flexible Cu(In,Ga)Se_2 Solar Cells Ha Kyung Park[1],

Kanghoon Yim[2], Jiyoon Lee[1], Jihye Gwak[2], Kihwan Kim[2] and William Jo[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of)

In recent development, efficiency of flexible $Cu(In,Ga)Se_2$ (CIGS) solar cells has exceeded 22%, marking a significant step towards commercial viability. [1] In particular, the deliberate alkali treatment boosted their efficiency, yielding a comparable effect to diffused alkali from soda-lime glass substrate. Besides alkali treatment, understanding stress-induced properties is crucial to maximize their performance. In this study, effects of alkalis on charge distribution under stress was investigated. Four flexible CIGS solar cells using a polyimide substrate were prepared with various alkali post deposition treatment including heavy alkalis (Rb and Cs). Among the CIGS solar cells, Na only treated sample showed the highest performance with an efficiency of 16.9% due to the highest carrier density and fill factor. Segregation of alkalis towards grain boundaries (GBs) was observed through transmission electron microscopy. Especially, Rb and Cs added after Na treatment occupied the GBs repelling the existed Na. Furthermore, surface charge transport under stress were probed via conductive-atomic force microscopy with curved holder. [2] Alkali treated CIGS thin film showed enhanced surface current along the GBs compared to CIGS without alkalis. Notably, surface current was degraded under convex bending state and the degradation was lower in the alkali treated CIGS. To explain the current distribution, defect energy levels were calculated using density functional theory and alkali related defects induced additional acceptors contributing to an increase in surface current. Additionally, energy level of electrically active defects changed with existence of compressive or tensile stress. As part of the future work, degradation of surface current will be quantitatively analyzed focusing on the redistribution of charges under stress.

5:00 PM EN11.08.03
Influence of The Growth Method of Sb_2Se_3 Absorber Layer for Thin-Film Solar Cells Víctor Bonal[1], Yudania Sánchez[2], Sanja Djurdjic Mijin[1], Iván Martín-Infantes[1], Fernando Chacón[3], Snezana Lazic[1], Rosalia Serna[3] and Raquel Caballero[3]; [1]Universidad Autonoma de Madrid, Spain; [2]IREC, Catalonia Institute for Energy Research, Spain; [3]Instituto de Óptica, IO-CSIC, Spain

In recent years, photovoltaic devices have gained considerable attention due to their potential to address the environmental problems associated with traditional energy resources, offering a clean and sustainable solution to meet the growing global energy demand through the direct conversion of solar radiation into electricity. Thin film solar cells (TFSC) have emerged as a suitable alternative to the traditional silicon technology. The best results in TFSC have been produced using CIGS and CdTe, but they use materials that are either toxic or scarce in the earth crust, limiting the future implementation of this technology. Other promising materials such as perovskite present toxicity and stability problems and the complexity of the growth control of CZTSSe kesterite-type material limits the device performance.
This is why there is a need for simple and stable compounds, with a low toxicity and earth-abundant materials. Among the many available candidates, binary Sb chalcogenides have emerged as promising alternatives due to their optoelectronic properties and good stability. Among them, Sb_2Se_3 has attracted interest not only as an absorber for photovoltaics, where it has already reached efficiencies above 10% [1], but also in battery and photochemical applications. Sb_2Se_3 presents a high absorption coefficient, which allows to reduce the absorber film thickness to 100-500 nm, a band gap energy of 1.2 eV, p-type conductivity, a high stability, and a low melting point, requiring low processing temperatures. In addition, this material presents a quasi-1D crystal topology, which could be one of its main advantages for high performance PV. This chain-structure provokes anisotropy in electrical conductivity, edge absorption and carrier transport. For this, the control of the fabrication process is crucial to obtain high efficiency solar cells.
In this work, we propose two different methods to prepare Sb_2Se_3 films to be used as absorber in a photovoltaic solar cell. The first one consists in the evaporation of a Sb film on top of Mo/SLG and SLG substrates followed by a thermal treatment in the presence of elemental Se under Ar atmosphere. The second method is the direct evaporation of Sb_2Se_3 into the substrate using vapor transport deposition (VTD). Both methods have been studied to prepare Sb_2Se_3 thin films of different thicknesses in the range 400-1000 nm. The goal of this work is to investigate and compare the properties of Sb_2Se_3 thin films grown by the two deposition methods. For that, the effect of the different fabrication parameters, such as deposition time, maximum temperature, amount of Se added or the temperature difference between source and substrate, on the orientation, morphology, structural, vibrational and optoelectronic properties of Sb_2Se_3 are investigated. The properties of the absorber layer are studied by GIXRD, SEM, AFM, Raman spectroscopy and transmittance measurements. In the case of the VTD process, the variation of substrate temperature is critical for the formation of a compact layer, observing a nanoribbon-type structure when temperature increases up to 400°C. In addition, there is a significant difference on the structure of Sb_2Se_3 when Mo is selenized before the deposition of the absorber layer. However, the selenization of evaporated Sb film leads to a much more compact and uniform morphology. First SLG/Mo/Sb_2Se3/CdS/iZnO/ITO substrate configuration photovoltaic devices are fabricated, achieving efficiencies of 3.8% for the thinnest active layer of 400 nm. Further studies are being performed to optimize the different growth processes that result in an enhanced solar cell efficiency.

5:00 PM EN11.08.04
Synthesis of Complex Pnictide Semiconductors Kirill Kovnir; Iowa State University, United States

Synthesis of complex inorganic materials is often a bottleneck of the materials by design concept. For complex pnictides, thermodynamic and kinetic limitations of conventional synthetic approaches areas are complicated with phase segregation of volatile components, such as P and As, together with extreme reactivity of alkali and alkaline-earth metals towards container materials. Such limitations often resulted in inability to synthesize predicted materials in ternary and quaternary systems with drastically different reactivities of the constituent elements. Several strategies to advance synthesis and produce challenging phases will be discussed, such as averaging precursor reactivity by atomic mixing of refractory components; and prebuilding chemical bonds in the precursor. In-situ studies are crucial for the development of effective synthesis, especially when backed-up with ex-situ synthetic explorations and DSC results.

5:00 PM EN11.08.05
Unveiling The Impact of Subtle Defect Fluctuations on Kesterite Thin Film Solar Cells: An Analysis of CZTSe/CdS Interface with 400 Devices Pedro Vidal-Fuentes[1], Jacob Andrade-Arvizu[1], David Payno[1], Fabien Atlan[1], Alejandro Perez-Rodriguez[1,2], Maxim Guc[1] and Victor Izquierdo-Roca[1]; [1]IREC, Spain; [2]Universitat de Barcelona, Spain

Renewable energy generation is intimately linked with the advancement of innovative photovoltaic technologies. The realization of large-scale production hinges upon emerging thin-film materials and device architectures built upon stable, environmentally conscious resources. $Cu_2ZnSnSe_4$ has surfaced as a promising contender in this realm, owing to its attributes such as stability, affordability, adaptability to flexible substrates, and tunable bandgap. While efficiency of the devices based on this promising material might not match conventional PV technologies, their potential for swift industrialization remains noteworthy. This transition from laboratory-scale small cells to more expansive formats is essential. It paves the way towards diverse applications, not just

extensive solar farms, but also for distributed implementations like IoT, indoor PV, and various emerging paradigms.
This shift, however, uncovers challenges that warrant early attention. In mature technologies such as CIGS, the cell-to-module efficiency gap ($\Delta PCE_{cell-module}$ = 5 %) underscores the importance of addressing limitations upfront. For CZTSe, achieving precise control over thin film composition is pivotal due to its profound impact on material properties and photovoltaic performance. Even subtle compositional deviations can detrimentally influence device efficiency by exacerbating defects and grain boundaries, which are known to impede charge transport and place a limit to the V_{oc}. The interactions between the commonly used CdS electron transport layer (ETL) and the absorber layer in kesterite-based solar cells are equally crucial. Upscaling magnifies lateral inhomogeneity due to the augmented area-to-thickness ratio, necessitating highly uniform deposition methods. Failure to achieve homogeneity in the absorber layer can lead to compositional irregularities, thereby altering optoelectronic properties.
This research investigates two samples (5×5 cm^2 each), representing the initial step towards large-scale $Cu_2ZnSnSe_4$ device fabrication. Each sample is subdivided into 3×3 mm^2 devices, facilitating discrete surface information for statistical analysis. Raman spectroscopy (RS), photoluminescence (PL) spectroscopy and current voltage characteristics (J-V) constitute the array of employed characterization techniques. This combination elucidates the interplay of physicochemical attributes within the CZTSe/CdS heterojunction and its consequent impact on device output. By scrutinizing a comprehensive dataset of 2 × 196 devices, noteworthy correlations emerge. Fluctuations in the CdS buffer layer, encompassing slight thickness variations, bandgap shifts, and non-uniform defect distribution, closely correlate with the efficiency of individual cells. These CdS layer dynamics establish patterns in optoelectronic performance across the 5×5 cm^2 surface. Subtle in-process changes, often masked in small discrete samples or those subjected to wide fabrication variations, wield substantial impact on device efficiency. This underscores the significance of comprehensive data analysis, which can guide quality control in CZTSe module fabrication.
This study underscores the intricate interplay of optoelectronic properties and defect characteristics in CZTSe/CdS photovoltaic technology. The investigation of large-area samples through a comprehensive suite of characterization techniques has unraveled significant insights. The unexpected lack of a direct correlation between open-circuit voltage (V_{oc}) and CZTSe quality control parameters highlights the complex nature of V_{oc} loss, predominantly governed by CdS layer defects. Notably, defects localized on the CdS surface exhibit a distinct correlation with V_{oc}, indicating their pivotal role in device performance. The correlation between CZTSe photoluminescence quantum yield and V_{oc}, although significant, does not fully elucidate V_{oc} loss.

5:00 PM EN11.08.06
Electronic and Defect Properties of BaCd2P2 as a Solar Cell Absorber Zhenkun Yuan[1], Diana F. Dahliah[2,3], Romain Claes[2], Andrew Pike[1], Gideon Kassa[1], Muhammad R. Hasan[4], Shaham Quadir[5], Gian-Marco Rignanese[2], Andriy Zakutayev[5], David Fenning[6], Obadiah Reid[5,7], Sage Bauers[5], Jifeng Liu[1], Kirill Kovnir[4,8] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]Université catholique de Louvain, Belgium; [3]An-Najah National University, Palestine, State of; [4]Iowa State University, United States; [5]National Renewable Energy Laboratory, United States; [6]University of California, San Diego, United States; [7]University of Colorado Boulder, United States; [8]Ames National Laboratory, United States

We present the electronic and defect properties of $BaCd_2P_2$, a new solar cell absorber identified from our high-throughput computational screening and experimental follow-up synthesis and characterizations. Using first-principles calculations, $BaCd_2P_2$ is shown to have attractive optoelectronic properties, including a direct band gap of 1.45 eV, high carrier mobilities, and large optical absorption coefficients. HSE hybrid-functional defect calculations show that $BaCd_2P_2$ is an intrinsically semi-insulating material but can be doped *p*-type. Crucially, $BaCd_2P_2$ presents only a few deep defects that have either high formation energies or small capture coefficients. The calculated nonradiative recombination rates in $BaCd_2P_2$ are slower than or comparable to those in high-efficiency solar absorbers such as the halide perovskites. The favorable defect properties of $BaCd_2P_2$ are confirmed by photoluminescence (PL) and time-resolved microwave conductivity (TRMC) measurements. We will discuss these experimental results. In addition, a comparison of bulk and defect properties between $BaCd_2P_2$ and existing phosphide solar absorbers (InP and Zn_3P_2) will be made.

5:00 PM EN11.08.07
First principles modeling of polaron formation and optical signature on titanium-based oxides for oxygen evolution reaction photocatalysis. Shay McBride[1], Michael Paolino[2], Tanja Cuk[2] and Geoffroy Hautier[1]; [1]Dartmouth College, United States; [2]University of Colorado Boulder, United States

The exact mechanism and surface coverage present on (photo)-catalysts used for the oxygen evolution reaction (OER) remain elusive. Ultra-fast spectroscopy on model single crystal surfaces has started to clarify these questions but would benefit from more first principles theoretical support to facilitate the interpretation of the spectroscopic signatures. Here, we focus on the first principles modeling of the optical signature of polarons on OER intermediates on titanium-based photocatalysts (e.g., $SrTiO_3$ and TiO_2). The trapping of photo-generated holes by polarons on adsorbs at the catalyst surface is a key step in the photo-driven OER. We report from first principles on how the polarons formation process and optical signature changes with adsorbates (OH_2, OH, O) on different surfaces and compare with experimental results when available. Our work is a first step towards a better connection between ultra-fast spectroscopy and first principles computations.

5:00 PM EN11.08.08
Enhancing Photoelectrochemical Water Splitting Performance via Controllable Deposition of $BiVO_4$ on YSZ(110) Zhaoyi Xi[1,2], Chenyu Zhou[1] and Mingzhao Liu[1]; [1]Brookhaven National Laboratory, United States; [2]Stony Brook University, The State University of New York, United States

Bismuth vanadate ($BiVO_4$, BVO) is an outstanding photoanode material for photoelectrochemical water splitting. In our recent work, single crystalline BVO photoanodes were synthesized by pulsed laser deposition (PLD) method on YSZ(110) substrates. Through tuning different characters of BVO films deposited, they were found to be effective and influential in photoelectrochemical water splitting. Generally, the various characters of BVO were realized by tuning the deposition conditions of PLD, the growth mechanism of BVO thin films between YSZ(110) and conventional substrate orientation YSZ(100) was also compared. Furthermore, all the differences will have a direct influence on photoelectrochemical water splitting. Detailed surface characterizations and mechanistic research were performed to understand the inherent correlation between BVO growth conditions and performance, which will have a heuristic effect towards future photoanode design for solar water splitting.

5:00 PM EN11.08.09
$BaZrS_3$ – Single Crystals, Growth and Properties Yvonne Tomm[1], Galina Gurieva[1], Joachim Breternitz[2] and Susan Schorr[1,3]; [1]Helmholtz-Zentrum Berlin, Germany; [2]FH Münster, Germany; [3]Freie Universität Berlin, Germany

Perovskite chalcogenide materials have gained increasing interest as potentially stable materials with promising optoelectronic properties owing to their structure type. These materials have the general formula of AMX_3 with A being a group II cation (i.e., Ca^{2+}, Sr^{2+}, or Ba^{2+}), M a group IV transition metal (i.e., Ti^{4+}, Zr^{4+}, or Hf^{4+}), and X a chalcogen anion (S^{2-} or Se^{2-}). These materials have been known for a long time and attempts to prepare them have been made in many ways. Single crystals of this group of materials were prepared by the flux method. However, most of the data regarding structure and optoelectronic properties were determined on polycrystalline thin films (e. g. [1, 2]).
$BaZrS_3$ as a representative of this class of materials crystallizes in the orthorhombic perovskite-type structure. For thin films of $BaZrS_3$ a band gap energy of 1.95eV [3] and 1.99eV [2], respectively, has been determined.
Here we report on the growth of single crystals of $BaZrS_3$ and their crystal structure and optoelectronic properties compared to thin films. The $BaZrS_3$

crystals were grown by chemical vapor transport (CVT) using iodine as a transport agent. The resulting material and grown crystals were characterized by powder X-ray diffraction (XRD) and LeBail analysis of the diffraction pattern, as well as by single-crystal X-ray diffraction. The chemical composition of the crystals was determined by X-ray fluorescence. The band gap energy was determined from the diffuse reflectance measured by UV-VIS spectroscopy.

Solution Based Synthesis of Low Dimensional Pnictogen Chalco-Halides based on (Sb,Bi)(S,Se)(Br,I) for Sustainable Energy Applications David Rovira Ferrer, Ivan Caño Prades, Joaquim Puigdollers and Edgardo Saucedo; Universitat Politècnica de Catalunya, Spain

Quasi one-dimensional (Q1-D) structures based on van der Waals materials are gaining increasing interest in the search for novel energy applications such as photocatalysis, energy storage or photovoltaics. This attention is driven by the high stability and low environmental impact of chalcogenides and chalco-halides in contrast to third generation solar cells, especially Pb-based perovskites. The optoelectrical properties of these materials can be easily tuned through compositional engineering. A wide bandgap range (from 1 to 3.5 eV) can be achieved with available candidates for single-junction solar cells. The Sb/Bi chalco-halide compounds, generally formulated as MChX (M = Sb, Bi; Ch = S, Se; X = I, Br), crystallise in an orthorhombic Pnma space group consisting of covalently bonded ribbons along one crystallographic direction, while they are stacked together by van der Waals interactions in the other directions. This feature gives rise to unique optoelectronic properties when the material is properly oriented, such as enhanced carrier transport and increased mobility. In addition, it has been suggested that these compounds might possess a defect-tolerant electronic structure due to the trivalent metal cation, which is encouraging their development.

Despite these encouraging properties, the correct synthesis of these materials containing a halogen and a chalcogen in the structure is still a big challenge. Binary materials such as $(Sb,Bi)_2(S,Se)_3$ can occur as secondary phases, as well as sub-optimal morphologies. Uneven and uncompact films with uncontrolled ribbon orientation can form. This presentation will introduce a new methodology to synthesize mixed chalco-halides developed by the authors of this work. Thin films of the complete set of ternary van der Waals (Sb,Bi)(S,Se)(Br,I) chalco-halide semiconductors have been synthesized by dissolving MX_3 and selenourea/thiourea in N,N-dimethylformamide (DMF), followed by multiple spin-coating and hot-plate annealings at low temperatures (< 400 °C). Additionally, antisolvent incorporation during spin-coating, followed by a drying step at a temperature below the solvent's boiling point, have been applied to ensure that all organic residues are removed. This one step methodology provides less complexity compared to previous sequential procedures relying on diffusion of one precursor in a previously deposited film, which can lead to a gradient in the composition. Different surface treatments over the molybdenum substrate are explored to selectively orient texture in the (00l) direction by improving the solution adhesion and increasing the nucleation sites.

In the second part of the presentation, the fundamental properties of these compounds obtained by electrical and optical characterisation will be discussed. The measurement of the bandgaps, band structures, optical and transport properties will be shown.

The last part of the presentation will be dedicated to the challenges and possible technological solutions for the fabrication of solar cell devices using this innovative absorber synthesis route. The use of different electrons and holes transport layers, and architectures inspired in bulk-heterojunction devices using blended ribbons of BiSI and BiSBr/SbSI as donor and acceptor, respectively, will be discussed. These solar cell prototypes will be shown, with very encouraging open circuit voltages around 500 mV, and conversion efficiencies exceeding 1%. Finally, the perspective of these materials and the possible advantages with respect to current chalcogenide and halide technologies, will be presented and discussed.

5:00 PM EN11.08.11

An ALD-Grown Al-Doped Zinc Oxide/n-Si Isotype Heterojunction for Solar Water Splitting C. S. Wang[1], P. H. Tseng[2], Y. S. Lai[3] and Klaus Y. Hsu[1]; [1]National Tsing Hua University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan; [3]Taiwan Semiconductor Research Institute, Taiwan

It is well known that zinc oxide (ZnO) films are good passivation layers to semiconductor solar cells. Doped ZnO also serves as an excellent transparent electrode material. The efficiency of many solar cells has been enhanced by adopting this oxide material in the device structures. Besides, ZnO can be prepared by several large-area growth methods such as sputtering, evaporation, CVD, sol-gel, spray, ALD, etc. This benefits the use of ZnO in solar applications. In addition to being a transparent passivation layer or conducting electrode, n-type doped ZnO thin film can directly form an anisotype heterojunction with p-type silicon (p-Si) or an isotype heterojunction with n-type silicon (n-Si). These heterojunctions function simply as solar cells. When converting light power to electrical power, compared with conventional semiconductor p-n junctions, the ZnO/Si heterojunctions show no power loss at the near-surface region in the devices if the incident light comes from the ZnO side, because the ZnO films are transparent to visible light. This advantage further extends the application of ZnO to the active region of devices. In particular, the current flow in the n-ZnO/n-Si heterojunction should be easier since it involves only majority carriers. While numerous studies on the n-ZnO/p-Si anisotype heterojunction were conducted, much fewer works on the n-ZnO/n-Si isotype heterojunction can be found in the literature. In this work, an aluminum-doped ZnO (AZO) thin film was grown on an n-Si substrate by atomic layer deposition (ALD) with in-situ doping technique to form an isotype heterojunction. And a self-powered solar water splitter formed by serially connecting several of such heterojunctions was demonstrated.

The device was fabricated by first using the ALD system to grow a 53 nm thick AZO film on a 0.685 mm thick n-Si (2-7 Ω-cm resistivity) substrate. The growth temperature was low and set at 280 °C for best (002) crystallinity of the AZO film. The AZO film thickness was designed for minimum visible light reflection. The aluminum doping was performed by using an in-situ doping technique which involves the introduction of the $Al_2(CH_3)_6$ (TMA) precursor during the deposition process, which helps precise film thickness control. The resultant AZO film was characterized by Hall measurement to have a low resistivity of 2.48×10^{-3} Ω-cm and a high electron concentration of 1.3×10^{20} cm^{-3}. Therefore, the fabricated AZO/n-Si junction behaves like a Schottky junction, and the AZO itself can be the anode contact. TiN was coated at the backside of the Si substrate as the cathode. When serially connecting several devices, copper tape was used as the interposer.

The rectifying dark I-V curve of the AZO/n-Si junction was measured, from which the Schottky barrier height was extracted as 0.632 eV. When illuminated by the light from a tungsten-halogen lamp with an irradiance of 100 mW/cm^2, the open-circuit photovoltage was measured to be 0.38 V and the short-circuit current density was about 1 mA/cm^2. To demonstrate the usefulness of the AZO/n-Si isotype heterojunction device, we tried to use it to split DI water under illumination. By using the linear sweep voltammetry (LSV), it was found that the threshold voltage of DI water splitting for the fabricated AZO and TiN electrodes is 1.6 V. This indicates that at least 5 fabricated AZO/n-Si junctions must be connected in series to initiate splitting DI water under illumination. Such experiment has been carried out and the production of hydrogen gas was successfully observed.

5:00 PM EN11.08.12

Electron Transport Layers for CO2 Reduction: Conductivity, Selectivity and Stability RajivRamanujam Prabhakar and Joel W. Ager; Lawrence Berkeley National Laboratory, United States

Electron transport layers (ETLs) used as components of photocathodes for light-driven CO_2 reduction (CO_2R) in aqueous media should have good electronic transport, be stable under CO_2R conditions, and, ideally, be catalytically inert for the competing hydrogen evolution reaction (HER). Here, using

planar p-Si (100) as the absorbing material, we show that TaO_x satisfies all three of the above criteria. TaO_x films were synthesized by both pulsed laser deposition (PLD) and radio-frequency (RF) sputtering. In both cases, careful control of the oxygen partial pressure during growth was required to produce ETLs with acceptable electron conductivity. p-Si/TaO_x photocathodes were interfaced with ca. 10 nm of a CO_2R catalyst: Cu or Au. Under front illumination with simulated AM 1.5G in CO_2-saturated bicarbonate buffer, we observed, for both metals, faradaic efficiencies for CO_2R products of ~50% and ~30% for PLD TaO_x and RF sputtered TaO_x, respectively, at photocurrent densities up to 8 mA cm^{-2}. p-Si/TiO_2/Cu photocathodes were also evaluated but produced mostly H_2 (>97%) due to reduction of the TiO_2 to Ti metal under CO_2R conditions. In contrast, a dual ETL photocathode (p-Si/TiO_2/TaO_x/Cu) was selective for CO_2R, which suggests a strategy for separately optimizing selective charge collection and the stability of the ETL/water interface. The maximum photovoltage obtained with p-Si/TaO_x/Cu devices was 300 mV which was increased to 430-460 mV by employing ion implantation to make pn^+-SiTaO_x/Cu structures. Photocathodes with RF sputtered TaO_x ETLs are stable for CO_2R for at least 300 min. Techno-economic analysis shows that the reported system, if scaled, could allow for an economically viable production of feedstocks for chemical synthesis under the adoption of specific CO_2 credit schemes, thus becoming a significant component to carbon-neutral manufacturing.
Further to understand the why PLD TaO_x electron transport layer exhibits higher product selectivity over RF sputtered TaO_x, we investigated using ambient pressure x-ray photoelectron spectroscopy (APXPS) how the Cu catalyst oxidation state changes with different CO_2 partial pressures. There was evidence on favorable change in the oxidation state of Cu towards Cu^{2+} when exposed to higher partial CO_2 pressures with different TaO_x supports.

5:00 PM EN11.08.13
Co-Solvent Engineering for Solution-Processed CZTSSe on a Transparent Substrate Alice Sheppard[1], Raphael E. Agbenyeke[1], Jacques Kenyon[2], Robert Harniman[1], Laurie King[1], Jude Laverock[1], Neil A. Fox[1] and David J. Fermin[1]; [1]University of Bristol, United Kingdom; [2]Loughborough University, United Kingdom

Recent breakthroughs in efficiencies of up to 14.9%[1] for $Cu_2ZnSn(S,Se)_4$ (CZTSSe) solar devices have reignited interest in CZTSSe as an inorganic thin-film solar absorber. Traditionally, Mo-coated soda lime glass (SLG) substrates have been the standard for chalcogenide thin-film photovoltaics (PVs). Such substrates, however, can hinder the applications of thin-film PV, namely, semi-transparent and bifacial irradiation for building integrated PV applications. In this study, we explore the deposition of CZTSSe directly onto fluorine-doped tin oxide (FTO) by solution-based methods. The precursor solutions containing copper(II) chloride dihydrate, tin(II) chloride, zinc chloride and thiourea are formulated by employing mixtures of dimethyl formamide (DMF) and isopropanol (IPA).[2,3] We also investigate the effect of adopting a one- or two-step heat treatment process at each layer during spin coating, prior to the reactive annealing step in the presence of Se. The effect of solvent composition and adopting an additional heat treatment step have been studied here by exploring the thin-film crystallinity, composition, secondary phase formation, and device performance, featuring CdS as buffer layer. Our data shows that solutions with a DMF:IPA mixture of 1:3 result in the most homogeneous grain growth and suppression of secondary phases, with a champion front illumination power conversion efficiency of 5.2%. We rationalise device performance in terms of the topography and surface electronic properties, as probed by energy-filtered photoemission electron microscopy.[4,5]

Photolithography Technologies for Metallic Meshes and Local Contacts on CIGS Thin Film Solar Cells with NIR-Transparent TCO Layers
SeongYeon Kim, Si-Nae Park, Dong-Hwan Jeon, Van-Quy Hoang, Jaebaek Lee, Ali Amanat, Shi-Joon Sung and Dae-Hwan Kim; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

A transparent conducting oxides(TCO) for CIGS thin film solar cells, Al-doped ZnO(AZO) is widely used because of their wide band gap energy(Eg = 3.37 eV), high optical transparency, conductivity and based on earth-abundant materials. However, for the application of TCO layer for modules fabrication, AZO has an issue about optical loss in the visible and near-infrared spectrum. This causes electrical, optical and fill factor(FF) losses in the integration of solar cells in a module, which is known as cell to module(CTM) losses. To solve those issues, we have fabricated CIGS solar cells with hybrid electrodes of metallic grids / TCO layers.
Photolithography is versatile technology to make the patterns as we desired and demanded for semiconductor devices. We have patterned metallic meshes on AZO layer of CIGS solar cells using by photo lithography technique with negative photoresists. We fabricated photoresist template by exposure and development processes and deposited aluminum or silver metallic layers on the template about 1 μm of thickness and lifted off the photoresists to complete metallic meshes with attempting to minimize the linewidth by 2~3 μm and also minimize transmittance loss controlling by grid distance about 100 to 200 μm.
As a result, Al meshes occupying from 2.20 to 2.84% in a cells whereas reference devices have 3.94 to 4.66 % of grid area. In both case of Al and Ag meshes devices, Jsc has been improved to 27.98 mA/cm^2 than 27.73 mA/cm^2 of the reference devices. In the case Ag meshes devices, Voc has been improved to 0.65 V which is closer to 0.66 V of the reference cell. By these results, we will discuss how to fabricate the solar cells with composite transparent electrode better way.
On the other hand, we have fabricated Hydrogen-doped Indium Oxide(In_2O_3:H) by sputtering process with H_2 and O_2 reactive gases with various mass flow controlling to improve NIR transmittance and high mobility. We have fabricated CIGS solar cells with In_2O_3:H instead of AZO layer and compare the parameters to clarify how NIR transparency and mobility improves the power conversion efficiencies.
Also, we fabrcated local contacts with MgF_2 passivation layer with dot-shaped local contacts with various diameters and spacings on Mo back contact before CIGS deposition. we will discuss how those diameter and distance affecting on solar cells power conversion efficiency improvements.

SESSION EN11.09: Chalcogenides PV/PEC I
Session Chairs: Sage Bauers and Andriy Zakutayev

CdSe Solar Cells with V_{OC} > 1V Sachit Grover[1], Mohammad Taheri[1], Taylor Hill[1,2], Elline Hettiaratchy[1], Xiaoping Li[1], Dmitry Krasikov[1], Gang Xiong[1], Darius Kuciauskas[3], Craig Perkins[3] and Angus Rockett[4]; [1]First Solar, United States; [2]Colorado State University, United States; [3]National Renewable

Energy Laboratory, United States; [4]Colorado School of Mines, United States

An efficient, low-cost, scalable, and stable top-cell photovoltaic absorber is needed to make thin-film based tandem solar cells. Using cadmium selenide (CdSe) as an example, we highlight our methodology for rapid assessment of novel photovoltaic absorber materials and identify challenges towards making high efficiency devices.
With a bandgap of 1.72eV, CdSe is well suited as a top-cell absorber in a two-junction tandem solar cell. We assess the potential of CdSe as an absorber through several measurements including external radiative efficiency (ERE), carrier density, polycrystalline grain-size and orientation. Well formulated thin films of CdSe are found to be n-type, hexagonal, and exhibit high ERE (>0.2%). Photoluminescence and sub-band external quantum efficiency confirm that this absorber is capable of implied open-circuit voltages above 1.1 V. A transparent conducting oxide coated on glass forms the electron-contact to the CdSe thin-film grown on top of it. The hole-contact is formed by organic hole-transport layers used in conjunction with a bilayer of transition metal oxide and thin-gold. Solar cells with measured V_{OC} > 1 V have been demonstrated with this device structure.
Despite good V_{OC}, the devices made so far exhibit a limited fill factor and short-circuit current that cannot be completely accounted for by resistive or optical losses. By connecting a multitude of metrology techniques to device modeling results we conclude that the minority carrier collection is limited as the mobility and lifetime product (mu*tau) product is about 10^{-9} cm^2/V. This is attributed primarily to low hole mobility. Another key challenge is the unusually large ionization potential of CdSe at -6.5eV. SCAPS simulations indicate that improving the mu*tau and reducing the band-offset at the hole contact should lead to improved carrier collection. Defect signatures identified through sub-band photoluminescence measurements suggest selenium vacancies could be problematic.
In conclusion, well researched p-type transparent contact layers with a deep valence-band alignment are needed as hole contacts for CdSe solar cells. Options for designing a CdSe device that can be used in a thin-film based tandem are limited by the n-type absorber and require improved minority-carrier diffusion length.

8:30 AM EN11.09.02
Cation Mutation in $Cu_2Zn(Ge_xSi_{1-x})Se_4$ Solid Solution as a Path Towards CRM-Free Top Absorber Layer for Tandem Solar Cells Galina Gurieva[1], Sara Niedenzu[1], Alicia Manjon-Sanz[2], David C. Matzdorff[1], Melanie Kirkham[2] and Susan Schorr[1,3]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Oak Ridge National Laboratory, United States; [3]FU, Germany

The search for sustainable, efficient, and cost-effective photovoltaic materials continues to be a challenge in the field of solar energy production. In particular, the development of critical raw material free top absorber layers for tandem solar cells is crucial in the effort to transition away from fossil fuels and towards a greener energy future. The emergence of compound semiconductors has provided an opening into low-cost fabrication of thin-film solar cells, made possible a reduction in absorber layer thickness, and therefore lead to a decrease in production costs.
In this work, we explore the potential of tetravalent cation mutation in Cu-based quaternary chalcogenide semiconductors ($Cu_2ZnSi_xGe_{1-x}Se_4$ [1]) with the aim of finding a material with increased bandgap (ideally around 1.7eV) and reduced structural disorder, which is considered to be the main culprit of the low V_{OC} in the only CRM-free material used in PV technology at the moment ($Cu_2ZnSn(S,Se)_4$). One of the ways, previously shown to completely block structural disorder, especially the Cu/Zn disorder, is a change of the atomic crystal structure, e.g. [2]. The substitution of the tetravalent cation in the compound semiconductor brings a drastic structural change from the tetragonal kesterite type structure in $Cu_2ZnGeSe_4$ to the monoclinic wurtz-kesterite type structure in $Cu_2ZnSiSe_4$, with a significant increase in the bandgap as well [3].
We studied crystal structure, cation distribution and intrinsic point defect scenario in $Cu_2ZnSi_xGe_{1-x}Se_4$ mixed crystals (powder samples) by neutron diffraction. This method enables us to differentiate the isoelectronic cations Cu^+, Zn^{2+} and Ge^{4+} in the crystal structure analysis. These investigations enabled us to deduce the structural transition scenario of the $Cu_2Zn(Ge,Si)Se_4$, series which is going via a region where two phases with different crystal structures but with the same chemical composition coexist. Interestingly both quaternary phases show the same cation distribution within the element specific cation sites. In the $Cu_2Zn(Ge,Si)Se_4$, series the distortion of the coordination tetrahedra is increasing with increasing Si content thus indicating that the structural transition from the kesterite type to the wurtz-kesterite type structure is distortion driven.
The results of this study highlight the importance of considering alternative materials beyond the known kesterites in the search for CRM-free top absorber layers and demonstrate that cation mutation in quaternary chalcogenides is a promising path towards the development of highly efficient tandem solar cells.

8:45 AM EN11.09.03
Enhancement of Open-Circuit Voltage in $Cu_2ZnSn(S,Se)_4$ Solar Cells with Defect Passivation via LiF Post-Deposition Treatment Geumha Lim[1], Ha Kyung Park[1], Wook Hyun Kim[2], Seung-Hyun Kim[3], Kee-Jeong Yang[2], Jin-Kyu Kang[2], Dae-Hwan Kim[2] and William Jo[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of); [3]Research Institute, YK Sintering Co., Korea (the Republic of)

$Cu_2ZnSn(S,Se)_4$ (CZTSSe) is a promising candidate for low-cost, non-toxic, and highly stable alternatives to traditional light-absorbing materials. The incorporation of light alkali metals in CZTSSe solar cells has considered as a possible way to address limited power conversion efficiency caused by a significant open-circuit voltage deficit. In this study, fine interface engineering with effective passivation of detrimental defects via LiF post-deposition treatment (LiF PDT) was reported.[1] Three samples, the sample without a LiF layer, the sample with an as-deposited 0.7 nm LiF layer, and the sample with an 0.7 nm LiF layer followed by additional annealing at 200 ºC, were prepared. Secondary ion mass spectroscopy shows that the diffusion of Li occurred only with additional heat treatment. Meanwhile, as-deposited LiF was lost during the CdS deposition process. Energy dispersive spectroscopy shows the possibility of Zn(S,Se) secondary phase migration to the surface of the absorber through additional heat treatment. To investigate the interface properties directly, mechanical dimpling of solar-cell devices was utilized. Uniform grinding condition was confirmed through Raman spectroscopy. Kevin probe force microscopy reveals that the work function difference between bulk and interface reduced as the sample was subjected to the LiF PDT process, resulting in a lower conduction band offset at the CdS/CZTSSe interface. Furthermore, an increase in surface photovoltage signal indicates reduced defect-assisted carrier recombination through Li incorporation. Li modified the dominant defect types from Cu_{Zn} and Zn_{Cu} to shallower Li_{Zn} and Li_{Cu} antisites, preventing recombination losses and promoting charge transport. As a result, the sample with LiF PDT process achieved 10.4 % efficiency with significant enhancement of V_{OC}.

In-depth carrier recombination mechanism at grain boundaries in flexible kesterite thin film solar cells with 12.2% efficiency Ha Kyung Park[1],

Dae-Ho Son[2], Shi-Joon Sung[2], Dae-Kyu Hwang[2], Jaebaek Lee[2], Dong-Hwan Jeon[2], Yunae Cho[1,1], Dae-Hwan Kim[2], Jin-Kyu Kang[2], Kee-Jeong Yang[2] and William Jo[1,1]; [1]Ewha Womans University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Kesterite $Cu_2ZnSn(S,Se)_4$ (CZTSSe), an earth-abundant and non-toxic material, is widely regarded as a promising light absorber for photovoltaic devices. Extensive research has focused on understanding recombination mechanism at the surface grain boundaries (GBs) which detrimentally impacts device performance, while their behavior within the material's bulk remains relatively unexplored. In this study, in-depth carrier recombination mechanism was investigated using atomic force microscopy-based characterizatio. A flexible CZTSSe thin film solar cell with an efficiency of 12.2% was prepared using a sputtering method on a Mo foil substrate. In particular, the sample was subjected to mechanical etching using a focused-ion beam to expose a plane at the specific depth. After that, electrostatic potential at the revealed surface was obtained by Kelvin probe force microscopy. At the surface and subsurface, formation of both conduction (E_C) and valence (E_V) upward bending was observed due to the widen band gap and increased charged defects at the GBs than in intra grains. This type of band bending is efficient for carrier separation as it repels electrons from the GBs while collects holes. [1] Additionally, large upward band bending contributed to a formation of conduction path along the intra grains. In contrast, center of absorber presented E_C downward and E_V upward band bending besides the E_C and E_V upward band bending, that is unfavorable as it can be the recombination sites. Hence, in-depth carrier recombination mechanism exhibited non-uniform behavior between the materials' surface and the bulk. In conclusion, the uniform E_C and E_V upward band bending at the GBs across the entire absorber layer is desirable to minimize the recombination. [2] Additionally, our research suggested the in-depth characterization methods that can be applied other materials beyond the kesterite thin film solar cells.

Manganese-Containing Quaternary Chalcogenides: New Earth-Abundant Semiconductors for Solar Energy Conversion Susan Schorr[1,2], Galina Gurieva[1] and David C. Matzdorff[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Freie Universitaet Berlin, Germany

The need of eco-friendly compound semiconductors in thin film photovoltaics has constantly pushed the research towards more environmental friendly materials, such as the Kesterite-type compounds Cu_2ZnSnS_4, $Cu_2ZnSnSe_4$ and $Cu_2ZnSn(S,Se)_4$ (CZTSSe). They present the only critical raw material (CRM) free thin film PV technology with tunable band gap energy and excellent long-term stability. The current record efficiency for CZTSSe solar cells of 14.9 % [1] highlights the great potential of this abundant chalcogenides to support a sustainable energy transition.
Recently, other quaternary semiconductors have raised attention: Cu_2MnSnS_4/Se_4. Photovoltaic devices based on their solid solution reached an efficiency of 1.8% [2]. An efficiency of 20.3% was calculated for a Cu_2MnSnS_4 based solar cell [3]. Including $Cu_2MnGe(S/Se)_4$, a band gap energy range of 1.2 to 2.1 eV can be covered by the respective anion as well cation mutations. Moreover Mn is more abundant than Zn (1100 ppm against 79 ppm) [4], leading to a potentially cheaper final device. Thus Mn-based quaternary compound semiconductors have a strong potential in solar energy conversion technologies.
In this work, we study four cation and anion mutation series: $Cu_2Mn(Ge,Sn)S_4$ and $Cu_2Mn(Ge,Sn)Se_4$ as well as $Cu_2MnSn(S,Se)_4$ and $Cu_2MnGe(S,Se)_4$ aiming for insights into the crystal structure, structural disorder and their band gap energies. In contrast to the kesterite-type materials discussed above, these Mn-containing quaternaries crystallize in the tetragonal stannite-type (when Sn is the four-valent cation) or orthorhombic wurtz-stannite-type (in case Ge is the four-valent cation) structure. This change in the crystal structure, with respect to the kesterites, can block Cu/B^{II} disorder (Cu/Zn disorder in kesterites), as shown before [5].
We studied the crystal structure, cation distribution and intrinsic point defect scenario in the mixed crystals of these four series (powder samples) by neutron diffraction. This method enables us to differentiate the isoelectronic cations Cu^+ and Ge^{4+} as well as electronic similar Mn^{2+} in the crystal structure analysis giving the possibility to conclude on anti site defects including these cations. From our experimental findings it became evident, that the off-stoichiometry type model developed for kesterites [6] also applies in Mn-containing quaternaries despite their different crystal structure.
We observed Cu-Mn swapping (very small fractional amount of Cu_{Mn} and Mn_{Cu} anti sites) in all compounds and mixed crystals with the exception of $Cu_2MnSnSe_4$ [7]. This type of cation swapping was also observed in Cu_2MnSnS_4 thin films [8].
We found that in the $Cu_2Mn(Ge,Sn)S_4/Se_4$ series Sn-rich mixed crystals adopt the stannite structure, whereas Ge-rich mixed crystals adopt the wurtz-stannite structure. Within the intermediate range, two chemically identical but structurally different quaternary phases coexist, adopting the tetragonal and the orthorhombic structure respectively. The structural transition is driven by an increasing structural distortion with increasing Ge-content. Both end members of the $Cu_2MnSn(S,Se)_4$ and $Cu_2MnGe(S,Se)_4$ series crystallize in the same structure type, avoiding a structural transition. But a change in the structural disorder can be noticed within these series, showing an increase around the center of the solid solutions.
Finally, the band gap energy variations within these four cation and anion mutation series will be presented, showing the correlation between crystal structure and this important optoelectronic material property.

Depth-Profiling of High Efficiency Kesterite Solar Cells: The Role of Co-Alloying Alex Jimenez Arguijo[1], Yuancai Gong[2], Tariq Jawhari[3], Lorenzo Calvo-Barrio[3], Alejandro Perez-Rodriguez[1], Sergio Giraldo[2] and Edgardo Saucedo[2]; [1]Institut de Recerca Energética de Catalunya, Spain; [2]Universitat Politècnica de Catalunya, Spain; [3]Universitat de Barcelona, Spain

The kesterite ($Cu_2ZnSn(S,Se)_4$, CZTSSe) absorber family is composed of low-toxicity, earth-abundant elements, and offers an unmatched stability which aligns with low-cost applications such as building-integrated and indoor photovoltaics. Moreover, it has recently experienced a breakthrough thanks to the research centered on solution-based precursors, showcasing a remarkable efficiency of 13% in 2022, which has now been further improved to 14.9%. This new paradigm for the Kesterite community has been possible through the smart design of solution chemistry in organic polar solvents yielding amorphous kesterite films, together with optimized thermal annealings for direct phase conversion from precursor to absorber, and the implementation of beneficial low-temperature heterojunction heat treatments. In addition, the alloying with isovalent elements (Ag, Cd, and Ge) has been shown to be crucial to achieve record efficiencies, suppressing lattice defects by improving the synthesis pathway.
A thorough understanding of the actual role of isovalent element alloying could enable the synthesis of high quality kesterite absorber materials without the need to use expensive, toxic and scarce elements during the synthesis. In this work, the role of additional elements will be studied by comparing the device performance of absorbers without alloying, with Ag alloying and with Ag,Cd co-alloying. Thus, demonstrating the beneficial role of these alloying strategies on the optoelectronic properties of the devices. Furthermore, the effects on the grain growth mechanism of Ag and Ag,Cd co-alloying will be

thoroughly investigated by secondary electron microscopy (SEM), X-ray diffraction (XRD) and Raman spectroscopy combined in break-off experiment at different temperatures. Finally, to shed more light on the performance improvement, depth gradient ion-milled samples will be fully analyzed by combining micro-Raman (325, 532 and 785 nm excitation wavelengths), micro-photoluminescence (PL) and X-ray and ultraviolet photoelectron spectroscopy (XPS and UPS), thereby showing the actual role of Ag and Ag,Cd alloying in high efficiency kesterite absorbers. In particular, the distribution of secondary phases, grain quality, defect concentration, sulfur content and carbon residues will be assessed by micro-Raman spectroscopy. Also, the in-depth compositional homogeneity as well as Sn and Cu oxidation states will be characterized by XPS, revealing insights on the deep-defect density (Sn, lifetime related) and the shallow defect density (Cu, doping related). Moreover, the combination of XPS, UPS and PL will allow reconstructing the in-depth band diagram, revealing key insights on the charge carrier transport of high quality kesterite materials.
Overall, the present study will reveal the most relevant factors induced by the Ag and Cd incorporation in the lattice of high efficiency kesterite absorbers, paving the way for further improvements without requiring the use of expensive, scarce and toxic elements.

9:45 AM EN11.09.07
Exploration, Prediction and Experimental Verification of Structure and Optoelectronic Properties in I_2-Eu-IV-X_4 (I = Li, Cu, Ag; IV = Si, Ge, Sn; X = S, Se) Chalcogenide Semiconductors Max McWhorter, Tianlin Wang, Garret C. McKeown Wessler, Yi Yao, Ruyi Song, Volker Blum and David B. Mitzi; Duke University, United States

Recent extensive research into the defect-resistant I2-II-IV-X4 (I = Li, Cu, Ag; II = Ba, Sr, Eu, Pb; IV = Si, Ge, Sn; X = S, Se) family of quaternary chalcogenide semiconductors suggests excellent potential for applications in photovoltaics, thermoelectrics, and nonlinear optics. Among these compounds, Eu containing members are understudied, with only five previously synthesized members. Herein, we undertake a comprehensive study of the possible structures and electronic properties of all eighteen of the Eu-based combinations within I2-Eu-IV-X4 (I = Li, Cu, Ag; IV = Si, Ge, Sn; X = S, Se). To further understand the broader I2-II-IV-X4 family and test the geometric tolerance factor (reported in our previous work) as a tool for predicting potential stable structures, we first use hybrid density functional theory to systematically study these rare-earth-including I2-Eu-IV-X4 semiconductors. Lowest-energy quaternary structure candidates, energy band structures, and densities of states are computationally predicted for all eighteen compounds. Following this screening process, the previously unknown compound Cu2EuSnSe4 was selected and synthesized due to its predicted photovoltaics-relevant direct band gap. Optimal synthesis conditions were determined, and the experimentally derived structure, lattice parameters, and bandgap of Cu2EuSnSe4 were found to be consistent with the predictions from both geometric tolerance factors and hybrid DFT, validating our predictive approaches and confirming a 1.55 eV band gap. Along with strong optical absorption in the visible range, this band gap suggests potential for Cu2EuSnSe4 in photovoltaic and other optoelectronic applications.

$AgBiS_2$ Nanocrystals: An Emerging Chalcogenide Absorber for Solution Processed Ultra-Thin Film Solar Cells Gerasimos Konstantatos; ICFO, Spain

In this talk I will discuss recent progress in our group on the development of a new class of thin film solar cells employing Silver Bismuth Sulfide as an emerging absorber for solution processed eco-friendly solar cells. I will first introduce our first report on AgBiS2 colloidal nanocrystal solar cells reporting power conversion efficiency of ~6% [1]. Then I will discuss on the opportunities of tuning the optical properties of this ternary compound via controlling cation disorder homogenization. We demonstrated that by homogenizing cation disorder in this compound we can drastically increase the absorption coefficient of this material as one with the high absorption amongst the semiconductors considered for photovoltaics. This taken together with advances on the device architecture led us to reach power conversion efficiencies of ~9% albeit using an absorber of only 35 nm [2]. In the last part of my talk I will describe our initial efforts on developing $AgBiS_2$ nanocrystal inks and their use with environmentally friendly solvents that led us to achieve efficiencies in excess of 7% [3]. I will conclude my talk with our most recent findings towards an improved passivation strategy of $AgBiS_2$ nanocrystal inks along with the formation of a double heterojunction in the device stack that led to power conversion efficiencies in excess of 10% with Voc of 0.5V, FF of 0.75 and Jsc of 28 mA/cm^2.

Generalizing Synthesis Approaches for $BaMS_3$ Chalcogenide Perovskites and Related Materials Shubhanshu Agarwal, Kiruba Catherine Vincent, Jonathan Turnley and Rakesh Agrawal; Purdue University, United States

Over the past decade, lead halide perovskites have witnessed a remarkable surge in solar device efficiencies. They possess a defect-tolerant crystal structure, showcasing outstanding optoelectronic and charge transport properties with tunable bandgaps. However, their progress is hindered by limited air, moisture, and thermal stability. While research on these exceptional materials should continue, there is a need to identify stable alternatives that exhibit similar appealing properties. Chalcogenide Perovskites have emerged as promising substitutes for lead halide perovskites. These materials also display defect tolerance and boast one of the highest light absorption coefficients. They demonstrate considerable stability against air, moisture, and thermal conditions, and their bandgaps can be tailored for either single-junction or tandem solar cell applications.

Nevertheless, Chalcogenide Perovskites face a challenge in high-temperature synthesis. Historically, they have been synthesized at temperatures exceeding 900°C, either as powders or vacuum-deposited thin films. Such high-temperature syntheses restrict the choice of substrates for material deposition. Additionally, not all the intermediary layers in a solar cell can endure such high temperatures. Therefore, it is imperative to synthesize these materials of the highest quality at low to moderate temperatures (<600°C). In recent years, multiple research groups have successfully synthesized nanoparticles or inhomogeneous solution-processed films at low temperatures. However, a comprehensive understanding of the critical parameters enabling this achievement is still lacking.

In this work, we present a comprehensive framework for the synthesis of low-temperature $BaMS_3$ compounds (M=Zr, Hf, Ti) while discussing the interplay of precursor reactivity, availability of a transport agent, and an oxygen sink as the primary factors governing low-temperature synthesis with

limited contamination. Furthermore, to validate our framework, we introduce four novel methods to synthesize $BaMS_3$ compounds at low temperatures, adhering to the guidelines outlined in the framework. Our results highlight a unique opportunity to synthesize $BaMS_3$ compounds using cost-effective precursors at low temperatures, offering guidance for future research on these materials.

11:15 AM EN11.09.10
Solution-Processed Chalcogenide Perovskite Thin Films Utilizing Amine Thiol Chemistry Kiruba Catherine Vincent, Jonathan Turnley, Shubhanshu Agarwal and Rakesh Agrawal; Purdue University, United States

Growing technological advancements necessitate the development of versatile semiconductor materials capable of addressing diverse challenges. These materials must demonstrate robust stability, natural abundance, environmental friendliness, and tunable properties to cater to diverse applications, such as transistors, photovoltaics, thermoelectrics, LEDs, and more. Additionally, they should enable efficient and high-throughput synthesis. In the domain of photovoltaics, we can recognize two material systems competing to meet these requirements – emerging chalcogenides and lead halide perovskites. Emerging chalcogenides, such as $Cu_2ZnSn(S,Se)_4$, offer low toxicity and earth-abundant elements but have struggled to achieve high efficiencies. On the other hand, lead halide perovskites are breaking efficiency records but are extremely sensitive to air, and moisture and suffer from toxicity issues.
An emerging class of materials that offers a compelling blend of the exciting properties of chalcogenides and lead halide perovskites are chalcogenide perovskites. Chalcogenide perovskites have shown superior stability and abundance in nature. They exhibit intriguing optoelectronic properties such as a tunable bandgap, high absorption coefficients, defect tolerance, and a high dielectric constant. However, despite their potential, chalcogenide perovskites have been constrained by their basic synthesis procedures, often requiring temperatures as high as 1000°C for extended periods, limiting their practicality. Solution processing has generally been seen as a low-temperature, ambient-pressure route to synthesize chalcogenide materials with high throughputs. Recent reports by Pradhan et.al provide promising results for solution-processed chalcogenide perovskites. They utilized CS_2 insertion chemistry to enable the synthesis of $BaMS_3$ materials at moderate temperatures. However, their method produced rough and cracked films with significant residual carbon (DOI: 10.1002/anie.202301049).
This study presents a versatile, moderate-temperature solution-processing synthesis approach for $BaZrS_3$, a notable chalcogenide perovskite for tandem solar cell applications and for the related $BaHfS_3$ perovskite, suitable for LED and water-splitting applications. We utilized the well-known alkahest amine-thiol solvent system to blade coat our films. This method produced crack-free films with minimal carbon residue and hence provided a promising step forward for the chalcogenide perovskite research. Subsequently, we conducted comprehensive material, morphological, and optoelectronic characterizations on these films to gain valuable insights that can guide the fabrication of high-performance devices.

11:30 AM EN11.09.11
Preparation, Structural and Optical Properties of Copper Chalcogenide Nanostructures and Thin Films (including 2D) for Photovoltaics, Thermoelectric and Electrochemical Applications Richard A. Taylor, Kimberly A. Weston, Sarika V. Chandoo, Sean Persaud and Stefan C. Ghany; University of The West Indies, Trinidad and Tobago

Copper chalcogenides have emerged as attractive materials because of their wide-ranging applications involving photovoltaics, thermoelectrics, electrochemical and light emitting/down-conversion. This is because as nano- and microstructures, their properties can be controlled by their composition including defects, phase structure, morphology, dimensionality, optical, electrical, and electrochemical properties. However, in several ternary phases such as copper indium sulphide (CIS), copper antimony sulphide (CAS) and the two-dimensional (2D) copper molybdenum sulphide (CMS), there remains a challenge in controllable scalable preparation. To address this, we have been exploring facile colloidal and template-assisted syntheses, and aerosol-assisted chemical vapor deposition (AACVD) to selectively prepare these materials and control their properties. For example, tetragonal I-phase multilayered 2D CMS nanosheets and nanorods prepared colloidally and by AACVD displayed tunable bandgaps (1.6 – 2.6 eV). Additionally, we demonstrated selective preparation of non-stoichiometric famatinite CAS nanoparticles at notably low temperatures (60 – 70 °C) with tunable bandgaps (1.9 – 2.2 eV) and high-quality non-stoichiometric tetrahedrite phase CAS thin films with Zn^{2+} ions incorporated with tunable bandgaps (1.7 – 2.1 eV) influenced by Zn^{2+} ion by point defects. Data from HR-SEM/TEM, EDS, XPS, confocal Raman and time-resolved PL spectroscopy, and cyclic voltammetry, suggest electronic properties implicated by point defects, and structural, morphological, optical characteristics dependent on synthetic conditions. We have also prepared tunable highly emissive CIS nanoparticles doped with Zn^{2+}/Mn^{2+} ions and alloyed/passivated with ZnS/MnS as candidates for nanocomposite emissive luminescent down-shifting films for windows in controlled environment agriculture systems. As a novel approach, we have demonstrated template-assisted growth of large domain sized (30 – 200 nm) 2D nanosheets of ZnS, CuS, CIS and CAS, which typically form 3D or 0D nanostructures. Overall, our synthetic methodologies demonstrate control over tuning structure, morphology, composition including defects and their attendant electronic properties of these copper-based nanostructures and microstructured thin films for luminescent downshifting, photovoltaic and photoelectrochemical applications.

11:45 AM EN11.09.12
Routes Towards Improved Open Circuit Voltage in Sb2Se3 Solar Cells Thomas Shalvey and Jonathan D. Major; University of Liverpool, United Kingdom

Sb2Se3 is a defect tolerant, earth-abundant, stable semiconductor which has shown promise for low cost thin film photovoltaic power generation. It has a large absorption coefficient, suitable band gap, simple binary composition and benign grain boundaries compared to typical 3D materials. These attributes have helped solar cell efficiencies to surpass 10% with relatively little research effort in comparison to other absorber technologies. Despite this encouraging progress, the rate of improvement appears to have slowed recently as record devices approach the detailed balance limit of short circuit current density. This means that further improvements are likely to originate primarily from increasing the open circuit voltage (Voc) and/or fill factor (FF).

Interfaces within a solar cell play a key role in both the Voc and FF, and therefore we have carried out a detailed study of the partner layers in the Sb2Se3 device structure either side of the absorber layer. We have replaced the standard CdS front contact with TiO2, which has a wider band gap and is far more robust, making it more amenable to the subsequent high temperature processing steps required for large grain, crystalline Sb2Se3 thin films. The initial solution processed TiO2 layer has been replaced with a sputter deposited film which improved device uniformity and increased FF, however was prone to run-to-run variations in TiO2 film quality and the inconsistent appearance of ‘S’-shape JV curves. This issue has now been resolved through careful control of the sputtering process, which has led to exceptionally high short circuit current densities and significantly improved FF, however the impact on Voc has been limited. The back interface was then studied to determine the role of the hole transport material (HTM) in Sb2Se3 devices, and assess whether this could be an area for improvement. Several commonly used organic HTM layers were compared against one another, and to a simple Au contact. The direct Sb2Se3-Au contact is limited by a secondary barrier causing ‘rollover’ in JV curves, despite seemingly favourable band positions. Each of the HTM layers demonstrated the ability to eliminate this secondary barrier, thereby lowering the series resistance and improving the fill factor. Whilst this increases the champion efficiency, the improvement is relatively minor, especially considering the gradual oxidation of the Sb2Se3 back surface produces a similar self-passivation effect. Instead, the HTM layers have a far more drastic effect on the average efficiency, which is attributed to a pinhole blocking effect by the solution processed organic films. Nonetheless, Voc remains below 500mV for all devices tested.

After thoroughly investigating the partner layers, we are now turning our attention to the Sb2Se3 layer itself. We are currently exploring several routes to

improve the quality of the absorber layer. This includes a comprehensive study of dopants and defects in Sb2Se3, whereby the growth of high purity single crystals with the controlled addition of selected extrinsic dopants will inform the most suitable compositions to target in thin films, both in terms of stoichiometry and p-type dopant incorporation. This is particularly important given the apparent chalcogen-poor stoichiometry reported by most groups, especially for PVD processed films, as well as the lack of rigorous control over doping type typically found in literature reports. The transfer of knowledge gained from this single crystal study towards full devices will be accelerated via the use of a novel dual source close space sublimation chamber. This will allow co-deposition of different source material with varying stoichiometry and dopant concentration, and therefore allow a wide range of material compositions to be rapidly deposited. These compositions will then be assessed in terms of their implied Voc in order to carry out a loss analysis to identify the different contributions to the remaining deficit.

SESSION EN11.10: Chalcogenides PV/PEC II

Raman Spectroscopy at The Nanoscale: From Materials to Devices for Energy Conversion Mirjana Dimitrievska; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The pace at which major technological changes take place is often dictated by the rate at which new materials are discovered, and the timely arrival of new materials has always played a key role in bringing advances to our society. Machine learning and advanced simulation and modeling techniques have recently massively accelerated the fast screening and discovery of new materials. There is however today a bottleneck in the exploitation of these emerging materials. Indeed, after the materials' existence and/or properties are predicted in silico, their synthesis and integration in devices to demonstrate functionality remain major challenge. Fast and reliable characterization can significantly accelerate materials optimization and bring them to the forefront of applications.

This talk will give an overview on the key role that Raman spectroscopy plays in accelerated semiconductor materials development for optoelectronic and energy conversion applications. I will show how Raman spectroscopy could be effectively used for probing fundamental properties of materials, such as crystal quality, phase purity, and defects. This will follow with presenting Raman-based methodologies for nanoscale detection of defects and impurities in materials, leading to establishing accurate phase diagrams and predictive synthesis-structure-property relationships. I will focus on wide range of material systems, from thin films to 1D and 2D materials. Finally I will discuss Raman-based mapping of the defect structure/space of thin film solar cells to optimize device structure.

2:00 PM EN11.10.02
Exploring Selenium Viability for Semi-Transparent Photovoltaics Arnau Torrens[1], Ivan Caño Prades[1], Alejandro Navarro[1], Axel Gon Medaille[2], Dioulde Sylla[2], Jose M. Asensi López[3], Sergio Giraldo[1], Kunal Tiwari[1], Edgardo Saucedo[1], Zacharie Jehl Li-Kao[1], Joaquim Puigdollers[1], Pablo Ortega[1] and Marcel Placidi[1,2]; [1]UPC, Spain; [2]IREC, Spain; [3]UB, Spain

Selenium (Se) holds historical significance as the first material used in a solar cell [1], in 1883, marking the initial exploration of materials capable of harnessing solar energy. However, it took over a century before being seriously considered for photovoltaics, achieving at this time an efficiency of 5% [2] with the following Au/Se/TiO_2/FTO architecture. In 2017, Todorov improved the device architecture with more suitable selective contacts (Au/MoO_x/Se/ZnMgO/FTO) and achieved the current worldwide efficiency record of 6.5% [3]. This breakthrough reignited interest in selenium for photovoltaics, resulting in many recent research publications, with a particular focus on its potential use as a top cell in tandem configurations, due to low temperature processing (melting point around 200 °C) and a direct bandgap of approximatively 1.95 eV. However, Se appears also well suited for semi-transparent and/or indoor applications. Although its energy bandgap may initially not seem ideal for semi-transparency, recent findings suggest that very thin (less than 50 nm) amorphous silicon devices can achieve high visible transparency and impressive efficiencies, with promising light utilization efficiencies (LUE) of 0.7% [4]. Notably, the current worldwide efficiency record involved a 100 nm layer, but there is variability in the literature regarding the optimal absorber thickness, ranging from 100 nm to several micrometers, which could compromise its suitability for semi-transparent applications.

To check the viability of Se for semi-transparent PV, several amorphous layers of different thicknesses were prepared using an evaporation system. These layers were optically characterized before and after hot plate crystallization at temperatures around 200 °C, a process widely reported in literature. This crystallization step, both on glass and FTO, resulted in the formation of separated Se crystallized islands. In an effort to enhance the Se adhesion during crystallization, we initially avoided the use of Te, known to improve it, but potentially detrimental for device performance. Additionally, we explored the option of performing the crystallization step on complete device architectures, incorporating various selective contact layers before Se deposition, both in substrate and superstrate configurations, yielding valuable insights. All the results of this work will be presented at the MRS Meeting and the viability of selenium for semi-transparent photovoltaics discussed.

Monolithic Selenium/Silicon Tandem Solar Cells Rasmus Nielsen, Andrea Crovetto, Alireza Assar, Ole Hansen, Ib Chorkendorff and Peter C. Vesborg; Technical University of Denmark, Denmark

Elemental selenium, the world's oldest photovoltaic material, is reemerging as a promising inorganic thin-film PV absorber. With a direct bandgap of 1.95 eV in its trigonal phase and a high absorption coefficient (>10^5 cm^{-1}) in the visible region, it is a promising candidate for the top cell in tandem devices. Furthermore, its long-term air stability, monoatomic composition, and low melting point of 220°C makes processing simple, low-cost, and compatible with most bottom cells.
We present the first monolithically integrated selenium/silicon tandem solar cell, demonstrating a highly encouraging open-circuit voltage of 1.68 V.

Guided by device simulations, we identify critical energy barriers restricting the flow of charge carriers and investigate the potential of using other carrier-selective contact materials, resulting in a tenfold increase in the overall power conversion efficiency. In parallel with the tandem devices, we fabricate and characterize bifacial single junction selenium solar cells to gain insights into the polarity-dependent PV performance. In view of these results, we set forth strategies for further improving the device performance to realize higher efficiency selenium/silicon tandem solar cells.

2:30 PM EN11.10.04
Advancing CO2-to-Fuel Conversion: Synthesizing Tellurium-Based Semiconductors Shaham Quadir, Sage Bauers and Andriy Zakutayev; National Renewable Energy Laboratory, United States

Converting CO_2 into energy-dense liquid fuels through the use of renewable energy sources is considered as an important component of addressing ongoing and future energy crises. The most elegant method for this conversion is the photoelectrochemical (PEC) reduction of CO_2, but the key challenge in realizing this process effectively lies in the development of highly efficient photoelectrode materials. In particular, operationally stable p-type photocathodes that can provide electrons to facilitate the required CO_2 reduction processes are required.

In this study, we synthesized new semiconductor thin film absorber material, $Zn_x(GaTe_2)_y$, via combinatorial sputtering approaches. The material was prepared using a 2-step process wherein room-temperature growth was followed with flash lamp annealing from 300 °C – 550 °C. Our X-ray diffraction study shows that $Zn_x(GaTe_2)_y$ goes through a phase transition from cubic (F-43m) to tetragonal (I-42m) upon increasing Ga content, indicating a nearly complete ordering of atoms and vacancies on the zincblende lattice. Upon changing the cation ratio, a new peak observed in the X-ray diffraction pattern at an angle of ~35° with cubic structured $Zn_x(GaTe_2)_y$ alloy, suggesting an intermediate amount of order can be achieved. At an optimal ratio of Zn:Ga:Te, Raman scattering reveals longitudinal optical (LO) peaks up to the third order when excited with a wavelength of 532 nm and displays superior photo luminescent properties, suggesting its potential to enhance CO_2 reduction capabilities. In the room temperature photoluminescence (PL) spectra, a defect emission is observed at 1.6 eV for all ratio of $Zn_x(GaTe_2)_y$. Time-resolved photoluminescence (TRPL) data indicates a shift in lifetime during the transition from an ordered to a disordered state.

2:45 PM EN11.10.05
Photovoltaic Efficiency of Transition Metal Dichalcogenides Thin Films by *Ab Initio* Excited-State Methods Pedro Venezuela[1], Enesio Marinho Jr[2], Cesar Villegas[3] and Alexandre Rocha[2]; [1]Universidade Federal Fluminense, Brazil; [2]Unesp, Brazil; [3]Universidad Privada del Norte, Peru

Transition metal dichalcogenides (TMDCs) have garnered significant interest in optoelectronics, owing to their scalability and thickness-dependent electrical and optical properties. In particular, thin films of TMDCs could be used in novel photovoltaic devices. In this work, we employ *ab initio* many-body perturbation theory within G_0W_0-BSE approach to accurately compute the optoelectronic properties of thin films of 2H-TMDCs composed of Mo, W, S, and Se. Subsequently, we evaluate their photovoltaic performance including exciton recombination effects, and show this is a key ingredient. We obtain efficiencies of up to 29 % for a 100-nm thick film of WSe_2, thus providing an upper limit. We also include other phenomenological recombination mechanisms that could be present in current samples. This slightly reduces efficiencies, indicating that even with current synthesis technologies, there is still potential for further enhancement of TMDCs' performance in photovoltaic applications.

3:30 PM EN11.11.01
Integrated Photoelectrochemical Systems for Scalable Water Splitting and CO_2 Reduction Virgil Andrei; University of Cambridge, United Kingdom

Photoelectrochemical (PEC) systems hold the potential to lower the costs of sustainable solar fuel production by integrating light harvesting and catalysis within one compact device.[1] However, current deposition techniques limit their scalability, while fragile and heavy bulk materials can affect their transport and deployment. Here, we first demonstrate the fabrication of lightweight artificial leaves by employing thin, flexible substrates and carbonaceous protection layers.[2] Lead halide perovskite photocathodes deposited onto indium tin oxide coated polyethylene terephthalate achieve an activity of 4266 $\mu mol\ H_2\ g^{-1}\ h^{-1}$ using a platinum catalyst, whereas photocathodes with a molecular Co catalyst for CO_2 reduction attain a high $CO:H_2$ selectivity of 7.2 under a lower 0.1 sun irradiation. The corresponding lightweight perovskite-$BiVO_4$ PEC devices display unassisted solar-to-fuel efficiencies of 0.58% (H_2) and 0.053% (CO),respectively. Their potential for scalability is demonstrated by 100 cm^2 standalone artificial leaves, which sustain a comparable performance and stability of ≈24 h to their 1.7 cm^2 counterparts. Bubbles formed under operation further enable the 30-100 mg cm^{-2} devices to float, while lightweight reactors facilitate gas collection during outdoor testing on a river. The leaf-like PEC device bridges the gulf in weight between traditional solar fuel approaches, showcasing activities per gram comparable to photocatalytic suspensions and plant leaves.[2] The presented lightweight, floating systems are compatible with modern fabrication techniques,[3] and may enable open water applications, while avoiding competition with land use. The carbonaceous protection layers and rational design principles are successfully applied to an underexplored BiOI light absorber, increasing the photocathode stability towards hydrogen evolution from minutes to months.[4] Similar PEC systems approaching a m^2 size can take advantage of the modularity of artificial leaves,[5] whereas thermoelectric generators can further bolster water splitting by utilizing waste heat to provide an additional Seebeck voltage.[6,7]

3:45 PM EN11.11.02
Photocorrosion of $CuBi_2O_4$ Monitored by *Operando* Surface-Sensitive X-Ray Scattering Davide Derelli[1], Francesco Caddeo[1], Kilian Frank[2], Kilian Krötzsch[1], Patrick Ewerhardt[1], Marco Krüger[1], Sophie Medicus[1], Lars Klemeyer[1], Marvin Skiba[1], Charlotte Ruhmlieb[1], Olof Gutowski[3], Ann-Christin Dippel[3], Wolfgang Parak[1], Bert Nickel[2] and Dorota Koziej[1]; [1]University of Hamburg, Germany; [2]Ludwig-Maximilians-Universität München, Germany; [3]Deutsches Elektronen-Synchrotron DESY, Germany

The low stability of most semiconducting materials is one of the key factors that hinders the development of efficient and durable PEC water splitting cells. Monitoring the semiconductor-electrolyte interface during operation is crucial to understand all the underlying photocorrosion processes and in turn establish appropriate mitigation strategies.
In this work, we show a novel method to study operando the semiconductor-electrolyte interface during PEC operation. In particular, we developed a custom-built PEC cell that allows to assess operando the crystalline and morphological evolution of the semiconductor surface by grazing-incidence X-ray scattering, making use of two detectors to collect simultaneously the total scattering (TS) and the small-angle X-ray scattering (SAXS) signals. We applied the technique to monitor the evolution of $CuBi_2O_4$ films, a promising p-type semiconductor to be used as a light harvesting material in the cathodic compartment of a PEC cell.
Our operando approach, together with complementary X-ray absorption near edge spectroscopy (XANES) and inductively coupled plasma mass spectroscopy (ICP-MS) measurements, allows us to uncover the multiple degradation pathways affecting $CuBi_2O_4$ films performance during PEC operation. We find that $CuBi_2O_4$ reduces to metallic Bi and Cu, with the first one being the fastest process. We also find that Cu ions are released in the electrolyte during long-term stability tests, while at the same time $BiPO_4$ is formed at the surface of the $CuBI_2O_4$ film, due to the presence of PO_4^{3-} ions in the electrolyte. Our work provides a detailed picture of the degradation mechanisms occurring at the surface of $CuBi_2O_4$ electrodes under operation and poses the methodological basis to study the photocorrosion processes of a wide range of PEC materials.

4:00 PM EN11.11.03
Spectroscopical Study on Electron Storage in Nano-Sized Tungsten Oxide Irene Martin[1,2], Luca Rebecchi[1,3], Andrea Rubino[1] and Ilka Kriegel[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Torino, Italy; [3]Università degli Studi di Genova, Italy

Dark photocatalysis is a promising technology for fuel production, which combines light harvesting properties with energy storing materials. The system involved would both work as a photocatalyst and rechargeable solar battery under illumination, so that electrons released during the discharge could be exploited for 'dark' reactions, *e.g.* CO_2 reduction reaction (CO_2RR) and hydrogen evolution reaction (HER). Thus, it also implies the investigation of materials capable of storing electrons for hours [1]. Tungsten(III) oxide (WO_3) has drawn interest owing to its ability of trapping electrons through intercalation of positive ions, accommodating negative charges at W centres [2], and being utilised for prolonged anti-corrosion activity in the dark (*i.e.* photocathodic protection) [3].
In the work herein presented we investigated the potential use of WO_3 nanoparticles for dark photocatalytic CO_2RR by means of photo-doping process. We analyzed the charge storing properties of the WO_3 colloidal nanoparticles via UV-VIS-NIR spectroscopy, by monitoring absorption changes under illumination. The increase of the LSPR peak and the blue shift of the band gap due to the Moss-Burstein effect indicate that WO_3 undergoes electron accumulation, similar to what has already been reported for indium tin oxide (ITO) and other metal oxide nanocrystals (MO NCs) [4]. The results obtained in our study suggest that these materials can be valid candidates for next generation of photocatalytic systems.

Layered Intergrowths with $SrBi_3O_4Cl_3$ and Bi_2GdO_4Cl as Building Blocks Towards Stable Visible Light Mediated Photocatalysis. Nayana Christudas Beena and Sara Skrabalak; Indiana University, United States

Photocatalysts capable of visible light absorption that are also durable against photocorrosion are crucial to achieving overall water splitting. A unique layered intergrowth comprised of $SrBi_3O_4Cl_3$ and Bi_2GdO_4Cl building blocks is achieved by a flux-based approach. The feasibility of tuning the intergrowth's optoelectronic properties was investigated by varying the stoichiometry of the intergrowths. Intergrowth formation resulted in the destabilization of the O-2p and Cl-3p orbitals, elevating the valence band maximum position. In addition, local symmetry changes around the Bi sites due to the presence of Sr^{2+} and Gd^{3+} cations play an important role in lowering the conduction band minimum position. Furthermore, the minimal recombination of photogenerated charge carriers can be attributed to the charge separation due to the presence of an internal static electric field between the layers. The systematic study of these materials conducted using X-ray diffraction and electron microscopy provides insights into how intergrowth stoichiometry serves as a lever to optoelectronic properties and photocatalytic performance of visible-light responsive multi-metal oxyhalide intergrowths.

Tuesday Morning, April 23, 2024
Room 425, Level 4, Summit

11:00 AM *ES01.01.02
Advanced Battery Materials from Labs to Markets Yi Cui; Stanford University, United States

This presentation covers two examples of how battery materials innovations take place in an academic lab and how these innovations are translated into products in markets. The first example is on Si anodes to enable high energy density batteries. Demonstration of Si nanowire anodes sparked global efforts on a variety of Si anode designs, leading to the formation of many startup companies and R&D effort in major battery companies. The second example is on metal-hydrogen gas batteries for grid-scale energy storage to integrate renewable electricity into the grids. I will highlight the lessons and guiding principles learnt from labs to markets.

11:30 AM *ES01.01.03
Empowering Advanced Battery Chemistries for "All-Electric Future" Mei Cai; General Motors, United States

As GM continues marching towards an all-electric, zero emission future with 25+ yrs experience in vehicle electrification, this mission has never been more important and urgent to our society than now. To accelerate EV adoption, the advancement of battery technology, in particular, battery chemistry requires starting with a solid and deep understanding in customer pain points. In this talk, we will discuss: 1) how to apply the approach of "begin with the end in mind" to further unleashing the power of advanced battery chemistry for EV; 2) a case study comparing EV battery systems integrated with different advanced chemistries by using above approach. Finally, the key aspects in battery chemistry advancement toward mass EV-adoption will be highlighted.

SESSION ES01.02: Advanced Battery Materials and Chemistry

Room 425, Level 4, Summit

1:30 PM ES01.02.01
Deciphering The Interfacial Chemistry and Degradation Pathway of Layered Cathode Materials Linqin Mu; Arizona State University, United States

The ever-increasing demand for renewable energy and electric vehicles calls for high-energy-density rechargeable batteries. Cathode materials such as layered oxides play a crucial role in determining batteries' energy density and safety. $LiNi_xMn_yCo_zO_2$ (NMC), as the dominating cathode, has been successfully commercialized for many years. In addition, there is a consensus that integrating NMC cathodes into all-solid-state batteries (ASSBs) is an effective way to achieve high energy densities. However, NMC cathodes are still facing many challenges, particularly, during the perusing of the high Ni concentration and high cut-off voltages. In the presentation, we will discuss the interface degradation of the NMC cathode at multiple length scales. By comprehensive imaging and spectroscopic techniques, we could bridge the degradation phenomenon from the electrode scale to the atomic scale. We will present the challenges of characterizing the surface properties of the cycled layered cathode and summarize our strategies that can enhance the surface stability of NMCs. Our fundamental understanding will inform the design principles at multiple length scales in batteries. Shifting our focus to solid-state batteries (SSBs), there is a growing body of research on SSBs incorporating NMC cathodes and argyrodite solid electrolytes (SEs). However, these advanced ASSBs face significant challenges in terms of low initial Coulombic efficiency and rapid capacity degradation. Therefore, we will also explore the interfacial degradation mechanisms in composite SE-NMC cathodes utilizing the NMC/Li_6PS_5Cl combination as a platform.

1:45 PM ES01.02.02
Unlocking The Full Capacity of Ni-Rich Layered Oxide Cathodes: The Impact of Lithium Site Defects on Diffusion and Stability Leonhard Karger[1,2], Svetlana Korneychuk[1], Wessel Van den Bergh[1,2], Aleksandr Kondrakov[2,3], Jürgen Janek[4,2] and Torsten Brezesinski[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]BELLA, Germany; [3]BASF Corporation, Germany; [4]Justus-Liebig-Universität Giessen, Germany

The automotive industry's transition to renewable energy relies, among others, on layered oxides, like $LiNi_xCo_yMn_zO_2$ (NCM) and $LiNi_xCo_yAl_zO_2$ (NCA), for high-performance applications. These materials promise enhanced capacities within a stable cycling range. While the theoretical specific capacity is above 270 mAh/g, in reality only around 240 mAh/g can be realized under conditions closely resembling real-world applications. Interestingly, specific capacities exceeding 260 mAh/g can be achieved upon very slow cycling, highlighting that capacity loss is caused by sluggish lithium diffusion. A structural characteristic strongly linked to charge transport is the presence of intercalation site defects, including Ni_Li substitutional point defects, which are inherently found in state-of-the-art Ni-rich layered oxide materials. To investigate the effect that these defects have on cycling performance, we have developed a synthesis method for perfectly layered $LiNiO_2$ (LNO) through sodium to lithium ion exchange. Our analyses, including X-ray techniques and NMR spectroscopy, confirm that this route produces a material entirely devoid of Ni_Li defects. Overall, this method serves as a foundation for re-evaluating the impact of factors that are well recognized for influencing the cyclability, such as nickel content, defect concentration and particle size.

We attribute an ambivalent role to Ni_Li defects, recognizing their negative effect on lithium diffusion, particularly limiting the discharge capacity. However, we also identify a secondary contribution of Ni_Li defects, which is not readily observable in state-of-the-art LNO materials due to the intrinsic presence of substitutional point defects. As the defect concentration approaches zero, the high-voltage regime (high SOC) becomes unstable, as evidenced by increased oxygen release and capacity loss of more than 10%. Owing to the ambivalent nature of Ni_Li defects, we propose a hypothesis that achieving an optimal balance between diffusion and stabilization is crucial to fully harness the material's capacity.

2:00 PM ES01.02.03
$LiNi_{0.5}Mn_{1.5}O_4$ Cathode Deterioration in Lithium-Ion Batteries Tracked through Intermittent Post-Mortem Material Characterizations Kelsey L. Duncan and Byron D. Gates; Simon Fraser University, Canada

Identifying high performing and cobalt-free transition metal-based energy storage solutions are a key feature for a cost-effective transition away from the fossil fuel economy. To inform the design of new materials, and the engineering of existing battery materials, a strong understanding of fundamental processes within the device is required. Lithium-ion batteries (LIB) are periodically evaluated by post-mortem (PM) autopsy, wherein a battery is disassembled and each cell component is analyzed separately, providing insights towards which areas of study are most critical to prevent device failure. When investigating cathodes in this manner, typically only whole-cathodes are studied where active material particles are encased in polymeric binders and adhered to a current collector. This provides some access to PM characterization through surface imaging, but cannot demonstrate a full understanding of the consequences of electrochemical cycling on the inner and base layers of cathode particles. Additionally, completing structural and composition characterizations are challenging due to the organics present. Seeking to develop a more detailed understanding of how cathodes particles deteriorate within an LIB cell, a procedure has previously been developed in the Gates Research Group to non-destructively harvest single cathode particles from their binder matrix for comprehensive post-mortem study. Building on this methodology, a systematic investigation into single cathode particles is presented.

In this work, cobalt-free $LiNi_{0.5}Mn_{1.5}O_4$ cathode particles are harvested at different points in their cycle life and characterized as PM isolated single particles to identify and track trends of cathode deterioration over time. High-resolution scanning electron microscopy images of hundreds of individual particles are systematically assessed for physical features of deterioration from cycling. These assessments are supported by x-ray diffraction and standard electrochemical analyses. With use of statistical analyses applied to the detailed imaging data, a template is created to enhance failure mechanism diagnostics and contribute experimental evidence to models of cathode degradation, informing the design of future cost-effective materials.

2:15 PM ES01.02.04
A Multimodal Investigation of Controlled Oxygen-Vacancy Formation to Prevent the Degradation in Ni-Rich NMC811 Cathode Sumaiyatul Ahsan and Faisal Alamgir; Georgia Institute of Technology, United States

Ni-rich $LiNi_xMn_yCo_zO_2$ (conventionally known as NMC, where x+y+z=1 and x>y; x>z) is one of the most used cathode materials in electric vehicles due to its low cobalt concentration and high capacity[1]. One of the significant degradation mechanisms of this material has been attributed to intragranular crack formation and propagation that can lead to mechanical failure of cathode particles[2–4]. Due to cracking, the electrolyte can attack the newly exposed surfaces, releasing oxygen species such as radicals, ions, and molecules[5,6].
To mitigate crack propagation to the surface, we can synthesize a heterogeneous particle with a dislocation-dense (oxygen-deficient) layer[3,7–9]. This surface layer can improve the stability of the cathode particles by shielding the core from electrolyte and annihilating the cracks generated in its core. Furthermore, the controlled oxygen vacancy (OV) layer on the surface of different transition metal cathodes has improved high C-rate capacity retention and cyclability[3]. Hence, it is crucial to investigate the control parameters for creating a dense OV layer on the surface of Ni-rich NMC material and associated lattice and oxidation change.
Herein, we explore a simple method for creating OV on the surface of NMC811 ($LiNi_8Mn_1Co_1O_2$) under a controlled atmosphere at elevated temperatures. The effect of different annealing temperatures has been analyzed using the in-situ X-ray diffraction (XRD) measurement. The intensity ratio of planes (003)/(104) decreases for oxygen-reduced structure, indicating a disordered cation layer with increased Oxygen loss[3]. Oxygen occupancy reduces from 0.99 to 0.975, indicating the presence of ~1.52% oxygen vacancy in the structure. Ni occupancy in the Li layer rises from 0.17 to 0.217, indicating increased Ni^{2+}/Li^{+} mixing. Increased concentration of Ni^{2+} induces more cation mixing[4]. Hence, the oxidation state of modified NMCs has been investigated with X-ray absorption near-edge spectroscopy (XANES). The coordination structure was further examined through extended XAS fine structure (EXAFS)[10,11]. A first-principal calculation-based computational model[12] was employed to calculate oxygen vacancy formation energy and a Quantum Espresso-based Xspectra[13–15] package was used to reproduce the experimental metal K-edge XANES data to analyze further the optimum vacancy concentration required for the higher oxidation state of Ni (3+,4+). Finally, an ex-situ transmission electron microscopy study of the modified structure reveals the crack propagation in surface layers and the effect of the dense dislocation layer in crack annihilation.

Single Crystal Ni-Rich Cathodes for Advanced Li-Ion Batteries Jie Xiao[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

High energy Ni-rich cathode will play a key role in advanced Li-ion batteries, but it suffers from moisture sensitivity, side reactions and gas generation. Single crystalline Ni-rich cathode has a great potential to address the challenges present in its polycrystalline counterpart by reducing phase boundaries and materials surfaces. However, synthesis of high-performance single crystalline Ni-rich cathode is very challenging. This talk will discuss a cost-efficient

drop-in approach to synthesize and scaleup high-performance single crystal Ni-rich cathode materials enabled by nanoscale phase segregation during calcination process.

Ceramic Nanowires for Li-Ion Batteries with Improved Safety, Energy and Power Gleb Yushin[1,2]; [1]Georgia Institute of Technology, United States; [2]Sila Nanotechnologies, Inc., United States

The recently discovered low-cost and highly scalable synthesis of ceramic nanowires or nanofibers enable their applications in high-performance Li-ion batteries, solid-state batteries and supercapacitors. Highly flexible ceramic separators produced from aluminum or magnesium oxide or oxyhydroxide nanowires of tunable dimensions enhance the safety, rate capabilities and energy density of a broad range of electrochemical energy storage devices. Compared to polymer or ceramic-coated polymer separator members, ceramic nanowire separators are not flammable or combustible and offer outstanding thermal stability, thereby improving battery safety. The higher porosity, smaller thickness and excellent wetting of ceramic nanowire separators by electrolytes result in lower resistance, higher efficiency, higher power, faster charging and often improved cycle stability of Li-ion batteries. Their lower attainable thickness also contributes to higher specific and higher volumetric energy densities in Li-ion cells. This invited talk will provide an overview of our progress in synthesis and energy storage-related implementations of this promising technology.

4:00 PM ES01.02.07
Porous Boron Nitride as Scaffold for Silicon Composite Anode Material Michael Karl[1,2], Alena Kalyakina[2], Johanna Rannigner[2], Christoph Dräger[2], Stefan Haufe[2] and Simone Pokrant[1]; [1]University of Salzburg, Austria; [2]Wacker Chemie AG, Germany

Aiming for higher specific energies and energy densities, lithium-ion battery (LIB) research explores silicon (Si) as an alternative high-capacity negative electrode/anode material. One of the challenges associated with employing Si materials in LIBs is their strong volume expansion upon lithiation (more than 300%), leading to significant stress in the particles. In the case of micrometre-sized Si particles, they tend to crack or detach from the conductive network of the electrodes. An effective way to overcome these issues is to apply nano-structured Si. However, reducing structure dimensions to the nanoscale results in increased specific surface areas, which promote a larger amount of electrolyte decomposition and subsequent solid electrolyte interface (SEI) formation. This irreversible process consumes electrolyte and diminishes the energy density of a LIB cell by immobilizing lithium.[1]

Composite materials address this challenge, one possible concept is combining carbon and nano-Si to micrometre-sized particles.[2] A successful approach to synthesize such composites is infiltrating silicon in porous carbon particles (~65% porosity) by chemical vapour deposition (CVD) using silane. Due to the micrometre particle size, the resulting composite exhibits a moderate surface area (below 25 $m^2\ g^{-1}$), significantly limiting SEI formation. The reduced volume expansion of the particles leads to promising electrochemical performance,[2] but some drawbacks persist. Porous carbon is not temperature stable in ambient atmosphere and may ignite at temperatures above 250 °C.[3] In addition, exposed carbon surfaces are conductive and promote electrolyte decomposition as well as subsequent Li consumption upon lithiation.[4]

Because of these drawbacks there is a growing interest in non-conducting and more safe alternatives. Hexagonal boron nitride (h-BN) fulfils the necessary requirements to replace carbon scaffolds in Si composites. It features a comparable low bulk density, and can be fabricated with a similar porosity to the previously employed carbon particles.[2,5] In addition, hexagonal boron nitride exhibits a high temperature stability of up to 800 °C in oxygen atmosphere[5], improving safety during material handling and cells in operation. As h-BN is an insulator, residual BN surfaces in contact with the electrolyte are not able to provide electrons for decomposition reactions. Thus, using insulating scaffolds is another factor reducing the undesired SEI formation, in addition to the generally low particle surface area of the Si composite concept.

In this work we present novel silicon-boron nitride composite materials, their fabrication, and their electrochemical performance as a negative electrode/anode material in a LIB. The synthesis of the highly porous h-BN scaffold is carried out in a furnace under nitrogen flow, using boric acid and an amide as precursors. Ammonia atmosphere forms inside the furnace upon heating, allowing the formation of h-BN sheets. By adjusting the processing time and temperature, a highly defective h-BN structure forms, exhibiting porosities of over 65%. The porosity is similar to those achievable for the porous carbon particles.[2,4] In the next step, pores are filled with silicon using the same CVD-process as reported in literature for carbon composite materials.[2] Employed in a LIB electrode, the composites show competitive cycle lives of over 500 cycles with 80% capacity retention at a capacity exceeding industry standard graphite by more than a factor of two.

Pre-Regulated Solid-Electrolyte Interphase for High-Energy Density Silicon -Containing Anode-Based Lithium-Ion Batteries Gebrekidan G. Eshetu[1], Viviane Viviane Maccio-Figgemeier[1], Hyunsang Joo[2], Michel Armand[3] and Egbert Figgemeier[1,2]; [1]RWTH Aachen University, Germany; [2]Helmholtz-Institut Münster/Forschungszentrum Jülich GmbH, Germany; [3]Centrefor CooperativeResearchon AlternativeEnergies (CIC energiGUNE), Spain

Next - Generation Lithium (Li) - based high-energy density rechargeable battery technologies utilizing silicon (Si) - containing anode materials coupled with high-capacity/high-voltage insertion-type layered ternary oxide cathodes (IC, e.g.;. Nickel-rich Lithium Nickel Manganese Cobalt Oxide, $LiNi_xMn_yCo_{1-x-y}O_2$)) have reaped significant courtesy from both the academic and industrial sectors.[1] This ensues from their unparalleled high theoretical specific capacity (e.g., Si: 4200 mAh g^{-1} for $Li_{4.4}Si$ phase at 415°C and 3590 mAh g^{-1} for $Li_{3.75}Si$ at 20 °C, which is 10 times higher than that of the state-of-the-art Graphite); natural abundance in the earth's crust and thus competitive price, environmentally friendliness and suitable operating potential window (0.2 – 0.4 V vs. Li/Li^+), all cumulatively offering a new possibility towards the large-scale adoption of electric vehicles and effective integration of renewable energy sources.

However, despite the above-mentioned benefits, Silicon-containing anode materials are featured with inherent shortcomings that deter their large-scale commercialization, including their colossal anisotropic crystallographic volume change (($\geq$ 300 %), much lower diffusivity (σe^-+ and DLi^+), unstable and fragile solid electrolyte interphase (SEI), high reactivity with electrode and electrolyte constituents at high states of charge, electrode swelling, and

electrolyte drying.

Among taming strategies, in-vitro electrochemical prelithiation making use of lithium chloride (LiCl)-based electrolytic medium has been hailed as one of the most effective approaches. This is attributed to the high solubility of LiCl in gamma-Butyrolactone (GBL). However, such electrolytic medium has been proved to result in notable amounts of gaseous chlorine (Cl_2) product that dissolve in the electrolyte, leading to a self-discharge Cl_2/Cl^- shuttling mechanism between the electrodes, lowering pre-lithiation efficiency, and thus causing current collector corrosion and rapid capacity decay after few cycles, even in the presence of state-of-the-art electrolyte additives such as Fluoroethylene carbonate (FEC).[2] Moreover, there could be a possibility for chlorination of GBL, leading to ring opening, and thus formation of soluble species concomitantly to the prelithiation process.

In this study, an alternative salt that result in inert gases instead of reactive shuttling species has been employed and proved to significantly improve the initial Coulombic efficiency, usable (reversible) capacity, long-term cyclability, and rate capability of Silicon-oxide/Graphite||NMC622 full cells compared to cells fabricated using LiCl salt-based electrolytic solution mediated electrochemically prelithiated and non-prelithiated (reference) SiO_x-Gr anode materials without any additive. The improvement could be attributed to the pre-formation of a highly tuned SEI layer with regulated properties. In-depth electrochemical analysis and investigations using various arsenal instruments proved different working mechanisms bamong the state-of-the-art salt, LiCl, the newly investigated salt-anion based electrolytic medium and reference battery cell.

The newly designed approach in this paper will spur a new avenue towards developing a highly tuned and pre-regulated solid electrolyte interphase via in-vitro electrochemical prelithiation to realize high Silicon Oxide (SiOx)-containing SiO_x/Gr anode-based high-energy density lithium-ion batteries.

Low Melting Alkali-Based Inorganic Molten Salts as Battery Electrolytes Chibueze Amanchukwu; University of Chicago, United States

Lithium metal batteries (LMBs) promise high energy densities for electrified transport. Liquid electrolytes are currently state-of-the-art, but they are highly volatile and flammable and exacerbate safety concerns. Solid state batteries promise to address the safety concerns plaguing liquids but suffer from highly resistive electrode/electrolyte interfaces. In our work, we explore the use of low melting inorganic molten salts as electrolytes for LMBs. These electrolytes do not contain organic moieties and are not susceptible to the reactions that plague organic moieties in conventional ionic liquids and small molecule electrolytes. Furthermore, they are non-volatile and nonflammable, retaining the promise of solid-state systems. We show these electrolytes have high ionic conductivities at ~80°C, enable smooth lithium deposits, support high Coulombic efficiencies, and can support battery cycling. These inorganic molten salts with accessible melting temperatures open a new class of electrolyte media for both conventional and next generation battery chemistries.

U.S. DOE Supports Data-Driven Strategies to Accelerating Battery Commercialization Changwon Suh; U.S. Department of Energy, United States

The Department of Energy's Advanced Materials and Manufacturing Technology Office (AMMTO) focuses on developing and deploying advanced manufacturing and materials technologies to support the DOE's mission to ensure America's energy security and environmental well-being. AMMTO invests in energy storage research, development, demonstration, and deployment (RDD&D) to help stakeholders improve efficiency, cut costs, and make materials, devices, and systems with superior performance. It is recognized in the energy storage space that effective utilization of data-driven experimentation, analysis and modeling is critical to accelerating the development and optimization of new technologies, improving manufacturing processes and reducing cost, leading to reduced time to commercialization and deployment of transformative technologies.

In this talk, AMMTO's approach to data-driven technology development and manufacturing will be highlighted. In addition, there will be a robust discussion of a wide variety of DOE's efforts in the context of technical and manufacturing challenges regarding scale-up and performance that still prevent the battery manufacturing community from achieving cost targets and commercial viability.

Resource-Aware Materials, System and Process Design for Battery Materials Elsa Olivetti[1], Kevin Joon-Ming Huang[1], Karan Bhuwalka[1], Mrigi Munjal[1], Richard Roth[1], Romain Guillaume Billy[2], Daniel Beat Müller[2], Thorben Prein[3] and Jennifer L. Rupp[3]; [1]Massachusetts Institute of Technology, United States; [2]Norwegian University of Science and Technology, Norway; [3]TU Munich, Germany

This presentation will provide a systems perspective on scaling needs in battery materials for electric vehicles ranging from our use of language model methods to source micro-challenges in the academic literature around electrode/electrolyte interfaces to materials supply chain issues including the impact on local communities for extraction of these materials. By providing a systems analysis on the extraction, beneficiation and refining complexities

associated with these technologies linked to the more fundamental research activities at the bench, this talk aims to provide insight at multiple length scales of the challenge in realizing next-generation EV battery materials.

9:00 AM MT02.04/ES01.04.02
Paradoxical Role of Structural Degradation of High-Nickel Layered Oxides and Electrode Crosstalk in Capacity Retention upon Storage of Lithium-Ion Batteries Hyejeong Hyun[1], Hyojung Yoon[2], Subin Choi[1], Juri Kim[2], Tom Regier[3], Zachary Arthur[3], Seokkoo kim[2] and Jongwoo Lim[1]; [1]Seoul National University, Korea (the Republic of); [2]LG Energy Solution, Korea (the Republic of); [3]Canadian Light Source, Canada

Batteries undergo both active cycling and prolonged idle storage throughout their lifespan. While degradation mechanisms induced by cycling and their mitigation techniques have been deeply studied, the specific effects of storage without cycling remain largely underexplored. Notably, battery performance also sees a unique decline over time, contingent on the state-of-charge (SoC) when the batteries are at rest. Capacity decline during SoC70 storage primarily arises from electrode slippage and Li inventory loss in a full cell. This is accompanied by a minor structural breakdown of Ni-rich layered oxide cathodes. Conversely, SoC100 storage leads to a more pronounced structural impairment of Ni-rich cathodes and pronounced side reactions. Intriguingly, these severe side reactions curb the Li inventory loss, electrode slippage, and the reduction of full-cell capacity during SoC100 storage. In addition to standard degradation processes, such as Li/Ni cation mixing, the formation of surface reconstruction layers, and the emergence of exhausted phases, cathodes stored at SoC100 displayed an unexpected contraction of interlayer spacing during post-storage cycling, highlighting the atypical effects of storage. Based on the mechanisms of capacity reduction highlighted in this study, we propose strategies to counteract the aging caused by storage. This research offers valuable perspectives for refining battery production and management to enhance their calendar lifespan.

9:15 AM MT02.04/ES01.04.03
Improving Rate Capability in High-Energy Thick Lithium-Ion Batteries through Graded and Structured Electrodes Chih-Hsuan Hung[1], Srikanth Allu[2] and Corie L. Cobb[1]; [1]University of Washington, United States; [2]Oak Ridge National Laboratory, United States

Next-generation electric vehicles (EVs) made with Lithium-ion batteries (LIBs) require both higher energy density and higher power density to reach $80/kWh at a 300-mile range as laid out by the US Department of Energy.[1] LIBs made with Nickel-rich layered oxide cathodes and graphite anodes can maintain energy densities around 250 – 300 Wh/kg at low charge and discharge rates.[2,3] However, due to slow ion transport encountered with increasingly thick electrodes, these LIBs exhibit poor rate capability, with more than 50% capacity loss experienced at 4C and higher charge/discharge rates.[4] Graded electrodes (GEs) are one approach that have been proposed to improve the efficiency of lithiation in thick electrodes. GEs assemble two or more electrode layers with differing porosity values into a single thick electrode. In addition to GEs, structured electrodes (SEs) are another means to enhance transport in thick electrodes by re-distributing electrode materials on a micron-scale into line- and grid-pattern electrode architectures. The controlled electrode architecture introduced by SEs reduces the effective electrode tortuosity and enables better electrolyte infiltration in thick battery electrodes.[5,6]
Our research aims to uncover new SE and GE electrode designs for EV batteries. In this study we explored the individual and combined benefits of SEs and GEs for improving the rate capability of high-energy LIBs through computational modeling in VIBE,[7,8] a suite of multi-scale and multi-physics battery modeling tools developed by Oak Ridge National Laboratory. A three-dimensional physics-based continuum-scale electrochemical model was used in VIBE to model a series of electrode designs for a comparative electrode design analysis, including conventional electrodes, GEs, SEs, and combined SE and GE geometries. A $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ cathode and graphite anode are used as model material systems due to their current relevance for EVs. To ensure a consistent analysis, the active material loading is held constant for all models to allow us to study the effect of mass distribution and electrode design on LIB rate capability. Our current results show that at high discharge rates of 2C, 4C, and 6C, SE LIBs demonstrate a 33 – 37 % improvement in energy density, and the combined SE and GE LIB electrode designs demonstrate a 46 – 67% improvement in energy density over conventional cells. This study demonstrates the advantage of implementing SEs and GEs for thick electrode LIBs with improved rate capability. These results affirm the need to purse new manufacturing approaches that enable SE and GE electrode designs to enhance the performance of existing LIB materials.

10:30 AM *ES01.05.01
Where does Na-Ion Fit in The EV space? Active Materials Chemistry, Commercial Scale-Up and Applications Daniel Friebel; Natron Energy, Inc., United States

The acceleration of electric vehicle adoption has elicited perceived and sometimes real shortages in raw materials supplies for Li-ion batteries that lead to price volatility [1] and motivate the search for alternative “post-Lithium” cell chemistries.
This presentation will begin with an overview of existing Na-ion cell chemistries and showcase their strengths and limitations in a comparison of currently achievable cell-level energy densities between Na-ion cells and Li-ion cells. Then, Prussian Blue analog (PBA) materials will be discussed in depth as active materials for Na-ion cells. Natron Energy has commercialized the first Na-ion battery that is entirely based on PBA active materials in both positive and negative electrodes. In contrast to earlier concepts that rely on hexacyanoferrate redox couples, we invented a PBA negative electrode material based on hexacyanomanganate(II/I) redox chemistry. Upon charging, sodium manganese hexacyanomanganate accepts an unusually high occupancy with intercalated Na ions, while the C-coordinated Mn site attains a +I oxidation state with low-spin configuration that is typically only encountered in organometallic Mn compounds. The combination of these two unique properties leads to a low sodiation potential near 1.9 V vs. Na/Na^+. When sodium manganese hexacyanomanganate negative electrodes are paired with positive electrodes based on hexacyanoferrate PBAs, full cell voltages up to 2V can be achieved. While the open structure of PBAs and low voltage limit cell energy density, these cells are capable of extremely fast full charge (up to 20C) and deep discharge (up to 60C) with high energy retention and no risk of thermal runaway. Owing to the minimal structural changes of the PBA host lattice (less than 3% volume change during cycling), this PBA-PBA cell architecture can achieve exceptionally long service life with tens of thousands of cycles [2]. Insight into Natron’s progress in scaling up active materials production and mass manufacturing of cells will be given, and the unique high-rate deep-discharge capabilities will be discussed in the context of commercial applications where Na-ion batteries can close important gaps that are not addressed with Li-ion batteries, especially behind-the-meter applications such as uninterruptible power supplies, demand charge management, and support for electric vehicle fast charging.

Chemical Pre-Processing of Transition Metal Chalcogenide Electrode Materials Joseph Stiles, Brianna L. Hoff, Fang Yuan, Scott B. Lee, Craig Arnold and Leslie Schoop; Princeton University, United States

We have identified H_xCrS_2, which is produced through proton exchange of $NaCrS_2$, as a new sodium ion battery electrode with improved performance over its parent material. H_xCrS_2 sees a measured capacity of 728 $mAhg^{-1}$ and an improvement in diffusion constant of three orders of magnitude better than $NaCrS_2$. Notably, the structure of H_xCrS_2 consists of an alternating crystalline/amorphous motif as a result of Cr migration during desodiation which is seemingly responsible for the improvement in performance. The alternating structure enables access to reversible Cr redox in the material which supports the high capacities. A range of techniques is used to study the mechanism by which the presence of the amorphous phase allows for these improvements. We then apply similar synthetic conditions to a library of other materials in which removal of the alkali ion results in transition metal migration to identify candidates which may feature similar structural motifs and study their electrochemical behavior. Through the development of pre-processing techniques such as proton exchange, we can re-explore electrode chemistries which may have previously been rejected due to migration of the transition metal in the absence of capacity limiting side reactions.

11:15 AM ES01.05.03
Developing Manganese- and Iron-Rich Cathodes for Sodium-Ion Batteries Iwnetim I. Abate; Massachusetts Institute of Technology, United States

Decarbonizing transportation, grid and industries require low-cost batteries made from abundant, environmentally friendly, sustainable elements in the critical minerals supply chain. To this regard, Mn- and Fe-rich sodium-ion battery cathodes are particularly interesting. However, the practical use of these materials is inhibited by their structural instability upon deep desodiation. In this talk, I will present how my group is combining insights from advanced computational (both ground and excited state) experimental (electrochemistry, x-ray scattering and electron microscopy) techniques 1) to prevent structural disorder during deep desodiation via thermodynamic and kinetic design principles and 2) to develop environmentally sustainable cathodes

11:30 AM *ES01.05.04
Pathways to Commercially Relevant Lithium Metal Batteries for EVs and Electric Aircraft Brett A. Helms; Lawrence Berkeley National Lab, United States

Lithium metal batteries are widely regarded as essential to the greater effort to electrify transportation beyond EVs, while also providing opportunities for fast charge and extended driving range. Yet, while energy density considerations have primarily driven this perspective and R&D investments, there are ongoing challenges in managing ion fluxes across interfaces, which impacts aspects of both performance and cycle life. Here, I will discuss the design of ion-transporting materials, both solids and liquids, which enable lithium metal cell chemistries to meet demanding performance requirements in conventional and emerging uses cases, including eVTOL. I will discuss data-driven research paradigms that accelerate the identification of ion-transporting materials and those that create useful interphases capable of high areal ion fluxes relevant to high power batteries and those capable of fast charge. I will further discuss how these discoveries have been translated into larger cell formats and provide context into how to advance to packs and modules.

SESSION ES01.06: Materials and Manufacturing

1:30 PM ES01.06.01
$NiFe_2O_4$/N-Doped rGO as Anode Material for Li-Ion Batteries Yi-Pin Chan and Che-Ning Yeh; National Tsing Hua University, Taiwan

Lithium-ion batteries (LIBs) have become an indispensable part of modern energy storage technologies, characterized by their high energy density, lightweight design, long lifespan, and low self-discharge rates. However, the relentless pursuit of innovation seeks to further elevate LIB capabilities. This study focuses on the development of a high-performance anode material for LIBs, introducing a composite combining nickel iron oxide ($NiFe_2O_4$) and nitrogen-doped reduced graphene oxide (N-doped rGO). $NiFe_2O_4$ is well-established for its high theoretical capacity, while N-doped rGO offers excellent conductivity and environmental sustainability. The $NiFe_2O_4$/N-doped rGO composite material exhibits several advantages. Firstly, it exhibits a high capacity, thanks to the synergistic combination of $NiFe_2O_4$ and N-doped rGO, resulting in increased energy storage capabilities. Secondly, the outstanding conductivity of N-doped rGO enhances charge transfer kinetics, enhancing the rate of lithium-ion transport and reducing energy losses during charging and discharging processes. Moreover, the $NiFe_2O_4$/N-doped rGO composite material demonstrates exceptional cycling stability, minimizing capacity degradation over extensive cycles. Its superior rate performance ensures efficiency even at high current rates, making it particularly suitable for high-power applications or scenarios requiring fast charging. Finally, the use of N-doped rGO and nickel iron oxide reduces reliance on finite natural resources and minimizes adverse environmental impacts, aligning with the vision for sustainable energy storage solutions. In conclusion, the $NiFe_2O_4$/N-doped rGO composite material developed in this work presents a promising solution to meet the present energy storage demands and provides a route for the development of environmentally friendly and sustainable energy technologies.

1:45 PM ES01.06.02
Solvent Design for Earth-Abundant, Mn-Rich Cathodes Qian Liu[1], Qijia Zhu[1,2], Jingtian Yang[1,3] and Zhengcheng Zhang[1]; [1]Argonne National Laboratory, United States; [2]Northern Illinois University, United States; [3]The University of Chicago, United States

As concerns regarding safety, cost, and material availability continue to rise, cathode chemistries based on earth-abundant, sustainable Mn become an appealing choice. The Li-rich, Mn-rich (LMR) layered-structure cathode materials are promising candidates as they have greater galvanometric energy density compared to conventional cathode materials like LFP and LCO. Existing LMR cathodes still encounter issues such as capacity degradation and surface impedance rise, which highly associated with Mn dissolution/deposition. In this presentation, we will discuss the design of electrolyte solvents that mitigate Mn dissolution. By eliminating highly solvating solvents like ethylene carbonate (EC) and introducing low-solvating solvents, it becomes possible to effectively inhibit Mn dissolution, resulting in significantly enhanced cyclability.

Anti-Corrosive Electrolyte Designs for Lithium Metal Batteries Jang Wook Choi; Seoul National University, Korea (the Republic of)

Electrolyte is a very critical component in lithium metal batteries (LMBs). It is recognized that the solvation structure near the Li ion plays a crucial role in determining the solid-electrolyte-interphase (SEI) properties and thus the reversibility of Li plating and stripping. The concepts of highly concentrated electrolyte (HCE) and locally highly concentrated electrolyte (LHCE) have received much attention these days because of their ability to induce inorganic-rich SEI that is beneficial in improving the cycle life. Nonetheless, most of fluorinated solvents used as diluents in LHCEs have low LUMO levels such that Li metal can easily corrode upon in contact with the electrolytes. I will introduce my group's recent approach of adding an inert solvent in the electrolyte to serve as a kinetic barrier for fluorinated diluents in the so-called swollen SEI layer. The given approach can be expanded to a variety of electrolyte combinations with which both the cycle life and calendar life of LMBs can be improved simultaneously.

Challenges and Solutions to Lithium Metal Battery Design for High Performance Applications Ali Firouzi; Cuberg, United States

Cuberg designs and manufactures high energy density, liquid electrolyte-based, lithium metal battery systems for an array of electric aviation and high performance automotive applications. The challenges and phenomena associated with reversibly cycling a lithium metal anode are numerous: the consumption electrolyte in side-reactions, the formation of thick and resistive solid-electrolyte interphases, and the formation of mossy, high surface area lithium deposits. The emergence of these phenomena and their role in limiting cycle life performance are also well-established in literature, but mostly limited to simple constant current charge and discharge profiles. However, when evaluating the cycle life performance of lithium metal pouch cells during realistic aviation flight missions or high-performance automotive drive profiles, these degradation phenomena can be considerably more subtle and complex. In this talk, we will discuss some of the challenges we observe, considerations we have, and design approaches we take when constructing lithium metal batteries for these realistic and high-performance applications.

4:00 PM ES01.06.05
Charging Ahead/All Charged Up: New Technology Goes The Extra Mile for Extreme-Fast Charging of Electric Vehicles Zhijia Du; Oak Ridge National Laboratory, United States

Realizing extreme fast charging (XFC) in lithium-ion batteries for electric vehicles is still challenging due to the insufficient lithium-ion transport kinetics, especially in the electrolyte. Herein, a novel high-performance electrolyte is proposed and tested in pilot-scale, 2-Ah pouch cells. The origin of improved electrochemical performance is comprehensively studied via various characterizations, suggesting that the proposed electrolyte exhibits high ionic conductivity and excellent electrochemical stability at high charging rate of 6-C. Therefore, the high performance electrolyte filled pouch cells deliver improved discharge specific capacity and excellent long-term cyclability up to 1500 cycles under XFC conditions, which is superior to the conventional state-of-the-art baseline electrolyte.

Updates in Lithium-Metal Battery Development Amal Mehrota; QuantumScape Corporation, United States

Today's conventional lithium-ion batteries fall short of meeting the needs of many automotive, consumer electronics, and stationary storage applications. Many believe that the unique cell design of solid-state lithium-metal batteries will help bridge this gap – particularly when it comes to electric vehicles – because the technology is designed to enable longer range, faster charging and enhanced safety compared to conventional lithium-ion batteries. In this talk, QuantumScape Senior Director of Cell Development, Amal Mehrotra, will highlight recent developments in solid-state lithium-metal technology and review some of the challenges in transitioning from R&D to a commercial product.

A Glycerol Triacetate based Flame Retardant High-Temperature Electrolyte for The Lithium-Ion Battery Xinsheng Wu, Tong Liu, Young-Geun Lee and Jay Whitacre; Carnegie Mellon University, United States

Rechargeable batteries that can operate at elevated temperatures (>70 °C) with high energy density are long-awaited for industrial applications including mining, grid stabilization, naval, aerospace, and medical devices[1]. However, the safety, cycle life, energy density and cost of the available high-temperature battery technologies remain an obstacle primarily owing to the limited electrolyte options available[2]. Here, we demonstrated a flame-retardant electrolyte that can enable stable battery cycling at 100 °C by incorporating triacetin into the electrolyte system. Triacetin has excellent chemical stability with lithium metal and conventional cathode materials can effectively reduce parasitic reactions and promises a good battery performance at elevated temperatures. Our findings reveal that Li-metal half-cells can be made that have high energy density, high coulombic efficiency, and good cycle life with triacetin-based electrolytes and three different cathode chemistries. The high-temperature failure mechanism of different cathode chemistries was also investigated and compared. Moreover, the nail penetration test in a commercial-scale pouch battery using triacetin-based electrolyte system demonstrated suppressed heat generation when the cell was damaged and excellent safety when using the triacetin-based electrolyte. These results demonstrated a new low-cost high-temperature flame-retardant electrolyte candidate which holds significant importance in developing a more robust electrolyte system for high-temperature secondary battery applications.

Bi-Doped Low-Cost P2 Layered Sodium Ion Battery Cathode with Improved Cycling Stability Xinsheng Wu and Jay Whitacre; Carnegie Mellon University, United States

Sodium-ion batteries, free from material scarcity concerns, offer potential for versatile applications across various industries. However, the development of an optimal cathode material for sodium ion batteries remains a challenge in part due to long term stability issues. Among the various cathode chemistries explored for sodium-ion battery applications, those based on layered transition metal oxides have displayed promise, primarily due to their high energy density and scalability. Our work demonstrated a novel modified P2 layered sodium ion cathode material created via the introduction of bismuth into a manganese and iron-based layered transition metal oxide material, specifically $Na_{0.8}Mn_{0.75}Fe_{0.2}Al_{0.05}$. Our research has demonstrated that even a small amount of bismuth doping can have a profound impact on the cycling stability of this cathode material, both in half cells and also in hard carbon anode full cells. Furthermore, ambient environment storage of the Bi-doped materials (even in humid environments) does not reduce performance and in some cases seems to improve it. This finding holds promise for enhanced feasibility and reliability in sodium-ion batteries and could be beneficial for advancing the application of sodium-ion batteries in large-scale applications.

5:00 PM ES01.07.03
Low-Cost Silicon from Natural Sand for Lithium-Ion Batteries and Its Electrochemical Response to Oxygen Content Zhigang Z. Fang, Zehua Lin, Pei Sun and Chengshang Zhou; University of Utah, United States

The cost-effectiveness is an essential factor to be considered for the commercial viability of Silicon (Si) anode for lithium-ion batteries, alongside factors such as electrochemical performance and safety considerations. Here, we utilized low-cost natural sand as raw material and employed the magnesiothermic reduction method to produce battery-grade silicon with an impressive ~98% yield rate. Additionally, Si with varying oxygen content was produced by adjusting the stoichiometry of magnesium and reduction temperature. We also explored the effect of oxygen content on the electrochemical performance as an anode. Our findings indicated a linear decrease in both the initial discharge capacity and initial coulombic efficiency with increasing oxygen content. In contrast, the capacity retention at the 20th cycle and the lithium-ion diffusion coefficient exhibited an opposing trend. By comparing the electrochemical impedance spectroscopy and lithium-ion diffusion coefficient of those samples, we observed that the sample with high-oxygen content samples displayed less change in charge transfer impedance after cycling, while their lithium-ion diffusion coefficient exhibited a more pronounced increase.

5:00 PM ES01.07.04
The Correlation between The Mechanical/Rheological Properties of Fibrin, a Novel Binder used in Silicon Anodes of Lithium-Ion Batteries, and Its Performance Woong-Ju Kim and Dong-Wan Kim; Korea University, Korea (the Republic of)

Silicon binders, in the context of lithium-ion batteries, refer to polymers that are used to hold the silicon particles together and adhere them to the current collector. These binders play a crucial role in maintaining the structural integrity of the electrode during the repeated lithiation and delithiation cycles. The unique properties of silicon binders can be described as functional groups for hydrogen bonding, flexibility and elasticity, adhesion and cohesion.
In this work, to optimize mechanical/rheological properties, the fibrin was modified through mixing with alginate and cation cross-linking. Fibrin is class of bio-polymer which contains abundant amino acids, also structured as 3D-network. When fibrin is mixed with alginate and then cross-linked, they stand as interpenetrating network, therefore enhances the mechanical strength. Furthermore, bonding mechanism with silicon was classified by FT-IR measurement. To measure mechanical properties of fibrin-based binder, peel test and advanced rheometric expansion system (ARES) were performed. Due to structural difference, fibrin based binder exhibits higher adhesion forces (3D network for fibrin, linear structure for alginate). In ARES measurement, alginate behaves like a viscous fluid (G" > G'). In contrast, for fibrin-based binders, G' dominates over G" at all ω values, indicating that they are more like elastic solids. However, in close look, at $\omega = 1$ rad s^{-1}, fibrin exhibits the highest stiffness (G' = 29 kPa) and the lowest stress relaxation (G" = 5.4 kPa). When fibrin is mixed with alginate at a 4:1 mass ratio (F4A1), the stiffness (G' = 26 kPa) decreases by only ~12%, but the relax stress (G" = 8.6 kPa) is enhanced near by 60%. Due to ionic cross-linking of the alginate chains of F4A1 (F4A1–10Ca), finally optimized mechanical and rheological properties. F4A1–10Ca exhibits G' (28 kPa), which is comparable to the fibrin while maintaining G" (7.9 kPa) that is comparable to the F4A1. As a result, when using a binder as F4A1–10Ca, it is expected to tightly hold electrode components while effectively relaxing stress. Upon these data, the electrochemical performance was conducted. As consequence, cycle stability was series of alginate<fibrin<F4A1<F4A1-10Ca, which is coincide with ARES prediction.

5:00 PM ES01.07.05
High-Performance CuO as an Anode Material via Facile Synthesis for Lithium-Ion Batteries Nischal Oli[1], Sunny Choudhary[1], Brad Weiner[2], Gerardo Morell[1] and Ram Katiyar[1]; [1]University of Puerto Rico, Rio Piedras, United States; [2]University of Puerto Rico at Río Piedras, United States

While carbon matrices have demonstrated effectiveness in enhancing the electrical conductivity and accommodating the volume expansion of CuO-based anode materials in lithium-ion batteries (LIBs), achieving an optimized utilization ratio of the active CuO component remains a challenging obstacle. In this investigation, we have devised a straightforward synthesis approach to fabricate ultrafine CuO nanoparticles integrated within a high surface area carbon matrix denoted as CuO@C. We discovered that with the use of sodium carboxymethyl cellulose binder and fluoroethylene carbonate additives, this anode exhibits enhanced performance compared to previous reports. This material, owing to its distinctive architecture, reveals a notable reversible capacity of 800 mA h g^{-1} at 100 mA g^{-1} following 100 cycles and exhibits prolonged cycling stability, recording a reversible capacity of 450 mA h g^{-1} at 400 mA g^{-1} over 500 cycles. The exceptional lithium-storage performance of CuO@C is attributed to its high surface area carbon matrix and the presence of ultrafine CuO nanoparticles, which afford a greater abundance of exposed active sites favorable to electrochemical reactions.

Keywords: CuO, high surface area, carbon matrix, lithium-ion batteries, electrochemical reactions

Investigation of 3-Dimensional Structured Anodes for Fast Charging in Lithium-Ion Batteries Michelle E. Katz[1], Vinh Q. Nguyen[1], Daniel Abraham[2] and Corie L. Cobb[1]; [1]University of Washington, United States; [2]Argonne National Laboratory, United States

Lithium-ion batteries (LIBs) with fast charging capabilities are a critical component in electric vehicles (EVs) to reduce charging times to 15 minutes or less.[1] Current research and development efforts are focused on optimizing fast charge behavior with graphitic and silicon-based anodes. However, these anode materials face challenges which include irreversible side reactions, lithium plating, and cracking caused by volumetric strain, all of which limit their fast charge behavior. As an alternative to graphite and silicon, the use of $Li_4Ti_5O_{12}$ (LTO) anodes in LIB cells has been discussed.[2,3] LTO is considered a zero-strain material and, furthermore, does not develop a solid-electrolyte-interphase (SEI) during electrochemical cycling. These properties help improve cycling stability and safety at high discharge rates. Although the higher nominal voltage of LTO (~1.5 V vs. Li^+/Li) leads to lower energy density, recent research into material modification and discharge strategies that improve LTO energy density make it more attractive for fast charging.[4] Additionally, 3-dimensional (3D) electrodes have been investigated by researchers over the last few decades to improve power density of battery cells.[5,6] In this work, we take this concept a step further and investigate the impact of 3D structural design on the fast charge performance of LTO anodes. Our objective is to determine if a re-design of electrode architecture can enable better fast charging behavior for rates up to 10C and make these LTO anodes competitive with graphite-based anodes.

Novel Design and Scalable Synthesis of Silicon Anodes for High-Energy Lithium-Ion Batteries Muqiao Su and Min-Kyu Song; Washington State University, United States

As the world races toward achieving net-zero emissions by 2050, there will inevitably be a surge in demand for high-energy batteries. Silicon is one of the most promising anode materials for next-generation lithium-ion batteries because it possesses a theoretical specific capacity that is almost ten times higher than that of the current graphite anode. However, silicon-based anodes usually suffer from a short cycle life due to the particle pulverization caused by the substantial volume change of Si (~300%) during the lithiation and delithiation process. To improve the cyclability of silicon anodes, we developed a novel scalable process for synthesizing bulk-core, porous-shell silicon that can alleviate the detrimental effects caused by volume expansion. By precisely controlling the processing parameters, both the size of the bulk core and the thickness of the porous shell can be tailored. The silicon with novel structure exhibits excellent electrochemical performances, much greater than 3D porous and bulk silicon counterparts. To further enhance the cycling performance of silicon, carbon coating was implemented via polydopamine precursor. The resulting Si-C composites showed good cycling performance up to 500 cycles. Our research offers a novel, scalable, low-cost production route for silicon anodes for high-energy lithium-ion battery applications.

Single-Pot Hydrothermal Synthesis, Characterization and Electrochemical Properties of SnO_2 Nanostructures Mushtaq Ahmad Dar[1], Hany Sayed Abdo[1], Mohammad Rezaul Karim[1], Nabeel H. Alharthi[1] and Dong-Wan Kim[2]; [1]King Saud University, Saudi Arabia; [2]Korea University, Korea (the Republic of)

Nanostructured materials have gained significant interest in the field of science owing to their exceptional characteristics and efficacy in numerous fields. Tin oxide (SnO_2) shows potential as a material for energy storage purposes, namely in lithium-ion batteries. The electrochemical properties of this material make it a promising candidate for anode materials, allowing for effective storage and release of lithium ions during charging and discharging processes. Tin

oxide's effective electrical conductivity enhances battery performance, making it a crucial constituent in the development of advanced and efficient energy storage technologies. This investigation into the electrochemical characteristics of tin oxide represents a significant advancement in the effort to enhance the efficacy and reliability of battery technology across several fields.
In this research, we successfully produced tin dioxide (SnO_2) nanostructures inspired by sea-urchins by using a hydrothermal process strategy. The hydrothermal approach, known for its low cost and effectiveness, enables the specific development and distribution of tin dioxide nanoparticles, replicating the unique structure of sea-urchins.
The growth of radially arranged rutile-SnO_2 nanostructures with a size range of 1.5-2 µm was confirmed by conducting an in-depth analysis using a variety of methods, such as x-ray diffraction (XRD), thermogravimetric analysis (TGA), fourier-transform infrared spectroscopy (FTIR), field-emission scanning electron microscopy (FESEM), and transmission electron microscopy (TEM). The combined results from these investigations have verified the formation of nanostructures with a high level of purity, that have a unique radial pattern. The nanostructures had a unique morphology consisting of separate nanorods, each measuring roughly 300 nm in length and with widths varying from 30 to 50 nm. The building of rutile-SnO_2 nanostructures exhibited a high degree of homogeneity and accuracy, as evidenced by the extensive characterization techniques. Interestingly, electrochemical experiments used to evaluate these nanostructures features revealed their remarkable reversible lithium storing ability. The nanostructures demonstrated a consistent and reversible lithium storage capacity of 590 mAh. g^{-1}, even after undergoing 30 cycles of charging and discharging. This demonstrates their potential as exceptional materials for lithium-ion battery applications.
The controlled synthesis of radially ordered rutile-SnO_2 nanostructures with excellent electrochemical characteristics is demonstrated in this work, which offers significant insights into the process.

Structure Relaxation Contributes to Spinel-Like Phase Transformation in High-Mn-Content Disordered Rock Salt Cathode Materials Tianyu Li and Raphaële Clement; University of California, Santa Barbara, United States

Li-excess Mn-based disordered rock salt structures (DRXs) are potential cathode materials due to the low cost of Mn and their high theoretical capacities. Recently it was discovered that high Mn content DRXs exhibit gradually enhanced capacity during cycling, potentially due to the formation of a new spinel-like phase (delta phase). We hypothesize that the formation of the spinel-like structure is driven by the thermodynamic stabilization of delithiated high Mn DRXs. To verify our hypothesis and isolate the influence of delithiation, chemically delithiated DRX is prepared. We systematically studied its structure behavior under heating to mimic the thermal relaxation process of the delithiated DRX in battery cycling. We confirmed that the thermal relaxation of delithiated DRXs leads to the formation of the spinel-like phase and the spinel-like phase contributes to the capacity enhancement. With synchrotron X-ray and neutron diffractions, we studied the structure of spinel-like phase in detail. Through comparing the thermal relaxation behavior of delithiated High-Mn and low Mn DRX, we revealed the potential origins of the phase transformation in high Mn DRX under battery cycling.

5:00 PM ES01.07.10
A New High-Valent Fe-Based Redox Couple in Intercalation Electrodes Hari Ramachandran[1], Edward W. Mu[1], Eder Lomeli[1], Augustin Braun[1], Masato Goto[2], Kuan Hsiang Hsu[1], Jue Liu[3], Grace Busse[1], Yuichi Shimakawa[2], Edward Solomon[1], Wanli Yang[4], Thomas Devereaux[1] and William C. Chueh[1]; [1]Stanford University, United States; [2]Kyoto University, Japan; [3]Oak Ridge National Laboratory, United States; [4]Lawrence Berkeley National Laboratory, United States

Layered transition metal (TM) oxides ($LiTMO_2$) are attractive positive electrode materials for use in portable energy storage applications such as electric vehicles, primarily due to their high energy densities and their robust charge-discharge behavior. However, the persistent use of TMs such as Co and even Ni, which are both limiting in their cost and abundance, will restrain current technology from keeping up with the rapidly growing demand for portable batteries. There is, therefore, a great incentive to incorporate inexpensive, earth-abundant elements in commercial batteries. Iron is the perfect candidate, given its availability and low mining/refining cost. However, high-voltage Fe-based redox systems based on the $Fe^{3+/4+}$ couple always exhibit simultaneous anionic redox and O_2 release, and as a result, always display highly hysteretic charge-discharge behavior.

Surprisingly, the compound $Li(Li_{1/3}Fe_{1/3}Sb_{1/3})O_2$ (Li_4FeSbO_6, referred to as LFSO henceforth) does form a layered system and exhibits remarkably stable electrochemical charge/discharge characteristics with < 0.2 V of hysteresis. LFSO forms a layered structure, with Li^+, $Fe^{3+,}$ and Sb^{5+} sites having honeycomb ordering in the TM layer. Upon electrochemical cycling, this material exhibits a voltage plateau at ~4.2 V, which is stable for multiple cycles and corresponds to an extraction of almost 2 Li^+ per formula unit during the first discharge. Several details about the electrochemistry of this material are striking. Firstly, the discharge potential is 4 V vs. Li^+/Li, which is greater than the reported average potential of conventional NMC-based systems (~3.8 V). The first cycle charge capacity is close to 175 mAh/g, which is similar to the theoretical capacity of $LiFePO_4$ (165 mAh/g, operating at 3.2 V). Many questions remain regarding the mechanism behind the electrochemical performance of LFSO. For instance, the nature of the electronic charge compensation that accompanies (de)lithiation is poorly understood. Additionally, the structural transformations that accompany the redox plateau have not been thoroughly characterized. Investigating the electronic and lattice structures of LFSO is of great importance, as Fe-based redox in layered systems has not been studied before.

In this work, we address this gap using a variety of synchrotron and lab-based characterization techniques. We use X-ray absorption spectroscopy (XAS)-based techniques to investigate the electronic charge compensation mechanism during (dis)charge. We use Fe-L edge Resonant Inelastic X-ray scattering (RIXS) in conjunction with O-K edge RIXS (both of which are known to be sensitive to TM-3*d* orbitals) to accurately characterize the changes in Fe and O valence orbital occupancies during (dis)charge. Coupled with ^{57}Fe Mössbauer spectroscopy and charge-transfer multiplet calculations, we present a complete picture of the electronic structure changes that accompany electrochemical (de)lithiation and identify the redox-active species in the reaction. We also perform X-ray diffraction (XRD) experiments to study the structural transformations during the (dis)charge.

Our results show that the 4.2 V plateau is accompanied by a classical two-phase transition, and the electronic charge compensation stems from a novel high-valent Fe-based redox couple. While the presence of Sb in the system limits its commercial interest, LFSO serves as the ideal model system in which to characterize high-valent Fe redox. Some preliminary work carried out into substitution/doping strategies opens the door to achieving low-hysteresis, high voltage Fe redox in layered oxides using earth-abundant elements, which could serve to reduce our dependence on Co/Ni-based positive electrodes.

5:00 PM ES01.07.11
Accessing *p*- and *n*-type Polyimide Covalent Organic Frameworks via Post-Synthetic Linker Exchange for High-Performance Cathodes in Sodium-Ion Batteries Swati Jindal, Zhengnan Tian, Osama Shekhah, Husam N. Alshareef and Mohamed Eddaoudi; King Abdullah University of Science and Technology, Saudi Arabia

Rechargeable metal-ion batteries have become a viable portable technology to fulfill the growing global energy demand and diminishing fossil fuel supply. Due to their abundance of reserves and wide operating temperature range, sodium-ion batteries (**SIBs**) have been predicted to be a rapidly emerging field in the post-lithium era. However, the sluggish intercalation kinetics of Na^+ ions with cathode materials have limited their usefulness.
Recently, researchers have been looking into alternate cathode materials to get around these limitations and enhance the energy density and cycle performance of SIBs. Therefore, we have done this study, which focuses on the synthesis of highly crystalline and porous bipolar redox-active polyimide-linked covalent organic framework (COF), and deployed it as a cathode material for SIBs. For this purpose, we have designed and synthesized a **TPDA-NDI-COF** by incorporating n-type carbonyl-based reversible redox centers into the p-type triphenylamine-based structure via a post-synthetic linker exchange technique. This approach was successful and led to the formation of a highly crystalline and purposeful polyimide, which was not achievable via direct synthesis. The **TPDA-NDI-COF** COF exhibits a wide potential window of 1.0 to 3.6 V vs. Na^+/Na, making it a good candidate as a cathode for SIBs. An advantageous specific capacity of 120 mAh/g at 0.02 A/g can be achieved by doping 50% CNT into the COF. This allows the capacity to be maintained at 92 mAh/g at 1.0 A/g, and even after 5000 cycles, COFs demonstrate the cathode's extraordinarily extended longevity. Our synthetic TPDA-NDI-COF shows an average discharge voltage of 2.1 V, outperforming most recently published COF hosts. We believe this approach will pave the way for boosting the synthesis and design of COFs with more desired properties for energy storage and other various applications.

5:00 PM ES01.07.12
Achieving a 3.0 V Cl-cHBC||LFP Battery via Antisolvent Crystallization-Induced Contorted Polycyclic Aromatic Hydrocarbons Jee Ho Ha and Seok Ju Kang; Ulsan National Institute of Science & Technology, Korea (the Republic of)

Organic materials, both small and polymeric, play vital roles in rechargeable Li-ion batteries (LIBs) due to their cost-effectiveness, tunability, and lightweight nature. Polymeric materials, known for their binding and insulating properties, serve as essential components, acting as binders and separators in LIBs. Recent advancements have explored organic materials as active components in both cathodes and anodes, displaying promising electrochemical performance.
Organic anodes, in particular, offer reliable performance compared to traditional graphite-based anodes but face challenges like solubility in electrolytes and conductivity issues. To address these limitations, crystalline conjugated small molecules, especially polycyclic aromatic hydrocarbons (PAHs), have emerged as potential organic anode materials. PAHs enable efficient Li-ion intercalation and deintercalation, enhancing rate performance.
Among these materials, Cl-cHBC, featuring large Cl atoms, stands out as a versatile anode applicable to LIBs, NIBs, and KIBs. Its crystalline structure accommodates various cation sizes, facilitating diffusion-controlled intercalation. Cl-cHBC exhibits superior rate performance and a single lithiation process, comparable to expensive LTO anodes.
In comprehensive battery experiments with LFP as the cathode and Cl-cHBC as the anode, superior electrochemical performance was observed compared to conventional setups. Cl-cHBC, when combined with inorganic cathode, offers potential cost-effective alternatives to conventional anodes, addressing previous limitations and improving power densities.

Topotactic Transformation of Lithium-Excess Spinel to Layered $LiMn_{0.5}Ni_{0.5}O_2$: The Interaction of 3D and 2D Li-Ion Diffusion Boyu Shi[1], Jihyeon Gim[1], Anh Vu[1], Tianyi Li[1], Dewen Hou[1,2], Yuzi Liu[1], Jacob Jorne[3], Jason Croy[1], Michael Thackeray[1] and Eungje Lee[1]; [1]Argonne National Laboratory, United States; [2]Boise State University, United States; [3]University of Rochester, United States

The cathode material plays a crucial role in shaping batteries' energy density and cycling performance, driving intensive research efforts for improvement.[1] Cathode materials such as LiNixCoyMnzO2 (NCM) and LiNixCoyAlzO2 (NCA) ($Co \leq 33\%$) have merged as prospective options for electric vehicle (EV) cathodes.[2] Despite their advantages in higher specific capacity and cost reduction when compared to cobalt-based cathodes, the high-nickel cathodes encounter challenges such as capacity degradation and instability, aggravated by the rising nickel prices. Consequently, the pursuit of novel cathode materials from economically viable and earth-abundant elements gains increasing attention, holding potential for enhanced thermal stability and cycling performance.[3]

Our recent study unveiled a novel Co-free, LxS-LiMn0.5Ni0.5O2 (LxS-LMNO) cathode based on a cubic lithium-excess spinel structure type. The LxS structure surpasses conventional spinels such as LiMn2O4 and LiMn1.5Ni0.5O4 by doubling the Li concentration in its pristine state, while maintaining its cubic symmetry. The Li/LxS-LMNO cell shows remarkable energy density, delivering ~225 mAh/g capacity from 2.5 – 5.0 V, with ~96% retention after 50 cycles. Additionally, the 3D Li-ion diffusion channels provided by its spinel framework allow faster lithium diffusion compared to layered LiMn0.5Ni0.5O2 polymorph, showing promise as a high-performance cathode.[4]

Our previous work demonstrated that LMNO stabilizes into the LxS structure at lower synthesis temperatures, while favoring the layered phase at higher temperatures. Such observation suggests a temperature-driven phase transition and structural integration occurring within the range typical for solid-state reactions. This dynamic interplay between these phases likely impacts the material's structure and electrochemical properties significantly. Gaining a comprehensive understanding of the temperature-dependent phase transitions holds promise for innovative cathode material design.

Thus, this study focuses on varying LMNO synthesis temperatures to probe the phase transition and its implications. Results indicate a parabolic relationship between the electrochemical performance of LMNO materials and synthesis temperature. This trend primarily stems from the dynamic transformation of Li-ion diffusion channels. This study not only enhance our understanding of LMNO materials but also lays the groundwork for the future development of cutting-edge cathode materials relying on the LxS structure.

Unveiling The Correlation between Synthetic Parameter and Structural Stability of O-Redox Cathodes via Time-Resolved XRD Analysis on The Solid-State Synthesis Seungmin Lee Lee[1], Sang Hyuk Gong[1], Kyungwho Choi[2], You Seung Rim[3], Teakjib Choi[3] and Hyungseok Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Sejong University, Korea (the Republic of)

The demand for high-energy-density sodium-based batteries has led to the investigation of the oxygen-redox (O-redox) reaction to increase the theoretical

capacities of conventional cathodes. This O-redox reaction is triggered by introducing substitutes or vacancies in the transition metal (TM) layer, which generate the non-bonding electrons of lattice oxygens, thus providing additional capacity [1]. In terms of O-redox stability, the atomic arrangement of substitutes or vacancies in TM layer, which affects the distance between redox-active oxygens and TM migration barrier, is considered crucial for determining O-redox stability [1-2]. However, the construction mechanism of O-redox cathodes during synthesis and its correlation with O-redox stability has not been fully understood.
Herein, we aim to investigate the construction mechanism of O-redox cathodes during solid-state synthesis and evaluate their O-redox stability. Specifically, we monitor the evolving structure of cathode precursors using time-resolved X-ray diffraction (TR-XRD) analysis by controlling the synthetic parameter. Subsequently, in-depth structural studies on the cathodes are conducted using advanced characterization tools such as high-resolution electron microscopy (HR-TEM) and X-ray absorption spectroscopy (XAS). Our structural analyses reveal how the synthetic parameter influence the final cathode structure, and we further correlate these findings with the O-redox stability using the electrochemical tests.

5:00 PM ES01.07.15
Thermo-Electrochemical Characterization of $LiNi_{0.8}Co_{0.15}Al_{0.05}O_2$/Graphite+Si Full Cells Across Commercial and Academic Form Factors Patrick J. West[1,2], Nicolas Leport[3], Rachel Carter[1], Corey T. Love[1], Laurent Pilon[3,3,3] and Gordon Waller[1]; [1]US Naval Research Laboratory, United States; [2]American Association for Engineering Education, United States; [3]University of California, Los Angeles, United States

As electrochemical systems increase in size from academic coin cells to commercial 18650's and beyond, so too do concerns about how excess heat generation can compromise the cell's safety and performance. Heat generation in lithium ion battery systems can be attributed to a number of factors, including (1) reversible heat from desired electrochemical reactions (2) joule heating from polarization effects (3) heat of mixing from concertation effects and (4) unwanted side reactions, all of which are influenced by the system's state of charge (SoC) and operating c-rate. Coupling galvanostatic cycling with isothermal calorimetry enables the observation of heat flow during cell operation and the quantification of the system's thermodynamic parameters, like enthalpy and entropy. Enthalpy calculations (kJ/mol of Li^+), found experimentally by the monitoring of heat flow during cell operation, must carefully correlate observed heat signatures and electrochemical processes. This requires low c-rates where overpotentials are suppressed and the observed heat flow is dominated by reversible heat. On the other hand, systematically recording the relationship between temperature and equilibrium voltage at various SoCs provides entropic information and informs the thermodynamics of the system at rest. [1] Theoretically, these thermodynamic measurements should be material specific that rely on the electrochemical redox pair's SoC, but experimental measurements are also influenced by form factor. When thermo-electrochemical characterization is performed on commercial 18650's, slow c-rates (<C/10) can be used to ensure that the observed heat is dominated by reversible heat from electrochemical reactions, but thermodynamic conclusions are limited to the cell level because both the cathode's and anode's active material exhibit changing entropic behavior with respect to their lithiation state. Academic coin cells, on the other hand, allow for entropic behavior to be attributed to the working electrode's active material through Li metal half-cell experimentation, but are not as robust as commercial cells.

In this work, entropic and enthalpic experiments were performed on a commercial $LiAl_{0.8}Co_{0.15}Al_{0.05}O_2$ (NCA)/Graphite+Si Li-ion 18650 cell using isothermal calorimetry coupled electrochemical testing. Then, in order to observe contributions from the anode and the cathode separately, the commercial 18650 was disassembled and the recovered electrodes were used to create coin cell half cell with Li metal anodes and coin cell full cells. Coin cell level calorimetry found that the majority of heat generation during (dis)charge originated from the electrode undergoing delithation. Additionally, full cell entropic potential measurements were reconstructed from coin cell half-cell data, elucidating which electrode-specific processes dictate the system's thermodynamics at different SoCs. Together, heat signature collected across commercial and academic form factors and cell configurations compile an index of thermodynamic and kinetic behaviors of the NCA/Graphite+Si system. These findings will be discussed through a lens meant to inform decisions around commercial cell operation conditions while also serving as an experimental template for thermo-electrochemical comparisons of Li-ion battery systems across commercial and academic form factors.

Synthesis and Electrochemical Properties of Si_xO Composite Anode Materials for Li Secondary Batteries Seunghyeok Jang and Jae-Hun Kim; Kookmin University, Korea (the Republic of)

The rising popularity of electric vehicles and advanced portable electronic devices has intensified the demand for power sources with higher energy density. Among the available options, Li-ion batteries (LIBs) emerge as a pivotal power source, appreciated for their elevated energy density, cost-effectiveness, and prolonged cycle life. Presently, graphite-based materials dominate as anode materials in LIBs due to their superior cycle performance. However, their capacities are constrained, necessitating the exploration of alternative materials.
Li-alloy-based materials have garnered significant attention due to their high reversible capacities achieved through Li-alloying reactions during Li insertion and extraction cycling. Among these materials, silicon (Si) stands out as a promising anode material, boasting a theoretical capacity (3580 mAh g^{-1}, $Li_{3.75}Si$ phase) approximately 10 times higher than that of graphite. However, the substantial volume fluctuations experienced by Si during repetitive Li-alloying/dealloying cycles in charge and discharge processes can result in the mechanical breakdown of the electrode. Consequently, electrical contact loss occurs between Si active material particles and the current collector.
Silicon oxides (SiO_x, $0<X<2$) have also become subjects of active investigation as Li-alloy-type anode materials. Their cycling performance is generally superior to Si-based materials because oxygen can mitigate the volume changes in active Si. However, the widespread use of silicon oxide is hindered by its low initial Coulombic efficiency.
In this study, we introduce a new SiO_x composite material that combines the advantages of both Si and silicon oxide. The materials were synthesized through a straightforward milling process, demonstrating remarkable electrochemical performance when utilized as an anode for LIBs.

5:00 PM ES01.07.17
Enhancing Interfacial Reaction Rates in Extremely Fast Charging Li-Ion Batteries Using Linear Carbonate-Based, High-Concentration $LiPF_6$ Electrolytes Hyuntae Lee[1], Hyeongguk An[1], Hongjun Chang[2], Janghyuk Moon[2], Sujong Chae[3] and Hongkyung Lee[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Chung Ang University, Korea (the Republic of); [3]Pukyong National University, Korea (the Republic of)

With the growing reliance on battery-operated vehicles, addressing the safety concerns associated with lithium plating, exacerbated by high cell polarization during extremely fast charging (XFC) of Li-ion batteries, becomes imperative. This research probes into the effects of Li^+ desolvation and the solid-electrolyte interphase (SEI) chemistry on cell polarizations through the use of linear carbonate (LC)-based, high-concentration $LiPF_6$ electrolytes (LPCEs). Within the LC group, dimethyl carbonate (DMC) is identified as the most thermodynamically favorable for enhancing desolvation kinetics, thus reducing the charge-transfer resistance at the graphite anode. To facilitate effective graphite passivation and accelerated Li^+ transport through the SEI, fluoroethylene carbonate (FEC) is employed to form a thin, fluorinated SEI layer. This enhances the XFC cycling stability in graphite||NMC622 full cells

(3.0 mAh cm^{-2}; N/P ratio = 1.1), achieving a remarkable 94.3% capacity retention after 500 cycles under a 10-minute charging regime. Compared to traditional electrolytes, the excellent XFC performance is further substantiated in a practical 1.2-Ah pouch cell, showcasing a tripling in capacity retention over 200 cycles and effectively mitigating Li plating-induced cell swelling. Unraveling the intricate mechanisms of cell polarization, as dictated by the electrolyte chemistry, furnishes pivotal insights for developing future electrolyte designs for XFC capabilities of Li-ion batteries.

5:00 PM ES01.07.18
X-Ray Photoelectron Spectroscopy Study of Solid Electrolyte Interface Formed on 3D NW Si Anodes Using RTIL-Based Electrolytes Abinaya Sankaran; University of Limerick, Ireland

Silicon, capable of delivering high specific capacity (3579 mAh/g) at low working voltage, is a promising alloying anode for next-generation LIB chemistry. Despite this benefit, the cycling stability of Si anodes is limited by large volume expansion, leading to pulverization and solid−electrolyte interphase (SEI) layer instability. The SEI layer formed on the Si due to electrolyte decomposition at low potentials acts as a protective film that allows for facile Li-ion transport, which is a crucial factor for achieving high reversible capacity. The electrolyte compositions directly impact the formation of the SEI, thus determining battery cycle life. This work studies the electrochemical stability of core-shell a-Si@$Cu_{15}Si_4$ nanowire anodes under different carbonate and ionic electrolytes. To synthesize the anode, we modify the commercially used copper foil using a facile solvent vapor growth (SVG) system to grow copper-rich silicide $Cu_{15}Si_4$ Nanowire architectures as a robust and electrochemically stable current collector. Using the PECVD technique, the structured copper-rich silicide foils were directly deposited with amorphous silicon (a-Si), forming a core-shell nanowire architecture. **T**he electrochemical performance of these synthesized binder-free electrodes with active areal loading up to 0.75 mg/cm^2 was evaluated using conventional carbonate **(**1M $LiPF_6$ in EC/DMC+3%FEC and $LiPF_6$ in EC/DMC+3%FEC) and ionic liquid electrolytes **(**0.2LiFSI-0.8EMIFSI, 0.2LiTFSI-0.8EMITFSI, 0.2LiTFSI-0.8EMIFSI**)** in a half-cell LIB configuration. The anode delivers superior performance compared to bare Cu foil with a reversible discharge capacity of 1350 mAh/g and 2000 mAh/g at C/5 rate in 1M $LiPF_6$ in EC/DMC+3%FEC and 0.2LiFSI-0.8EMIFSI ionic electrolyte—the improved adhesion and increased porosity help in preventing anodes' structural deterioration. The chemical composition and morphology of the SEI layer formed on the anodes were studied using ex-situ XPS and FIB-cross-sectional analysis. The chemical components of the SEI (inner and outer) developed using carbonate and Ionic electrolytes are explained. These findings could shed light on the decomposition pathway of Ionic electrolytes.

5:00 PM ES01.07.19
Fabrication of High-Performance Organic Electrodes through Field-Induced Charge Transfer for Li-Ion Batteries Jihye Park[1], Jun Hyung Gu[2], Dong Hwa Lee[2], Hosun Shin[1], Jung-Yong Lee[3] and Jae Yong Song[2]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of); [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Despite promising theoretical predictions, the practical performance of organic-based electrodes often falls short of expectations due to a low density of active sites, limited ion diffusivity, and high solubility in the electrolyte. In this study, we present an organic nanocomposite cathode with exceptional electrochemical stability achieved through an electric field-induced charge-transfer reaction in the nanocomposite, comprising 5,10-dihydro-5,10-dimethylphenazine (DMPZ) and perylene-3,4,9,10-tetracarboxylic dianhydride (PTCDA). Cryogenic milling was adopted to form a porous nanocomposite structure. The charge-transfer reaction effectively suppresses elution, and the porous structure increases the density of active sites. As a result, the porous nanocomposite showed a remarkable improvement in organic cathode performance, including an unprecedented high capacity retention of 90% over 600 cycles, a high initial capacity of 209 mAh g-1, and excellent reversibility at high current densities. The performance enhancement mechanism of the organic nanocomposite cathode is elucidated through experimental analyses, including ex-situ XPS, PiFM, FTIR, and DFT calculations on the energy levels of organic components.

SESSION ES01.08: Battery Analysis, Recycling and Sustainability

8:15 AM ES01.08.01
***In-Silico* Investigation of Promising Anode Materials for Li-Ion Batteries** Priya Johari; Shiv Nadar University, India

Development of computational resources and methods have taken a lead in current times to reliably predict promising electrode materials for the rechargeable batteries in a cost and time effective manner. This may provide an efficient route to guide experimentalists in improving the battery performance and realizing the next-generation energy efficient batteries for grid storage and electrical vehicles in terms of capacity and energy density. In view of that, using various approaches like the first-principles density functional theory and evolutionary algorithms, we comprehensively study a variety of materials to develop an understanding at the atomistic level and predict efficient anode materials for the Li-ion batteries.

8:30 AM ES01.08.02
Multiscale Modeling of Phase Evolution and Li-Ion Transport Kinetics in Boron Nitride Membranes Yilong Zhou, Marcos Calegari Andrade, Bo Wang, Tae Wook Heo, Tuan Anh Pham, Sergei O. Kucheyev and Liwen Wan; Lawrence Livermore National Laboratory, United States

Boron nitride (BN) has gained attention in the field of electrochemistry due to its controllable surface chemistry and adjustable bandgap, along with mechanical robustness, thermal stability, and chemical inertness. In this work, we examine Li-ion migration behavior in defected hexagonal BN (hBN) using first-principles methods, towards applications as a separator or protected membrane in Li batteries. By comparing the activation energies of Li-ion diffusion along in-plane (between the BN layers) and out-of-plane (across the BN layers) pathways, we find that pristine hBN permits in-plane Li-ion diffusion with a relatively low energy barrier of 0.34 eV, while prohibiting out-of-plane Li-ion diffusion due to a high energy barrier (6.68 eV). Introducing defects is found effective to unlock the out-of-plane diffusion pathway despite the fact that local vacancies can trap Li and influence its consequent in-plane diffusion near the vacancy sites. In addition to the investigation of Li-ion transport behavior in hBN, we evaluate its phase stability by directly extracting its phase evolution kinetics from large-scale molecular dynamics simulations enabled by a machine-learning interatomic potential. We further investigate the impact of microstructure on the BN phase evolution kinetics and link it to various experimentally relevant conditions, which can ultimately allow us to establish strategies to fabricate BN membranes with desired properties.

This work was performed under the auspices of the U.S. DOE by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

8:45 AM ES01.08.03
Electro-Chemo-Mechanics and Multiscale Battery Architecture Giovanna Bucci; Lawrence Livermore National Laboratory, United States

The properties of rechargeable lithium-ion batteries are determined by the electrochemical and kinetic properties of their constituent materials as well as by their underlying microstructure. The discovery of novel 2D and 3D mesoscale architectures tailored to diverse applications remains an open challenge and it cannot be fully addressed empirically. It requires comprehensive modeling, embedding multiple time and length scales, with dynamic coupling of thermo-electro-chemo-mechanical phenomena. In this talk we will showcase multiscale modeling integration, prototyping, and an optimization algorithm to design energy storage devices that are tailored to function under a wide set of environments and use cases. This integrated workflow is also used to guide fundamental mechanistic understanding of the phenomena that degrade device performance, namely ion transport, morphological evolution, and solid mechanics.

9:00 AM ES01.08.04
On-Demand Capacity Extraction of Cu Current Collector for Li Batteries Jun Ho Lee, Wenbo Zhang, Sanzeeda B. Shuchi, Sarah Holmes, Sang Cheol Kim and Yi Cui; Stanford University, United States

Irreversible loss of lithium due to its high reactivity lead to decrease in the energy density of lithium batteries. The decomposition of electrolyte forms electrochemically inactive solid electrolyte interface (SEI) layer on the surface of anodes, and lithium used to form SEI cannot be retrieved. Especially, large portion of Li^+ from cathodes are consumed during the initial cycle of LIB, and the energy density of full cells are significantly decreased afterwards. In order to supplement this loss, various prelithiation strategies such as introducing additional lithium compounds on either anodes or cathodes have been reported. However, Cu current collector, has not been considered as a source of extra lithium and considered as dead weight, mainly due to its electrochemical inactivity with lithium.
Here, we introduce a novel concept that involves utilizing Cu current collector as a lithium reservoir and extracting lithium on-demand during cycling to enhance the capacity of lithium batteries. By annealing Li and Cu, we show that Li-Cu alloy, a two-phase alloy, is formed with controllable capacity of lithium at an extraction potential of 1.2 V vs Li/Li^+. Electrochemical and structural analyses revealed the irreversible extraction of Li during the phase transformation of the alloy. Based on electrochemical analyses, we demonstrated that Li-Cu alloy can serve as a prelithiated current collector in LIB, resulting in substantial increase of initial coulombic efficiency of anodes of half cells. Furthermore, relatively high extraction potential of Li-Cu alloy enabled on-demand extraction of lithium during discharging in full cells. In addition, prelithiated current collectors can also be employed to anode-free Li metal batteries, and capacity retention and cycle life of were observed to be improved. We anticipate that using current collector for lithium storage could enhance energy density of batteries while reducing reactivity of Li.

9:15 AM *ES01.08.05
Exploring Electrolyte Corrosion and Compatibility Across Lithium-Ion and Lithium-Metal Batteries Chengcheng Fang; Michigan State University, United States

Developing next-generation electric vehicle (EV) batteries remains challenging regarding improving energy density, cycle life, and safety. Efforts are required to understand the materials' failure mechanisms quantitatively and develop new battery chemistry that breaks the energy density bottleneck. In this presentation, I will first talk about a systematic re-evaluation of the low-concentration ether-based electrolyte (LCEE), which is a promising, low-cost electrolyte system for lithium metal batteries (LMBs) but has long been believed to have “inferior” anodic stability. We identify the true failure mechanism of this electrolyte to be various electrochemical corrosion reactions with different working electrodes, while the intrinsic anodic stability window of LCEE is above 4.5 V, a value feasible for practical LMB operation. We also provide and verify design rationales to mitigate electrode corrosion and thus improve the full-cell performance of LMBs under realistic conditions. I will then introduce our recent work in designing electrolytes that are compatible with both graphite and lithium metal, enabling controlled lithium metal plating on graphite to realize hybrid lithium-ion/lithium-metal batteries with improved energy density (> 300 Wh/kg) and cycle life (> 1000 cycles) at fast charging conditions (up to 4C).

Direct Recycling in The ReCell Center Jessica Durham; Argonne National Laboratory, United States

The Department of Energy's ReCell Center for Advanced Battery Recycling has recently expanded its program scope to cover Direct Recycling of Materials, Advanced Resource Recovery, Design for Sustainability, and Modeling and Analysis. The Center continues to scale-up its existing technologies and develop new technologies, applying them to the processing of both manufacturing scrap and end-of-life batteries. The presentation will highlight the expansion and progress of the Center's Direct Recycling of Materials focus area.

10:45 AM ES01.08.07
Styrene-Butadiene Rubber Patterned Current Collector for Enhanced Li-Ion Kinetics for High Energy Density Li-Ion Batteries Seungcheol Myeong[1], Seungwoo Lee[1], Insung Hwang[1], Joonhyeok Park[1], Jaeik Kim[1], Ganggyu Lee[1], Chanjin Park[1], Han Seung Min[1,2], Taeseup Song[1,1] and Ungyu Paik[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

During the drying process, the migration of the styrene-butadiene rubber (SBR) binder, driven by capillary forces, can lead to a concentration gradient in the anode. This gradient adversely affects the adhesion strength at the interface between the anode film and the Cu current collector, as well as the Li-ion kinetics. In this study, we propose a solution to this issue through the use of a Cu current collector patterned with SBR. The pre-patterned SBR demonstrates strong adhesion to the Cu current collector, effectively preventing migration during the drying process. A uniform distribution of SBR along the longitudinal direction of the anode enhances both adhesion strength and Li-ion kinetics. Improved adhesion strength also allows for a reduction in SBR content in the anode, further enhancing Li-ion kinetics. Anodes utilizing this patterned SBR on Cu exhibit enhanced constant current charging capacity retention and improved cycling stability compared to those with a pristine Cu current collector.

11:00 AM ES01.08.08
Stress Evolution Prediction for Silicon Anode Particle during Charging/Discharging and a Comparison with *In-Situ* Test Results Jifa Mei, Wenqing Zhou, Yao Ren, Peiran Ding, Weiran Jiang and Hui Li; Farasis Energy USA, United States

To unleash the potential of high-capacity Si-based anode in lithium-ion battery application, stress evolution and volume expansion mitigation within Si particles is of utmost importance in overcoming early degradation and side reactions caused by pulverization. An extensive and critical overview of the volumetric expansion, elastic, elastic-plastic behaviors of lithiated silicon at different concentrations is carried out by reviewing experimental and simulation studies available thus far. We summarized for the first time a quantitative characterization of these properties that are generally reached by

researchers through looking into these research progress as a whole. A coupled diffusion-mechanical model is then proposed to simulate the silicon lithiation process by incorporating concentration-dependent volumetric change and elastic-plastic properties. The stress state within a Si anode particle is studied when a charging and discharging profile is applied. It is found that the stress evolution throughout the lithiation and de-lithiation process is in good agreement with in-situ experimental measurements reported. Furthermore, the current modeling methodology has the potential to be applied to Si-C related anode composites for microstructure evaluation and design optimization.

11:15 AM ES01.08.09
Manufacturing Structured Lithium-Ion Battery Electrodes Using Acoustophoresis Emilee Armstrong[1], Keith E. Johnson[2], Ozgenur Kahvecioglu[3], Matthew R. Begley[2] and Corie L. Cobb[1]; [1]University of Washington, United States; [2]University of California, Santa Barbara, United States; [3]Argonne National Laboratory, United States

Scalable manufacturing of high-energy and high-power Lithium-ion batteries (LIBs) with fast charge behavior is crucial for lowering the cost and enhancing the performance of LIBs for electric vehicles (EVs) to meet DOE's current target of $80/kWh by 2030.[1] Commercial LIBs are composed of planar electrode cell stacks that can be optimized for energy or power, but not both simultaneously. Structured electrodes (SEs) mitigate these performance trade-offs by using three-dimensional architecture in the anode or cathode to engineer porosity and tortuosity to enable fast ion transport in thick battery electrodes.[2,3] However, a scalable manufacturing process for creating SEs over the large areas at the time scales required for cost-effective LIB manufacturing is still needed. To address this, we have developed a manufacturing process based on principles of acoustophoresis. Using acoustic forces, acoustophoresis rapidly assembles particles in a fluid on a micron scale, generating SE patterns over large, cm-scale areas.[4,5] To date, we have used acoustophoretic principles to pattern SE cathodes made from size specific Lithium Nickel Manganese Cobalt Oxide (NMC-622). NMC-622 was selected as our electrode patterning material due to its relevance for EV applications. We have investigated how processing conditions can be used to tune the thickness and features of NMC-622 SEs and have conducted initial electrochemical testing.

1:30 PM ES01.09.01
Argyrodite Solid-State Electrolytes: Overcoming Barriers to Interfacial Stability for Advanced Manufacturing of Solid-State Batteries Udochukwu Eze[1,2] and Zachary D. Hood[1]; [1]Argonne National Laboratory, United States; [2]Georgia Institute of Technology, United States

Lithium argyrodite solid-state electrolytes (SSEs) exhibit many desirable properties such as high ionic conductivity (>1 mS/cm) at room temperature[1,2,3] and greater ductility than most oxide SSEs,[2] enabling roll-to-roll cell fabrication relevant for EV battery packs. However, their instability in ambient air and at the Li||SSE and cathode||SSE interfaces presents challenges for scaled production and limits their cell performance.[3,4] In this presentation, we present two interfacial strategies – those that involve dopants as well as pseudocapacitive interlayers – to overcome interfacial stability issues associated with argyrodite-type SSEs (Li_6PS_5Cl) in solid-state batteries. By using zinc, oxygen, and chlorine as dopants, we show that members within the $Li_{6-2x-y}Zn_xPS_{5-x-y}O_xCl_{1+y}$ ($x \leq 0.25$, $y \leq 0.25$) phase space exhibit reduced reactivity under dry and H_2O-saturated oxygen as well as improved room temperature symmetric cell cycling performance at relatively high capacity and current densities. We also demonstrate a scalable, liquid-phase processing method for spraying adhesive pseudocapacitive interlayers on copper current collectors. These interlayers, constructed of MXenes ($Ti_3C_2T_x$) decorated with metal nanoparticles, can regulate the morphology of lithium metal during plating and stripping. Both strategies take advantage of Li alloy formation at the Li||SSE interface to form beneficial decomposition products that improve cycling performance and enhance the stability of the SSE with Li metal anodes as shown in recent work.[5] Development of high performance next-generation solid-state batteries, those envisioned for EVs, will require interfacial tailoring, such as those presented in this work, in order to reduce impedance, alleviate poor rate performance, and reduce side reactions that lead to capacity fade.

Low-Temperature, Scalable Synthesis of Electrolyte Films: Spray Deposition of Sulfides and Oxides Colton Ginter[1,2] and Zachary D. Hood[1]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States

Given the projected tenfold increase in global battery demand over the coming decade,[1] it is imperative to prioritize the advancement of cost-effective, secure, and high-energy-density energy storage solutions for electric vehicles. Solid-state synthesis methods, those that are traditionally used for inorganic solid-state electrolytes (SSEs), generally require higher process temperatures, are incompatible with roll-to-roll processing, and produce millimeter-thick pellets, barring integration in energy-dense solid-state batteries (SSBs).[2] New, scalable methods for low-temperature manufacturing of SSEs at thicknesses comparable to polymer separators (~20 μm) are required for widespread adoption of SSBs.[2,3] Here, we describe a spray deposition process to form dense Li_6PS_5Cl (LPSCl) and Li_3BO_3 (LBO) films with room-temperature ionic conductivities greater than or equal to 10^{-4} S/cm and 10^{-8} S/cm, respectively, as determined by electrochemical impedance spectroscopy (EIS). Through precise control of spray parameters (including total mass, concentration, deposition rate, and substrate temperature), we successfully crafted dense, crack-free amorphous films, reaching thicknesses of 14.2 ± 0.3 μm for LPSCl and 0.188 ± 0.054 μm for LBO, all at remarkably low temperatures, below 200 °C. We augmented our findings with concurrent in situ Raman spectroscopy and EIS during the film annealing process, which revealed the presence of polyamorphism in the deposited films and a crystallization process occurring at temperatures lower than conventional solid-state methods. Our research also delves into the diverse applications of these materials in SSBs and other next-generation electrochemical devices.

First-Principles Calculation Study on Degradation-Related Phenomena around Cathode/Solid Electrolyte Interfaces in Solid-State Battery
Yoshitaka Tateyama[1,2,3]; [1]National Institute for Materials Science, Japan; [2]Tokyo Institute of Technology, Japan; [3]Waseda University, Japan

Control of battery degradation has been a critical issue for the EV application, and a variety of technologies have been developed so far. However, understanding of the microscopic behavior of ions and electrons is still very lacking, and thus the degradation control has room to be improved. In this respect, we have investigated the microscopic interfacial and mechanical phenomena around cathode / solid electrolyte interfaces via density-functional-theory (DFT) based first-principles calculations, and drawn general theories effective for larger-scale consideration.
In this talk, I introduce our recent works related to degradation; (1) stress/strain effects on Li^+ diffusion in Li_xCoO_2 [1], (2) oxygen evolutions and cation migrations around the surfaces of Li_xCoO_2 [2], (3) Li^+ transfer around cathode/coating layer/solid electrolyte interfaces [3,4].
(1) We found that the barrier in the single vacancy mechanism decreases with biaxial expansion, contrasting with an increase in the double vacancy mechanism. This phenomenon is attributed to the c-axis position in the Li^+ diffusion pathway. Our DFT-MD simulations revealed that compressive biaxial strain enhances Li^+ diffusivity in Li-deficient Li_xCoO_2 (decreased to 0.22 and 0.21 eV), while tensile biaxial strain and hydrostatic pressure hinder it. Surprisingly, "Co layer distances" play a pivotal role in Li^+ diffusion, and our study uncovers intricate interactions between Li-Li Coulomb interactions, state-of-charge (SOC), and Li^+ diffusion in Li_xCoO_2. Besides, we reported the activation volume of $LiCoO_2$ under hydrostatic pressure and show that compressive biaxial strain weakens Li-O bond interactions, reducing the Li intercalation potential.
(2) We examined oxygen release and Co-ion migration both in the bulk and on the surfaces (001), (104), and (110) of Li_xCoO_2, taking into account the process of spinel-like Co_3O_4 formation. The calculated oxygen vacancy formation energies are 2.38, 2.42, 1.46 and 1.10 eV for bulk, the (001), (104) and (110) surfaces, respectively. These trends are reasonably consistent with the experiments. We also clarified the significant reduction in activation energies of Co-ion migration in the presence of oxygen vacancies, indicating the correlation among the oxygen vacancy formation and the Co-ion migration.
(3) Focusing on $LiCoO_2$ / $LiNbO_3$ / Li_3PS_4 interfaces in typical solid-state battery, we calculated ionic PES across the interfaces by first-principles calculations, and demonstrated how such energy profiles look like around the interfaces. The results correspond to the discharging situation, and indicate how to understand the charging situation by separating ion and electron movements. Our interface analyses also suggested a way of understanding interfacial ion and electron transfer by DFT-based standard electrochemical potentials of Li, Li^+ and e-. The picture well accounts for the mitigation of ionic interface resistance by insertion of oxide coating layer between cathode and sulfide electrolytes. This DFT-based framework gives a crucial insight

into ion as well as electron transfer across general interfaces.

Mechano-Electrochemical Phenomena in Solid-State Batteries Jeff Sakamoto; University of Michigan, United States

There is tremendous interest in making the next super battery, however Li ion technology continues to improve and has inertia in several commercial markets. Recent material breakthroughs in solid-electrolytes (SE) could enable a new class of non-combustible solid-state batteries delivering twice the energy density (>1,300 Wh/L) compared to Li-ion. However, technological and manufacturing challenges remain, creating the impetus for fundamental and applied research.

This discussion will consist of fundamental aspects such as the mechano-electrochemical phenomena at solid interfaces as well as manufacturing challenges related to the integration of Li metal electrodes. The underlying physics that control the stability and kinetics of Li/SE interfaces are fundamentally different from interfaces in Li ion technology. Moreover, the mechano-electrochemical phenomena that occur during discharge and charge at the Li/SE interface are considerably different. For example, during charging at higher rates Li metal filaments can initiate at defects and propagate through relatively hard ceramics. During discharge, if the Li stripping rate is sufficiently high and the temperature is sufficiently low, voids form at the interface causing delamination at of the interface.

In another example, novel mechano-electrochemical phenomena are emerging when analyzing the formation of Li anodes in using the Li^0-free manufacturing approach. Using this approach for solid-state batteries, Li metal in interposed between a current collector and the SE. The mechanics at this interface will determine the feasibility of this approach by controlling the homogeneity of the *in situ* formed Li anode. While significant progress is advance the technological maturity of solid-state batteries, there remain fundamental questions regarding the physics at interfaces and whether or not they exhibit sufficient stability and kinetics that are relevant to EVs.

3:30 PM ES01.09.05
Recent Breakthroughs in All-Solid-State Sulfide Ceramic Batteries: Performances, Safety and Future Developments Benoit Fleutot, Emmanuelle Garitte, Fabien Nassoy, Benjamin Cruel, Steve Duchesne, Jean-François Filion, Isabelle Filteau, Amélie Forand, Marie-Claude Girard, Karine Tremblay and Chisu Kim; Hydro-Québec, Canada

Despite some progress performed, state-of-the-art lithium-ion batteries still require improvements in energy and power to extend the range of electric vehicles and reduce charging time. In this domain, all-solid-state batteries are viable alternatives to conventional batteries employing organic electrolytes because of their benefits, i.e., high power density, high energy density, long-life operation and safety. These advantages stem from the great features of inorganic solid electrolytes, which are single ion conductor, so a high lithium-ion transport number, and no-liquid nature. In particular, the sulfide-based solid electrolytes possess favorable mechanical properties, high ionic conductivity allowing improved all-solid-state batteries performances at room temperature but suffer of moisture exposure that could induce H_2S generation.

Sulfide-based solid-electrolytes can potentially be employed in conjunction with a lithium metal negative electrode and 5V-class high voltage positive electrode material. Indeed, lithium metal is believed to be the most promising negative electrode due to its specific large capacity (3862 $mAh.g^{-1}$) and the lowest electrochemical potential (-3.03V vs ENH). Ceramic solid electrolytes and especially sulfide composite solid electrolyte have been considered to be the ideal solution to prevent dendrite growth because of their high shear modulus and high lithium transference number. At the same time, the chemical nature and composition of ceramic solid electrolyte can affect the dendrite growth by the interfacial chemical and electrochemical stability with lithium metal. In parallel, the sulfide solid electrolyte reacts with all components constituting the positive electrode as active material, electronic conductor, binder, current collector… Hence, all interfaces can generate side reaction, increase of polarisation, and so rapid battery fading. As demonstrated in literature, an important average pressure increase during cycling and aging can’t allow a future commercialisation of this technology. The safety is a crucial point and the generation of H_2S in the case of all-solid-state battery based on sulfide electrolyte during scale-up phase and operation must be take into account and evaluated specifically.

In this field and since a few years, Hydro-Quebec has decided to conduct specific research on all-solid ceramic batteries and especially in the field of sulfide-based ceramic electrolytes. Based on Hydro-Québec's knowledge with polymers, a solution of all-solid composite battery with ceramic tendency has been developed by generating several industrial properties at the different levels of the battery. The interaction previously observed in positive electrode mixture without binder have been resolved and integrated in slurry. In parallel, the impact between solid electrolyte ceramic film composition, density, reactivity with lithium metal and flexibility were studied to offer high conductivity and easily manipulation. Unlike the general perception that the sulfide electrolyte is not compatible with lithium metal, we successfully stabilized the lithium metal interface reaching the cycle life more than 500 cycles under industry-relevant pressure conditions at moderate temperature under pouch-cell configuration. The constraints of the use of li-ion equipment’s, cost reduction and safety have been considered at each level with quantitative measurements. The different improvements in positive composite electrode, in solid electrolyte ceramic film and in lithium metal interfaces will be explained. The presentation will show how technical and economical issues of sulfide electrolyte can be addressed to bring the technology closer to the market.

3:45 PM ES01.09.06
Comprehensive Safety Assessment of All-Solid-State Batteries: Using Calorimetry, X-Ray Radiography and Blast Testing Techniques Juliette Charbonnel[1,2], Rémi Vincent[1,3] and Pierre-Xavier Thivel[2]; [1]CEA, France; [2]LEPMI, France; [3]Laboratoire, France

In the context of the energy transition, researches on batteries are devoted to improving their energy density, i.e. their autonomy and their safety, particularly in relation to the risk of fire. Among the different types of battery, all-solid-state batteries are promising because of their high energy density. A ceramic or a glass electrolyte replaces some traditional components of lithium-ion batteries as the liquid electrolyte and the polymer separator. However, safety concerns related to ASSBs have remained relatively unexplored. This investigation is focused on understanding the behaviour of reassembled all-solid-state batteries subjected to overheating abuse. Specifically, two batteries compositions: Gr|LLZO|NMC811 and Li|LLZO|NMC81 are

studied. The first cell aids in comprehending the impact of the electrolyte (liquid or solid) safety and the second enables to assess the safety of a reconstructed lithium-metal all-solid-state cell.
An innovative approach to assess the safety of all-solid-state cell in-development has been devised. This approach incorporates three distinct techniques: calorimetry, X-ray radiography and blast testing. This methodology could significantly contribute to the development of future battery technologies. Ensuring the integration of safety concerns right from the beginning is crucial, encompassing both cell performance and safety aspects.
Substituting liquid electrolyte with a solid electrolyte, the initiation and the maximal temperatures remain unchanged. It reduced by 10 % the heat released and reduced by 40 % the amount of gas released and the duration of thermal runaway. Using solid electrolyte no prevent from thermal runaway.
Substituting liquid electrolyte with a solid electrolyte and substituting the lithiated graphite with a lithium-metal foil, the initiation temperature remains unchanged. The maximum temperature is at least increased by 40 %; the amount of gas and the duration of thermal runaway are decreased by 90 % and 95 %. Furthermore, the Li|LLZO|NMC811 cell is not an explosive but a 188 mbar aerial pressure has been measured. It corresponds to an mass equivalent TNT of 2.7 g.
Furthermore, the characteristic parameters of thermal runaway are different. Therefore, the means to mitigate its thermal runaway are different and should be taken into account when all-solid-state batteries are developed.
The impact of blast wave on the casing and battery pack integrity should be taken into when all-solid-state batteries are developed.
To conclude, all-solid-state batteries are neither safer nor less safe than lithium-ion batteries. However, their the characteristic parameters of thermal runaway are different. This work underlines the importance of evaluating the safety of all-solid-state batteries with respect to users and the environment.

4:00 PM ES01.09.07
Transforming EV Battery Materials into Reserve Batteries via Advanced Manufacturing Justin A. Sadowski[1,2] and Zachary D. Hood[2]; [1]Air University, United States; [2]Argonne National Laboratory, United States

The expanding electric vehicle (EV) market fuels research into advanced battery materials, particularly solid-state electrolytes (SSEs), to enhance energy storage technology, offering the promise of higher energy density, improved safety, and cost-efficiency. These materials show potential for deployment in reserve or primary batteries, addressing issues found in current technologies such as self-discharge, inadequate energy density, limited operational temperature ranges, and safety concerns associated with flammable liquid electrolytes. Our investigation centers on argyrodite-type sulfide-based SSEs, boasting exceptional Li^+ conductivity (>1 mS/cm) at room temperature, lithium metal anodes with substantial energy capacity (theoretical limit: 3860 mAh/g)[1], and cathode active materials (CAMs) meeting the criteria for reserve or primary battery applications.[2] This study investigates the pivotal role of advanced manufacturing techniques in addressing the challenges associated with reserve batteries, focusing on sulfide-based SSEs and lithium metal, with a positive outlook on potential solutions. We present a comprehensive review of state-of-the-art solid-state battery technology in current reserve or primary battery applications, discuss CAMs' performance in sulfide-based SSE composites in half cells, and provide detailed postmortem analyses. These insights serve as fundamental guidelines for future optimizations in advanced battery material manufacturing, transcending the scope of EV-specific applications.

Development of Oxide-Based Solid-State Batteries Kazunori Takada; National Institute for Materials Science, Japan

Solid-state batteries they provide high reliability to lithium-ion batteries are regarded as promising next-generation batteries. Solid-state batteries with sulfide electrolytes were reported to attain higher performance than lithium-ion batteries, and they are under development aiming at vehicle application. However, sulfide electrolytes are unstable and hygroscopic materials, and the batteries should be assembled under strictly-controlled atmosphere. Therefore, replacement of the sulfides with stable oxides is strongly required; however, performance of the oxide-based solid-state batteries is much lower than that of the sulfide systems.
Although the highest conductivities having reported for oxides are of the order of 10^{-3} S cm^{-1}, which is lower than that of sulfides by one order of magnitude, they are not the main reason for the poor battery performance: the conductivities are almost comparable to lithium-ion conductivities of organic-solvent liquid electrolytes used in the current lithium-ion batteries. High resistance of oxide-based solid-state batteries originates from the interfaces.
Oxide-based solid electrolytes often show high grain boundary resistance. The grain boundary resistance can be lowered by increasing sintering temperature, indeed; however, it does not lead to high performance in the solid-state batteries. The solid electrolytes are in contact with active materials in the batteries. Sintering at high temperatures induces mutual diffusion between the solid electrolytes and active materials, which forms resistive impurity layers at the interfaces. Sulfide-based solid-state batteries have achieved the high performance not only by the high ionic conductivities of sulfide-based solid electrolytes but also by their deformability. Since sulfide solid electrolytes are deformable, they can be closely contacted to active materials only by cold pressing, where mutual diffusion takes place. Therefore, it is necessary to lower sintering temperature of the oxide solid electrolytes for realizing oxide-based solid-state batteries. I have been leading some research projects on oxide-based solid-state batteries. Achievements in the projects will be presented at the meeting.

8:30 AM *ES01/ES05/MT02.02

Sudden Capacity Loss in Lithium Metal Cells Louis G. Hector[1], Meinan He[1], Mei Cai[1], Charles Wampler[1], Surya Kolluri[1], Michael Dato[2], Khalil Amine[1] and Chi Cheung Su[2]; [1]General Motors Global Research and Development Center, United States; [2]Argonne National Laboratory, United States

Rechargeable Li-metal batteries have higher energy density relative to batteries based upon intercalation electrodes. They are therefore attractive energy storage candidates for electric vehicles. However, a main barrier to their commercial deployment is a relatively short cycle life. Re-engineering the electrolyte offers advantages towards acceptable cycle life; however, the cells exhibit a sudden capacity loss. In this presentation, we detail a new method for analyzing voltage profiles during cycling to differentiate between the capacity loss originating from loss of cathode capacity loss versus growth in cell resistance. We show that sudden capacity loss is preceded by acceleration of the rate of growth of cell resistance. Cycling of multiple cells suggested that this behavior is sensitive to the initial quantity of electrolyte. Alternatively, the cathode capacity degraded at a constant rate independent of the electrolyte quantity. Loss of active lithium and/or the loss of active cathode material were not the primary causes of sudden capacity loss. Rather, consumption and decomposition of electrolyte led to the drastic capacity loss at end of life.

9:00 AM *ES01/ES05/MT02.03
Challenges for Organic Active Materials for Stationary Electrical Energy Storage Michael J. Aziz; Harvard University, United States

We have developed high performance flow batteries based on the aqueous redox behavior of small organic and metalorganic monomers composed of earth-abundant elements. These redox active materials can be inexpensive and exhibit rapid redox kinetics and high solubilities, potentially enabling rapid scaling of flow batteries at reduced cost. Adequate molecular lifetime has been one of the most challenging requirements to satisfy. We have shown that the amount of lost capacity is determined by the molecular calendar life, which can depend on state of charge, but is independent of the number of charge-discharge cycles imposed. I will discuss problems in measuring extremely small capacity fade rates and how an understanding of molecular decomposition mechanisms has permitted us to design molecules with decadal projected lifetimes and even to reverse capacity fade by recomposing decomposed molecules within the functioning battery electrolyte.

9:30 AM *ES01/ES05/MT02.04
Semantic Technology for Accelerated Battery Materials Research and Innovation Simon Clark and Eibar Flores; SINTEF Industry, Norway

Materials research and innovation are pivotal to advancing battery technology and enabling the green transition. However, widely used trial-and-error approaches are too slow and under-utilize the valuable data that they generate. This presentation explores the pivotal role semantic technology - a fusion of artificial intelligence and web technologies - plays in accelerating research efforts towards next-generation battery materials. Semantic web technology like ontologies and knowledge graphs, helps researchers integrate heterogeneous data sources. This not only simplifies data retrieval by enabling precise, context-aware queries, but also augments the capabilities of machine learning. With semantically enriched data, researchers can craft models that are more adept at predicting material behaviours and identifying promising compositions.

This talk introduces the fundamentals of semantic technology and presents real case studies from battery materials research. This includes a specific focus on examples coming from both experiments and simulations. It is shown how semantic annotations can enable both human- and machine-readability of battery data to automate analysis and enable interoperability between different modelling frameworks. Harnessing the power of semantic technology in materials research not only expedites the development of next-generation battery materials but also fosters data-driven innovation and collaboration across diverse research domains.

Real-Time Probing of Solid-Liquid Interfaces for The Alkaline Oxygen Evolution Reaction of Oxides Vaso Tileli; EPFL, Switzerland

The design of active and stable oxygen-evolving oxide catalysts can be aided by their real-time probing, which provides information on how the catalysts perform and evolve under operating conditions [1]. Among the operando characterization techniques applied to electrocatalysis, electrochemical liquid-phase transmission electron microscopy (ec-LPTEM) is capable of visualizing the electrochemically induced processes in liquid environments at the single particle level. In this talk, I will discuss the progress made in the application of ec-LPTEM for monitoring solid-liquid interface processes occurring on Co-based and iridium oxide OER catalysts [2,3]. By analyzing the contrast of the lateral liquid electrolyte surrounding the catalyst particle in TEM images, the surface wetting dynamics with respect to the applied potential is revealed. The overall decrease in the lateral liquid thickness indicates a switch from hydrophobic to hydrophilic character under anodic potential due to electrowetting induced by ion accumulation at the interface. Within the pre-OER potential, the change in the surface wetting behavior on Co-based oxides suggests a link to the underlying Co II/III redox reaction and surface transformation of the oxyhydroxide phase. I will also demonstrate the direct probing of electrocatalytic molecular oxygen using operando electron energy-loss spectroscopy (EELS). Progress toward facet selectivity probing of the evolving molecular oxygen will be discussed and evidence of highly-pressurized electrocatalytic gas formation in the microcells will be presented.

***Operando* Studies of Dynamic Evolution of Cu Nanocatalysts during CO2 Reduction** Yao Yang; Cornell University, United States

In an era of shifting the energy paradigm from fossil fuels to renewable energy, CO_2 reduction reaction (CO_2RR) emerges as a promising approach to convert greenhouse gas into valuable chemical fuels and close the carbon cycle for a sustainable energy supply. Since Cu remains the sole element for CO_2RR to multicarbon products (C_{2+}), significant efforts have been devoted to developing Cu electrocatalysts with higher selectivity and activity. However, the complex nature of active sites and the intrinsic structures under reaction conditions have remained largely elusive due to the lack of *operando*/*in situ* methods. In this work, we present a comprehensive *operando* correlative study of size- and potential-dependent dynamic evolution of Cu nanoparticle electrocatalysts under CO_2RR conditions. *Operando* electrochemical liquid-cell scanning transmission electron microscopy (EC-STEM) and 4D-STEM, driven by machine learning, resolve microscopic dynamic morphological and structural evolution at the nm scale. Correlated *operando* synchrotron-based high-energy-resolution fluorescence-detected (HERFD) X-ray absorption spectroscopy (XAS) reveals dynamic macroscopic changes in valence states and coordination environment. The methodology described herein can serve as a general strategy to resolve the electrocatalytic interface of nanoparticle catalysts under real-time operating conditions across multiple time and length scales.

9:30 AM ES02.01.03
Recovery of Isolated Lithium through Discharged State Calendar Aging Wenbo Zhang[1], Philaphon Sayavong[1], Xin Xiao[1], Solomon Oyakhire[1,2], Sanzeeda B. Shuchi[1], Rafael A. Vila[1], David T. Boyle[1], Sang Cheol Kim[1], Munsek Kim[1], Sarah Holmes[1], Yusheng Ye[1], Donglin Li[1], Stacey F. Bent[1] and Yi Cui[1]; [1]Stanford University, United States; [2]University of California, Berkeley, United States

Rechargeable Li-metal batteries (LMBs) have the potential to more than double the specific energy of the state-of-the-art rechargeable Li-ion batteries (LIBs), making Li metal a promising anode material for future generation rechargeable batteries. However, Li metal anodes suffer from greater cycle degradation compared to their Li-ion counterparts due to excess formation of capacity depleting byproducts.[1] Two major byproducts generated are: 1) the solid electrolyte interphase (SEI), a product of Li, salt and organic species reactions at the Li metal and the electrolyte interface to form a 'passivation' layer and 2) 'dead' or isolated Li, which traps capacity as Li metal detached from the electrochemical circuit. Recent studies have revealed that charged state calendar aging promotes further corrosion reactions between active Li and the surrounding electrolyte, leading to additional byproduct generation and further capacity loss.[2-3] Although these studies highlight the detrimental effects of calendar aging in the charged state, they have not reported on the effects of discharged state calendar aging on cell performance. In the discharged state, all electronically active Li has been stripped away leaving only isolated Li and SEI on the anode.[4] In this environment absent of active Li corrosion, the effects of rest on isolated Li, SEI, and cycle performance have not been explicitly explored and remain unknown.

In this work, we report calendar aging in the discharged state improves capacity retention through isolated Li recovery, a surprising contrast to the well-known phenomenon of capacity degradation observed during aging in the charged state. Discharged state rested cells achieve a sustained greater than 1% average CE increase over both continuously cycled and charged state rested cells. Additionally, running cells on a hybrid continuous/discharged state rest cycling protocol in combination with titration gas chromatography (TGC) reveal isolated Li recovery as the main contributor to capacity gain. Furthermore, a novel operando optical setup in combination with electrochemical quartz crystal microbalance (EQCM) reveal that the process of SEI dissolution during discharged resting promotes excess isolated Li recovery. These insights into a new pathway for capacity recovery through discharged state calendar aging emphasize the significant effects cycling strategies have on LMB performance.

Quantitative O*perando* Mapping with Nanoscale Resolution of 3D Mechanical Properties of Surface Electrolyte Interphase in Li-Ion and Na-Ion Batteries Oleg V. Kolosov[1], Yue Chen[2], Mangayarkarasi Nagarathinam[1], Svetlana Menkin Bachbut[3] and Dominic Wright[3]; [1]Lancaster University, United Kingdom; [2]Fujian Normal University, China; [3]University of Cambridge, United Kingdom

A nanoscale thin but extremely important component of any rechargeable battery is the solid electrolyte interphase (SEI), a passivation layer that that defines the fundamental battery properties - capacity, cycle stability and safety. Local mechanical properties of SEI hold a clue to its performance, but their *operando* characterisation is very difficult as one has to probe nanoscale surface features in electrochemical environment that are also dynamically changing. Here, we report novel 3D nano-rheology microscopy (3D-NRM) that uses a tiny (sub-nm to few nm) lateral dithering of the sharp SPM tip at kHz frequencies to probe the minute sample reaction forces. By mapping the increments of the real and imaginary components of these forces, while the tip

penetrates the soft interfacial layers, we obtain the true 3D nanoscale structure of sub–mm thick layers. 3D-NRM already allowed us to elucidate key role of solvents in SEI formation and predict the conditions for building SEI for robust, safe and efficient Li-ion batteries [1]. We combine 3D NRM with magnetic excitation to investigate molecular-level solvation force spectroscopy and use molecular dynamics simulations to understand two morphologically dissimilar but chemically identical surfaces of typical carbon electrode material (basal and edge graphene planes) and different solvent-electrolyte systems (strong and weakly solvating electrolytes, as well as ionic liquid electrolyte). These approaches allowed us to get direct insight into the atomistic pictures for the underlying influence of cation's intercalation and solvation structures on the initial SEI formation.
Furthermore, here we explore the extension of these studies on smooth HOPG and inhomogeneous and rough copper anodes as sodium ion battery electrodes. Essentially, the new approach allows nanoscale characterisation of SEI with a few nm precision on the electrodes with 1000 nm roughness, and, importantly, to quantitatively evaluate the real and imaginary parts of the elastic moduli over the whole thickness of SEI layer. The observation of the change in moduli and the tip-surface distance helps to evaluate the growth of SEI as a function of the electrolyte, additives, electrode material and charge-discharge rate. Our understanding of these key interfacial structural factors in SEI formation allows targeting an electrochemically and mechanically robust surface passivation layer and guiding the development of efficient and safe rechargeable batteries. We believe that such evaluation of key interfacial nanomechanical properties of SEI will allow us to develop the electrochemically and mechanically robust SEI surface passivation layer and the development of efficient and safe rechargeable batteries.

10:00 AM BREAK

10:30 AM *ES02.01.05
Real Time Electron Microscopy Observations of Electrode Materials for Li-Ion Batteries Sooyeon Hwang; Brookhaven National Laboratory, United States

Transmission electron microscopy (TEM) has played a vital role in providing nano- and atomic-scale insights into the morphology, microstructure, and chemical properties of Li-ion batteries at both anode and cathode materials. Moreover, improvements of in-situ capabilities, as enabled by specialized biasing TEM sample holders, offers an exciting opportunity to monitor the changes taking place in the electrode materials under external stimuli at an unparalleled resolution, enabling a deeper understanding of how the materials behave under various operating conditions. In-situ capability is also applicable to investigate structural changes of electrode materials during lithium removal or insertion under biasing conditions. Such operando characterization of the electrode materials is critical for gaining a fundamental understanding of how lithium-ion batteries function and degrade.
My presentation will focus on real-time TEM observations of the phase transformations that take place in electrode materials during lithium migration. A dry-cell setup was developed inside the TEM column based on the Nanofactory STM-TEM sample holder, and lithium movement was controlled by applying bias to the samples. A multi-step lithium insertion reactions within tin sulfide will be presented as a proof-of-concept, and the nanoscale structural evolutions in these solid-state-cells will be further discussed. My talk will illustrate that dynamic investigations of electrode materials not only enhance our understanding of the structural changes induced by lithium but also provide intriguing insights into the underlying origins of battery performances.

11:00 AM *ES02.04.07
Unravelling Battery Interface: Speciation and Structure Feifei Shi; The Pennsylvania State University, United States

Interface speciation and structure significantly influence a battery's energy density, cycle life, and safety. However, the reduced signal strength and inherent fragility pose significant challenges when conducting the ex-situ and destructive characterizations. In this talk, I will initially provide an overview of surface science methodologies tailored to address interface-related issues in batteries, showcasing their practical applications. Subsequently, I will delve into the considerable promise of angle-resolved spectroscopy for discerning intricate interfacial speciation. Finally, I will introduce an innovative technique, time-resolved electrocapillarity, capable of offering precise insights into potential and concentration distribution across the electrode/electrolyte interface.

11:30 AM ES02.01.07
***In Situ* Imaging of Ion Transport in Electrochemical Cells for Predictive Solar Fuel Generation** Livia Belman-Wells[1], James Utterback[2], Anwesha Maitra[1], Alex King[3,1], David Larson[3], Leo Hamerlynck[1], Adam Weber[3] and Naomi S. Ginsberg[1]; [1]University of California, Berkeley, United States; [2]Sorbonne Université, France; [3]Lawrence Berkeley National Laboratory, United States

Ion transport underpins the functionality of many modern electrochemical devices involved in energy generation and storage. Despite its importance, label-free spatiotemporal imaging of ion transport in the solution phase in-operando has not been widely explored. Here we have performed interferometric reflection microscopy (IRM) measurements of voltage-induced ion transport in aqueous solution, spatiotemporally mapping ion concentration gradients and extracting transport parameters. We developed an electrochemical cell composed of a narrow channel etched into a microscope coverslip with vertical electrodes running along its sides to drive a reaction in a ferricyanide-based aqueous redox electrolyte. Applying a voltage while imaging the cell, we measure the evolution of concentration profiles through their changes to the local refractive index. Analysis of the evolving ion concentration gradients allows us to extract a diffusion coefficient consistent with that of aqueous ferricyanide, demonstrating the ability to do label-free optical imaging of ion transport in an aqueous electrolyte. This work serves as a basis to proceed to study CO2 reduction for solar fuel generation. We anticipate imaging in situ mass transport to characterize the involved reactions and to compare local and global efficiency and durability across photoelectrode systems for improved device performance.

SESSION ES02.02: Operando X-ray Microscopy of Energy Storage Materials
Session Chairs: Raphaële Clement and Feng Lin
Wednesday Afternoon, April 24, 2024
Room 424, Level 4, Summit

1:45 PM *ES02.02.01

Characterizing The Morphological and Crystallographic Behavior of Ni-Rich Li-Ion Cathodes Donal Finegan; National Renewable Energy Laboratory, United States

High Ni content cathodes display large volumetric changes and can incur crystallographic phase changes during formation and initial activation. The heterogeneous geometric and crystallographic evolution of the electrodes greatly influence their cycle-life performance. This work will focus on the application of advanced electron and X-ray microscopy techniques to characterize the evolution of heterogeneous particle morphology and crystallographic phases during formation, activation, and throughout the cycle-life of the cathodes. Focused-ion beam electron back scatter diffraction (FIB-EBSD) is applied to characterize the grain size distribution and orientations through the particle architectures. X-ray nano- computed tomography (nano-CT) is applied before and after formation and cycling to quantify morphological change such as crack growth throughout the life of the cathode materials. Finally, synchrotron X-ray diffraction computed tomography (XRD-CT) captures the efficacy of high-voltage activation steps during formation to irreversible form a stable layered phase for high performance long-life cycling. The multi-modal approach provides a comprehensive description of the morphological and crystallographic phenomena that determine the performance of earth-abundant cathodes and sheds new light on performance limiting material properties.

Advanced *Operando* Analaysis for Interface Observation uinsg Synchrotron X-Ray Computed Tomography for Lead-Acid Batteries Seongjun Kim[1,2], Mark Wolfman[1,2], Tiffany Kinnibrugh[1,2], Alan Kastengran[1,2], Tim Fister[1] and Paul Fenter[1]; [1]Argonne National Laboratory, United States; [2]Advanced Photon Source, United States

In the realm of battery technology, a field that has profoundly influenced various industries, including the automotive sector with the widespread adoption of lithium-ion batteries (LIBs), trust in these energy storage solutions remains challenged by issues related to safety, cost, and environmental impact. This has ignited an ongoing competition between traditional and emerging battery technologies.
Lead acid batteries (LABs), a technology dating back to 1859, have endured as preferred secondary power sources in many applications, primarily due to their economic advantages. Nevertheless, LABs face significant hurdles in order to compete effectively with other battery types. Deep discharges can lead to rapid sulfation, while the irreversible crystallization of lead sulfate (PbSO4) can compromise battery lifespan and performance. Therefore, understanding the structural transformations of two critical components, the positive active material (PAM) and negative active material (NAM), becomes imperative for enhancing battery capacity and cycle life. Variations in internal morphology can influence electrode porosity and surface area, both pivotal factors in determining battery performance. Traditional post-mortem analysis methods, such as scanning and transmission electron microscopy (SEM and TEM), fall short in capturing real-time changes during cycling.
Synchrotron X-ray computed tomography (XCT) emerges as a non-destructive methodology for characterizing material morphology and interfaces across a wide spectrum of scales, from sub-micron to centimeters. This technique facilitates both two-dimensional (2D) and three-dimensional (3D) visualization, proving invaluable for investigating interface transformations in solid-phase materials. In situ or operando measurements enable the identification of morphology changes due to phase transitions during cycling. XCT-generated images can be reconstructed into 2D slices and further assembled into 3D representations, aiding in the interpretation of porosity and particle evolution across different states of charge (SOC). Additionally, complementary synchrotron X-ray techniques, such as diffraction (XRD) and transmission X-ray microscopy (TXM), contribute to unveiling the intrinsic chemo-mechanical dynamics within lead-acid batteries.
This presentation promises to shed light on LABs, offering insights into their mechanism through various synchrotron X-ray techniques. The application of in situ and operando X-ray measurements enhances our understanding of LABs, contributing to broader comprehension of this enduring energy storage technology.

2:30 PM BREAK

The Applications of *Operando* X-Ray Fluorescence Microscopy in Electrochemical Systems Luxi Li[1], Feng Lin[2] and Barry Lai[1]; [1]Argonne National Laboratory, United States; [2]Virginia Tech, United States

X-ray Fluorescence Microscopy (XFM) has been an invaluable tool for investigating the elemental composition of specimens in both 2D and 3D contexts. Its versatile application spans across various scientific domains, including biology, medicine, and environmental science. Recently, operando XFM has emerged as a powerful technique for monitoring the transition element dissolution and redeposition in electrochemical systems. This method enables us to measure both the projective 2D elemental distribution and the interfacial elemental distribution through in-situ and operando XFM approaches [1,2].

The Advanced Photon Source (APS) 2-ID-D/E beamlines are the state-of-the-art hard X-ray microprobe XFM beamlines. In this presentation, I will provide an overview of the current instrumentations at 2-ID beamlines, followed by a selection of compelling showcase applications. To conclude, I will explore future perspectives in post-APS-U in-situ/operando research with multiscale and multimodal approaches.

2. Yuxin Zhang, Anyang Hu, Evan Maxey, Luxi Li, Feng Lin, “Spatiotemporal visualization and chemical identification of the metal diffusion layer at the electrochemical interface” J. Electrochem. Soc. 169, 100512 (2023).

4:00 PM ES02.02.05
***Operando* Bragg Coherent Diffraction Imaging of Commercial NMC811 Electrodes** Alice V. Llewellyn[1], Jiecheng Diao[2], Hamish Reid[1], Charlie Kirchner-Burles[1], Ian Robinson[1], Paul Shearing[3] and Rhodri Jervis[1]; [1]University College London, United Kingdom; [2]ShanghaiTech University, China; [3]University of Oxford, United Kingdom

Commercial candidates for electric vehicle batteries include Ni-rich Li(Ni0.8Mn0.1Co0.1)O2 (NMC811) cathodes due to their high specific capacity (200 mAh/g) and reduced cobalt content, which has positive socio-economic repercussions. Despite all of the advantages, these materials suffer from a range of degradation modes, many of which are associated with the redox and crystallographic behavior at high states of charge and are thought to be the cause of rapid capacity fade. NMC811 suffers from anisotropic changes in the crystal structure during cycling, which induce strain and can then lead to issues such as particle crack formation. Gathering data at multiple length scales is imperative for understanding the discrete mechanisms at play. Bragg Coherent Diffraction Imaging (BCDI) is a key tool for obtaining data at the nano-scale by providing high spatial resolution images of individual particles. BCDI also affords the unique opportunity to resolve the strain of individual crystals at the picometer scale, producing data with the highest quantifiable imaging resolution of battery electrodes and allowing for the detection of evolving defect modes such as shearing and stacking faults in the crystals during cycling. NMC811 typically employs the archetypal cathode particle morphology, consisting of a secondary particle agglomerate (~ 10 μm) made up of nanometer-sized primary particles. It is widely accepted that crack formation occurs at grain boundaries between primary particles. One mitigation method is to switch

to a single crystal morphology, reducing the number of grain boundaries within particles and therefore improving overall performance. However, there is still a limited understanding of the subtle mechanistic differences between the two morphologies during cycling.
In this work, Operando BCDI was employed to study both polycrystalline and single crystal NMC811 electrodes in both pristine and aged states. Non-uniform distributions of inter- and intracrystal strain were observed for both polycrystalline and single crystal morphologies, even in the pristine state. The nucleation of crystal splitting was observed for a pristine single crystal during cycling, which could subsequently result in intergranular cracking. This feature is only resolvable with extremely high-resolution techniques such as BCDI. This work ultimately adds to the understanding of the central role of crystal-scale dynamics during cycling and the potential ramifications for a cell's electrochemical performance, leading to informed material design.

4:15 PM ES02.02.06
GRaylevel Analysis of Particles in ElectrodeS (GRAPES); Data Workflows and Analytics for Computed Tomography (CT) Data of Degradation in Battery Materials Matthew P. Jones and Rhodri Jervis; UCL, United Kingdom

GRAPES is a python module designed to help researchers analyze electrode particles in tomography data. GRAPES transforms 3D image data into tabular dataframes that facilitate the rapid and intuitive processing of particles and particle properties relevant to the study of battery materials. Each row in the dataframe represents a unique particle with 20+ columns of particle characteristics such as sphericity, surface area, and volume. Additionally, battery degradation specific properties are included such as damage factor, and radial layer damage factors. The data transformation from image volumes to GRAPES dataframe can be executed in one line and allows users to more rapidly understand the relationship between different particle characteristics in their datasets. Furthermore, this format of large tabular data can be easily integrated with open-source machine learning libraries in python (sklearn, pytorch, etc.) to train classical machine learning models such as multiple linear regression, random forests, and gradient boosting.

In this work we report on two use case examples with a specific focus on the underlying data workflow used. These case examples are the degradation of silicon anode particles and NMC cathode particles during cycling. We cover the image processing, image registration, and image segmentation (binary and instance segmentation) required to prepare a time-lapse CT dataset. Additionally, we will discuss the importance of removing edge cases from the GRAPES dataset. This allows us to use GRAPES and other analytics to track how particles are damaged at different cycles, the spatial distribution of damaged particles, the regions of highest damage within particles, and track the percentage of particles that observe particular behaviors during cycling. Through this work we have demonstrated a state-of-the-art data workflow for processing CT datasets of electrode particle degradation. This method allows for large statistically relevant volumes to be analyzed during cell cycling whilst still tracking the changes in individual particles throughout time-lapse datasets. We believe that moving forward this workflow can be replicated for a broad range of electrochemical materials that observe volume and density change during use.

4:30 PM ES02.02.07
***Operando* Detection of Cracking in High Ni Battery Cathode Materials by X-Ray CT** Huw Parks[1,2] and Rhodri Jervis[1,2]; [1]University College London, United Kingdom; [2]Faraday Institution, United Kingdom

In a drive for ever-increasing energy density and reduction in use of cobalt in lithium ion battery cathodes, high-nickel content layered cathodes (Ni>80%) of the form $LiNi_xMn_yCo_zO_2$ (NMC) have received significant recent attention. These materials undergo considerable anisotropic lattice changes during cycling (lithiation and delithiation) which has been attributed to the creation of microcracks in polycrystalline agglomerate cathode particles. This cracking behaviour has long been suspected to cause increased surface reactions leading to impedance rise, reduction of electronic conductive pathways and eventually complete particle detachment from the conductive matrix and pulverisation; however, the pre-existence of particle cracks and defects from manufacturing and calendaring of the electrodes can make it difficult to assess the contribution of the electrochemical history alone in causing cracks[1]. In a bid to reduce this, so-called single-crystal materials have been proposed to be more resistant to degradation[2] due to their resilience to cracking[3] and lower surface exposure to electrolyte, which can cause parasitic reactions and drive oxygen loss[4].

Assessing the origins of cracking and its evolution with battery ageing is complex due to the small and internal nature of the cracks, often requiring either destructive imaging techniques (such as FIB SEM or TEM on lamella) or small sample sizes in non-realistic environments to facilitate non-destructive imaging by methods such as X-ray computed tomography (CT). In previous work, we have developed methods for producing electrodes with optimised tab geometries for in situ and operando X-ray CT and related characterisation methods[5, 6], which we use here to allow for a pseudo-in situ nano-CT study of electrochemically induced cracking in NMC811 particles with minimal pre-existing damage[7]. This allows for direct observation of first-cycle cracking within the particles using lab-based CT on identical particles in the discharged and charged state, showing that even on the first cycle, significant intergranular cracks can develop in the polycrystalline materials. Additional ex situ studies on non-identical particles have revealed cracking in polycrystalline materials occurs at relatively low potentials, in the early stages of charging, and is at least partially recovered on discharge[8].

In this presentation we will extend this methodology to assess the progression of first cycle cracking throughout the charge and discharge range on thousands of identical particles from the same electrode within a realistic pouch cell environment. The use of the tab electrode geometry within a working pouch cell and larger field of view afforded by synchrotron micro-CT studies, combined with automated image processing and analysis, allows us to follow the behaviour of around 5,000 NMC particles through multiple states of charge, revealing the diversity of cracking behaviour within working, commercially relevant, Li ion battery electrodes. Advanced grey-scale analysis of the data reveals sub-resolution limit information about the damage to the particles throughout their states of (de)lithiation and provides a statistically relevant quantification of the extent of crack closure behaviour.

4:45 PM ES02.02.08
Heterogeneous Lithium Transport within Individual Single-Crystalline NCM Battery Particles Bonho Koo[1], Jinkyu Chung[1], Danwon Lee[1], Chihyun Nam[1], Martin Z. Bazant[2] and Jongwoo Lim[1]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

Probing the lithiation kinetics in solid-state electrodes is foundational for advancing high-efficacy battery technologies. Typically, a consistent and monotonic lithium gradient is anticipated across solid-solution single-crystalline battery constituents throughout the cycling process. Our exploration, centered on the heterogeneous lithium distribution within single-crystalline LiNi0.333Mn0.333Co0.333O2 nanostructures, utilized operando scanning

transmission X-ray microscopy for precision. Contrary to the prevailing Fickian diffusion paradigm, our insights highlight the emergence of regions both rich and deficient in lithium, which exhibit dynamic behavior across battery cycles. This intricate interplay of intra-particle strain fields, capable of either concentrating or dispersing lithium, was authenticated using Bragg coherent X-ray diffraction methodologies. Significantly, we elucidated that regions with sparse lithium proximal to the particle surface can modulate the overarching charge transfer resistance and offer avenues for in-situ optimization. This investigation provides a renewed perspective on the intricacies of nanoscale solid-state guest diffusion, heralding implications for battery rate performance and durability.

SESSION ES02.03: Poster Session
Session Chairs: Livia Belman-Wells and Wenbo Zhang
Wednesday Afternoon, April 24, 2024
Flex Hall C, Level 2, Summit

5:00 PM ES02.03.01
Substitution Effects on Nucleation and Crystal Growth of Lead Sulfate on Barite for Battery Applications Shannon J. Lee[1], Carinna Lapson[1,2], Colin T. Campbell[1], Ajay Karakoti[1], Dan Thien Nguyen[1], Celsey Price[2] and Vijayakumar Murugesan[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Oregon, United States

The common and widespread use of lead-acid batteries is due to the reliability and cost-efficiency of this energy storage option. These batteries contain a Pb anode, PbO_2 cathode, and a microporous separator, all saturated with H_2SO_4 electrolyte. The common failure mechanism of “hard sulfation” involves the irreversible large crystal growth of non-electroactive $PbSO_4$ on the surface of the anode. Expanders are chemical additives, such as $BaSO_4$, used to uniformly distribute $PbSO_4$ nucleation sites and to minimize hard sulfation in the battery. Our studies combine methods using both *in-situ*, *ex-situ,* and *in-operando* imaging using 3D optical microscopy during electrochemical cycling to observe and better understand the nucleation and growth mechanisms of $PbSO_4$ on crystals of expanders $BaSO_4$ and $Ba_{1-x}Sr_xSO_4$. Fine tuning the ability of expanders (by Sr-substitution) to limit large crystal growth of $PbSO_4$ may improve overall lead-acid battery cycling.

SESSION ES02.04: Operando Spectroscopy of Energy Storage Materials
Session Chairs: Raphaële Clement and Andrej Singer
Thursday Morning, April 25, 2024
Room 424, Level 4, Summit

8:30 AM *ES02.04.01
Improving The Sensitivity of *Operando* Nuclear Magnetic Resonance for Electrochemical Studies Khashayar Bagheri[1,2], Ludivine Afonso de Araujo[1,2,3], Raphaël Praud[1,2,3], Vincent Sarou-Kanian[1,2], David Sicsic[3], Michael Deschamps[1,2] and Elodie Salager[1,2]; [1]CNRS-CEMHTI, France; [2]Réseau sur le Stockage Electrochimique de l’Energie (RS2E), France; [3]Renault SAS, France

Nuclear Magnetic Resonance (NMR), as a bulk technique, is nicely suited for studying, *operando*, multi-component electrochemical cells. The NMR signal of atoms can be detected in many phases, independently of their degree of order: liquid, crystalline or amorphous. In addition NMR measurements deposit little power into the material, so that there is no risk of battery or material degradation during measurement. This comes however at the cost of a relatively low intrinsic sensitivity, which results in a limited temporal resolution.

In this talk we will present our latest developments to improve the sensitivity of *operando* NMR studies of batteries. Our approach is two-pronged: we work on reducing parasitic signals and on increasing intrinsic sensitivity, while controlling electrochemical behavior.

A first part will report on how we improved the *operando* setup and analysis for the early detection of the onset of metallic Li plating in NMC622//graphite cells at low temperature and fast charge [1]. Direct detection of metallic Li in the cell for various conditions of temperature and charging rate is precious to identify the exact conditions favoring metallic lithium plating and its evolution. A better grasp of this degrading phenomenon could lead to optimized charging protocols.

The second part explores how the sensitivity of the measurement itself can be increased. Most *operando* NMR measurements follow the signal of ^{7}Li or ^{23}Na atoms, as they are taking part in the redox reactions. The NMR signals from the paramagnetic solid electrodes however suffer from large broadenings, due to the interaction of the atomic spins with unpaired electrons. Here we approached the problem from another side and explored ways to exploit the NMR signal of the liquid electrolyte solvent inside the battery. Sensitivity is enhanced thanks to the narrower signal of liquid, and the intrinsic sensitivity of 1H higher than that of ^{7}Li and ^{23}Na. We demonstrate that the ^{1}H NMR spectrum of the carbonates in the liquid electrolyte is mainly sensitive to the redox state of the positive electrode. This parameter is difficult to obtain without a three-electrode measurement, but is essential for understanding the mechanisms of capacity loss and developing adequate models for battery management systems.

Finally, proper electrochemical behavior may require pressure applied to the cell during cycling. This brings an additional challenge to NMR sensitivity, as the metallic parts applying pressure tend to disturb and shield the radio-frequency waves used for the measurement. We will present our progress on a design for *operando* NMR that is compatible with applying greater pressure on large pouch cells.

[1] L. Afonso de Araujo, V. Sarou-Kanian, D. Sicsic, M. Deschamps, E. Salager, Journal of Magnetic Resonance. 354 (2023) 107527. https://doi.org/10.1016/j.jmr.2023.107527.

9:00 AM ES02.04.03
Lab-Scale *Operando* X-Ray Emission and Absorption Spectroscopy to Monitor Redox Processes of Transition Metals in Lithium-Ion Batteries

Abiram Krishnan[1], Dong-Chan Lee[2], Ian Slagle[1], Sumaiyatul Ahsan[1] and Faisal Alamgir[1]; [1]Georgia Institute of Technology, United States; [2]Hongik University, Korea (the Republic of)

Tracking changes in the electronic structure of transition metal during cycling of lithium-ion batteries (LIBs) is crucial to investigate the nature of redox reactions occurring at the electrodes. X-ray absorption spectroscopy (XAS) is often utilized to study the role of individual elements in the redox processes during the cycling of batteries through oxidation state information in real-time (operando). In this study, X-ray emission spectroscopy (XES), a complementary core-hole method to XAS is presented as an alternate method to study the characteristic emissions from battery to investigate chemical and spin state changes in electrode material during C/10 constant current cycling.

XAS measures the energy-dependent absorption coefficient of a material in the process of generating core electron holes. Chemical state sensitivity from the XAS near-edge structure (XANES) and local atomic structure sensitivity through extended x-ray absorption fine structure (EXAFS) allows us to keep track of changes in the constituent elements during cycling. XES, a complementary method is obtained by capturing characteristic photons resulting from quenching generated core holes. Kβ emission line (3p-to-1s transition) of XES obtain their chemical state sensitivity through interaction between the 3p and valence orbital (exchange interactions). Element-specific emissions of sufficient energy resolution are simple to process and inform us on the chemical state, spin state, and local structure of transition metal allowing us to study the redox processes in real-time (operando) during charge/discharge of batteries. The high flux requirement of such real-time (operando) experiments often limits these studies to synchrotron sources. Limited access to synchrotron radiation has hastened the development of lab-scale instruments that employ bremsstrahlung sources and monochromators with sufficient energy resolution. The lab-scale instrument used in this study can perform both XAS and high energy-resolution XES experiments using a scanning setup which employs the Rowland circle geometry.

Here, we present the spectral changes of transition metal $K\beta_{1,3}$ and Kβ' features of XES are utilized to track state of charge (SoC) and study redox processes during C/10 operando cycling for the following cathode materials: $LiCoO_2$ (LCO), $Li[Ni_{1/3}Co_{1/3}Mn_{1/3}]O_2$ (NMC111), $Li[Ni_{0.8}Co_{0.1}Mn_{0.1}]O_2$ (NMC811), and $LiFePO_4$ (LFP). The results obtained from operando Kβ XES are compared with K-edge XAS, which serves as a benchmark. Additionally, the sensitivity of XES towards the total spin of the transition metal valence is used to investigate the change in magnetic properties resulting from nucleation of a new phase in electrochemically delithiated LCO samples in the range of 2-10% lithium removal.

9:15 AM ES02.04.04
Investigation on Photocorrosion of TiO_2 during The Photoelectrochemical Process by *In-Situ* ICP-MS Characterization Yiqun Jiang; Max Planck Institute for Iron Research, Germany

With the growing environmental deterioration and ever-increasing energy demand, exploring a renewable and clean energy for human development has been regarded as a promising research subject. Hydrogen is one of the most desirable energy carriers because of its abundance, high energy density and only byproduct of water. A breakthrough was made by Fujishima and Honda in 1972, who founded that hydrogen could be generated from water splitting on a TiO_2 photoelectrode under UV light. However, the energy conversion efficiency of TiO_2 semiconductor for photo(electro)catalytic process is relatively low owing to their fast recombination of electron–hole pairs and its large bandgap (3-3.2 eV). Fortunately, various methods are designed to improve the performance of photo(electro)catalyst which is closely associated with its nanostructure.
TiO_2 is considered to be quite stable since its redox potential has been calculated to be more positive/negative relative to the water oxidation/reduction potential, which means that photogenerated charge carriers participate in driving the desired redox potential rather than oxidizing or reducing semiconductor photoelectrodes. Nevertheless, the real photocorrosion (decomposition or degradation) depends on specific kinetic parameters such as illumination intensity, electrolyte property, radiation adsorption, charge transport and mass transport. We use inductively coupled plasma mass spectrometry (ICP-MS) to reveal the dissolution products of TiO_2 photoelectrode during PEC water splitting. It is unveiled that TiO_2 photoanode experiences photocorrosion from its oxidation with photogenerated holes. We demonstrate how the atomic scale structure of TiO_2 correlates with its PEC performance and photocorrosion process to enable a better understanding of the complex structure-activity-stability relationship in photoelectrocatalysis. ICP-MS analysis under solar water splitting conditions reveals the chemical instabilities that are not predicted from thermodynamic considerations of stable solid oxide phases represented by the Pourbaix diagram. Our investigation of photochemical corrosion pathway of TiO_2 thin film proves the competition between water splitting and semiconductor oxidation experimentally.

9:30 AM ES02.04.05
***Operando* Raman Spectroscopy for Aqueous Organic Redox Flow Batteries** Lara Lubian, Rubén Rubio-Presa, Virginia Ruiz, Álvaro Colina and Edgar Ventosa; University of Burgos, Spain

Generation of electricity from renewable sources is crucial for achieving the transition to a sustainable and decarbonization energy system. While solar and wind power are becoming increasingly popular, their intermittency requires the deployment of efficient and cost-effective energy storage systems (ESSs) to match energy production and demand. Among the various EESs, redox flow batteries (RFBs) that are featured by their independent scalability of energy and power are promising ESSs candidates for stationary energy storage application. The all-vanadium redox flow battery (AVRFB) is currently the state-of-art of RFB, but the large-scale implementation of AVRFBs presents an intrinsic challenge; vanadium is considered a critical material. Aqueous organic redox flow batteries (AORFBs) gaining much interest as vanadium-based species are replaced by organic redox-active species. While many organic molecules have demonstrated suitable redox potentials, kinetics and solubilities, their cycle stability should be further improved for large-scale deployment. Therefore, advanced techniques are required to investigate the capacity fading mechanisms in operando conditions.

In this contribution, the implementation of Raman spectroscopy for AORFBs will be discussed. Raman spectroscopy is a very useful technique that provides chemical information on redox-active molecules. Surprisingly, this powerful analytical technique has not been exploited in RFBs despite its intrinsic advantages to investigate highly concentrated solutions of strongly colored active species over more commonly used UV-Vis spectroscopy. Overall, the aim of this contribution is to promote the use of Raman spectroscopy within the RFB community by disclosing technical details for its implementation and discussing a couple of case-studies . Specifically, this contribution will be structured in three sections. First, the specific design, fabrication and practical implementation of Raman spectroscopy in a redox flow system for RFB research will be disclosed. Second, Raman spectroscopy will be used to monitor the state-of-charge and potential degradation of the catholyte of ferrocyanide-based redox flow batteries (both in alkaline and neutral pH). Finally, results on degradation of viologen-based anolytes in the unavoidable presence of oxygen traces will be presented. Importantly, the methodology presented here may be of interest to other communities since it is implementable for other electrochemical flowing systems such as semi-solid flow batteries, electrochemical oxidation of pollutants, electrosynthesis, etc.

Hollow-Core Optical Fibre Sensors for *Operando* Raman Spectroscopy on Li-Ion Battery Liquid Electrolytes Ermanno Miele[1,2], Wesley Dose[3,2], Michael Frosz[4], Zach Ruff[3,2], Michael De Volder[3,2], Clare Grey[3,2], Jeremy J. Baumberg[1,2] and Tijmen G. Euser[1,2]; [1]Cavendish Laboratory, University of Cambridge, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]University of Cambridge, United Kingdom; [4]Max Planck Institute for the Science of Light, Germany

Liquid-filled hollow-core fibres (HCF) are excellent sample cells in which light propagates in well-defined modes at the centre of a microchannel. The internal sample volumes in HCF can be as small as a few nL per cm interaction length, while long optical paths enable sensitive absorption, fluorescence, and Raman spectroscopy [1,2]. This talk will introduce optofluidic hollow-core fibres and briefly review their applications as microreactors. It will then demonstrate a new operando Raman spectroscopy method that tracks the chemistry of liquid electrolytes during battery cycling. An optofluidic hollow-core fibre is integrated into a working Li-ion cell and used to analyse sub-microlitre electrolyte samples at different stages of the charge-discharge cycle by background-free Raman spectroscopy. The observed changes in electrolyte composition are related to the solid electrolyte interphase (SEI) formation [2]. In addition, Raman measurements over multiple cycles reveal early signs of battery electrolyte degradation and we demonstrate that lost capcity can be recovered by infiltration of fresh electrolyte into a degraded cell. The new methodology contributes to understanding better the limitations of Li-ion batteries and paves the way for studies of degradation mechanisms in different electrochemical energy storage systems.

***Operando* electrochemical Raman and IR spectroscopic studies of covalent organic frameworks for energy storage and conversion systems** Hye Ryung Byon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

I present designs of covalent organic frameworks (COFs) and underpin their significant applications in organic Li-ion batteries and electrochemical CO_2 reduction. Our COF designs encompass various tunable characteristics such as pore sizes, functional groups, and film thickness, ranging from nanometers to micrometers. These COFs serve as versatile platforms for Li^+ storage electrodes, electrolytes, and CO_2/CO gas adsorption, which have been explored using *operando* electrochemical Raman and IR spectroscopy.
As a representative example, we have successfully incorporated redox-active azo groups into COFs to facilitate two-electron transfer, examining their potential as organic electrodes. Ensuring reversibility and stability proved crucial, with results highly contingent on neighboring functional groups. We explored three distinct linkages: beta-ketoenamine, imine, and thiazole-fused rings, each exhibiting varying cycling stabilities under identical operational conditions. It underscores the significance of fully conjugated organic systems. Furthermore, the overlap of vertical pi orbitals stemming from the azo moiety enhanced rate capability. *Operando* electrochemical Raman spectroscopy for the surface of cross-sectional COF electrode demonstrated reversible azo reaction with Li^+ during the charging and discharging process.

11:15 AM ES02.04.09
The Local Structure in Zn-Cl Electrolytes and The Potential for *Operando* Study of The Interfacial Electrolyte Structure in Zn Ion Batteries using Valence-To-Core X-Ray Emission Spectroscopy Gerald Seidler[1], Diwash Dhakal[1], Darren Driscoll[2], Tim Fister[2], Niranjan Govind[3], Andrew Stack[4], Nikhil Rampal[4], Gregory Schenter[3], Christopher Mundy[3], John Fulton[3] and Mahaling Balasubramanian[2]; [1]University of Washington, United States; [2]Argonne National Laboratory, United States; [3]Pacific Northwest National Laboratory, United States; [4]Oak Ridge National Laboratory, United States

The determination and modeling of the local structure around ions in electrolytes is a classic problem in physical chemisry that also has contemporary impact spanning electrical energy storage, geochemistry, and ionic liquids (broadly defined). This problem is greatly enriched by the occurrence of cation-anion correlations, such as in contact ion pairing, giving at its extreme the 'water in salt electrolyte' (WiSE) regime that poses extreme theoretical challenges while also showing improved energy density in some batteries. Here, we report several studies of ion pairing in the aqueous Zn-Cl solutions as a function of concentration, anion activity, nanoconfinement, and temperature. To this end, we demonstrate that laboratory-based valence-to-core x-ray emission spectroscopy (VTC-XES) gives an improved method to determine the local symmetry and average composition of the Zn(II) first shell coordination. Starting with bulk solutions at ambient conditions, analysis of VTC-XES gives a robust characterization of the first coordination shell without the analytical complications of extended x-ray absorption fine structure (EXAFS), for which the changing second-shell population at high concentrations generally requires independent theoretical modeling by advanced molecular dynamics simulation. Next, we find that nanoconfinement by nanoporous carbon electrode material increases the mean ion pairing and also, in agreement with prior WiSE results, increases the electrochemical window for Zn-ion batteries. Finally, we return to the bulk system to study the temperature dependence of ion pairing, giving new insight into the geochemical problem of Zn transport in brines while also clearly demonstrating the limitations of models based on extrapolation of solubility and thermodynamic information from the dilute regime.
These results illustrate the power of VTC-XES to investigate electrolyte structure, even when measured in the laboratory rather than at synchrotron x-ray light sources. The future extension to non-aqueous electrolytes would have even more direct relevance for beyond-Li-ion batteries. In addition, the work here lays important groundwork for future operando studies of the near-electrode interfacial structure of Zn-ion and other metal-ion electrolytes via synchrotron-based measurements. Such studies would immediately interrogate the connection between electrolyte structure and the operating voltage window for Zn-ion and other metal-ion battery systems.

11:30 AM *ES02.04.10
Understanding Electrochemical Properties of $LiNiO_2$ as a Cathode for Lithium-Ion Batteries Minkyung Kim; Kwangwoon University, Korea (the Republic of)

Cathode materials have been developed toward having high energy density and low cost with decreasing cobalt and increasing nickel. However, as Ni content increases, structural and electrochemical stabilities become poor. Cathode materials exhibit a trade-off relation between capacity and stability. It is challenging to break the trade-off relationship because ‘high capacity’ generally accompanies high structural and volumetric change. However, both properties are important to utilize materials. Recently single crystal cathodes are paid attention to solve the issue. Here, we synthesized single crystal $LiNiO_2$ and investigated the electrochemical properties depending on surface planes, crystal sizes and anti-site defects. Its impact will be addressed in this presentation.

Characterization of Advanced Positive Electrode Materials for Li-Ion Batteries Naoaki Yabuuchi; Yokohama National University, Japan

The demand for electric vehicles equipped with Li-ion batteries is growing to develop low carbon society. Ni-enriched layered materials are used as electrode materials of Li-ion batteries for electric vehicle applications. However, available reversible capacity of Ni-enriched layered materials is approaching its theoretical limit. Therefore, innovation and development of new positive electrode materials are necessary. Recently, many cation-disordered rocksalt oxides have been proposed as a new series of electrode materials. Nevertheless, insufficient electrode kinetics for the cation-disordered rocksalt system limits its use for practical applications. One simple strategy is synthesizing nanosized materials to overcome a problem of electrode kinetics (for electrons, holes and ions), and electrode kinetics are significantly improved through nanosizing.[1-4)] Structural disordering also triggers unique electrode properties associated with different local environments for cations/anions.[4-7)] From these results, we discuss the advantage and uniqueness of nanostructured cation-disordered rocksalt materials for high-energy advanced Li-ion batteries.

Understanding The Dynamics of Electrodes (Crystalline and Amorphous) and Interphases in Lithium Batteries Enyuan Hu, Muhammad Rahman, Sha Tan and Nan Wang; Brookhaven National Laboratory, United States

Lithium batteries are complicated systems of electrodes and electrolytes. The inherent thermodynamic instability between the electrode and the electrolyte frequently results in the formation of an interphase. Understanding the dynamics of the electrodes and this interphase during battery operation is pivotal to advancing battery technologies. However, several challenges render the characterization process particularly daunting: 1. the processes can be far from equilibrium, making them unpredictable through traditional methods like phase diagrams; 2. instead of a well-defined crystalline structure, the electrode may assume an amorphous form, complicating our understanding; 3. the interphase exists in extremely trace amount, making its observation and study very demanding. We will discuss how we address these challenges using synchrotron-based scattering tools.

2:30 PM ES02.05.03
Revealing the Sodium Storage in Hard Carbon Pores Luis Kitsu Iglesias, Emma Antonio and Michael Toney; University of Colorado Boulder, United States

Sodium-ion batteries (NIBs) are an attractive candidate to support the increasing demand of energy, especially amid growing concerns about the sustainability of lithium resources for lithium-ion batteries. NIBs provide advantages due to the abundance of sodium, its low cost, and electrochemical performance. Hard carbon (HC) is the most promising anode for the commercialization of NIBs, however, due to its structural complexity, a general mechanism for sodium storage in HC remains unclear, obstructing the development of highly efficient anodes for NIBs. To elucidate the mechanism of sodium storage in HC pores, we combined *operando* synchrotron small-angle X-ray scattering, wide-angle X-ray scattering, X-ray absorption near edge structure, Raman spectroscopy, and galvanostatic measurements. Through this multimodal investigation, we provide mechanistic insights into the sodium pore filling process across various HC microstructures including the pore sizes that are preferentially filled, the extent to which different pore sizes are filled, and how the defect concentration influences pore filling. We observe that sodium in the larger pores exhibits an increased pseudo-metallic sodium character, indicative of larger sodium clusters. Furthermore, we show that the hard carbons prepared at higher pyrolysis temperature have a larger capacity from sodium stored in the pores, and that sodium intercalation between graphene layers occurs simultaneously to the pore filling in the plateau region. Our results suggest that the engineering of defect sites in pore walls, together with increasing the pore size distribution and/or volume fraction of closed pores are key to designing superior HC anodes. Moreover, our study also gives a systematic approach to study other porous functional materials and to understand how ions store in the pores.

2:45 PM ES02.05.04
Comparing the Insertion Properties of Mg^{2+} into $V_3O_7 H_2O$ in Organic and Aqueous Electrolytes Daniela Söllinger and Simone Pokrant; University of Salzburg, Austria

Batteries are indispensable in our society due to their ability to store renewable energy efficiently and provide it on demand. [1] In this context, lithium-ion batteries offer one of the highest energy densities and are already used in numerous mobile applications. However, lithium reserves and their accessibility are limited, which motivates researcher to find alternatives with similar electrochemical properties, i.e. low redox potentials and high volumetric/gravimetric specific capacities as counter electrode in batteries compared to lithium.

In this context, magnesium is attractive because it is more abundant, has a low redox potential vs. SHE and a small ionic radius, comparable to lithium. [2] The double charge of magnesium results in advantages and disadvantages; on the one hand it offers the possibility to store a higher amount of charge, while on the other hand the stronger polarization of Mg^{2+} compared to Li^+ leads to challenges concerning the intercalation process. Therefore, cathode materials, which allow the reversible intercalation of Mg^{2+}, offer high theoretical capacities and are stable in various chemical environments *e.g.* in organic and aqueous electrolytes, are of great interest in current magnesium-ion battery research. One promising cathode material, which can fulfil these requirements, is hydrated vanadium oxide $V_3O_7 H_2O$. [3]

In this context, we show via *operando* XRD how the structural evolution of $V_3O_7 H_2O$ during ion insertion is affected by adding small quantities of water to the organic electrolyte. In addition, we study Mg^{2+} insertion into $V_3O_7 H_2O$ in a completely aqueous electrolyte for the first time. Then we compare the structural properties of hydrated vanadium oxide as cathode material with respect to Mg^{2+} insertion in organic and aqueous electrolytes.

In the next step we investigate to which extent the chemical environment influences the electrochemical properties. Hereby, $V_3O_7 H_2O$ shows promising initial specific capacities of ~300 mAh g^{-1} in a pure aqueous electrolyte at practical current densities of 100 mA g^{-1}, which demonstrates the versability of $V_3O_7 H_2O$ as cathode material for Mg^{2+} insertion.

3:00 PM BREAK

3:30 PM *ES02.05.05
***Operando* Synchrotron-Based X-Ray Characterization of Battery Degradation** Johanna N. Weker; SLAC National Accelerator Lab, United States

Synchrotron-based X-rays are a powerful characterization tool that can probe across many relevant length scales (from atomistic to millimeter) with different techniques that are sensitive to distinct features such as microstructure, chemistry, and morphology. Because of the high flux available and penetrating power of synchrotron-based X-rays, batteries can be probed under realistic (*operando*) conditions, which enables us to understand and overcome failure mechanisms of the next generation of battery materials. At the Stanford Synchrotron Radiation Lightsource at SLAC National Accelerator Laboratory, we have a suite of advanced X-ray characterization tools and have enabled a robust means of multimodal, *operando* characterization using a standard pouch cell geometry. With transmission X-ray microscopy (TXM), we capture morphology changes on either the cathode or anode during battery operation. Combined with absorption spectroscopy, the TXM provides maps of the local state of charge of active material particles. With high speed X-ray diffraction and X-ray absorption spectroscopy, we track the changes in crystallographic phases, local coordination, and chemistry. Results from all of these techniques can be combined together to get a more complete picture of the key degradation pathways of active battery materials to develop mitigation strategies for longer lasting energy storage.

4:00 PM ES02.05.06
***Operando* X-Ray Diffraction from Tape Casted Electrodes to All-Solid-State Batteries** Kriti Kriti, Jean-Noël Chotard and Vincent Seznec; LRCS, France

The ever-growing field of energy storage needs the development of fast cycling rate and high energy density batteries and substantial research efforts are required to characterize them for improved performances. Operando X-ray diffraction is the most effective and convenient laboratory technique to get a deep insight into structural and electrochemical changes during operating conditions of batteries. In this work, we presented our newly developed operando LeRiChe'S Cell v2 which has been used to study NMC electrode materials not only with liquid electrolyte but also in solid-state batteries. The high brilliance of our laboratory diffractometer combined with our newly developed operando LeRiChe'S Cell v2 allowed us to investigate electrode materials at high C rates in a very short span of time. Moreover, we can also use our cell at low and high temperature to study battery materials. The operando cell has been tested not only for X-ray diffraction but also for X-ray absorption spectroscopy, coherent diffraction and X-ray photoemission spectroscopy on different beamlines at large scale synchrotron facilities.

4:15 PM ES02.05.07
Using *Operando* XRD to Characterize High-Temperature Oxidation and Reduction of Fe-X Energy Storage Materials Samuel M. Pennell and David C. Dunand; Northwestern University, United States

High temperature reduction/oxidation cycling of Fe materials is an attractive energy storage paradigm for the solid-oxide metal-air rechargeable battery (SOMARB). Using laboratory XRD sources, *operando* characterization of different Fe-X alloys during cycling enables detailed examination of the effects of the alloying element on the redox cycling process. Using these techniques, the extreme degradation resistance of hierarchically porous Fe-Mo and Fe-W metallic foams during redox cycling is shown. The foams are able to maintain their multi-level porosity through sintering inhibition, chemical vapor transport during reduction, and phase evolution that encourages mixing rather than segregation. These factors result in faster reaction kinetics with increased cycling, particularly over the first five cycles. These results are contrasted with Fe-Ni, Fe-Co, and Fe-Cu foams which show enhanced reduction kinetics but ultimately degrade due to poor sintering inhibition and lack of microscale porosity. These results guide further development of the energy storage material for SOMARBs and can be translated across domains into carbon utilization and chemical looping combustion.

4:30 PM ES02.05.08
Insights into Vanadium Electrocatalysis with High-Resolution *In-Situ* X-Ray Spectroscopy: Bi Nanoparticles on Graphene for Enhanced V Redox Flow Batteries Yue Wen and Rhodri Jervis; University College London, United Kingdom

Aqueous redox flow battery systems present notable benefits such as affordability, safety, and superior ionic conductivity. However, a central obstacle across all applications lies in effectively functioning within the limited electrochemical stability range of aqueous electrolytes, preventing their decomposition. Our research here is centred on investigating the side reaction of hydrogen evolution (HER) in the context of an all-Vanadium redox flow battery (VRFB), using it as a representative case [1]. VRFB is a crucial technology for large-scale energy storage on the grid, although they presently suffer from performance challenges and suboptimal coulombic efficiency due to detrimental side reactions. The hurdle lies in finding suitable catalysts for VRFBs—ones that promote essential redox reactions without concurrently promoting hydrogen evolution.
Leveraging a novel synthesis approach employed in creating robust Pt/graphene catalysts for fuel cells [2], we have successfully engineered a novel Bi-based catalyst tailored for VRFB. A precise and gentle synthesis method ensures the uniform dispersion of bismuth metal nanoparticles on a highly conductive graphene support, resulting in a substantial boost to battery performance that demonstrates an impressive energy efficiency of 75% over 100 cycles at a relatively high current density of 200 mA cm^{-2}. To unravel the catalytic mechanism, we conducted in situ X-ray absorption near edge structure (XANES) experiments, employing high energy resolution fluorescence detection (HERFD) and extended X-ray absorption fine structure (EXAFS) at the Bi L_{III} and L_I edges within electrolytes containing H^+ or both H^+ and V^{3+}. The XANES experimental data, enriched by HERFD, were meticulously compared with ab initio calculations to elucidate the relationship between electronic structure and potential. Utilizing density functional theory-based theoretical simulations, we unveiled a concentration-dependent relationship between H-ions and V-ions on Bi crystal surfaces. Given their inherent high V-ion concentration in the electrolyte to boost energy density, Bi holds promise for significantly suppressing HER side reactions. This work also provided insights into the role of ionized water molecules (H*) and their implications on electrochemical processes, which is of utmost importance for advancing the development of efficient electrocatalytic systems in aqueous environments.

4:45 PM ES02.05.09
***Operando* X-Ray Absorption Spectroscopy for Lithium-Sulfur Batteries** Xueli Zheng; Stanford University, United States

Operando sulfur K-edge X-ray Absorption Spectroscopy (XAS) has emerged as a powerful tool to unravel the complex sulfur redox chemistry in lithium-sulfur (Li-S) batteries. Li-S batteries are promosing as a compelling alternative to conventional lithium-ion batteries due to their exceptional theoretical energy density. However, their practical implementation faces challenges related to capacity fading, limited cycle life, and complex sulfur redox chemistry. *Operando* XAS plays a crucial role in understanding and addressing the above-mentioned challenges.

In this abstract, we first explore the application of *operando* sulfur K-edge XAS to gain real-time insights into the sulfur redox chemistry occurring at the sulfur cathode during Li-S battery operation. Using *operando* sulfur K-edge XAS, we revealed the dynamics of intermediate polysulfide species and the sulfur electrochemical conversion. Furthermore, the result guides us to design the multi-metal interaction with polysulfides. Li-S battery performance significantly enhanced by incorporating multi-metal to accelerate the Li-S reaction kinetics.

Then, we designed the cross-sectional Li-S battery cell to quantify polysulfide diffusion rate using sulfur K-edge X-ray spectromicroscopy. We found that elemental sulfur discharged to higher-order polysulfide species (Li_2S_8 and Li_2S_6) on the cathode and quickly diffused to the entire separator. This polysulfide diffusion resulted in the majority capacity decay in Li-S batteries.

In summary, we highlight the crucial role of *operando* XAS and X-ray spectromicroscopy as a transformative tool to overcome the fundamental challenges in Li-S batteries. Our study offers the potential for high-energy-density and sustainable energy storage solutions.

10:30 AM *ES03.01.01
Lithium Penetration through Solid Electrolyte Porosity and The Effect of a Ag-C Buffer Layer Gerbrand Ceder; University of California, Berkeley/Lawrence Berkeley National Laboratory, United States

Growth of lithium through connected porosity is one of the ways that Lithium filaments can penetrate through the solid electrolyte. By performing experiments on electrolyte pellets with controlled porosity we show that the relation between time to short-circuit and porosity is highly non-linear. I will also discuss the mechanism by which buffer layers, and in particularly a Ag-C buffer layer can lead to highly efficient and uniform Li plating. By combining continuum + ab-initio modeling we can understand how Ag nanoparticles regulate the Li nucleation and growth. The understanding from this work also enables a rational selection of which other metals may or may not work.

11:00 AM *ES03.01.02
Materials Design for Super-Ionic Conductors for Solid State Li, Na, and Li-S Batteries Z. Lu, Y. Yu, Y. Wang, B Singh and Linda F. Nazar; University of Waterloo, Canada

All-solid state Li-ion and Li-S batteries (ASSBs) have emerged as very attractive alternatives to conventional liquid electrolyte cells for e-mobility, owing to their enhanced safety and higher energy densities. Similarly, low-cost solid state Na-ion batteries may prove an promising alternative for stationary applications.
ASSBs are founded on high performance fast-ion conducting electrolytes, and in the important search for new materials, alkali thiophosphates (sulfides) and (oxy)halides are particularly promising classes of materials owing to their excellent mechanical properties. Sulfide-based solid catholytes are especially promising materials for high-performance solid-state sulfur cells that operate on the reversible conversion of S ↔ Li2S. However, their electrochemical decomposition above 2.5 V vs Li+/Li causes progressive degradation in the operating window of the cell, because the free S2- ions are oxidized to sulfur at a similar potential as Li2S. Oxyhalides show particular advantage owing to their good interface stability with high voltage NMC-type cathodes.
The talk will cover an overview of the state-of-the art in the field, followed by a focus on recent findings in our laboratory and the understanding of superionic conductivity in these materials using a combination of structural elucidation via single crystal X-ray/powder neutron diffraction, ion conductivity mechanisms, and *ab initio* molecular dynamics simulations. We correlate crystal structure with ionic conductivity in a range of our newly developed fast ion Li and Na conductors. These considerations lead to an overarching understanding of the relative importance of interstitial alkali ion migration, defect concentration, and the factors that govern thermodynamic (meta)stability. The talk will also highlight their application in solid state batteries and factors that govern the cathode-electrolyte interface.

11:30 AM *ES03.01.03
Crystal Chemistry of Argyrodites and A_3PS_4-Type Solid Electrolytes (A=Li, Na) for Batteries Christian Masquelier[1], Ulas Omer Kudu[1], Dhanush Y. Shanbhag[1], Duy Linh Pham[1], Theodosios Famprikis[1], Jean-Noël Chotard[1], Virginie Viallet[1], Elodie Salager[2], Pieremanuele Canepa[3], Saïful Islam[4], Marc-David Braida[5], Thierry Le Mercier[5] and Florencia Marchini[6]; [1]Université de Picardie Jules Verne, France; [2]Université d'Orléans, France; [3]National University of Singapore, Singapore; [4]University of Bath, United Kingdom; [5]Solvay R & I, France; [6]Umicore, Belgium

Solid electrolytes are crucial for next-generation solid-state batteries and immense activity is going on worldwide on many structural families of interest, including the ionic conductors Na_3PS_4, Li_3PS_4, Li_4PS_4I and Argyrodite $Li_6PS_5(Cl,Br,I)$. We will present our recent crystal chemistry findings on these materials.

Li_3PS_4 is an attractive solid-electrolyte material that possesses high RT ionic conductivity (10^{-4} S.cm^{-1}) but the effects of specific synthesis parameters on the material's local structure and transport properties still demand clarifications. In particular, mechano-chemistry induces the formation of a variety of $P_xS_y^{a-}$ moieties that strongly influence the global transport properties of Li_3PS_4.

Na_3PS_4 is another very interesting material with complex crystal chemistry that we will present. The effects of mechanochemical synthesis that lead to increased ionic conductivity in an archetypical sodium ion conductor Na_3PS_4 were not fully understood and we undertook comprehensive analysis based on diffraction (Bragg and pair distribution function), spectroscopy (impedance, Raman, NMR and INS), and ab initio simulations.

1:30 PM *ES03.02.01
Exploring The Mechanism and Mitigation of Lithium Dendrites in Solid-State Batteries Dominic L. Melvin[1], Ziyang Ning[1], Dominic Spencer-Jolly[1], Guanchen Li[2], T. James Marrow[1], Charles Monroe[1], Peter Bruce[1] and Dominic Melvin[1]; [1]University of Oxford, United Kingdom; [2]University of Glasgow, United Kingdom

Solid-state batteries based on a ceramic electrolyte and lithium metal anode promise to revolutionise battery safety and energy density, but charging these batteries at practical current densities while avoiding dendrites remains a barrier to progress. Dendrites (filaments of lithium) penetrate the ceramic, resulting in short-circuit and cell failure. Important efforts have been made to understand dendrites in ceramic electrolytes and to mitigate them.
In recent work, we used *operando* X-ray computed tomography (XCT) to image a lithium anode solid-state cell during the charging process to understand the formation and progression of lithium dendrites through the solid electrolyte. Dendrites are found to follow a two-stage process of initiation then propagation, with different mechanisms for each. Initiation occurs in sub-surface pores where pressure builds to exceed the local fracture strength at the grain boundaries, by the mechanism of slow lithium extrusion. Propagation involves dry cracks, with Li driving the crack forward from the rear by a wedge-opening mechanism, rather than lithium at the crack tip, as has often been assumed previously. Reducing pressure at the lithium/solid electrolyte interface from 7 MPa to atmospheric pressure can significantly extend cycle life before cell failure.
Informed by the description of dendrite cracks, we control the microstructure of an Argyrodite (Li_6PS_5Cl) solid electrolyte and examine the impact of different microstructures, including pore size and distribution, crack length and width, on the dendrites. These studies consider how microstructure influences critical current densities for dendrite growth.

Electrodeposition and Dissolution of *In Situ* formed Lithium and Sodium Metal Electrodes Jeff Sakamoto; University of California, Santa Barbara,

United States

Solid-state batteries consisting of lithium or sodium metal electrodes made using the anode-free manufacturing process are garnering significant interest. Anode-free manufacturing eliminates the need to handle and prevent oxidation and produces pure metal electrodes. However, little is known about the properties and mechano electrochemical behavior of these metal electrodes. Collaborative research conducted within the Department of Energy, Energy Frontier Research Center (Mechano-chemical Understanding of Solid Ion Conductors (MUSIC)) is exploring methods to characterize the behavior and properties of electrodeposited and electro dissolved lithium and sodium. Two model solid electrolyte systems were selected for this research based on their high conductivity and stability against their respective metal electrodes; LLZO for lithium and NaSICON for sodium. The results of this work will deepen the fundamental understanding of *in situ* formed lithium and sodium and advance commercialization of viable solid-state battery technology.

Fast and Cooperative Ion Transport in Polymer Based Materials Valentino R. Cooper and Catalin Gainaru; Oak Ridge National Laboratory, United States

A major bottleneck limiting the advancement of energy storage and conversion technologies is the development of multifunctional, selective, and highly conductive membranes and solid electrolytes. State-of-the-art batteries rely on liquid electrolytes that exhibit low ion selectivity, poor electrochemical and thermal stability, and are plagued by potential safety hazards associated with dendrite formation, high volatility, and flammability. Similarly, polymer membranes in flow batteries and fuel cells have not achieved the necessary conductivity and selectivity for fast ion transport and suffer from water management issues that restrict operating temperatures due to the need for water (i.e., hydrogen bonding networks) to transport protons. In this presentation, I will discuss progress in the Energy Frontier Research Center on Fast and Cooperative Ion Transport in Polymer-Based Materials (EFRC FaCT) to understand and control fast, correlated ion and proton transport at multiple length and time scales. In particular, I will highlight two recent outcomes: (i) examining the mechanisms controlling the energy barriers for ion hopping in polymer electrolytes and (ii) the design of nanorod-composite systems exhibiting fast ion conductivity. These showcase the synergistic research across the center and the potential for the discovery and design of novel, fast ion conducting polymer electrolytes for next generation storage devices.
This work was supported as part of the Fast and Cooperative Ion Transport in Polymer-Based Materials (FaCT), Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences at Oak Ridge National Laboratory.

Interface Potentials inside Solid-State Batteries: Origins and Implications Yue Qi[1], Michael Swift[2], Elliot J. Fuller[3] and Alec Talin[3]; [1]Brown University, United States; [2]U.S. Naval Research Laboratory, United States; [3]Sandia National Laboratories, United States

Interface resistance has become a significant bottleneck for solid-state batteries (SSBs). Most studies of interface resistance have focused on extrinsic mechanisms such as interface reactions and imperfect contact between electrodes and solid electrolytes. Interface potentials are an important intrinsic mechanism that is often ignored. Here, we highlight Kelvin probe force microscopy (KPFM) as a tool to image the local potential at interfaces inside solid-state batteries, examining the existing literature and discussing challenges in interpretation. Drawing analogies with electron transport in metal/semiconductor interfaces, we showcase a formalism that predicts intrinsic ionic resistance based on the properties of the contacting phases, and we emphasize that future battery designs should start from material pairs with low intrinsic resistance. We conclude by outlining future directions in the study of interface potentials through both theory and experiment.

4:00 PM *ES03.02.05
Understanding Fundamental Mechanisms of Materials and Interfaces in Solid-State Batteries through Atomistic Simulations Yifei Mo; University of Maryland, United States

The improvements of solid-state batteries are limited by the performances of the materials and their interfaces. We will present our recent atomistic simulation studies on the fundamental mechanisms underlying these critical materials and interfaces, in particular, what are the fundamental kinetic limitations in ion-conducting materials and solid-solid interfaces at the atomistic level. Through our atomistic level understanding, we will propose strategies for designing better materials and interfaces with faster kinetics.

4:30 PM *ES03.02.06
Constriction Susceptibility of Anode Materials in Solid State Batteries Xin Li; Harvard University, United States

This talk introduces a new concept of cconstriction susceptibility of anode materials found in all-solid-state batteries. X-ray diffraction, transmission electron microscpy, scanning electron microscopy, and elelemntal analysis techniques were used to characterize the structural and chemical details of the anode. Density functional theory simulation and high-throughput computation were used to analyze the constriction suscepibility of materials at anode, which helps categorize and design new anode materials. A proper utilization of the phenomenon can lead to fast plating and stripping of Li metal in the anode at high areal capacity in experiment. A pouch cell made by slurry-casting technique was used to demonstrate the stable and fast cycling capability of such anode design.

SESSION ES03.03: Poster Session
Session Chairs: Howard Qingsong Tu and Yan Yao
Tuesday Afternoon, April 23, 2024
Flex Hall C, Level 2, Summit

5:00 PM ES03.03.01
Formation of Intimate Interfacial Contact between The NCM and Li_6PS_5Cl Solid Electrolyte for All-Solid-State Batteries Jaeik Kim, Seungwoo Lee, Hyungjun Lee, Joonhyeok Park, Jiwoon Kim, Gunwoo Cha, Hongjun Park, Bobae Lee, Ungyu Paik and Taeseup Song; Hanyang University, Korea (the Republic of)

All-solid-state batteries (ASSBs) with sulfide-based solid electrolytes (SEs) have been considered the most promising next-generation energy storage

system due to their high energy density. However, mechanical instability such as initial insufficient physical contact and physical contact loss during cycling at the cathode active materials/solid electrolyte interface impede the practical use of ASSBs. Here, we report high-performance ASSBs using a Ni-rich NCM as cathode active materials coated with argyrodite-type sulfide solid electrolyte through the mechano-fusion method. The uniformly coated solid electrolyte layer guarantees solid physical contact between cathode active materials and solid electrolytes, enabling sufficient ion transport pathways. Furthermore, the firmly attached solid electrolyte does not detach from NCM when the cathode active material shrinks during de-lithiation. Making intimate initial physical contact and maintaining physical contact repress the interface resistance effectively. As a result, a full cell with argyrodite-coated NCM shows significantly enhanced electrochemical performances.

5:00 PM ES03.03.02
Multifunctional Covalent Organic Framework Solid Electrolyte Facilitating Fast Li-Ion Diffusion in Solid-State Batteries Jun-Hyeong Lee, Jaewoo Lee, Yoonhee So, Hong-Won Kim, Yujin Choi and Jong-Ho Kim; Hanyang University, Korea (the Republic of)

Ensuring the safety, high energy density, and long-term cycling performance of all-solid-state Li metal batteries (LMBs) requires the development of compatible organic solid electrolytes. However, it remains a challenge to develop an approach that enables organic solid electrolytes to easily dissociate strong Li-ion pairs and facilitate rapid Li-ion transport. In this study, a diethylene glycol-modified pyridinium covalent organic framework (DEG-PMCOF) with a well-defined periodic structure is prepared as a multifunctional solid electrolyte with a cationic moiety of high polarity, an additional flexible ion-transporter, and an ordered ionic channel for all-solid-state LMBs. The DEG-containing pyridinium groups within DEG-PMCOF lower the dissociation energy of Li salts as well as the energy barrier for Li-ion transport, resulting in an enhanced ion conductivity and a high Li-ion transfer number at room temperature in the solid electrolyte. Furthermore, the DEG-PMCOF solid electrolyte offers a wide electrochemical stability and effectively prevents the formation of Li dendrites and dead Li in all-solid-state LMBs. Molecular dynamics and density functional theory simulations provide insights into the mechanisms underlying the improved Li-ion transport in DEG-PMCOF, involving integrated diffusion processes such as hopping motion, vehicle motion, and free diffusion. The all-solid-state LMB constructed with a DEG-PMCOF solid electrolyte exhibits a high specific capacity, excellent retention, and outstanding Coulombic efficiency at various C-rates during long-term cycling. This DEG-PMCOF approach represents an effective strategy for designing a variety of solid-state Li batteries.

5:00 PM ES03.03.03
Enhancing Lithium Transport in Garnet-Type Solid Electrolyte for High-Performance All-Solid-State Batteries Young-Geun Lee and Jay Whitacre; Carnegie Mellon University, United States

Garnet-type $Li_{6.4}La_3Zr_{1.4}Ta_{0.6}O_{12}$ (LLZTO) is a promising solid-state-electrolyte for all-solid-state batteries; it has a good chemical stability in contact with Li metal and high ionic conductivity. However, insufficient interfacial contact and associated voids caused by poor wetting between Li metal and LLZTO can lead to a huge interface resistance and thus poor electrochemical performance including a high overpotential and limited critical current density (CCD). In addition, Li dendrites can be formed and will propagate through the LLZTO microstructure within the pores and grain boundaries, which can cause cell short circuiting. In this work, $LiAlO_2$ (LAO) was used as a sintering additive to improve a LLZTO microstructure with a denser structure, lower porosity, and compacted grain boundary regions. LLZTO with LAO (LLZTO-LAO) showed a higher relative density (~95%) and reduced porosity (~4.2%) compared to pure LLZTO (88% of relative density and 9.5% porosity). To calculate the ionic conductivity and activation energy of the LLZTO, a blocking electrode sputtered by gold on both side LLZTO was fabricated. LLZTO-LAO displays an improved ionic-conductivity (0.59 S cm^{-1}) and Li-ion activation energy (0.38 eV). In order to investigate interface resistances between LLZTO-LAO and Li metal, Li-Li symmetric electrochemical test cells were used. An enhanced interfacial resistance (72.5 Ω cm^2) was demonstrated for the LLZTO-LAO cell.
Li plating/stripping tests with critical current density (CCD) and cycling performance of Li symmetric cells were investigated by galvanostatic cycling experiment. While LLZTO delivers a lower CCD of 0.1 mA cm^{-2}, a higher CCD of 0.3 mA cm^{-2} is demonstrated within the symmetric cell with LLZTO-LAO. In addition, LLZTO-LAO showed lower overpotentials than LLZTO at the various current densities. The improved CCD and overpotential of LLZTO-LAO can be attributed to LAO additives that cause an improved microstructure with a reduced porosity resulting in a good interfacial contact between electrolyte and Li metal.

5:00 PM ES03.03.04
The Effect of Slurry pH Values on The Electrochemical Properties of Manganese-Based-Oxide Electrode for Solid-State Batteries Tzu-Hao Kuo, I-Han Lee, Chia-Chien Ma and Tri-Rung Yew; National Tsing Hua University, Taiwan

With the rapid growth of electric vehicles, their conventional lithium-ion batteries (LIBs) are suffered from insufficient energy density and potential safety risks. High-capacity, earth- abundance, and low-flammability make manganese oxides a promising active material for anodes. Furthermore, the pH value of solid-state batteries (SSBs) influences lithiation and delithiation reactions, which in turn impacts the lithium wettability and interface resistance of SSBs. It is critical to study the effect of pH range so as to optimize the active materials and binders in manganese-based-oxide anodes.

In this work, the different pH values of electrode slurries will be investigated to improve the stability of binders and active materials. Furthermore, the pH value will be optimized to inhibit the unnecessary irreversible reactions during charge and discharge. It is expected that the optimized pH value of electrode slurries will enhance the retention, Coulombic efficiency, and rate-capability of the manganese-based-oxide anode in SSBs.

For the optimization of the pH value for manganese-based-oxide electrode slurries, water-based slurries will be produced by mixing manganese oxide powders, carbon black (super P), carboxymethyl cellulose (CMC), and styrene-butadiene rubber (SBR). The pH value of slurries will be adjusted with an oxalic acid. After that, the premixed slurries will be coated on copper foils by using a doctor blade, and then baked in a vacuum oven. After battery assembly, the electrochemical impedance spectroscopy (EIS) and galvanostatic charge-discharge (GCD) analyses will be applied to analyze the Coulombic efficiency, cycling life, and impedance variation resulted from different pH values. The composition and structure of active materials will be characterized by field-emission scanning electron microscopy (FE-SEM), energy-dispersive X-ray spectroscopy (EDX), and X-ray diffraction (XRD). This work will shed a light on controlling the pH value of manganese-based-oxide electrode slurries, for the improvement of SSB retention.

5:00 PM ES03.03.05
Zwitterionic Covalent Organic Framework Solid Electrolyte with Ordered Ionic Channels for All-Solid-State Lithium-Metal Batteries Jaewoo Lee, Jun-Hyeong Lee, Jae-Hoon Shin, Yoonhee So, Yejoo Yu, Yujin Choi, Hong-Won Kim and Jong-Ho Kim; Hanyang University, Korea (the Republic of)

Organic solid electrolytes are considered a promising way to enhance the energy density of Li rechargeable batteries. However, practical applications of organic solid electrolytes have suffered from extremely low ionic conductivity at room-temperature due to strong ion pairs of Li salts and lack of ordered ionic channels for Li+ diffusion. Covalent organic frameworks (COFs) with well-defined chemical and pore structures can be considered excellent candidates for solid electrolytes due to their uniform channels for the migration of ionic species. Herein, the zwitterionic covalent organic framework

(Zwitt-COF) was developed as a solid electrolyte with not only the superior ability to dissociate strong Li-ion pairs but also well-organized ionic channels for fast Li+ diffusion. Theoretical simulations revealed that zwitterion can effectively dissociate the strong Li-ion pairs, and the linear hexagonal ion channels can be reopened in the Zwitt-COF solid electrolyte by reconstructing AA stacking structures due to the dissociative adsorption of Li+ on Zwitt-COF. The Zwitt-COF electrolyte exhibited high ionic conductivity at room-temperature and stable Li plating/stripping performance without formation of Li dendrite and dead Li. Furthermore, the Zwitt-COF electrolyte displayed a wide electrochemical stability window and outstanding thermal stability. All-solid-state Li metal full cells prepared with a Zwitt-COF electrolyte exhibited excellent cyclic performance for a long duration with high retention of discharge capacity. The strategy for incorporating zwitterions into a COF structure can provide an effective way to develop various all-solid-state batteries.

5:00 PM ES03.03.06
Development of Solid Polymer Electrolyte with Excellent Electrochemical Properties Using High-Energy Electron Beam Irradiation Wookil Chae and Taeshik Earmme; Hongik University, Korea (the Republic of)

Lithium-ion batteries (LIBs), an energy storage system used in various fields such as electronic devices, electric vehicles, and unmanned aerial vehicles, consist of a cathode, anode, separator, and electrolyte. Currently, commercialized LIBs employ a liquid electrolyte that utilizes carbonate-based organic solvents. When an exothermal reaction is triggered by overcharge or external shock, the thermally unstable organic solvent can generate flammable gases and lead to ignition, ultimately causing a thermal runaway in LIBs. Due to the safety concerns associated with organic solvent-based liquid electrolytes, research has been conducted on solid electrolytes (SEs) as an alternative to liquid electrolytes (LEs).
Among various SEs, polymer electrolytes (PEs) have garnered attention for their advantageous interfacial properties, form factor, and processability. In this study, the fabrication method for PEs involves *in-situ* polymerization. PEs created through *in-situ* polymerization are prepared by injecting a liquid precursor comprising monomers, lithium salt, initiators, and other components into the cell. Typically, thermal initiation is employed as the primary method for PE fabrication. However, thermal initiation comes with drawbacks, including challenges in controlling precursor reactions and the requirement for extended heat treatments.
To address these issues, solid polymer electrolytes (SPEs) are prepared using high-energy electron beam irradiation. SPEs are produced with just tens of seconds of electron beam exposure. Optimized SPEs exhibit an average ionic conductivity of 0.54 mS cm^{-1}, a lithium transfer number (t_{Li+}) of 0.69, a wide electrochemical window exceeding 5 V, and excellent properties in suppressing the growth of lithium dendrites. Furthermore, in the NCM811‖SPEs‖Li cell configuration, a discharge capacity of 183 mAh g^{-1} (0.1 C, 25 °C) was achieved, with 80% capacity retention after 200 charge/discharge cycles at 0.5 C and 25 °C.

5:00 PM ES03.03.07
Rational Design of Electrolyte and Interface for High-Performance and Safer Solid-State Li Batteries Donggun Kim, Baozhi Yu and Ying Chen; Deakin University, Australia

Solid-state Li metal batteries (SSLMB) gained increasing attention from researchers. Free of flammable organic liquid electrolytes by replacing solid-state electrolytes (SSE) greatly enhances battery safety, and employing Li metal anode possessing ultrahigh specific capacity and lowest redox potential delivers higher energy density than current state-of-art Li^+ ion batteries. However, the safety crisis still exists, due to the extremely high reactivity of Li metal and the uneven plating-stripping behavior of Li anode. Unwanted side reactions pulverize SSE and electrode-electrolyte interface. Dendritic Li deposition accumulates dead Li, penetrates SSE, and eventually invokes internal short-circuit. Moreover, incomplete solid-solid contact between SSE and electrode induces severe polarization during battery operation. The poor interfacial compatibility of SSE to Li metal, both (electro-)chemically and physically, hinders the practical application of SSLMB so far.
Here, we suggest some effective approaches to resolve interface issues in the SSLMB. Firstly, we prepared an artificial solid electrolyte interphase (SEI) layer using poly(vinyl alcohol) and hydroxyl-functionalized boron nitride nanosheets. The artificial SEI alleviates the side reaction between Li metal and electrolyte, which mitigates electrolyte degradation. We found that this artificial SEI also assists uniform Li plating-stripping and suppresses dendritic Li deposition, by boosting Li^+ ion transport at the electrode-electrolyte interface.
Secondly, we designed multi-layered SSE with inorganic-gel hybrid SSE and *in-situ* prepared SSE. The inorganic-gel hybrid layer supports excellent mechanical stability and fast Li^+ ion conduction with a high Li^+ ion transference number. The *in-situ* prepared SSE greatly improves interfacial compatibility between SSE and Li metal anode. It provides intimate contact at the interface and prevents inorganic electrolyte decomposition in the hybrid. Moreover, by comparing different layered SSEs, we found that the bulk electrolyte layer assists cycling stability, while the interfacial layer dictates the practical current density of layered SSE. When this multi-layered SSE is applied in the Li-S full cell, the layered SSE only allows polysulfide dissolution in the *in-situ* SSE layer and halts its further diffusion into the bulk electrolyte.

5:00 PM ES03.03.08
Covalent Organic Framework Based Solid State Electrolytes Chaoqun Niu; Westlake EDU, China

The development of high-performance solid-state electrolytes is a key milestone in advancing the safety, performance, and energy density of energy storage technologies, particularly in lithium-ion batteries. Covalent Organic Frameworks (COFs), with their unique structural tunability, high thermal and chemical stability, and inherent porosity, have emerged as a promising candidate for solid-state electrolytes. Our work explores cutting-edge research in the design, synthesis, and characterization of COF-based solid-state electrolytes and their transformative potential in the realm of energy storage.
We will discuss the rational design of COFs tailored for solid-state electrolyte applications, focusing on factors such as framework stability, and ion conductivity. By judiciously modifying COF structures, we can enhance their ion transport properties, leading to improved ionic conductivity and electrochemical stability. These studies shed light on the mechanisms of ion transport, electrochemical stability, and long-term performance of COF-based electrolytes.
In conclusion, this research represents a significant advancement in COF-based solid-state electrolyte development, offering solutions to the pressing challenges in energy storage technology. We anticipate that the insights and breakthroughs presented here will pave the way for the practical implementation of COF-based solid-state electrolytes, fostering discussions and collaborations within the materials science community, and catalyzing the transformation of energy storage technologies toward a safer and more efficient future.

5:00 PM ES03.03.09
Development of an All-Solid State Li-Ion System Djamel Mourzagh; CEA - LITEN - Grenoble Alpes, France

Li-ion batteries are considered as the most suitable electrochemical energy storage systems for a wide range of applications including automotive applications in order to contribute to the reduction of CO_2 emissions responsible for climate change.
In recent years, the majority of the works on batteries has consisted in developing solid electrolytes with the goal to improve their safety and the possibility of using a negative electrode based on metallic lithium which will ultimately make it possible to achieve high energy densities.
CEA-Liten and Saft have jointly developed a solid-state polymer electrolyte system. The polymer PTMC (Poly trimethylene carbonate) has been selected for its high transport number, over 0.7, and its stability with respect to lithium both at high potential and at low potential despite its modest conductivity.
The Solid Polymer Electrolytes (SPE) realized is a crosslinked membrane based on PTMC, with good mechanical properties that allow an easy handling and integration into a complete system (Fig 1).
The electrodes containing PTMC and NMC622, Graphite or SiOx as active material were manufactured with a surface capacities around 1mAh/cm^2. Their mechanical properties are similar to conventional Li-ion electrodes.
Solid-state prototypes with a capacity around ten milliampere-hours have been assembled with these components. The performances of the all-solid prototypes containing PTMC are encouraging. Indeed, they operate correctly at a C/20 rate at 80°C but also at room temperature with the addition of plasticizers.

5:00 PM ES03.03.10
Development and Characterization of Flexible PVDF-TrFE-Ti3C2 MXene-Based Composite Co-Polymer Solid Electrolytes: Towards Application in Solid-State Li-Ion Batteries Harshkumar Bhatt[1], Derek Xiong[1], Armando Correa[1], Prakhyat Gautam[1], Parshwa Khane[1], David Ryman[1], Saquib Ahmed[2,2] and Sankha Banerjee[1,3]; [1]California State University, Fresno, United States; [2]Buffalo State College, United States; [3]University of California, Davis, United States

Efficient energy storage systems are essential for renewable energy sources. While lithium-ion batteries are prominent in this regard, there are ongoing challenges related to safety and cycling stability. These issues can be addressed by adopting solid polymer electrolytes (SPE) as an alternative to the conventional separator/electrolyte setup. One of the issues with developing solid-state batteries is the development of functional materials and materials systems that have a combination of thermal stability, tunable surface chemistry, and charge carrier mobility characteristics. MXene and its composites have presented a fascinating opportunity in the realm of functional materials. This is due to their unique layered structures that exhibit several advantageous characteristics, such as higher electrical and thermal conductivity, increased charge carrier mobility, a high negative zeta-potential, strong mechanical properties, a tunable bandgap, excellent hydrophilicity, metallic properties, and rich surface chemistry. However, when considering applications in electrochemical energy storage, an inherent issue is the tendency for agglomeration and restacking of MXene nanosheets and nanoflakes that significantly hamper the accessibility of active surface sites for electrolyte ions. The following work involves the fabrication and characterization of PVDF-TrFE-Ti3C2 MXene-based co-polymer composite solid-state electrolytes. The microstructure of these composites will be studied using scanning electron micrographs. The dielectric and impedance characteristics will be tested using electrical impedance spectroscopy. The ionic conductivity characteristics will be categorized using electrochemical impedance spectroscopy.

5:00 PM ES03.03.11
Recent Advancements and Prospects Of Lithium-Ion Batteries: Smart Features, High Performance Anode, Cathode and Electrolyte Materials Shahria Ahmed, S M Anyet Ullah Shohag, Md Wasikur Rahman and Jasim Uddin; The University of Texas, United States

Nowadays, lithium-ion rechargeable batteries (LiBs) are the predominant source for energy storage and have promising prospects in the future. Monitoring the health status of the LiBs has become a pressing need to prolong the life and increase the security of LiB-powered applications. This need has opened new possibilities for smart LiBs research, enhancing battery life and safety. Herein, the scheme of sensors for Li-ion smart batteries has been discussed, which use a straightforward beam structure towards the measurement of different parameters, for instance, force, temperature, and displacement. Besides, we have discussed the most recent high-performance anode, cathode, and electrolyte materials used for and the modification of the materials by using different techniques to make them suitable for high-energy density Li-ion batteries. Finally, it has been concluded with promising future outlooks of the LiBs research by using these high-performance materials.

5:00 PM ES03.03.12
Enhancing Sodium Ionic Conduction of β"-Alumina-YSZ Composite Electrolytes by Controlling The Surface Composition Anisa R. Nurohmah[1], Yebin Cho[1], Junyeong Jeon[1], Keeyoung Jung[2] and Younki Lee[1]; [1]Gyeongsang National University, Korea (the Republic of); [2]Research Institute of Industrial Science and Technology (RIST), Korea (the Republic of)

β″-alumina, a sodium aluminate with the non-stoichiometric formula of $Na_2O.(5\text{-}7)\ Al_2O_3$, has received considerable interest as a solid electrolyte in sodium batteries due to its high sodium ionic conductivity and remarkable thermal stability using inexpensive elements. Recently, a vapor-phase conversion process based on the reaction between Na_2O vapor and α-alumina has been reported, which allows for thinning and strengthening of β″-alumina solid electrolytes (BASEs). The new process requires a composite with approximately 30 vol.% of yttria-stabilized zirconia (YSZ) to achieve O^{2-} diffusion during the entire α-to-β″ phase conversion. Nonetheless, the incorporation of YSZ, an O^{2-} conductor, reduces the Na^+ transport pathway, so that a decrease in ionic conductance across the electrolyte is inevitable.
This study focuses on the effect of the proportion of β″-alumina near the surface region of the composite electrolyte on the conductance. The lamination of α-alumina – 30 vol.% YSZ green tapes was used for the fabrication of BASEs, and the α-alumina content of both two outermost tapes was varied in 90 to 40 vol.% to create “core-shell” structure. Although the outermost layers, known as the “shell”, comprises only about 10% of the total thickness, the electrolyte with the surface incorporating more than 90 vol.% of β″-alumina demonstrates 13.4 mS cm^{-1}, measured by blocking electrode method at 190°C; This value exhibits more than 20% increase as compared to the conventional electrolyte without the shells. When used with the symmetrical molten sodium electrodes at the same temperature, the novel electrolyte demonstrates 2.55 Ω cm^{-2} of area-specific resistance; Additionally, this value represents a 28% reduction from the value of the conventional composite electrolyte without the shells. This finding suggests that adjustments to the composition of the surface region alone could considerably enhance ionic transport through the vapor-phase converted β″-alumina-YSZ composites by expanding the conducting channels.

5:00 PM ES03.03.13
Investigation of Mechanical Characteristics of Catholytes in Composite Cathode of All Solid-State Batteries Joseph M. Vazquez and Howard Qingsong Tu; Rochester Institute of Technology, United States

All-solid-state batteries (ASSBs) are leading the path to safer and more efficient energy storage. The solid electrolyte is a critical component in determining the performance and stability of ASSBs, responsible for both ion transfer and resisting dendrite growth. A robust solid electrolyte that excels in these

functions is essential for advancing ASSB technology. Existing solid electrolytes face challenges like poor interfacial contact, mechanical debonding, and mechanical failure. While the field predominantly focuses on ion transfer and micro-scale mechanical properties, there is a noticeable gap in understanding macro-scale mechanics. This study addresses this gap by examining prevalent solid electrolytes, including Li_6PS_5Cl, Li_3YCl_6, $Li_3YBr_3Cl_3$, and $Li_7La_3Zr_2O_{12}$. Through traditional compression testing supported by video analysis, we reveal the correlations between pellet density and slenderness with elasticity, strength, and toughness across sulfide, halide, and oxide solid electrolyte materials. Our findings underscore the macro-scale mechanical advantages of LPSCl, exhibiting a relatively large elastic range (5–83 MPa), high compressive strength (~103 MPa), significant toughness (~16 MPa), and semi-ductile nature. The notable differences in elastic, non-linear, and failure mechanics among solid electrolytes emphasize the relevance of macro-scale mechanical properties in predicting cell failures such as capacity fading, dendrite growth, and contact loss.

5:00 PM ES03.03.14
Long-Durable Three-Dimensional Garnet-Type $Li_{6.4}La_{1.4}Zr_{1.4}Ta_{0.6}O_{12}$ Solid-State Li-Metal Batteries Sung Ryul Choi, Seojeong Yoo and Jun-Young Park; Sejong University, Korea (the Republic of)

Lithium-metal (Li-metal) holds promise as an anode material for next-generation high-energy density lithium-ion batteries (LIBs) due to its exceptional theoretical capacity of up to 3860 $mAhg^{-1}$ [1]. However, technical challenges are remained, notably concerning safety due to dendrite formation during charge-discharge cycles [2]. Even in conventional aqueous-LIBs, preventing the penetration of Li dendrites remains unresolved despite extensive efforts [3]. To address this challenge, solid-state electrolytes (SSEs) have emerged as promising alternatives due to their high ionic conductivity, stability against Li-metal, and wide electrochemical windows [4]. SSEs encompass various categories such as polymer electrolytes, inorganic sulfide electrolytes, and inorganic oxide electrolytes [5]. Among these, the garnet-type $Li_{6.4}La_{1.4}Zr_{1.4}Ta_{0.6}O_{12}$ (LLZTO) stands out for its excellent ionic conductivity, ranging from 10^{-4} to 10^{-3} Scm^{-1}, and its thermodynamic stability against Li-metal [6, 7]. However, the formation of Li dendrites persists even at low current densities, primarily due to the inhomogeneity between Li-metal and the LLZTO electrolyte, particularly poor Li-metal wettability on the LLZTO electrolyte [8, 9]. Efforts to address the lithiophobic nature of LLZTO electrolytes have involved surface polishing, which enhances lithium wettability [10-12]. Another approach for improving Li-metal wettability is the introduction of nanometer-scale metal/metal oxide interlayers at the Li-metal– LLZTO interface [13, 14]. However, these strategies have not completely prevented dendrite formation, evident from low critical current density (CCD) results [15]. In our study, we present a three-dimensional (3D) tri-layer structure created *via* the tape-casting technique. This structure comprises porous-dense-porous regions. The porous layer plays a crucial role in enhancing the heterogeneity of the interface between the Li-metal anode and LLZTO electrolyte, facilitating Li-metal wetting and infiltration into the pores. Additionally, the dense morphology acts as a protective layer, impeding Li dendrite penetration, as dendrites tend to propagate along porous regions and grain boundaries of the LLZTO electrolyte. This architecture resulted in stable Li-metal cycling at high current density and improved critical current density performance.

Keywords: Lithium-ion batteries, $Li_{6.4}La_{1.4}Zr_{1.4}Ta_{0.6}O_{12}$, solid-state electrolyte, dendrite.

Converting Primary Alkaline Batteries to Rechargeable Solid-State Batteries via Single-Anion Conducting Polymer Electrolytes Eric G. Ruzicka, Hunter O. Ford, Brian Chaloux, Jeffrey Long, Debra R. Rolison and Megan B. Sassin; Naval Research Laboratory, United States

Demand for energy storage devices to supply society with its ever-increasing energy needs necessitates the development of portable power systems with enhanced energy efficiency, long cycle life, and improved safety. Lithium-ion batteries currently dominate the rechargeable battery market, but their reliance on expensive and non-US sourced active materials and flammable electrolytes leave the door open for researchers to develop rechargeable batteries based on alternative chemistries.
Here, we report on the synthesis and characterization of a polymeric hydroxide-conducting solid-state electrolyte (SSE) and demonstrate that this SSE facilitates rechargeability in alkaline Ag–Zn cells that are conventionally used as primary batteries. Utilizing a library of inhouse-synthesized styrenic monomers to generate custom SSEs, we found that the architecture of the polymer not only influences the stability of the SSE, but also the capacity and cycle life. Infrared (IR) and x-ray photoelectron spectroscopies (XPS) were utilized in conjunction with scanning electron microscopy (SEM) to assess the SSE and electrode chemistries before and after electrochemical cycling to evaluate for stability and active material-crossover. Combining electrochemistry (impedance spectroscopy, cyclic voltammetry, and galvanostatic cycling) with these results, we determined that crosslinking, chemistry of the quaternizing agent, and the electrode quality/geometry influence Ag–Zn cell performance.

5:00 PM ES03.03.16
Solid State Polymer Electrolyte for Lithium Ion Batteries Djamel Mourzagh, Lionel Picard and Thibaut Gutel; CEA - LITEN - UGA, France

Li-ion batteries are considered as the most suitable electrochemical energy storage systems for a wide range of applications including automotive applications in order to contribute to the reduction of CO_2 emissions responsible for climate change.
In recent years, the majority of the works on batteries has consisted in developing solid electrolytes with the goal to improve their safety and the possibility of using a negative electrode based on metallic lithium which will ultimately make it possible to achieve high energy densities.
CEA-Liten and Saft have jointly developed a solid-state polymer electrolyte system. The polymer PTMC (Poly trimethylene carbonate) has been selected for its high transport number, over 0.7, and its stability with respect to lithium both at high potential and at low potential despite its modest conductivity.

The Solid Polymer Electrolytes (SPE) realized is a crosslinked membrane based on PTMC, with good mechanical properties that allow an easy handling and integration into a complete system (Fig 1).
The electrodes containing PTMC and NMC622, Graphite or SiOx as active material were manufactured with a surface capacities around 1mAh/cm2. Their mechanical properties are similar to conventional Li-ion electrodes.
Solid-state prototypes with a capacity around ten milliampere-hours have been assembled with these components. The performances of the all-solid prototypes containing PTMC are encouraging. Indeed, they operate correctly at a C/20 rate at 80°C but also at room temperature with the addition of plasticizers.

SESSION ES03.04: Fabrication and Scale Up I
Session Chairs: Robert Sacci and Fengyu Shen
Wednesday Morning, April 24, 2024
Room 423, Level 4, Summit

8:15 AM ES03.04.01
Scale Up of The Synthesis and Processing of Halide-Based Solid Electrolytes for Li Metal Batteries Robert L. Sacci[1], Yan Yao[2], Liqun Guo[2], Teerth Brahmbhatt[1] and Jagjit Nanda[3]; [1]Oak Ridge National Lab, United States; [2]University of Houston, United States; [3]SLAC National Accelerator Laboratory, United States

Rare-earth alkali halides (REAHs) have been shown to have high ionic conductivity and are promising electrolytes for all solid state lithium batteries. Li3InCl6 and Li3YCl6 have been shown to adopt a layered structure with reported ionic conductvitys approaching 2 mS/cm2. A significant advantage these materials have over other solid electrolytes, such as garnets, is their low synthesis and processing cost. As an example, we will describe how Li3InCl6 and Li3YCl6 can be synthesized from concentrated aqueous solution through controlled dehydration. We probed the reactions by combining in situ neutron diffraction, thermogravimetry, differential scanning calorimetry, and *in situ* impedance spectroscopy. This presentation provides a pathway for the direct synthesis and processing of REAHs from concentrated aqueous solutions and we will discuss making thin membranes through dehydration and other casting methods.

The US Department of Energy's Energy Efficiency and Renewable Energy Vehicles Technologies Office provided funding for this work.

8:30 AM ES03.04.02
Unveiling The Mechanical and Electrochemical Evolution of Nano Silicon Composite Anodes in Sulfide based All-Solid-State Batteries Hongli Zhu; Northeastern University, United States

The utilization of silicon (Si) anodes in all-solid-state lithium batteries (ASLBs) provides the potential for high energy density. However, the compatibility of sulfide solid-state electrolytes (SEs) with Si and carbon is often questioned due to potential decomposition. To investigate this, operando X-ray absorption near-edge structure (XANES) spectroscopy, ex-situ scanning electron microscopy (SEM) and ex-situ X-ray nano-tomography (XnT) were utilized to study the chemistry and structure evolution of nano Si composite anodes. Results from XANES demonstrated a partial decomposition of SEs during the first lithiation stage, which was further accelerated by the presence of carbon. But the performance of first three cycles in Si-SE-C was stable, which proved the generated media is ionically conductive. XnT and SEM results showed that the addition of SEs and carbon improved the structural stability of the anode with fewer pores and voids. A chemo-elasto-plastic model revealed that SEs and carbon buffered the volume expansion of Si, thus enhancing mechanical stability. The balance between the pros and cons of SEs and carbon in enhancing reaction kinetics and structural stability enabled the Si composite anode to demonstrate the highest Si utilization with higher specific capacities and better rate than pure Si and Si composite anodes with only SEs.

8:45 AM *ES03.04.03
On The Journey toward Competent All Solid State Electrolytes Rana Mohtadi[1,2]; [1]Toyota Research Institute of North America, United States; [2]Tohoku University, Japan

Energy storage systems poised to offer improved performances beyond that afforded by Li-ion batteries are intensely being studied. Of these, all solid state batteries ASSBs promise to dramatically improve the energy storage densities and efficiencies by way of utilizing non-flammable solid state electrolytes SSEs that possess high compatibility with reactive anode and cathode materials, such as metallic anodes and high voltage cathodes. Unfortunately, all known families of SSEs fall short from fulfilling this demand and thus new SSE materials are required. We will herein discuss the status of these technologies and report critical SSEs advancements conducted in our group.

9:15 AM ES03.04.04
Fast Room-Temperature Mg-Ion Conduction in Clay-Like Solid Electrolytes Xiaochen Yang[1,2], Sunny Gupta[3], Yu Chen[2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Rice University, United States

The discovery of mechanically soft solid-state materials with fast Mg-ion conduction is crucial for the development of solid-state magnesium batteries. Herein, we report a novel solid magnesium electrolyte that achieve high ionic conductivity of 0.47 mS/cm at room temperature. These Mg-ion conductors exhibit clay-like mechanical properties, enabling intimate contact at the electrode–electrolyte interface during battery cycling. With a combination of experimental and computational analysis, we identify that the soft-clay formation is induced by partial anion exchange. This partial anion exchange creates undercoordinated magnesium ions, yielding fast Mg-ion conduction. Our work demonstrates the potential of clay-like halide electrolytes for all-solid-state magnesium batteries, with possible further extension to other multivalent battery systems.

9:30 AM ES03.04.05
Scale-Up of Halide-Based All-Solid-State Batteries Fengyu Shen[1], Michael McGahan[2], John D. Pietras[2], Marca M. Doeff[1], Vincent S. Battaglia[1] and Mike Tucker[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]SGR North America, United States

All-solid-state batteries (ASSBs) offer improved safety and potential higher energy density for energy storage. Among the components of ASSBs, the solid electrolyte plays an important role as it is the key component to prevent dendrite growth and forms interfaces with the cathode and anode. Halide solid electrolytes gain significant attention due to the high ionic conductivity, low processing temperature, good formability, oxygen resistivity and high-voltage

stability. Our previous study demonstrated the feasibility of scaling up halide electrolyte and halide-containing cathode by tape casting, using toluene as a solvent and MSB1-13 as a binder.[1] A low-voltage cathode ($LiFePO_4$) was used and cell performance was tested in button cell size with a 0.5 cm^2 area. In this study, pouch cells are manufactured, involving 80% cathode active material ($LiNi_{0.82}Mn_{0.07}Co_{0.11}O_2$) loading and Li/In alloy anode. A pouch cell is cycled under a lower stack pressure and results of long-term cycling will be reported. The interfacial resistance of pouch cells is higher than that of button cells with the same composition as the stack pressure for button cells is much higher (100 MPa). Cells with Li metal anode are also explored with an anode interlayer, cycling in a voltage window of 3-4.3 V, and the cell performance will be compared with that of the cells with Li/In alloy anode.

9:45 AM ES03.04.06
Robot-Assisted Sol-Gel Exploration of Cation-Disordered Rocksalt (DRX) Materials for Li-Ion Batteries Tim Kodalle[1], Yuxing Fei[1,2], Nathan Szymanski[1], Yan Zeng[1], Gerbrand Ceder[1,2] and Carolin M. Sutter-Fella[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Rechargeable Li-ion batteries are omnipresent in our daily lives and demand is increasing. To satisfy the tremendous growth, there is a great interest in developing novel high-performance electrode materials at reduced cost, and nickel and/or cobalt free.[1] In this regard, Li-excess cation-disordered rocksalt (DRX) metal oxides have been identified as promising cathode materials with energy densities that can exceed traditional layered cathodes such as $LiTMO_2$ with TM being a combination of transition metals.[1,2] Some drawbacks of these DRX materials include significant first-cycle capacity loss, limited cycle life, and voltage fade.[1] Several factors have been identified to mitigate these drawbacks, including greater disorder of the TMs as well as controlled particle size and shape.[3] Each of these characteristics can be manipulated by modifying the choice of precursors and synthesis techniques. Conventionally, solid-state synthesis is employed for the fabrication of electrochemically active materials including Li-ion batteries.[4] The typical sequence of synthesis steps includes mixing, grinding, pelletizing, and annealing. Such reactions are driven by solid-state diffusion, which is predominantly controlled by time and temperature.[4] In comparison, the sol-gel approach to synthesis mixes elements at the molecular level by dissolving precursors in a solvent (e.g. water) with the addition of chelating agents (e.g. citric acid) to form a viscous gel. This is followed by solvent evaporation, gel decomposition, and annealing to form powders or thin films.[4] In this study, we compare the nucleation and crystallization pathway of Li-Mn-Ti oxide (LMTO) deposited both by solid-state as well as sol-gel synthesis. Using automated, robot-assisted synthesis approaches, we systematically investigate the parameter space of both syntheses and the influence of precursors and precursor ratios on phase purity, final composition, oxidation states, reaction temperatures, and sample uniformity.
In the cathodes fabricated by solid-state synthesis, we find strong competition between two intermediate spinel-like phases, $LiTM_2O_4$ and Li_2TMO_3, depending on the oxidation state of the TMs as well as the Li-TM ratio in the selected precursors. While the intermediates forming in cathodes deposited via the sol-gel method appear to be less sensitive to these parameters, we find a strong dependency on the solvents and chelating agents used for fabrication. Additionally, we observe a strong interdependency between the choice of solvents and the ratio of Li:TMs influencing the reaction temperature of target phases and intermediates. Based on these findings, we will propose reaction pathways as well as a nucleation model for LMTOs prepared by sol-gel synthesis.

SESSION ES03.05: Conductivity and Transport I
Session Chairs: Pieremanuele Canepa and Richard Remsing
Wednesday Morning, April 24, 2024
Room 423, Level 4, Summit

10:30 AM *ES03.05.01
Chloride Solid Electrolytes: Structural Complexity, Ion Transport and Reactivity Raphaële Clement; University of California, Santa Barbara, United States

Chloride solid electrolytes have spurred significant research interest over the past few years due to their high ionic conductivities and good stability against high voltage cathodes. While their bulk conduction properties depend sensitively on synthesis conditions, these materials often constitute a challenge for characterization due to their ability to accommodate various polymorphic structures, cation disorder, as well as planar defects. In this talk, I will show how solid-state nuclear magnetic resonance (NMR), when combined with X-ray diffraction, computational simulations, and other complementary tools, provides detailed insights into the links between ion transport and the complex structural landscape of this relatively new class of ion conductors, as well as their reactivity against sulfide electrolytes for dual electrolyte solid-state batteries.

11:00 AM ES03.05.02
Electronic Paddle-Wheels Facilitate Transport in Solid-State Ionic Conductors Richard Remsing; Rutgers University, United States

Solid-state ionic conductors (SSICs) are promising alternatives to liquid electrolytes in energy storage technologies. The rational design of SSICs and ultimately their deployment in battery technologies requires a thorough understanding of their ion conduction mechanisms. In SSICs containing molecular ions, molecular rotations couple to translational diffusion to create a “paddle-wheel” effect that facilitates conduction. This paddle-wheel mechanism explains many important features of molecular SSICs. However, we lack a similarly detailed explanation for anharmonic lattice dynamics and ion conduction in SSICs composed of monatomic ions. I will discuss our recent theoretical work that provides such an explanation. We predict that ion conduction in many SSICs involves “electronic paddle-wheels,” in which localized lone pair electrons rotate, and these rotations couple to and facilitate ion diffusion. After discussing our evidence from simulation results, I will make analogies to molecular SSICs and argue that the electronic paddle-wheel mechanism creates a unifying principle for understanding ion conductivity in both monatomic and molecular materials. We anticipate that a predictive

understanding of electron paddle-wheels in ionic conduction can be leveraged to create design principles for engineering solid-state electrolytes from the electronic level on up.

11:15 AM ES03.05.03
How Correlated are Ion Hoppings in Inorganic Solid-State Electrolytes? Cibrán López Álvarez[1,2,3], Edgardo Saucedo[1,2] and Claudio Cazorla[1,2]; [1]Polytechnic University of Catalonia, Spain; [2]Barcelona Research Center in Multiscale Science and Egineering, Spain; [3]Institute of Materials Science of Barcelona, Spain

Despite playing a central role in the design of novel solid-state electrolytes (SSE), little is known about the processes governing ionic diffusion in these materials and the spatio-temporal correlations acting on migrating particles. However, molecular dynamics (MD) simulations can reproduce the trajectories of individual diffusing ions with extraordinary accuracy, thus providing incredibly valuable atomistic data that in practice cannot be resolved by experiments.

The identification of hopping events from these simulations typically relies on active supervision and definition of arbitrary material-dependent geometrical parameters, thus frustrating high throughput screenings of diffusing paths and mechanisms across simulation databases and the assessment of many-diffusing-ion correlations.

Here, we introduce a novel approach for analyzing ion hopping events in MD simulations in a facile and totally unsupervised manner, that allows to determine key atomistic ionic diffusion descriptors. In particular, our approach identifies with precision which and when particles diffuse in a simulation and the exact migrating paths that they follow as well.

We apply such a powerful analysis tool to a comprehensive database of density functional theory ab initio MD (DFT-AIMD) simulations [1,2], comprising several families of SSE and tens of millions of atomic configurations. By doing this, we are able to (1) quantify correlations between many diffusing ions, (2) identify predominant collective migrating mechanisms and (3) determine how specific and novel migration descriptors such as the length and duration of individual ionic hops correlate with ionic diffusion coefficients, all under realistic finite-temperature conditions.

We show that the probability for N-ions to concertedly diffuse decreases exponentially with N, and that such many-ion correlations practically do not depend on temperature. Interestingly, it is found that despite N = 2 correlations are largest, higher order many ion (N > 2) coordination is more frequent in concerted diffusion. The explained unsupervised analysis approach has been implemented in the IonDiff software [3], a python code that is publicly available.

11:30 AM ES03.05.04
Path Integral Approaches to Ion Diffusion Jarvist M. Frost and Lucius Liu; Imperial College London, United Kingdom

Classical ion diffusion theories rely on simplified hopping models lacking concerted motion. Molecular dynamics can capture correlations but requires extensive sampling. This fairly brute-force approach has become the standard way to calculate ion diffusion rates, recently accelerated with the use of machine learning force-fields trained against density functional theory calculations.

We revisit path integral techniques to bridge this gap. Integrating state-of-the-art graph neural network potentials [1] with the 1990s path-integral approach of Chakraborty et al. [2] offers an efficient route to model correlated transport, and understand the physical processes. Generally these more sophisticated mathematical models developed in the 70s to 90s, have mostly been neglected as attention has shifted to explicit simulation on fast computers.

We show how a semi-numerical path integral approach parameterised by lighter weight machine-learning force-field molecular dynamics, can describe and understand correlation effects in representative lithium, sodium, and halide ion conductors.

11:45 AM ES03.05.05
Enhancing Li-Ion Conductivity in Argyrodite Li_6PS_5Cl through Disorder Engineering Investigated by Machine Learning Potential Jiho Lee, Suyeon Ju, Seungwoo Hwang, Jinmu You, Jisu Jung and Seungwu Han; Seoul National University, Korea (the Republic of)

Solid-state electrolytes (SSEs) have emerged as promising candidates for next-generation batteries, offering improved safety and higher energy density compared to conventional liquid electrolytes. Nevertheless, the practical utilization of SSEs has been hindered by the challenge of achieving high ionic conductivity at room temperature. Among SSEs, argyrodite systems have achieved a high conductivity of 10 mS/cm at room temperature through strategies involving disorder engineering and doping. To further optimize ionic conductivity and gain a comprehensive understanding of the underlying mechanisms, theoretical calculations based on density functional theory (DFT) have been applied. However, recent DFT studies have faced challenges in accurately quantifying transport properties in argyrodite systems compared to experiments, primarily due to computational limitations. For instance, small simulation cells introduce spurious correlations in Li-ion motions between periodic boundaries, while a scarcity of diffusion events makes direct simulation at room temperature difficult.

In this presentation, we present the use of Behler-Parrinello-type neural network potentials (NNPs) to overcome the aforementioned challenges and obtain Li-ion conductivities in argyrodite Li_6PS_5Cl with varying S/Cl disorders (0−100%). Utilizing cost-effective and accurate NNPs allows for direct simulations at room temperature, unraveling the effects of S/Cl disorders. We select the SCAN functional, which reproduces the lattice parameter within 0.2% of the experimental value. To train the NNPs, we utilize the SIMPLE-NN package and employ strained bulk crystals and ab initio MD data at 600 and 1200 K. Several validations are conducted to ensure the quality of our NNP in terms of both structural and dynamic properties. To obtain the ionic conductivity with a statistical convergence error range of 10%, we carry out systematic tests on the supercell and ensemble sizes. As a result, NNP MD

simulations are performed using 5×5×5 supercells containing 6500 atoms for up to 25 ns. In calculating the diffusivity, we neglect the initial 5 ns, where most of the Li-ions remain within the cage at room temperature, resulting in non-linear mean squared displacements. Our predicted activation energies and ionic conductivities align well with experimental data. Interestingly, the conductivity peaks at 25% S/Cl disorder. By analyzing the diffusion mechanism, we find that the peak observed at 25% disorder arises from the synergetic effects of two contributing factors; the enhancement of rotational motion and the disorder effect which facilitates the Li diffusion between cages. Additional free energy analysis shows that these structures are thermodynamically accessible, suggesting the potential for optimizing Li-ion conductivity through disorder engineering in Li_6PS_5Cl. This work paves the way for estimating and studying the transport properties of SSEs using accurate and cost-effective NNPs.

SESSION ES03.06: Electrode Interface I

1:30 PM *ES03.06.01
Interfacial Engineering for Lithium Metal Batteries Employing Garnet-Type Electrolyte Ju-Sik Kim[1], Sewon Kim[1], Gabin Yoon[1], Michael Badding[2], Zhen Song[2] and Dongmin Im[1]; [1]Samsung Advanced Institution of Technology, Korea (the Republic of); [2]Corning Incorporated, United States

Garnet-type solid electrolytes, represented by the composition $Li_7La_3Zr_2O_{12}$ and its derivatives, have recently garnered significant attention due to their good compatibility with lithium metal anode. However, several issues remain unsolved, hindering the commercialization of lithium metal batteries employing garnet-type electrolytes: (1) Carbonates and hydroxides easily form on the surface of garnet electrolytes, leading to high interfacial resistance when incorporated into batteries. (2) While the chemical stability of garnet-type electrolytes against lithium metal is reasonably good, it is frequently observed that lithium dendrites penetrate through the electrolyte layer, causing short circuits between the cathode and anode. (3) During cell discharge or lithium metal stripping, voids often form at the interface. This results in fluctuations in local current density, accelerates short-circuiting, and worsens cycling stability. In this presentation, we will demonstrate that surface treatment of garnet with acid and the introduction of a carbon or carbon-metal composite interlayer are highly effective in addressing these issues. Stable cell cycling performance is achieved even at room temperature, with an areal capacity comparable to that of commercial lithium-ion batteries. We will also discuss the working mechanisms of these methods.

2:00 PM *ES03.06.02
Sodium Solid-State Electrolyte and Electrode Interfaces Jin An Sam Oh[1] and Y. Shirley Meng[1,2]; [1]University of California, San Diego, United States; [2]The University of Chicago, United States

An ideal solid-state electrolyte requires a high ionic conductivity, low electronic conductivity, and matched electrochemical window with the electrode. Often, it needs to possess mechanical properties with rigidity to acts as a separator while having the ability to form intimate interface with the electrode to realize the all-solid-state batteries. In this talk, I will share our recent efforts in material development and architecture design to enable all-solid-state sodium batteries as a complimentary and safe energy storage system.

2:30 PM BREAK

Room 423, Level 4, Summit

3:30 PM *ES03.07.01
High-Rate Cycling in 3D Dual-Doped NASICON Architectures toward Room-Temperature Sodium-Metal-Anode Solid-State Batteries Prem Jaschin, Christopher Tang and Eric D. Wachsman; University of Maryland, United States

Sodium metal-based solid-state batteries hold tremendous potential for next-generation batteries owing to low-cost earth-abundant sodium resources. However, fabricating thin free-standing solid electrolytes that could cycle sodium at high current densities has been a major challenge in developing room temperature solid-state sodium batteries. By developing high conducting Zn^{2+} and Mg^{2+} dual-doped $Na_3Zr_2SiPO_{12}$ (NASICON) solid electrolytes and fabricating a 3D porous-dense-porous architecture (with an ultrathin, 25 µm, dense separator) coated with a nanoscale ZnO layer, an extremely low anode interfacial resistance of 3.5 Ω cm^2 was realized. This enabled a record high critical current density of 30 mA/cm^2 at room temperature with no stack pressure and a cumulative sodium cycling capacity of 10.8 Ah/cm^2 was achieved. Furthermore, pouch cells were assembled as a proof-of-concept with $Na_3V_2(PO_4)_3$ cathodes on dense-porous bilayer electrolytes with sodium metal anodes and cycled up to 2C rates at room temperature with no applied stack pressure.

4:00 PM ES03.07.02
Dyanmic Coupling of Internal Strain-Stress Field and Lithihum Pathway within Individual Cathode Particles goverend by Solid Electrolyte in All-Solid-State Batteries Jinkyu Chung, Junho Bae, Hanbi Choi and Jongwoo Lim; Seoul National University, Korea (the Republic of)

In all-solid-state batteries (ASSBs), (electro)chemo-mechanical aspects such as uneven interfaces, cathode-electrolyte interphase formation, delamination, fracture, defects, etc., are the major factors in capacity fade but remain largely unknown.

Nonhomogeneous transfer of lithium ions can cause significant variations in strain and stress within battery electrodes, leading to degradation in battery performance. In all-solid-state batteries (ASSBs), the lithium pathway and the associated strain/stress field become more intricate due to the (electro)chemo-mechanical reaction at the electrode-electrolyte interfaces. The dynamic volume change in active particles are heavily influencing by strength of the solid electrolyte and interfacial conformality. This can continually alter the lithium pathway and the internal stress field, leading to recurrent redefinitions of (electro)chemo-mechanical environment.

Here, we have developed an operando coherent X-ray imaging platform and associated analysis methodologies. Named PICASSO (Primary particle In-situ X-ray imaging with Chemical-composition Analysis and Strain-Stress Observation), this technology can track the nanoscale transport of lithium and the strain evolution of individual electrode particles in ASSBs. With this platform, we gained a comprehensive electrochemical and mechanical understanding of the cycling properties of single electrode particles in ASSBs.

4:15 PM ES03.07.03
Competition Between Lithiation-Induced Stress and Concentration Gradients in 3D Geometries David M. Stewart, Paul Albertus and Gary W. Rubloff; University of Maryland, United States

A comprehensive understanding of electro-chemo-mechanical (ECM) phenomena in solid-state batteries (SSBs) requires not only theoretical models, but validation of the models by direct measurement in well-defined geometries. We will highlight a few intriguing results using 3D models of SSBs and measurements on thin film electrodes, which motivate novel methods for measuring local stress and Li concentration in situ. These results emphasize that the inclusion of ECM effects is essential in understanding the fluxes in 3D geometries.

Using muti-physics modeling we have simulated the electrochemical behavior of a battery operating in the confined space of a nanopore. The 3D geometry produces large concentration gradients that affect the Li flux: rather than a conformal flux field, largely along the radial axis of the pore, the Li flows up and down the pore. However, the same geometry, when including electro-chemo-mechanical coupling, has entirely different behavior. Due to the stress gradients produced by the confined volume expansion of the cathode, the Li flux is further influenced, and achieves the fully conformal distribution that we expected from intuition.

Experimentally, we have measured ECM coupling in two model systems using Si electrodes, whose electrochemical and mechanical properties are well known. We employed micro-Raman mapping to measure the shift in the Si peak, and ultimately translated that to a strain/stress profile in the electrode during lithiation. In single-crystal Si wafers we measured bi-axial stress maxima around 0.6 GPa, localized to the lithiation front, and post-mortem SEM shows lateral cracks that form at this same depth, causing delamination and breakdown the electrode. Furthermore, XPS depth profiles and EBSD cross sections show that the lithiation front is not sharp, as seen elsewhere in the literature. Due to ECM effects, the diffusion lengths in this experiment are 100x larger than predicted by concentration gradients alone.

In subsequent experiments, using a square Si island approximately 10 μm on a side, dynamic stress profiles are measured. The Raman stress measurement is fast enough to be done in operando, allowing us to see transient stress states for comparison with models. Existing literature treated the cracking and delamination of these islands entirely from a mechanical perspective. Our ECM models, parameterized to the experimental observations, reveal that the origin of the failure is not simply mechanical, but due to a competition between Li concentration gradients and stress gradients.

While the theory of ECM coupling is rather well studied, it's application in 3D geometries is not well explored. At the same time, validation of the theory is nascent in electrochemical systems, where material properties change dynamically with state of charge. Together, our models and experiments are providing the fundamental understanding of SSB performance required for next generation designs.

Towards Improved All-Solid-State Batteries: A Multi-Scale Simulation of Cation Inter-Diffusion and Mechanical Failures at NASICON-Oxide/$LiCoO_2$ Interfaces Ming-Yuan Hong and Hong-Kang Tian; National Cheng Kung University, Taiwan

All-solid-state batteries (ASSBs) hold great promise, yet their commercialization has faced challenges due to interfacial complications, which encompass issues such as solid electrolyte decomposition, mechanical degradation, and Li dendrite growth. Specifically, NASICON-type solid electrolytes, like $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (LATP) and $Li_{1+x}Al_xGe_{2-x}(PO_4)_3$ (LAGP), have attracted attention because of their stability against $LiCoO_2$ (LCO) and remarkable ionic conductivity (ranging from 10^{-4} to 10^{-3} S/cm). However, a decline in discharge/charge capacity due to mechanical breakdown at their interfaces has been a concern. Leveraging an integrated multi-scale simulation approach that combines Density Functional Theory (DFT) with Finite Element Analysis (FEA), we delved into the issues of cation inter-diffusion and the resulting mechanical challenges at LATP/LCO and LAGP/LCO interfaces. Our DFT studies pinpointed energetically favorable sites for Co to replace Ti atoms, mirroring atomic structures emerging from Co and Li inter-diffusion events. Evaluations of the elastic attributes of Co-LATP and Co-LAGP configurations showed a decline in modulus values (both Young's and Shear), signaling an interfacial softening. However, the diffusion of Co and Li away from LCO transforms into Co_3O_4, characterized by a greater Young's modulus compared to LCO and both LATP/LAGP. By channeling these insights into a 2D continuum model through FEA, we could visualize the Li-ion concentration gradient adjacent to the LCO particle and the subsequent stress distribution across various discharge phases. Our results identified peak first-principal stresses at the interfaces, reaching approximately 800 MPa for LATP/ LCO and around 1000 MPa for LAGP/ LCO. In comparison, non-interface scenarios registered values between 400-500 MPa. These findings accentuate the importance of inhibiting Co diffusion to safeguard ASSB integrity. Furthermore, simulations suggest that enhancing the interfacial contact area to 75% of optimal contact can effectively counteract peak stress induced by interfaces, underscoring the significance of this parameter in counteracting interface-induced mechanical degradation. In conclusion, this study offers a thorough exploration into the alterations in material properties and the potential mechanical decline triggered by cation inter-diffusion at these interfaces, urging its prevention in subsequent ASSB innovations. The analytical methods adopted here also present a valuable methodological framework for probing other ASSB material pairings, potentially guiding the prediction and alleviation of mechanical setbacks during the discharging phases.

Microstructure-Aware Mesoscale Modeling of Chemomechanical Stress Evolution during Cycling in Solid Electrolyte-Cathode Composite Bo Wang, Longsheng Feng, Kwangnam Kim, Liwen Wan, Tae Wook Heo and Brandon Wood; Lawrence Livermore National Laboratory, United States

The volume change of cathode active materials during charge-discharge cycling is responsible for the capacity fading of all-solid-state Li batteries due to mechanical degradation in the cathode such as delamination and crack formation. Many strategies to alleviate the chemomechanical stress buildup have been proposed in experiments but rationale of the stress release mechanisms at the mesoscale remain elusive. In this presentation, we present a microstructure-aware mesoscale model to quantitatively predict the stress distribution during cycling in a secondary particle agglomerate of the cathode active material embedded within a solid electrolyte matrix, taking the $LiCoO_2$-$Li_7La_3Zr_2O_{12}$ (LCO-LLZO) as a model system. We find that the mechanical stress hotspots develop at different stages within the grain boundaries of the LCO agglomerate and the LCO-LLZO interfaces. We investigate the influences of microstructural morphology (columnar versus equiaxial), grain orientations (textured versus random), mechanical properties at the grain boundaries and heterogeneous interfaces, and anisotropy of chemical expansion on the stress hotspot evolution and provide optimal mitigation strategies. The theoretical results can help gain mechanistic understanding on cathode degradation and inform guidelines for experimental design of mechanically optimized cathode materials for long-life solid-state batteries.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Phase Study of Lithium-Niobium-Tantalum Oxides as Cathode Coating Materials Hengning Chen[1], Zeyu Deng[1] and Pieremanuele Canepa[1,2]; [1]National University of Singapore, Singapore; [2]University of Houston, United States

Although all-solid-state batteries (ASSBs) exhibit great potential for providing high energy density and enhanced battery safety, the stability of electrode−electrolyte interfaces is still a serious challenge. Niobate and tantalate materials have been widely applied as coating materials to mitigate the interfacial reactivities in ASSBs, especially amorphous $LiMO_3$ (M=Nb or Ta) with high ionic conductivities and appreciable electronic resistance.[1] Compared with pure $LiMO_3$ (M=Nb or Ta), partially-crystallized Li-Nb-Ta oxides were found to show even higher ionic conductivity and higher permittivity, which can be more effective for fast charge-transfer reactions at the cathode/electrolyte interfaces in ASSBs.[2] However, the mechanism behind Nb/Ta mixing and the improved properties needs to be further understood.

Leveraging a combination of density functional theory, cluster expansion formalism, grand canonical Monte Carlo (gcMC) simulations, and machine-learned molecular dynamics, we reveal the phase transition nature of $LiTa_{1-x}Nb_xO_3$ and the improved Li-ion conduction properties brought by Nb/Ta mixing. As studied in our previous work, the crystalline Li-M-O coating contains mixtures of $LiMO_3$ and Li_3MO_4, and we extend the mixing study into Li_3MO_4 as well.[3] Our investigation of the phase behavior and the structure-property relationships in the Li-Nb-Ta oxides helps to develop more suitable synthesis protocols to maximize the functional properties of these coating materials.

Interplay of Interfacial Adhesion and Mechanical Degradation in Anode-Free Solid-State Batteries Imtiaz Ahmed Shozib and Howard Qingsong Tu; Rochester Institute of Technology, United States

Degradations at the interface between the solid electrolyte (SE) and the anode have been identified as one of the primary reasons for solid-state battery (SSB) failure. Interfacial adhesions and mechanical conditions are important factors need to be investigated for SSB. This article investigates the impact of assembling pressure on the performance of an anode-free solid-state battery (AFSSB) with an AgC || Li_6PS_5Cl (LPSCl) || NMC811 full cell configuration. Results demonstrate that an optimal assembling pressure of 530 MPa significantly improves specific capacity. Notably, an increase in capacity is observed when the assembling pressure is increased from 350 MPa to 530 MPa, while pressures beyond this threshold lead to a significant decrease in capacity due to soft short effect. The highest discharge capacity was achieved at an optimal assembling pressure of 530 MPa, corresponding to a high gravimetric energy density of 409.62 Wh/kg. This notable enhancement over alternative assembling pressures is likely a result of the intricate interplay between interfacial adhesion and mechanical stability. This assembling pressure incrementally improves the interfacial adhesion between the SE and the AgC interlayer. At 450 and 530 MPa, where interfacial adhesion is moderately higher, lithium deposition predominantly occurs at the AgC/CC (current collector) interface, enhancing electrochemical performance by improving lithium transport to this interface. However, above 530 MPa, cracks form in the SE, disrupting performance despite increased interfacial adhesion between SE and AgC layer. This higher-pressure range (560 to 650 MPa) exhibits poorest mechanical stability due to SE cracks. This research provides insights into optimizing assembling pressure for enhanced capacity and energy density in LPSCl-based AFSSBs, offering a straightforward approach to improving overall battery performance.

Visualizing The Chemical Incompatibility of Halide and Sulfide-Based Electrolytes in Solid-State Batteries Carolin Rosenbach and Wolfgang Zeier; University of Münster, Germany

Because of the ongoing demand on energy consumption, high energy density batteries are needed. Solid-state batteries can lead to higher energy densities compared to commonly used liquid lithium batteries and avoid the flammable organic solvents. The class of halide electrolyte (Li_3MX_6, M = metal, X = Cl, Br, I) provide promising characteristics in solid-state batteries due to their reasonable conductivity values and their larger electrochemical stability window compared to sulfides. Due to the good conductivity value of 1 $mScm^{-1}$, the broad theoretical electrochemical stability window and the water-based synthesis possibility the electrolyte Li_3InCl_6 is a good candidate for the use with high potential cathode materials like $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$. It was shown that the Li_3InCl_6 is not stable at the lithium metal anode, therefore a bilayer setup with a sulfide and a halide layer is commonly used to study halides at the cathode side. Omitting the halide layer and only using a sulfide layer, like Li_6PS_5Cl, lead to a capacity loss over the cycling and decomposition products.

Based on this literature we studied three different cell setups with the halide electrolyte Li_3InCl_6 and sulfide electrolyte Li_6PS_5Cl in combination with the cathode material $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$. Cycling of the cells over 100 cycles revealed the fast capacity fading of the cell setup with the $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$:$Li_3InCl_6$ cathode composite in direct contact to the Li_6PS_5Cl, whereas the cells with avoiding this triple phase boundary cycle more stable. Within the cycling process, electrochemical impedance spectroscopy was performed and showed a significant increase of the interfacial resistance in the fast capacity fading cell, which was not the case for the pure sulfide and the bilayer cell setup.
For further analyzation of the fast capacity fade, time-of-flight secondary ion mass spectrometry and focused ion beam scanning electron microscopy analysis were performed to understand the interfacial resistance increase. At the buried interface of the cathode composite to the sulfide separator an indium-sulfide species could be detected, which were also slightly less present at the separator-separator interface of the halide and sulfide electrolyte. This indicates the incompatibility of the Li_3InCl_6 and Li_6PS_5Cl electrolytes, which is more pronounced in the presence of $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$.

This work highlights that in the search for new battery components the chemical stability of the materials to each other should not be overseen. Adding more components in a battery cell, like bilayers, increases the number of interfaces and possible degradation areas. Therefore, studies of solid-state batteries should also consider more properties besides electrochemical stability windows of single components.

Quantifying The Structural Properties of The Lithium-Solid Electrolyte Interface Kelsey Uselton[1], Dylan C. Hamilton[1], Elizabeth Allan-Cole[1], Samuel Marks[1], Annalise Maughan[2] and Michael Toney[1]; [1]University of Colorado Boulder, United States; [2]Colorado School of Mines, United States

All-solid-state batteries (ASSBs) are poised to meet the rising demand for high energy density electrochemical energy storage and safety in lithium-ion battery technology, a crucial aspect for the widespread adoption of electric vehicles [1]. However, the solid-electrolyte interphase (SEI) layer arising from chemical incompatibility and a narrow solid electrolyte electrochemical window poses a significant hurdle due to high resistance to ion transfer resulting in poor performance and cyclability of promising solid-state electrolyte materials [1]. Therefore, probing interfacial properties between the lithium and solid-state electrolyte is paramount to assess the interfacial changes that adversely impact battery performance through multiple charge–discharge cycles [2]. According to a review from Paul et al. there have been several studies characterizing the chemical composition of the SEI in ASSBs, but there is limited evidence probing the Li-SSE interphase structure [3]. Structural properties impact interfacial transport and are difficult to assess due to the limited quantity of material available for examination and for the “buried” nature of the interphase [4]. We implemented a Li/Li symmetric cell system to isolate the interactions between lithium and an argyrodite (Li_6PS_5Cl) solid electrolyte. To understand and quantify the structure of reaction layers that form and evolve at Li-SSE interfaces during cycling, we have performed interface-sensitive *operando* transmission X-ray Diffraction (XRD) experiments with high energy, high flux synchrotron radiation. Electrochemical cycling and electrochemical impedance spectroscopy paired with XRD measurements quantified SEI formation, degradation, and specific resistance contributions. Our results show evidence for crystalline reaction layers that evolve with time and potential providing insight into the formation and evolution of dominant crystalline phases throughout the interphase region.

Impact of Structure and Interfaces on Li Ion Transport in Composite Solid Electrolytes Markus Wied[1], Christian Prehal[2], Moritz H. Futscher[3], Anne Bonnin[4] and Vanessa Wood[1]; [1]ETH Zurich, Switzerland; [2]University of Salzburg, Austria; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [4]Paul Scherrer Institute, Switzerland

Increasing the Li ion battery energy density is a major challenge, which needs to be addressed in order to reduce their size and weight. Switching to metallic Li anodes would provide such a significant increase in energy density. However, this comes alongside many challenges, among them stability towards the electrolyte or Li dendrite growth. Solid electrolytes (SEs) are a promising replacement for state-of-the-art liquid electrolytes as they are electrochemically more stable and better at preventing Li dendrite growth. For high performance all-solid-state-batteries (ASSBs) the electrode-electrolyte interfaces and electrolyte ionic conductivity are crucial to reach high C-rates.
There are three major classes of SEs, consisting of inorganic ceramics, polymers, or composites of both. Ceramics generally feature high electrochemical stability, high voltage operation, and good ionic conductivity but they are brittle, difficult to manufacture and expensive. Polymers are cheap, easy to manufacture and compatible with slurry-based processes, and form and maintain SE-electrode interfaces well. Yet, their ionic conductivity at room temperature is limited. By combining both polymers and ceramics in composite-solid-electrolytes (CSEs), it is possible to take advantage of both material classes while maintaining the scalability of the fabrication process. However, there is a lack of understanding of lithium ion transport in CSEs.
We investigate the impact of the polymer ceramic structure and the properties of the polymers, ceramic, and their interfaces on transport in CSEs using 3D simulations on realistic CSE structures. We obtain relastic 3D x-ray tomography data on different CSEs made from Al-doped LLZO (LLZO) particles dispersed in a PEO (LiTFSI) matrix. We validate finite element simulations of the ionic conducitivity of these 3D structures with experimentally obtained ionic conductivity data. With the simulation tools and the realistic structures we can gain insight into the relative importance of structure and material properties and their impact on heterogeneity of ionic transport with respect to the properties of the CSE heterostructure. This understanding is crucial as it shows that there can be quite significant local differences in ionic current that will affect cycle life or lithium plating behavior. Our findings emphasize the importance of interface treatments to minimize interface resistances in CSE heterostructures. We also highlight that properties such as mechanical stability and integrity or ionic current heterogeneity need to be considered for performance assessment besides the ionic conductivity.

Pulsed Laser Deposition and Characterization of Ceramic Battery Thin Film Bi-Layers: Interfacing a Solid State Electrolyte, Lithium Lanthanum Zirconate, with a High Voltage Cathode, Lithium Manganese Oxide Isaac D. Dyer[1], Hana T. Gobena[2], Jennifer L. Rupp[2] and Sossina M. Haile[1]; [1]Northwestern University, United States; [2]Technical University of Munich, Germany

Solid-state batteries have the potential to introduce higher energy densities and add improved safety into our power storage network. However, the electrochemical stability at the interface of a solid state electrolyte and a high voltage cathode remains an inhibitor of this technology. A precisely defined interface of phase pure constituents is needed in order to investigate this interfacial stability. Here, using pulsed laser deposition, we created such an interface by the formation of a thin film bilayer, a solid state electrolyte interfaced with a high voltage cathode. Tantalum doped Lithium Lanthanum Zirconate & Lithium Manganese Oxide bilayers were deposited onto Magnesium Oxide substrates. The resulting thin film bilayer was analyzed using X-ray Diffraction, Raman Spectroscopy, and Cross-Sectional Scanning Electron Microscopy. Here we show the capability to grow densified phase pure thin film bilayers of a solid state electrolyte and a high voltage cathode by pulsed laser deposition. This capability opens avenues towards the interfacial investigation of a precisely defined solid state electrolyte and high voltage cathode.

Design of Trigonal Halide Superionic Conductor by Regulating Cation Order-Disorder Seungju Yu, Joo-hyeon Noh and Kisuk Kang; Seoul National University, Korea (the Republic of)

Lithium-metal-halides have been recently revisited as promising solid electrolyte (SE) candidates that can provide solutions to the interfacial instability issues found in sulfide- and oxide-based SEs. Although early studies on halide-based SEs indicated that poor ionic conductivities (typically < ~10^{-6} S cm^{-1}) constituted a major bottleneck, recent breakthroughs revealed that the ionic conductivity can be boosted by identifying appropriate synthetic routes, introducing a wide range of halide-based Li_3MX_6 (M = Y, Er, or In, X = Cl, Br, or I)[1]. Notably, moving from the classical ampule synthesis to mechanochemical synthesis significantly improved room-temperature ionic conductivity up to ~10^3 order of magnitude for the Li_3MCl_6 (M = Y, Er)[2,3]. It was speculated that the higher degree of cation disordering from the mechanochemical synthesis could open up the bottleneck transition triangular area for lithium diffusion. Although the factors leading to the hidden superionic conductivity of halide SEs remain unclear, these previous findings strongly suggest a close interplay between superionic conduction and cation arrangements/occupancies attainable from various synthetic methods[4,5]. Hence, understanding the fundamental relationship between the superionic conduction mechanism and structural factors in trigonal Li_3MCl_6 halides is critical for realizing significant advancements in their ionic conductivities.
Herein, we employ first-principles calculations and experiments to investigate the conduction mechanism, propose, and validate our design strategies for enhancing ionic conductivity, using Li_3YCl_6 (LYC) as a model system. Consistent with previous reports, we find that the lithium diffusion occurs three-dimensionally in LYC, which exhibits anisotropic behavior with faster ionic conduction along the *c*-axis channel than in the ab-plane[6]. However, it is revealed that the lithium diffusion in the ab-plane leverages the superionic conduction in LYC, and, more importantly, it is primarily determined by the partial occupancies of the yttrium (Y) ion in the structure. Our theoretical calculations demonstrate that the presence of Y in the ab-plane interrupts the lithium diffusion with the electrostatic repulsion associated with the tetrahedral site hopping mechanism of lithium ions, resembling that of conventional layered lithium transition-metal oxides. Furthermore, the partial occupancy of Y over a certain ratio entirely disconnects the percolation diffusion pathways of lithium ions in the ab-plane. On the other hand, it is conversely observed that the lack of Y in the ab-plane leads to the collapse of the interlayer space, indicating that Y cations serve as a pillar of the layered lithium diffusion framework. This contradicting effect of Y in the structure signifies the importance of the composition/ordering of M cations in the trigonal Li_3MCl_6. Accordingly, we propose a target region for M partial occupancy that can lead to cation arrangements with percolating and non-collapsed lithium diffusion pathways. Our design rules for the target cation arrangement are experimentally confirmed by an M-deficient $Li_3M_{0.8}Cl_6$ (i.e., $Li_3Y_{0.2}Zr_{0.6}Cl_6$), a new halide superionic conductor that exhibits the highest reported room-temperature ionic conductivity (1.19×10^{-3} S cm^{-1}) among trigonal halide superionic conductors. This study illuminates the detailed superionic conduction mechanism in halides for the first time and suggests that searching for a new compositional space that balances the lithium percolation and stacking slab distance is an unexplored and efficient pathway for the design of superionic halide SEs.

Free-Standing Sulfide Electrolyte Thin Film for Solid-State Lithium Battery Applications Seokyoon Yoon[1,2], Dong Ok Shin[1,2], Seok Hun Kang[1], Jaecheol Choi[1], Ju Young Kim[1], Young-Gi Lee[1] and Young-Sam Park[1,2]; [1]Electronics and Telecommunications Research Institute, Korea (the Republic of); [2]University of Science and Technology (UST), Korea (the Republic of)

The great attention to low carbon economy through the electric vehicles grows the market of lithium ion battery (LIB) rapidly because of its high power and energy density. However, a liquid carbonate electrolyte employed in the LIB is flammable, thus being able to cause severe safety issues. To reduce the safety issues, a solid electrolyte (SE) instead of the currently commercialized liquid electrolyte has been introduced to fabricate solid-state lithium batteries [1,2]. Even though the prevailing SEs (that is, sulfide, polymer, garnet and sodium superionic conductor) do not simultaneously satisfy all the stability requirements such as mechanical, chemical, electrochemical and thermal stabilities, sulfides have the highest ionic conductivities and the favorable mechanical properties among them, thereby being considered to work reasonably well in the conventional sandwich battery structure [2].
To prepare the sulfide SE, a slurry coating technology has been generally used. However, the traditional wet method charges additional cost coming from using an environmentally harmful organic liquid solvent and the resulting production of a solvent recovery system. In addition, strong reactivity between a polar liquid solvent and the sulfide leads to the decrease in the ionic conductivity of the sulfide SE [2]. Thus, the introduction of a liquid-free dry process is necessary to obtain the sulfide electrolyte. Furthermore, thin and free-standing SEs are preferred for high efficiency batteries with a high degree of freedom of electrode material selection.
In this work, separate sulfide electrolyte films with a thickness of several dozens of micrometers are demonstrated by a dry procedure which is composed of the following three steps [3]: first, an agyrodite-type sulfide and a binder powders are mixed. Next, the two nonsticky powders are ground homogeneously to fabricate a sticky sulfide-binder dough. Then, the dough is fed into rollers to obtain the independent SE layer with a thickness of below one hundred micrometers.
Microstructural and elemental analyses are carried out utilizing a field emission scanning electron microscope and energy dispersive X-ray microanalysis, respectively. Alternating voltages are applied by a frequency response analyzer (10^{-1}-10^5 Hz, Solartron HF 1225, AMETEK Scientific Instruments) to get Nyquist plots and calculate ion conductivities of dry- and wet-processed sulfide SE samples. Charging-discharging cycling experiments are performed under galvanostatic cycling condition from 3.0 to 4.3 V (Toscat-3000, Toyo System). The test results are presented and discussed in the talk.

Fabrication of Y-Doped and Ce-Doped NaSICON through Integrated Mechanical and Thermal Activation Method Madeline Barickman, Abigail Barickman and Shan-Ju Chiang; North Central College, United States

NaSICON (Na Super Ionic CONductor) materials have emerged as promising candidates for a wide range of applications such as all-solid-state Na-ion batteries, sodium-air batteries, electrochemical sensors, as electrolytes for thermoelectric generators, and membranes due to their high availability, profound ionic conductivity, high thermal and chemical stability, and good electrochemical compatibility. To be used in energy storage devices, the high ionic conductivity with relatively low interfacial resistance has to be possessed. However, the Na-ion conductance at room temperature remains several orders of magnitude lower than organic electrolytes even NaSICONs have relatively high ionic conductivity at elevated temperature. Therefore, there is still a need in developing a consistent manufacturing process to further increase the ionic conductivity of NaSICON and reducing the production cost for synthesizing NaSICON membranes.

This study aims to improve the density and ionic conductivity of yttrium and cerium-doped NASICON materials through mechanical activation and one-step sintering process while suppressing the manufacturing cost of NaSICONs. Here, we report the feasibility of integrated mechanical and thermal activation method in doping the zirconium site in NaSICON. Fully densified Y-doped NaSICON has 100% higher total conductivity at the room temperature then the same material prepared from general solid-state sintering method, while Ce-doped NaSICON demonstrates the good bulk conductivity of 4.7 x 10^{-4} S/cm. This study will provide an alternate solution for synthesizing high ionic conductivity NaSICON at low cost for many energy storage systems.

Assessing Correlations between Phonon Features and Migration Barriers in Multivalent Solid Electrolytes Samuel M. Greene and Donald Siegel; The University of Texas at Austin, United States

Solid ion conductors with high ionic conductivity can enable the development of solid-state batteries with improved safety and performance. Most materials exhibit insufficient conductivity for commercial applications, particularly for multivalent ions. High-throughput computational approaches, which involve screening large databases of compounds, can accelerate the discovery of new materials with sufficient conductivity. Directly calculating ionic conductivity from first principles is expensive and difficult to automate, which renders such calculations incompatible with screening approaches. Previously, others have proposed the phonon band center (mean phonon frequency) as a metric that is easier to calculate and measure, and they have demonstrated that it is correlated with the energetic barrier for ion migration in lithium and sodium conductors. I will discuss our efforts to extend this approach to investigate magnesium, calcium, and zinc conductors using first-principles calculations of phonon features. In addition to frequencies, we consider the directions of phonon modes as predictors for migration barriers. We compare our results with previous trends for monovalent conductors.

SESSION ES03.10: Fabrication and Scale Up II

2:00 PM ES03.10.01
Stable Anode-Free All-Solid-State Lithium Battery through Tuned Metal Wetting on The Copper Current Collector David Mitlin; The University of Texas at Austin, United States

Stable anode-free all-solid-state battery (AF-ASSB) with sulfide-based solid-electrolyte (SE) (argyrodite Li6PS5Cl, LPSCl) is achieved by tuning wetting of lithium metal on “empty” copper current-collector. Lithiophilic 1 μm Li2Te is synthesized by exposing the collector to tellurium vapor, followed by in-situ Li activation during the first charge. The Li2Te significantly reduces the electrodeposition/electrodissolution overpotentials and improves Coulombic efficiency (CE). During continuous plating experiments using half-cells (1 mA cm-2), the accumulated thickness of electrodeposited Li on Li2Te-Cu is more than 70 μm, which is the thickness of Li foil counter-electrode. Full AF-ASSB with NMC811 cathode delivers an initial CE of 83% at 0.1 C, with a cycling CE of 99.5%. Cryo-FIB sectioning demonstrates uniform electrodeposited metal microstructure, with no signs of voids or dendrites at the collector-SE interface. Electrodissolution is uniform and complete, with Li2Te remaining structurally stable and adherent. By contrast, unmodified Cu current-collector promotes inhomogeneous Li electrodeposition/electrodissolution, electrochemically inactive “dead metal”, dendrites that extend into SE, and thick non-uniform solid electrolyte interphase (SEI) interspersed with pores. Density functional theory and mesoscale calculations provide complementary insight regarding nucleation-growth behavior. Unlike for conventional liquid-electrolyte metal batteries, the role of current collector/support lithiophilicy has not been explored for emerging AF-ASSBs.

A Unique Platform for High-Throughput Combinatorial Coating of Thiophosphate Thin-Film Electrolytes onto Bulk Battery Electrodes Andrea Crovetto; Technical University of Denmark, Denmark

I will showcase a recently acquired, highly customized materials synthesis platform dedicated to air-sensitive materials containing sulfur and phosphorus. To the best of my knowledge, this is the only synthesis platform in the world where it is possible to deposit thin-film thiophosphate superionic conductors of any elemental composition in a high-throughput, combinatorial fashion.

This platform is of significant interest for solid-state battery research for two main reasons:

1) It enables intimate coating of bulk electrode particles with a thin solid electrolyte, with potentially improved interface properties and an increased energy density to a lower weight.

2) Bulk synthesis of solid electrolytes is not amenable to parallelized, high-throughput experimentation by combinatorial methods. Conversely, our thin-film deposition setup is designed to easily obtain compositional gradients (e.g., a P/S ratio gradient in one direction and a Li/Ge ratio in the perpendicular direction). Together with the automated, mapping-type characterization instruments in our laboratories, these combinatorial methods enable fast screening of multicomponent phase diagrams (as well as process parameters at constant composition) in the search for optimal properties in emerging or completely new battery materials. Materials of interest can be either electrodes or solid electrolytes.

As a synthesis-oriented material scientist within the optoelectronics field, I hope that this contribution will promote discussion and potential future collaboration with battery experts.

2:30 PM ES03.10.03
TiO_2(B) Epitaxial Thin Film Electrode for All-Solid-State Nanobattery Deok-Hwang Kwon[1] and Shinbuhm Lee[2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Due to its pseudocapacitive, one-dimensional, rapid ion channels, TiO_2(B) holds promise as a Li-ion rechargeable battery anode electrode. Despite its potential for high capacity and superior rate capability, realizing its theoretical capacity and full rate capability remained challenging. Partly owing to its metastability, instead of pure or single crystalline TiO_2(B) materials, multiphase or polycrystalline samples are synthesized. In this study, assisted by an isostructural VO_2(B) template layer, we successfully synthesized single-phase TiO_2(B) films epitaxially, with well-aligned ion diffusion channels. Using a liquid electrolyte, TiO_2(B) epitaxial electrode demonstrates a capacity close to the theoretical value of 335 mA h g–1 and exceptional charge–discharge cyclability for ≥200 cycles, surpassing the performance of other TiO_2(B) or alternative phase nanostructures. Moreover, by applying LiPON as a solid electrolyte, we demonstrated the feasibility of an all-solid-state configuration, showing excellent stability. These findings suggest significant potential for downsizing all-solid-state nanobatteries for application in self-powered integrated circuits.

2:45 PM ES03.10.05
Large Area, Rapid Spray Plasma Processed Amorphous Lithium Lanthanum Zirconium Oxide Thin-Film Electrolytes for Solid State Batteries Thomas W. Colburn, Gabriel Crane, Sarah Holmes, Junyoung Lee, Yi Cui and Reinhold H. Dauskardt; Stanford University, United States

Lithium lanthanum zirconium oxide (LLZO) and other solid-state electrolyte (SSE) materials are widely heralded for their high lithium ionic conductivity, low electrical conductivity, and stability against lithium metal. However, the difficulty in manufacturing solid electrolytes, especially in the thin film geometry, has hindered widespread deployment. Multiple critical challenges need to be solved to produce low-cost SSEs for solid-state batteries at-scale: reproducibility of the thin-film deposition to achieve dense mixed-metal oxides, the intrinsic reactivity of lithiated metal oxides to environmental species like water and carbon dioxide that result in the formation of secondary surface phases like Li_2CO_3, and the necessity of low-throughput and energy-intensive curing steps.

Here, we present a rapid spray plasma process to manufacture large-area thin-film LLZO SSEs for solid state batteries. The LLZO is first generated via blade coating to form an oxide network. The oxide is then cured and densified in one step at 3.6 cm/min linear processing speed by a nitrogen plasma discharged into a low-humidity, ambient pressure environment. Plasma allows for a reduction in processing time by orders of magnitude compared with many traditional vacuum-based thin film routes owing to the combination of radical ions, ultraviolet photons, and heat present in the curing process along with the lack of vacuum. The resulting amorphous phase LLZO thin films have low carbonate contamination, high ionic conductivity of $1x10^{-5}$ S/cm at room temperature, low surface and through-plane defect density, and surface roughness of <40 nm. This work is a step toward the high-throughput manufacturing of LLZO for solid state batteries.

Thursday Afternoon, April 25, 2024
Room 423, Level 4, Summit

3:30 PM ES03.11.01
Insights into The Reactivity and Lithium Plating Mechanisms of Ultra-Thin Metal Oxide Coatings for Anode-Free Solid-State Lithium Metal Batteries Sanja Tepavcevic[1], Michael J. Counihan[1], Taewoo Kim[1], Teodora Zagorac[2], Yingjie Yang[2], Meghan Burns[2], Jordi Cabana[2], Robert F. Klie[2], Luke Hanley[2], Justin Connell[1], Anil Mane[1] and Jeffrey Elam[1]; [1]Argonne National Laboratory, United States; [2]University of Illinois at Chicago, United States

Solid-state batteries (SSBs) using lithium metal anodes are the best candidates for high energy density battery applications. The energy density can be further increased by eliminating the lithium metal excess in an “anode-free” cell format. However, low Coulombic efficiency from heterogeneous lithium metal plating and stripping along with charge loss due to solid electrolyte interphase (SEI) formation severely limit the cycle life of anode-free SSBs. Here, we explore the use of ultra-thin (5-20 nm) Al2O3 and ZnO coatings deposited by atomic layer deposition (ALD) on copper electrodes for anode-free cells with a solid polymer electrolyte. Voltammetry shows that lithium inventory loss due to SEI formation is reduced by over 50% with Al2O3@Cu electrodes, but these electrodes experience orders of magnitude higher interface resistances than bare Cu and ZnO@Cu electrodes due to their inherently low ionic and electronic conductivities. The electrochemical differences between Al2O3 and ZnO coatings are reflected in X-ray photoelectron spectroscopy (XPS) experiments that show Al2O3 undergoing a self-limiting lithiation reaction with Li metal, while ZnO reacts completely with Li to form a LiZn alloy and Li2O. These chemical differences at the interface result in higher and lower lithium plating nucleation overpotentials for Al2O3 (up to 220 mV) and ZnO (down to 15 mV) coatings, respectively, relative to uncoated Cu electrodes (35 mV). Time-of- flight secondary ion mass spectrometry (ToF-SIMS) reveals lithium plating underneath a reacted LiyAlOx coating and through emergent defects and pinholes with Al2O3@Cu electrodes, while it plates exclusively on top of the electronically conductive converted ZnO@Cu electrodes. Scanning electron microscopy (SEM) corroborates these mechanisms by showing sparse coverage of isolated Li clusters plated with Al2O3@Cu electrodes, while Cu and ZnO@Cu grow more dense and interconnected lithium deposits. Despite both coatings improving different aspects of anode-free battery design, unmodified Cu electrodes show higher Coulombic efficiencies (~77%) than

Al2O3@Cu (up to 70%) and ZnO@Cu (up to 75%) electrodes. Increasing Al2O3 coating thickness decreases the practical current density compared to unmodified Cu (30 μA/cm2) but increasing ZnO coating thicknesses can double or triple this value. These (electro)chemical and morphological observations lead to the proposal of two mechanisms, where less-reactive metal oxides develop lithium-ion conductivity through the metal oxide structure to plate lithium underneath the coating, while more-reactive metal oxides undergo full reduction and conversion reactions that allow lithium to plate above the coating. The fundamental research here open paths for future work to leverage these mechanisms and explore other materials for high-efficiency anode-free SSBs.

3:45 PM ES03.11.02
Electrochemical Transport and Reaction in Polymer and Hybrid Electrolytes for Lithium Metal Batteries Daniel Hallinan[1,1], Anna Mills[1,1], Guang Yang[2] and Jagjit Nanda[3]; [1]Florida A&M University-Florida State University College of Engineering, United States; [2]Oak Ridge National Laboratory, United States; [3]SLAC National Accelerator Laboratory, United States

Increasing the energy density of lithium-ion batteries requires, among other advances, electrolytes that are compatible with lithium metal and next-generation cathodes. Polymer electrolytes play an important role in this regard, but overcoming slow ion transport is a major challenge. Recent advancements in time-resolved infrared spectroscopy to characterize salt diffusion in polymer electrolytes will be reported as well as efforts to electrochemically measure transference number and electrochemical reaction kinetics in these electrolytes. In addition to our efforts in developing characterization techniques, we will report recent progress in solid electrolyte development. Hybrid electrolytes that combine fast ion transport of ceramic electrolytes and processability of polymer electrolytes are promising. This requires either 1) low binder contents that maximize ceramic transport pathways or 2) unity polymer transference number that takes advantage of transport in both phases. Our progress in both of these directions will be discussed, focusing on 1) free-standing sulfide solid electrolytes with small amounts of inert binder and 2) polymer blend electrolytes. Both exhibit single-ion conduction, which yields numerous transport and efficiency advantages. The effect of processing solvent on binder-containing sulfide electrolyte properties will be covered. State of the art in the polymer blend electrolytes will also be reviewed including recent advancements from our team using precision polyanions with polyether solvating polymer. This presentation will cover miscibility, conductivity, and transference numbers as a function of composition and temperature. Distinct differences between blends containing different anionic forms will be explained in the context of ion correlation. Important future directions for polymer blend and hybrid electrolytes will also be discussed.

4:00 PM ES03.11.03
Enhancing Li Ion Conduction in Argyrodite Solid Electrolytes through Anion Site-Exchange Jing-Sen Yang and Ping-Chun Tsai; National Taiwan University of Science and Technology, Taiwan

The superionic solid electrolyte Li_6PS_5Cl (LPSC), featuring ionic conductivity on par with those of liquids, has gained intense interest in the development of all-solid-state batteries. However, the mechanisms behind such extraordinarily high ionic conductivity remain unclear. In previous works, a phenomenon involving positional exchange between S and Cl anions was observed, which we referred to as "S/Cl site-exchange." We disclosed the correlation between Li ion conduction and the S/Cl site-exchange by integrating DFT, AIMD and NEB simulations, along with ^{7}Li PFG NMR diffusivity measurements for the first time. A remarkable increase of ~10^2 times in Li ionic conductivity and a substantial reduction of ~160 meV in energy barriers are observed when the S/Cl site-exchange is introduced. We found out that transportation bottlenecks of Li ions are overcome through beneficial neighboring Li configuration induced by the S/Cl anion exchange. The comprehensive understanding of ion transport mechanisms in LPSC would help the design of solid-state fast ion conductors.

4:15 PM ES03.11.04
Partial Transport Optimization and Mechanochemical Characterization of The Cathode Active Material Li_2FeS_2 in all Solid-State Batteries Tim Bernges; Inorganic and Analytical Chemistry, University Muenster, Germany

Solid-state batteries spark tremendous interest given their potential to overcome the limitations of energy density that are present in conventional Li ion batteries. At the same time, with current state-of-the-art cathode active materials (CAM) employing critical elements such as Nickel and Cobalt, concerns regarding their scarcity and cost are raised even before the wide-spread implementation of the technology. To overcome these concerns, in this work, we evaluated the cation- and anion-redox (cathode) active material Li_2FeS_2 as an alternative candidate for solid-state batteries with a promising theoretical specific capacity of 400 mAh/g. By combining electrochemical characterization with studies of the partial conductivities, cathode composites are optimized in regard to their CAM and solid electrolyte composition, leading to an optimum between high initial capacities and capacity retentions. Half cells employing 50 to 60 wt.% CAM are shown as most promising candidates, without the necessity of carbon additives due to the intrinsically high electronic conductivity of Li_2FeS_2 >30 mS/cm. The kinetic limitations of the cells are further elaborated by current density dependent cycling (rate testing), showing that higher electronic conductivities, i.e., higher intermediate CAM loadings, benefit faster charging rates in comparison. This is a promising result given that higher loadings are thought after to reduce the amount of electrochemically inactive materials in solid-state batteries.
The study of kinetic limitations is complemented by mechanochemical characterization of the cells. Tracing the pressure changes during cycling, both with lithium-indium and LTO as reference electrodes, is used to gather insights into the origin of capacity fading. While usage of lithium-indium allows to capture the mechanochemical response of the system including effects of lithium intercalation and deintercalation in the reference anode, the use of LTO, i.e., a zero-strain material during cycling, allows characterizing the response of the cathode specifically. Thereby, the latter approach could be utilized to characterize not only the general mechanochemical response of Li_2FeS_2 cathodes, but also to capture how these change as a function of cathode composition, ultimately providing insights into the failure mechanism of Li_2FeS_2 containing cathodes.
In conclusion, this work represents an initial introduction of Li_2FeS_2 as a cathode active material candidate for all solid-state batteries. Furthermore, partial transport and mechanochemical characterization are utilized to optimize the cathode composition to achieve both, high average specific capacities, i.e., active material utilization, and high capacity retention. With that, this work is a foundation for further optimization of cells employing Li_2FeS_2 as CAM, and allows a general comparison to established solid state battery CAM, e.g., $Li(Ni,Mn,Co)O_2$ (NCM).

4:30 PM ES03.11.05
Investigation of Microstructural Impacts on Ionic Transport in $Li_7La_3Zr_2O_{12}$-$LiCoO_2$ Composite Structures Longsheng Feng, Bo Wang, Kwangnam Kim, Liwen Wan, Brandon Wood and Tae Wook Heo; Lawrence Livermore National Lab, United States

The ionic transport property of a solid composite cathode is sensitive to its microstructure, which has a critical impact on variability of the overall solid-state battery performance. In this presentation, we will discuss our recent microstructure-aware modeling effort on unraveling the relationship between microstructural features and effective ionic transport properties. Specifically, using $Li_7La_3Zr_2O_{12}$-$LiCoO_2$ composite cathode as a model system, we combine atomistically informed mesoscale modeling approach and machine learning (ML) analysis to examine how the local transport properties of individual microstructural constituents and their topological features affect the effective diffusivity of Li in the two-phase composites. In addition, our ML analysis identifies key microstructural descriptors for the effective transport property. Our framework can be extended for elucidating the intricate microstructure-transport property relationship in generic multiphase materials, which offers insights highlighting the importance of microstructure

engineering in tuning the properties of composite materials in diverse energy applications.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

SESSION ES03.12: Inorganic Electrolyte II

8:15 AM ES03.12.01
Mechanical Milling – Induced Microstructure Changes in Argyrodite Li_6PS_5Cl Solid-State Electrolyte and Influence on Electrochemical Performance Yixian Wang and David Mitlin; The University of Texas at Austin, United States

In the early stages of sulfide solid-state electrolyte (SSE) research, sulfides like Li_6PS_5Cl (LPSCl) were primarily synthesized in laboratories using fine precursors such as Li_2S, LiCl, and P_2S_5, employing meticulous synthetic procedures involving milling and sintering. This approach resulted in grams of as-synthesized SSE materials with a uniform particle size distribution and well-controlled morphology. Consequently, large-scale synthesis methods for LPSCl SSE have been developed, leading to the availability of commercial LPSCl SSE. Nonetheless, compared to lab-scale synthesis, commercial production of LPSCl SSE often yields a wide range of particle sizes and particle distributions. In-depth understanding is needed regarding how microstructural features such as the average particle size and distribution, and pore size and distribution, affect the compressed SSE's electrochemical performance.

In this presentation, we investigate mechanical milling – induced microstructure changes of LPSCl SSE and their influence on electrochemical performance. Planetary mechanical milling in wet media (m-xylene) is employed to alter commercial LPSCl powder. Quantitative stereology demonstrates how extended milling progressively refines grain and pore size/distribution, increases compact density, and geometrically smoothens the SSE-Li interface. Mechanical indentation demonstrates that these changes lead to reduced site-to-site variation in the compact's hardness. Microstructure, in turn, profoundly influences electrochemical behavior. For example, symmetric cells with 8 and 24-hour milled electrolytes remain stable after 190 cycles at 1 mA cm^{-2}/2 mAh cm^{-2}, while the unmilled baseline cells short-circuit during initial activation. The Li/Ni asymmetric half-cells with milled electrolytes allow for stable electrodeposition of approximately 20 mAh cm^{-2} (100 µm Li thickness), while the baseline shorts at 1.2 mAh cm^{-2}. Combined cryogenic focused ion beam (cryo-FIB) and X-ray photoelectron spectroscopy (XPS) demonstrate that milled microstructures promote uniform early-stage electrodeposition on foil collectors and stabilize solid electrolyte interphase (SEI) reactivity. Mesoscale modeling reveals the relationship between Li-SSE interface morphology and the onset of electrochemical instability, based on underlying reaction current distribution.

8:30 AM ES03.12.02
Formation of Lithium Lanthanum Zirconium Oxide Nanofibers: Insight from *In-Situ* Synchrotron X-Ray Scattering Study Jungkuk Lee[1], Michael J. Counihan[1], Wooseok Go[2], Pallab Barai[1], Sanja Tepavcevic[1], Mike Tucker[2], Marca M. Doeff[2], Venkat Srinivasan[1] and Yuepeng Zhang[1]; [1]Argonne National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States

Lithium lanthanum zirconium oxide ($Li_7La_3Zr_2O_{12}$) with a cubic crystal structure is a promising candidate for a solid-state electrolyte due to its good ionic conductivity, thermal stability, and relatively large electrochemical window against Li metal anodes. The formation of the cubic phase usually requests elevated temperatures and a relatively long annealing time. However, we have observed cubic phase LLZO at significantly lower temperatures in nanofibers than their bulk counterparts. To understand the phase transformation and stability of the LLZO nanofibers, we performed in-situ simultaneous Small-Angle and Wide-Angle X-ray Scattering (SAXS/WAXS) for the LLZO precursor nanofibers during their annealing between RT and 800 °C. In this study, we investigate the structural evolution and microstructure changes of the nanofibers as a function of temperature. The electrochemical properties of the LLZO nanofibers were also evaluated.

8:45 AM ES03.12.03
The Effect of Particle Size and Spatial Distribution on The Ion Transport Barrier in Polymer-Ceramic Composite Electrolytes Xi C. Chen[1], Ji-young Ock[1], Abigail Lee[2], Amit Bhattacharya[3], Tao Wang[1], Catalin Gainaru[1], Md Anisur Rahman[1], Sheng Dai[1], Raphaële Clement[3] and Alexei Sokolov[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States; [3]University of California, Santa Barbara, United States

Significant efforts have been made to develop composite electrolytes combining polymer matrix with Li-ion conducting inorganic solids for feasible construction of solid-state batteries. Two main mechanisms have been proposed to enhance the ionic conductivity of the polymer matrix: 1) through a fast ion-transport interface layer along the ceramic particle-polymer interface, and 2) through percolated ceramic particles. However, without proper selection of ceramic and polymer chemistries and control of interfacial interactions, the resulting composite often even exhibits decreased conductivity[1, 2]. Furthermore, even with favorable interfacial interactions, the size and spatial arrangement of the ceramic particles may significantly impact the electrochemical performance of the composite electrolyte.
In this work, we investigate the effect of particle size and spatial distribution in polymer-ceramic composite electrolytes. Two sizes of ceramic particles, $Li_{0.34}La_{0.56}TiO_3$ (LLTO) nanorods with average diameter of approximately 20 nm, and commercial LLTO particles with average diameter of 1 µm are dispersed in two polymer matrices, a single-ion-conducting polymer electrolyte and a dual-ion-conducting polymer electrolyte. The total ionic conductivity in composites made with the single-ion-conducting polymer electrolyte shows a two-fold increase with the addition of LLTO nanorods, compared with neat polymer electrolyte. In addition, Li ion diffusion is also getting faster in this composite. In comparison, composites made from commercial LLTO does not show improvement in conductivity. We explain these results by increased Li ion mobility in the polymer interfacial layer surrounding nanoparticles. The ion transport energy barrier in the composites is analyzed and quantified as a function of temperature through broadband dielectric spectroscopy (BDS) analysis.
The spatial distribution of LLTO particles within the polymer matrix also plays a role in ion transport of the composite. Two morphologies of composites are created for this comparison, a relatively uniform morphology where particles dispersed throughout the matrix, versus a layered morphology where the majority of the particles reside on one side of the matrix. Constriction factor significantly decreases the total ionic conductivity in the layered morphology. Through these investigations, we shed light on how to design composite electrolytes to maximize favorable ion transport paths and minimize barriers.

Preparation of Structured Garnet LLZO Composite Solid Electrolyte Using Graphene Oxide as a Template Daniel Chang, Wan-Yun Lee and Che-Ning Yeh; National Tsing Hua University, Taiwan

All-solid-state lithium-ion batteries are viewed as a promising candidate for next-generation batteries due to their safety and high energy density. Despite the enhanced safety of these batteries owing to the use of solid-state electrolytes (SSEs), there is still ample room for improvement in terms of their ionic conductivity. Among various types of SSEs, composite solid electrolytes (CSEs) stand out as they combine the benefits of polymer matrix and ceramic fillers. The ionic conductivity and transport behavior of CSEs is strongly influenced by the tortuosity and continuity of the ceramic fillers. Thus, achieving low tortuosity structures with straight, interconnected ion pathways in CSEs is highly desirable but challenging. In this work, we choose the garnet-type $Li_7La_3Zr_2O_{12}$ (LLZO) as the ceramic filler, because of its high ionic conductivity (10^{-4}-10^{-3} S/cm) at room temperature and its great chemical stability against lithium metal anodes. Additionally, we use poly(ethylene oxide) (PEO) as the polymer matrix to form the CSE. While most aligned ceramic scaffold are made by templating fixed structures, such as wood, cotton, or cellulose, we harness graphene oxide (GO) as a template to fabricate oriented LLZO structures. This method allows us to establish versatile processing techniques for designing distinct ceramic structures with interconnected pathways, including honeycomb and layered structure. Utilizing a uni-directional freeze-drying process, we successfully create interconnected ceramic structures with low tortuosity. Consequently, the corresponding CSE exhibits significantly improved ionic conductivity compared to CSEs with randomly mixed ceramic fillers. Our work provides a promising approach to the realization of CSEs with superior ionic conductivity and further advancing the prospects of safer, more efficient, and higher energy density batteries.

9:15 AM ES03.12.05
Understanding The Reactivity between $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ and Sintering Aids to Minimize Densification Temperatures in All-Solid-State Batteries Morgan Guilleux[1,2], Christel Gervais[1], Arnaud Perez[1,2] and Christel Laberty Robert[1,2]; [1]LCMCP, Sorbonne Université, France; [2]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), France

NaSICON-type materials like $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (LATP) are considered promising solid electrolytes for all-solid-state batteries due to their good total ionic conductivity of 10^{-4} S.cm^{-1} at room temperature. However, a critical issue concerns the processability of the solid electrolyte in the composite positive electrode[1]. Indeed, LATP must be densified by heat treatment (>900°C) to approach its maximum ionic conductivity and form an intimate contact with the active material. Nevertheless, chemical reactivity in the composite cathode has been observed as low as 700°C for some systems[2,3].
To prevent this reactivity, one strategy is to lower the densification temperature of this solid electrolyte. Multiple reports in the literature propose to use lithium salts as a sintering aid to achieve this goal. For example, $LiBF_4$ and LiF have been shown to densify the solid electrolyte LATP to relative densities above 90% of the theoretical density at temperatures ranging from 800°C to 900°C, respectively[4,5]. However, these sintering temperatures remain too high and close observation of powder X-ray diffraction data reported in the literature, confirmed by our own experimental results, shows that resistive impurity phases such as $LiTiOPO_4$ and $Li_4P_2O_7$ already form.
In this work, we investigated the chemical reactivity mechanism during the densification and sintering processes. We first studied the reactivity of several lithium salts with LATP (x = 0.3), using *in situ* and *ex situ* X-ray diffraction, Raman spectroscopy and *ex situ* solid-state NMR spectroscopy (^{7}Li, ^{27}Al, ^{31}P). We identified new intermediate phases for the first time, bringing a new light on the reactivity and sintering mechanisms. We show that lithium salts react with LATP at low temperature, long before they melt. This result interrogates the liquid phase sintering mechanism proposed in the literature and explain that the sintering temperature is not correlated to the melting point of the salt.
Decreasing the sintering temperature of LATP is a key challenge to achieve a viable composite positive electrode for all-solid-state batteries. Our work shows that the chemical reactivity between lithium salts and LATP is a limiting factor in decreasing the sintering temperature of the material below 700°C. This new knowledge enables us to reexamine sintering of oxide ceramics and explore new paradigms to address this challenge.

Low-Density Fast-Ion Conductors for High Energy Density Batteries Nahong Zhao, Aniruddh Ramesh, Rayavarapu Prasada Rao and Stefan N. Adams; National University of Singapore, Singapore

In order to realize the promise of superior energy density, the solid electrolytes in solid state batteries have to combine fast ionic conductivity with a low contribution to the overall cell mass. While the dead mass of the "separator" solid electrolyte layer can be minimized by reducing its thickness to the extent limited by operational safety and processability, in high energy density batteries 80-90% of the electrolyte in the cell will be the catholyte material within the inevitably thick composite cathodes. Thus, in the absence of fast-ion conducting high energy density cathode materials, low density catholytes are of key importance for the achievable energy density of all-solid state batteries. Additional constraints for low-density fast-ion conducting solids include of course electrochemical and electromechanical compatibility, as well as interface wettability with the active materials.
Here we discuss examples for two design strategies to realize such low density fast-ion conductors. The first strategy involves ultrathin ceramic-in-polymer Composite Solid State Electrolytes (CSSEs). We developed CSSEs combining Li-doped polyacrylonitrile with various ceramic electrolytes ($Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$, $LiTa_2PO_8$ etc.) with and without plasticizers. Optimized composites reach conductivities of 0.1 – 1 mS cm^{-1} at densities < 2 g cm^{-3} and retain wide electrochemical windows. Temperature-dependent analysis of Li^+ paths shows that the ceramic filler induces a percolating network of fast ion-conductive interphases below the glass transition of the bulk polymer. Spin coating and in situ UV-curing the precursor slurry on Li anode or composite cathode drastically reduces interfacial resistance. The electrochemical and mechanical performance of CSSEs are investigated. Symmetric cells cycled with up to 2 mA cm^{-2} over 500h retain a stable overpotential and no dendrite growth is observed. LFP/SSE/Li cells achieve a maximum specific discharge capacity of 148 mAh g^{-1} and retain 89% of that after 200 cycles. Stable room temperature cycling is demonstrated for cells with a cathode mass loading of 6 mg cm^{-2}. The strong binding and 3-dimensional architecture of the in situ-formed interfaces is crucial for the favourable cycling stability.[1]

An alternative all-ceramic strategy is to systematically explore the correlation between fast ionic conductivity, density and glass forming ability in crystalline and glass-ceramic oxides and oxyhalides [2]. The higher number of monovalent light halides required to balance the charges of (typically heavier) high valent glass-former cations helps to reduce the overall density and turns the materials less brittle. Compared to often close-packed halides, oxyhalides typically have reduced coordination numbers, which helps to create free volume for ionic motion. In view of their favorable oxidation stability yet limited reduction stability, oxyhalides should in particular be suitable for use as catholytes. The recent report of fast room temperature ionic conductivity of 10 mS cm^{-3} in $LiMOCl_4$ (M=Nb,Ta) [3] exemplifies the strong potential of the so far hardly explored class of oxyhalides. While the phases have originally been reported as orthorhombic and isostructural to moderate ion conductor $LiVOF_4$, our redetermination of $LiNbOCl_4$ (density 2.7 g cm^{-3}) finds a simpler, but Li-disordered, tetragonal crystal structure with smaller unit cell. The revised structure model yields more plausible bond valence sums and is consistent with DFT energy minimizations. Molecular dynamics simulations utilizing our bond-valence related embedded-atom method type forcefield softBV-EAM reveal the ion transport mechanism and its relation to the local rotational mobility of the $(MOCl_4^-)_n$ chains [4].

Electrochemical Performance of Si/C-Argyrodite Solid-State Composites: Limitations of The Effective Ionic Transport Yannik Rudel[1] and Wolfgang Zeier[1,2]; [1]University of Münster, Germany; [2]Helmholtz-Institut Münster Forschungszentrum Jülich, Germany

Silicon-graphite composite electrodes have emerged as an alternative to lithium metal or silicon anodes in all solid-state batteries due to their resistance to electro-chemomechanical failure, while maintaining low lithiation potential.[1] While those materials are designed for lithium-ion batteries, their limited intrinsic ionic conductivity hinders application in all-solid-state batteries requiring efficient charge carrier transport in the all-solid electrodes. Therefore, a design of the effective conductivities is imperative to achieve the best electrochemical performance. This can only be achieved by understanding the relations of charge carrier transport in the used materials as well as their composites under careful consideration of their preparation.[2]
In our study, we focus on understanding the impact of charge carrier transport within a composite of silicon on graphite and argyrodite solid electrolyte on the electrochemical performance. Through a systematic variation of the Si/C to solid electrolyte ratio we show an exponential increase of the effective ionic conductivity in the anode composite with increasing content of solid electrolyte. Simultaneously, the electronic transport remains high (~S/cm) and virtually independent of the volume fraction. This enhanced effective transport in the composites translates to a substantial improvement in the specific capacities achievable when charging and discharging across various C-rates.[3] In addition, we investigate the influence of temperature to gain information about the activation energy of the ionic transport in the composites. Our results underscore the importance of tailoring charge carrier transport properties in solid-state composite anodes to achieve optimal electrochemical performance.[3]

Room 423, Level 4, Summit

10:30 AM ES03.13.01
Design of a Polymer Electrolyte with High Ionic Conductivity through an *In-Situ* Polymerization Approach Md Anisur Rahman, Catalin Gainaru, Georgios Polyzos, Xi C. Chen, Valentino R. Cooper and Alexei Sokolov; Oak Ridge National Laboratory, United States

Solid-state lithium metal batteries have risen as highly promising contenders for the next generation of energy storage systems, primarily because of their inherent safety, stability, and higher energy density. Nevertheless, they have yet to reach practical viability, primarily due to challenges related to solid-state electrolytes. In this study, we introduce a groundbreaking method for generating a polymer electrolyte with superior room-temperature lithium-ion conductivity and excellent interfacial stability. This approach involves the in-situ copolymerization of standard ionic-conducting and single-ion-conducting monomers in the presence of a lithium salt. This polymer significantly enhances the cation transference number and facilitates uniform contact with electrodes, resulting in the suppression of dendrite growth. This is attributed to the even distribution of charge at the electrolyte-electrode interface. This research presents a successful strategy for establishing a stable electrolyte/Li interface, thereby laying the foundation for the accelerated development of long-lasting solid-state lithium metal batteries. This presentation provides an overview of our ongoing endeavors to design a polymer electrolyte with exceptional ionic conductivity, aimed at enhancing the safety and stability of solid Li-Metal batteries.

10:45 AM ES03.13.02
TFSI-Based Single-Ion Conducting Polymer Electrolytes for Solid State Batteries Ain Uddin[1], Michelle Lehmann[1], Catalin Gainaru[1], Alexei Sokolov[1,2] and Tomonori Saito[1,2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

The development of high performance ion conducting materials that are lightweight and flexible with improved safety are imperative for next generation energy storage technologies, including lithium (Li)-ion batteries, sodium (Na)-ion batteries, supercapacitors, fuel cells, flow batteries, and many others.

High-performance solid-state polymer electrolytes have the potential to address various challenges in electrical energy storage devices if they can meet the requirements of (i) high ionic conductivity; (ii) sufficient mechanical strength; (iii) high transport number; and (iv) wide electrochemical stability window. However, dry polymer electrolytes lack sufficient ionic conductivity to meet cell power requirements. While improving ion conductivity of polymer electrolytes is generally a challenge due to a trade-off between ion conductivity and polymer segmental dynamics, mechanically robust single-ion conducting solid polymer electrolytes provide promise due to maintaining high transport number and enabling high conductance. This presentation will discuss our progress on the design of trifluoromethanesulfonimide (TFSI)-based single-ion conducting polymer electrolytes for Li- and Na- ion batteries, as well as other energy storage applications. Specifically, we have successfully synthesized TFSI-functionalized polynorbornene (PNB) derivatives. Due to the polyolefinic structure of PNB backbone, TFSI-PNBs form a new family of single-ion conducting polymers with particularly high mechanical and electrochemical stability. In addition, the ionic conductivity of TFSI-PNB is significantly higher (8 orders of magnitude) compared to other TFSI-based polymer electrolytes such as TFSI-polystyrene or TFSI-polymethacrylate. The structure-property relationships of ion conductivity, plasticization, mechanical and electrochemical properties as well as their cell performance will be discussed.

11:00 AM ES03.13.03
Covalent Organic Framework based Solid State Electrolytes: A Breakthrough for Safer and High-Performance Energy Storage Devices Chaoqun Niu; Westlake Education, China

The development of high-performance solid state electrolytes is a key milestone in advancing the safety, performance, and energy density of energy storage technologies, particularly in lithium ion batteries. Covalent Organic Frameworks (COFs), with their unique structural tunability, high thermal and chemical stability, and inherent porosity, have emerged as a promising candidate for solid state electrolytes. Our presentation explores cutting-edge research in the design, synthesis, and characterization of COF-based solid-state electrolytes and their transformative potential in the realm of energy storage.
We will discuss the rational design of COFs tailored for solid state electrolyte applications, focusing on factors such as framework stability, and ion conductivity. By judiciously modifying COF structures, we can enhance their ion transport properties, leading to improved ionic conductivity and electrochemical stability. These studies shed light on the mechanisms of ion transport, electrochemical stability, and long-term performance of COF-based electrolytes.
In conclusion, this research represents a significant advancement in COF-based solid-state electrolyte development, offering solutions to the pressing challenges in energy storage technology. We anticipate that the insights and breakthroughs presented here will pave the way for the practical implementation of COF-based solid-state electrolytes, fostering discussions and collaborations within the materials science community, and catalyzing the transformation of energy storage technologies toward a safer and more efficient future.

A Super-Ionic Solid State Block Copolymer Electrolyte Stephan Foerster[1], Daniel Krause[2], Beate Förster[1], Jürgen Allgaier[1], Monika Schönhoff[2] and Hans-Dieter Wiemhöfer[2]; [1]Forschungszentrum Jülich, Germany; [2]Universität Münster, Germany

Lithium ion batteries are a key energy storage technology for electric vehicles and mobile portable devices. The related electrolyte materials are intensely investigated with respect to improvements in ionic conductivity, stability and safety. Solid polymer electrolytes represent a promising alternative, because of their compatibility with large-scale manufacturing processes, mechanical stability and toughness and good electrode adhesion, and improved safety. However, their low lithium ion conductivity, particularly at room temperature, has so far limited their applications. Ion conduction in solid polymer electrolytes is coupled to the segmental motions of the polymer chains, which is particularly slow for crystalline polymers and polymers with low glass transition temperatures. For polyethers such as polyethylene oxide (PEO), Li ion conduction occurs via coordination with the oxygen atoms by intersegmental hopping from one coordination site to another. Since PEO is crystalline below its melting temperature of ca. 60 °C, its segmental mobility at room temperature is very low, limiting its applications.

We systematically investigated the Li ion conductivity of PEO block copolymers loaded with LiTFSI-salt at high salt loadings from [Li:EO] = 0.1 – 10. We observe that super-stochiomeric addition of LiTFSI leads to the formation of a crystalline PEO/LiTFSI-phase that shows super-ionic conductivity. Concomitantly, the addition of LiTFSI increases the PEO-volume fraction in the block copolymers, thereby inducing a phase transition from hexagonally ordered cylinders to the bicontinuous gyroid phase. The crystalline superionic PEO/LiTFSI phase within the bicontinuous gyroid phase leads to solid electrolyte block copolymer membranes showing exceptionally high Li ion conductivities. We find ion conductivities of > 10 $mScm^{-1}$ at 0°C, and values of > 100 $mScm^{-1}$ at 80°C, which are in the range of the best inorganic Li ion conductors such as LGPS. The very low activation energies, in the range of 0.2 – 0.3 eV, the sharp increase of the ion conductivity at superstochiometric addition, and the narrow relaxation time distribution as measured by ^{7}Li-NMR indicate a super-ionic conduction mechanism in the solid polymer electrolyte. Therefore, these materials open the way for solid polymer electrolytes with sufficiently high ion conductivites for commercial applications.

11:30 AM ES03.13.05
Submicron-Thick Single-Ion-Conducting Polymer Electrolytes via Initiated Chemical Vapor Deposition Hunter Ford, Ramsay B. Nuwayhid, Brian Chaloux, Michael Swift, Christopher Klug, Youngchan Kim, Xiao Liu, Battogtokh Jugdersuren, Jeffrey W. Long, Debra R. Rolison, Rachel Carter and Megan B. Sassin; U.S. Naval Research Laboratory, United States

Three-dimensional (3D) electrodes and architectures are becoming more prevalent in next generation batteries leading to enhanced performance. For instance, in the case of Zn-based batteries, a 3D Zn electrode alleviates current hotspots mitigating shape change[1], while in the case of Li–S batteries a 3D porous carbon nanofoam helps to prevent dissolution and diffusion of active material.[2] Additional functionality and flexibility can be unlocked via modification of the extensive surface area of the 3D components, such as incorporating coatings to enhance electrolyte wettability, serve as an artificial solid-electrolyte interphase, or as a solid-state electrolyte. Conformally and homogeneously coating the interior and exterior surfaces of a complex, macroscopically thick 3D structure necessitates the use of non-line-of-sight deposition techniques.
Initiated chemical vapor deposition (*i*CVD) is a non-line-of-sight method that has demonstrated utility to generate conformal polymer coatings with tunable thickness on both 2D and 3D substrates. Recently, we have reported on the post-deposition modification of *i*CVD-derived polymer films to produce a submicron-thick anion-conducting polymer electrolyte.[3,4] To build off of these results, we move to generate cross-linked co-polymer systems via *i*CVD,

based off of divinylbenzene and 4-dimethylaminomethylstyrene (DVB-co-DMAMS), and use post-processing protocols to impart specific performance functionalities. The co-polymer can be rendered as a single-anion conducting solid-state electrolyte (SSE) and we show that the ionic conductivity of the SSE depends upon the DVB/DMAMS ratio, the mobile ion identity, and network plasticization, with anion conductivity nearing 1 x 10^{-4} S cm^{-1} under optimal conditions. Molecular dynamic simulations are further used to probe ion transport, which coupled with mechanical property analysis enables structure-chemistry-property relationships to be determined. The *i*CVD generated SSEs facilitate anionic redox chemistry (Zn/ZnO, Ag/ZnO) without the use of an additional separator or free salt, a major advancement for improving specific cell capacity. Coupling iCVD with mass-scalable post-processing protocols to impart specific performance functionality of submicron-thick SSEs opens the door to advanced 3D electrodes and components to enable next-generation energy storage systems with high performance metrics.

11:45 AM ES03.13.06
Facile Synthesis of Li Argyrodite Materials as a Solid Electrolyte JaeSeong Yoo and Jae-Hun Kim; Kookmin University, Korea (the Republic of)

Recently, research on next-generation secondary batteries has been actively pursued to develop high-energy-density and safe battery technologies. Currently, liquid electrolytes are utilized in Li-ion batteries (LIBs), which are flammable and volatile. Replacing the liquid electrolyte with solid materials could facilitate a high-capacity Li metal anode and enhance the safety of LIBs. Solid electrolyte materials in all-solid-state batteries (ASSBs) are categorized into oxides, sulfides, and polymers. Among these, sulfide-based materials offer several advantages, including high ionic conductivity and excellent processability.
The Li-argyrodite materials (Li_6PS_5X, X= Cl, Br, and I) are exemplary sulfide-based materials renowned for their high ionic conductivity and electrochemical stability. However, a challenge exists in the current synthesis of argyrodite due to the elevated cost of lithium sulfide (Li_2S), an essential precursor for producing argyrodite-type materials. The high expense associated with Li_2S amplifies the production costs of solid electrolytes, presenting a significant barrier that impedes the widespread commercialization of ASSBs. Consequently, there is a growing demand for an economical method to synthesize Li_2S at a lower cost. Another approach involves synthesizing sulfide-based materials without the reliance on Li_2S.
In this study, we introduce a novel method for synthesizing argyrodite materials, employing Li_3N as the primary starting material instead of Li_2S. Li_6PS_5Cl can be efficiently prepared through a one-step ball milling process. The resulting material (Li_6PS_5Cl) demonstrated an ionic conductivity of 1.1 mS cm^{-1}, comparable to the room temperature conductivity of established Li_6PS_5Cl solid electrolytes. This approach has the potential to lower the cost of solid electrolyte synthesis and enhance time efficiency.

Sequencing Polymers for Room-Temperature Solid-State Batteries Xinrong Lin[1], Shantao Han[2] and Mao Chen[2]; [1]Duke Kunshan University, China; [2]Fudan University, China

For decades, liquid electrolytes have been adopted in lithium-ion batteries to bridge the interspace between electrodes and transport ions. In an era aspiring deep electrification and decarbonization in transportation and power sectors, polymers are expected to double energy density at the system level when combined with lithium anode, and enable all-solid-state battery (ASSB) that offers enhanced safety, processability and flexibility. Unfortunately, the long-standing crux to designing high-performance polymer electrolytes is their poor ion conductivity, which is limited by chain mobility and number of dissociated ions in polymer matrix. Previously, researchers have almost always focused on increasing segmental chain motion to improve ion transport, such as adding plasticizing additives or changing molecular compositions, which could lead to compromised mechanical integrity and polarization-related transport loss. In the meantime, though the importance of dissociated ions is empirically considered, the sequence strategy to modulate polymer transport and achieve delicate control of ion dissociation is almost universally overlooked.

Inspired by natural macromolecules that can achieve complex regulation by delicately controlling sequential arrangement of the backbone, we envision that manipulating polymer sequence could facilitate ion dissociation and strengthen control of transport in polymers. Herein, with a combination of experimental and computational methods, we prove the fundamental significance of polymer sequencing in ion transport and create homogeneous Li^+ distributions, non-aggregated Li^+ solvation structures and enhanced Li^+-anion dissociation in a designed solid-state fluorinated single-ion polymer electrolyte with alternating sequence (alter-SIPE). Perhaps most remarkably, in dry polymers, the alternately sequenced polymer leads to a concerted PEO-Li^+-anion migration pathway, allowing conductivity tuned up by 1-3 orders of magnitude at 30 degC, which is comparable to that of liquid-state polyethylene oxide (PEO). In addition, we demonstrate that the exceptional ionic conduction capacity of our alter-SIPE could enable dendrite-free operation and reversible cycling in Li‖$LiFePO_4$ (LFP) ASSBs with a high coulombic efficiency.

8:15 AM ES03.14.02
A Metal-Free Quasi-Solid-State Battery for Better Safety and Sustainability Ying Wang; Louisiana State University, United States

Solid-state rechargeable batteries promise high energy, low cost, and improved safety/stability. Hence, they are considered as the new-generation battery technology for electric vehicles and grid-scale electricity storage, and expected to meet other critical needs for more compact and higher-capacity energy storage devices. On another note, current commercial batteries are mainly metal based, with metal elements in charge carriers and/or electrode materials, which poses potential economic and environmental concerns due to the heavy use of nonrenewable metals. Thus, metal-free batteries provide a more sustainable and environmental-friendly alternative to these batteries, though the relevant research is still in its infancy. Recently, rechargeable batteries based on aqueous electrolytes have shown high potential attributed to their low cost and intrinsic safety. An appealing choice is an aqueous battery using

non-metal ions as charge carriers, such as ammonium ion with a lighter molecular weight (18 g/mol) and a small hydrated ionic size of 3.31 Å, leading to faster ion diffusion in the electrolyte. Furthermore, by combining with organic electrodes, nometal ammonium-ion charge carreries make it possible to realize metal-free batteries that offer affordable, eco-friendly, and sustainable alternatives to current metal-based batteries.
In this work, a novel quasi-solid-state metal-free battery is assembled using a hydrogel electrolyte sandwiched between polypyrrole cathode and polyaniline anode. A hydrogel is a hydrophilic polymeric network containing large amounts of water. Herein, the quasi-solid-state hydrogel electrolyte is simply synthesized using ammonium sulfate, water, and xanthan gum that is edible and biodegradable. Concentrated salts are used to decrease the amount of free water molecules in the hydrogel electrolyte, and thus reduce hydrolysis and side reactions from water. Both the salt concentration and the polymer content in the hydrogel can be facilely tuned and optimized, to minimize side reactions and maximize ionic conductivity and mechanical strength of the electrolyte, as monitored by XRD, SEM, XPS, Raman spectroscopy, electrochemical characterizations, impedance measurements, tensile and adhesion tests, leading to superior performance of the battery. As such, this study presents the first quasi-solid-state non-metal battery with lower cost and better performance, which opens the door to future metal-free electronics that would generate long-term benefits to environment.

8:30 AM ES03.14.03
Electrolytes for Lithium and Sodium Ion Batteries: The Road from Ionic Liquids to Deep Eutectic Solvents and from Solid Ionogels to Eutectogels
An Hardy[1,2,3], Jonas Mercken[1,2,3], An-Sofie Kelchtermans[1,2,3], Bjorn Joos[1,2,3], Dries De Sloovere[1,2,3] and Marlies K. Van Bael[1,2,3]; [1]Hasselt University, Belgium; [2]IMEC, Belgium; [3]Energyville, Belgium

In order to increase the energy density as well as the safety of alkali ion batteries, efforts over the past years have focused on solid electrolytes, mainly for Li^+ conduction. Among these, the solid composite electrolyte (SCE) consists of a liquid immobilized in a solid skeleton, for example the ionogel which confines an ionic liquid within an inorganic or hybrid solid matrix.
Since deep eutectic solvents have advantages over ionic liquids, such as ease of preparation, cost etc. we proposed a eutectogel (ETG) for lithium ion batteries composed of a DES (LiTFSI/NMA) in a solid silica matrix with a high ionic conductivity of 1.46 mS/cm, high thermal (130°C) and electrochemical stability (up to 4.8V)[1]. However, these materials also are brittle, which in the final cell will influence the interfacial resistance as the contact with the electrode may be limited, besides cracking, limiting the cell performance. Therefore, two strategies were followed for improvement. First, the silica matrix was replaced by a polymer matrix, called the P-ETG, achieving 0.78 mS/cm, stability up to 4.5 V and improved fire safety in comparison to the conventional liquid electrolyte (1M $LiPF_6$ in EC/DEC)[2]. Depending on the polymer that is used to build the matrix, the stability could be further improved (1.5-5.0V), which allows stable cycling with high energy density NMC622 cathodes[3]. Furthermore, insights into the DES-polymer interaction allow to optimize the conductivity from 0.4 mS/cm to 1 mS/cm at 25°C[4].
Second, turning to sodium ion batteries, the silica matrix was organically modified with phenyl groups in ionogels, which reduces the Young's modulus from 29 to 6 MPa. This improves the charge transfer resistance in $Na/Na_2Ti_3O_7$ half cells, but also decreases the ionic conductivity somewhat to 3 mS/cm; the anodic stability was 3.9V vs. Na^+/Na [5]. The reason that the latter material was an ionogel, was that to the best of our knowledge, at the time there wasn't any suitable sodium ion conducting DES available in literature. Therefore, its development became the subject of our research as well. A first DES consists of NaTFSI and NMA, demonstrating that high concentrations of salt are needed to improve the electrochemical (up to 4.65 V) and fire hazard stability, while compromising the conductivity, which for the most stable electrolyte is 0.3 mS/cm at 20°C[6]. A remaining issue for this DES is that even the highest concentrated one is not stable in contact with Na metal. This is tackled by a novel composition, with optimized sodium metal compatibility and anodic stability up to 4.0 V vs. Na^+/Na, and half cells with cycle life and coulombic efficiency on par with cells built with conventional carbonate-based electrolytes[7]. The development of these novel Na^+ conducting DES, paves the way to their incorporation into a solid matrix towards the formation of Na^+ ion conducting eutectogels[8].
In summary, in this presentation an overview of the group's work of the past 5 years will be given, to show that quite a distance has been travelled on the road from ionic liquids to deep eutectic solvents as liquid electrolytes for sodium ion batteries, and from ionogels to eutectogels in both lithium ion batteries and sodium ion batteries. This has allowed to achieve improvements in cell performance regarding energy density, stability, safety and compatibility with metal anodes.

Effect of $Li_x(MgCoNiCuZn)_{1-x}O$ as High-Dielectric Permittivity Fillers for Composite Polymer Electrolytes
Sebastian I. Calderon Cazorla[1], Joseph Libera[2], Juan Carlos Verduzco[1], Kaiqi Zhang[1], Alexander Wei[1] and Ernesto Marinero[1]; [1]Purdue University, United States; [2]Argonne National Laboratory, United States

Composite polymer electrolytes (CPEs) are leading hybrid solid-state materials to replace flammable liquid electrolytes in lithium-ion, lithium-metal, and lithium-sulfur batteries (LIBs). Their advantage lies in the possibility to combine the flexibility and chemical stability of polymers with the mechanical and electrochemical robustness of ceramics, enhancing the typically poor ionic conductivity (σ) and transference number of the organic component. A full understanding of the mechanisms of ion conduction in such systems is still not fully well understood resulting in a limitation to produce materials having optimum transport properties. In previous work, we have observed that the increase in ionic conductivity of CPEs is not proportional to the low weight load of fillers utilized, suggesting that their surface properties may be more influential than their bulk features. One of such properties is the filler nanoparticle dielectric permittivity, which describes the ability of a material to be polarized in an electric field. In this regard, the Anderson-Stuart model suggests that dielectric permittivity is inversely proportional to the strength of interaction between Li^+ and ether-O-atom in a polymer like PEO. In consequence, our work focuses on evaluating CPEs containing fillers with different dielectric constants such as $Li_6La_3ZrBiO_{12}$ garnets ($\varepsilon \sim 30$) and high entropy oxides (HEO) such as $Li_x(MgCoNiCuZn)_{1-x}O$ which are reported to have "colossal" dielectric constants reaching values of 10^5 at 420°C and 20Hz. We propose to

understand whether the relationship between dielectric constant and ionic conductivity is expressed as changes in the microstructure of the polymer/ceramic interface, improvement in the salt dissociation and/or immobilization of the anion on the surface of these fillers. Dielectric spectroscopy results show a good correlation of dielectric permittivity at low frequencies versus ionic conductivity, for example EIS analysis show a monotonic overall increase in ionic conductivity of membranes when decreasing EO:Li, each series showing a σ_{max} at 4% wt. HEO. More importantly, when decreasing the particles size from 2µm to 200nm, we saw an order of magnitude increase in σ to $5.3x10^{-5}$ Scm^{-1} when keeping EO:Li as 20:1. To provide a mechanistic understanding of our observations, in addition to transport measurements, we utilize XRD, SEM, DSC, polarizing light microscopy and Raman spectroscopy to elucidate changes in polymer morphology and microstructure as well on Li-salt dissociation that are responsible for the improvements in ion transport observed.

9:00 AM ES03.14.05
Stable Hydroborate Solid-State Lithium Battery with High-Voltage NMC811 Cathode Hugo Braun[1], Ryo Asakura[1], Arndt Remhof[1] and Corsin Battaglia[1,2,3]; [1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland; [3]EPFL, Switzerland

Hydroborate solid electrolytes offer high ionic conductivity and are stable in contact with alkali metal anodes, but are challenging to integrate into batteries with high-voltage cathodes [1-3]. Here, we demonstrate stable dis-/charge cycling of solid-state lithium-ion batteries combining a $Li_3(CB_{11}H_{12})_2(CB_9H_{10})$ hydroborate electrolyte with a 4 V-class $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ (NMC811) cathode, exploiting the enhanced kinetic stability of the $LiCB_{11}H_{12}$-rich and $LiCB_9H_{10}$-poor electrolyte composition [4]. Cells with lithium metal and indium/lithium anodes achieve a discharge capacity at C/10 of ~145 mAh g^{-1} at room temperature and ~175 mAh g^{-1} at 60 °C. Indium/lithium cells retain 98% of their initial discharge capacity after 100 cycles at C/5 and 70% after 1000 cycles at C/2. Capacity retention of 97% after 100 cycles at C/5 and 75% after 350 cycles at C/2 is also achieved with a graphite anode without any excess lithium. The energy density per cathode composite weight of 460 Wh kg^{-1} is on par with the best solid-state batteries reported to date.

Synergistic *In-Silico* Design and Electrochemical Characterization of Solid-State Electrolytes with Fully Earth Abundant Chemical Compositions for Na/K-Metal Batteries Ivano Eligio Castelli, Chiara Spezzati, Benjamin Sjølin and Mohamad Khoshkalam; Technical University of Denmark, Denmark

The concept of corner-sharing frameworks is fundamental to the design of oxide solid-state electrolytes with superionic conductivity for alkali-metal ions such as Li^+ and Na^+. These structures are composed of a highly covalent skeleton of corner-sharing polyhedra, allowing alkali-metal ions to diffuse through interconnected and highly metastable interstitial positions within the framework.In this study, our focus is on a class of earth-abundant rock silicates as solid-state electrolytes (SSE) for Na/K-metal batteries. Through a synergistic approach involving in-silico design and electrochemical characterization, we investigated the relationship between structural features—such as migration energy barriers for Na^+ and K^+, bottleneck pathways in the skeleton structure, polyhedron packing ratio, and continuous symmetry measure—with SSE performance indicators such as ionic conductivity and phase stability under ambient conditions. Our preliminary investigations indicate that a high Continuous Symmetry Measure value in Na/K-polyhedra, along with a low packing ratio of the skeleton structure, are key features in achieving fast kinetic transport for Na^+ and K^+. Experimental results demonstrate that by applying this hypothesis, it is possible to achieve Na^+/K^+ ionic conductivity levels in the range of 10-0.1 mS/cm at 50 °C, using a fully earth-abundant chemical composition without relying on rare-earth or multi-valent transition metal ions. An SSE based on the Na-Mg-Al-Ca-Si-O oxide system was fabricated into thin, self-standing tape-cast layers under ambient conditions. These thin, self-standing layers, in a symmetrical cell configuration of Na/SSE/Na, cycled for more than 50 cycles up to 1 mA/cm2 at 50 °C. The utilization of earth-abundant rock silicates as SSE, demonstrated through synergistic in-silico design and experimental characterization, offers a promising avenue for the development of high-performance and sustainable solid-state batteries, showcasing significant potential in achieving enhanced ionic conductivity and phase stability without relying on rare-earth or multi-valent transition metal ions.

Polymerized Acrylonitrile Artificial SEI for Long-Life Li-Metal Battery and Enhanced Stability for Li/$Li_{10}GeP_2S_{12}$ Interface Binh K. Hoang[1], Roya Damircheli[1], Madison Brausch[1], Victoria Castagna Ferrari[2], Nhi Nguyen[1] and Chuan-Fu Lin[1]; [1]The Catholic University of America, United States; [2]University of Maryland, United States

Lithium metal anode batteries have attracted significant attention as a promising energy storage technology, offering a high theoretical specific capacity and low electrochemical potential. Utilizing lithium metal as the anode material can substantially increase energy density compared to conventional lithium-ion batteries. However, the practical application of lithium metal anodes has encountered notable challenges, primarily due to the formation of dendritic structures during cycling. These dendrites pose safety risks and degrade battery performance. Addressing these challenges necessitates the development of a reliable and effective protection layer for lithium metal. This study presents a cost-effective and convenient method to produce lithium metal protective layers by creating ex-situ polymer layers using acrylonitrile (AN). This method extends the lifetime of lithium metal anodes by a remarkable factor of six under high current (1 mA/cm^2) cycling conditions. While the cycle life of bare lithium metal is approximately 150 hours under high current conditions, AN-treated lithium metal anodes exhibit an impressive longevity of over 900 hours.
Furthermore, with the increasing attentions on solid-state electrolytes – which address the safety concerns and energy density limitations associated with conventional liquid electrolytes in lithium-ion batteries, the interface between Li metal and solid-state electrolytes has been the major challenges. For example, $Li_{10}GeP_2S_{12}$ (LGPS) stands out among these solid electrolyte materials, boasting high ionic conductivity (1 x 10^{-2} S cm^{-1}). Nonetheless, the severe instability of the interface between lithium metal anodes and solid electrolytes, including dendrite formation and electrolyte degradation, hindering their practical implementation. This work also goes deeply to explore the stability and performance of Li | LGPS systems by utilizing a polymerized acrylonitrile interfacial. By elucidating the mechanisms governing the interfacial layers, this low-cost fabrication of AN-treated lithium metal holds significant potential for advancing the commercialization of future lithium-metal batteries, surpassing the capabilities of traditional lithium-ion batteries.

10:45 AM ES04.01.06
Computational Analysis of a Promising Earth Abundant, Stable, Lithium Solid Electrolyte Benjamin A. Williamson, Daniel Rettenwander and Sverre Selbach; Norwegian University of Science and Technology, Norway

Solid state electrolytes offer the potential to drastically increase the overall stability of rechargeable lithium batteries as well as provide the means to realise the use of Li-metal anodes maximising the charge capacity of a device. At present, batteries use liquid electrolytes such as $[LiPF_6]^-$ which although they possess high ionic conductivities of $1x10^{-2}$ S cm^{-1}limit the safe temperature ranges a battery can be operated at as well as forbidding the use of Li-metal anodes due to dendrite formation leading to short circuiting and “thermal runaway”. Solid electrolytes such as the Li-rich garnet materials, LLZO, or anti-perovskites, Li_3OCl, have demonstrated low migration barriers (<0.3 eV), however issues arise regarding stability or a competing lower conductivity phase. In this work, we have identified a promising Earth-abundant, non-toxic, stable Li-solid electrolyte. Using a combination of density functional theory and experiment, we show that this material possesses thermodynamic, dynamic and electrochemical stability, ideal defect chemistry and low migration barriers leading to undoped conductivities of ~10^{-5} S cm^{-1} which are expected to rise to at least 10^{-3} S cm^{-1} with minimal doping.

Lithium Metal Solid-State Batteries: Anode-Free vs. Lithium Excess Matthew McDowell; Georgia Institute of Technology, United States

Solid-state batteries offer the promise of improved energy density and safety compared to lithium-ion batteries. The electro-chemo-mechanical evolution of materials at solid-solid electrochemical interfaces is different than at solid/liquid interfaces, and contact evolution in particular plays a critical role in determining the behavior of solid-state batteries. Lithium metal anodes in solid-state batteries are intrinsically limited by void formation during stripping and dendrite growth during plating. Anode-free solid-state batteries, in which there is no initial lithium metal at the anode interface, offer extremely high energy density, but there is a lack of understanding of how their behavior differs from excess-lithium electrodes. Using X-ray tomography, cryo-FIB, and finite-element modeling, we show that anode-free solid-state batteries are intrinsically limited by current concentrations at the end of stripping due to localized lithium depletion. This causes accelerated short circuiting compared to lithium-excess cells. Based on these results, the beneficial influence of metal alloy interfacial layers on controlling lithium evolution and mitigating contact loss from localized lithium depletion, including at low stack pressures, will be discussed. X-ray tomography is further shown to be particularly useful in observing the dynamic evolution of lithium metal, including void formation and filament growth. Finally, lithium metal composites offer a “middle ground” between lithium-excess and anode-free electrodes, and we show that composite electrode structure can act to enhance the effective transport of Li to the interface and therefore enable improved lithium operation at practical stack pressures < 2MPa.

11:30 AM *ES04.01.08
Critical Current Densities for Short-Circuiting of Solid-State Electrolytes Ryo Kurose[1], Yasutoshi Iriyama[1] and Munekazu Motoyama[2]; [1]Nagoya University, Japan; [2]Kyushu University, Japan

The cubic phase $Li_7La_3Zr_2O_{12}$ (LLZ) exhibits Li^+ conductivity on the order of 10^{-4} S cm^{-1} at room temperature and has sufficient stability even in contact with molten Li [1)]. Additionally, its shear modulus is several times greater than those of sulfide solid electrolyte materials [2)], and it is thus expected to act as a promising solid-state electrolyte for preventing dendrite growth of Li metal. However, it has been reported that repeated charging/discharging of Li metal anodes causes short circuits, even with LLZ. Similar results were reported by subsequent researchers, and it was gradually realized that the short-circuit problem was more difficult to solve than originally thought.
Various models of the short-circuit mechanism of LLZ have been discussed [3,4)], but there is no experimental confirmation of what determines the critical current density (CCD) that induces shorts. This is partly because Li voids are easily formed at the Li/LLZ interface, making it difficult to compare the CCD values under fair conditions. In the present study, the CCD was measured by keeping the Li/LLZ interface constant. The temperature dependence of the CCD was also clarified, and the short-circuit mechanism was discussed based on the activation energy values of the CCD.

SESSION ES04.02: Li Metal—Electrolyte and Interface
Session Chairs: Tao Gao and Yuzhang Li
Tuesday Afternoon, April 23, 2024
Room 422, Level 4, Summit

2:00 PM ES04.02.01
Indigo as Single Additive in Liquid Electrolyte for Lithium Metal Batteries Charlotte Mallet, Emmanuelle Garitte and Rochon Sylviane; Center of Excellence in Transportation Electrification and Energy Storage, Canada

Rechargeable lithium ion batteries (LIBs) have been successfully developed and widely used to power today's portable electronic devices. The long term success in electric vehicles and energy storage system relies on rising the energy density, low temperature efficiency, safety and increased cycle life.
In parallel, lithium metal batteries (LMBs), described as a system with Li^0 as anode and metal oxide as cathode (NMC, LFP, LMO) are arising as aim of research for a plethora of groups. Lithium metal anode is considered as ideal anode due to high theoretical capacity (3860 $mAhg^{-1}$), lower negative electrochemical potential and lower density (0.534 $g.cm^{-3}$).[1] Researchers used complex liquid electrolyte (ionic liquid, etc.) systems in order to avoid lithium dendrite and degradation, conventional liquid electrolyte ($LiPF_6$, carbonate solvants) degraded faster than expected, and consequently, generated cells fading. Therefore conventional liquid electrolyte in such cell was not used.
Use of organic additives in electrolyte and/or electrodes is considered as one of the most economical and effective approaches for solving many problems as cited previously. The additive can interact with electrolyte or anode to prevent degradation or enhanced cell performances.
This presentation will outline commercial organic compounds: Indigo and his derivatives use as single additive in NMC/Li batteries with conventional liquid electrolyte, which considerably increased the cycle life of Li metal batteries. Dyes such Indigoïd contain electron density donor (-NH-) and acceptor (-C=O) groups linked by conjugated bonds, which participate to their versatile electrochemical properties.

When used as additive in cathode materials or electrolyte, indigo modified the electrode structure and changed the composition of the Li-ions battery electrolyte and solid electrolyte interface (SEI) on lithium metal.

SINS of The SEI Layer: On The Origins of Electrode Passivity of Li-Metal Anode Robert Kostecki, Jonathan M. Larson, Andrew Dopilka and Asia Sarycheva; Lawrence Berkeley National Laboratory, United States

Li-ion and Li-metal batteries performance limitations are associated with physico-chemical processes at electrode/electrolyte interfaces, which lead to high impedance, electrochemical instability, and inhomogeneous Li plating and stripping. In fact, battery performance is largely determined by thermodynamic, kinetic, and mechanical properties of such electrochemical interfaces and interphases. These electrochemical systems tend to operate far away from equilibrium. A thin passive film, the so-called solid electrolyte interphase (SEI) layer, that forms at the electrode/electrolyte interface during battery assembly/formation, which gradually reforms during its operation is critical for its basic function and lifetime.
However, our overall understanding of heterogeneous ionic interfaces and interphases is still very limited due to two main reasons. First, characterizing such interfaces and interphases in their native environment is extremely challenging, as they are buried between two dissimilar materials. Second, the interfaces and interphases have complex structure and chemistry, and can even evolve by chemical inter-diffusion, lattice strain, defects, and space charge effects which lead to a variety of chemical reactions across multiple spatial and temporal scales. Interface evolution is further propelled by the large amount of charge and mass transfer between electrodes in a battery over its lifetime (generally leading to degradation, performance loss, and eventual battery failure.
In this work, we overview and exploit the nanoscale spatial resolution, chemical selectivity, and surface sensitivity of near-field infrared nanospectroscopy to characterize electrode/liquid and solid electrolyte interfaces. Near-field infrared measurements in combination with standard surface characterization tools reveal that intrinsic molecular, structural, and chemical heterogeneities at the interface. This work provides a unique insight into the mechanisms of early-stage interphase formation at electrochemically active buried interfaces, and an experimental diagnostic means to aid in the development of methods to control local nanoscale variations in electrolyte chemistry, structure, and ionic conductivity at the surface of the electrode.

Stable and Ion-Conductive Polymeric Lithicone for Lithium Metal Anode Protection Ridwan Ahmed[1], Xin Wang[2], Ju-Myung Kim[1], Xiangbo Meng[2], Ji-Guang Zhang[1] and Wu Xu[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Arkansas, Fayetteville, United States

Lithium (Li) metal batteries are becoming increasingly appealing for electric mobility and other high-tech applications as they offer high energy density advantage coming from the utilization of Li metal anode with an ultrahigh theoretical specific capacity and an extremely low reduction potential. However, the practical application of Li metal anode is hampered by a variety of issues. These include dendrite formation which poses a risk for fire, formation of unstable solid electrolyte interphase (SEI) and "dead" Li resulting in a fast capacity fading, which are aggravated at high current densities. In this work, we report Li metal protection by a lithium-glycerol lithicone (LGL) layer formed by utilizing *tert*-butoxide and glycerol precursors in a molecular layer deposition process. The as-formed protection layer shows a good stability and a high ionic conductivity. The performance of the LGL-protected Li metal anode (LGL@Li) is demonstrated in both symmetric and full cell configurations at high current densities. The LGL@Li||LGL@Li cells demonstrate improved cycling stability compared with Li||Li cells during Li metal stripping/plating process at ~ 2.3 $mAcm^{-2}$ (2C) and areal capacity of 1.1 $mAhcm^{-2}$. Furthermore, LGL@Li||NMC622 cells show a capacity retention of ~ 87 % compared with ~ 35 % for Li||NMC622 cells after 200 cycles at a high current density of 2.1 $mAcm^{-2}$ (C/2). Our results show that LGL protection strategy is promising for practical Li metal batteries.

Lithium Metal Batteries with Improved Thermal Stabilities Xia Cao, Wu Xu and Ji-Guang Zhang; Pacific Northwest National Laboratory, United States

Lithium Metal Batteries with Improved Thermal Stabilities
Xia Cao, Wu Xu, Ji-Guang Zhang*
Energy and Environment Directorate, Pacific Northwest National Laboratory
Richland, Washington 99354, United States

Development of lithium (Li) metal batteries (LMBs) has attracted worldwide attention in recent years due to their much higher theoretical energy densities than those of conventional Li ion batteries.[1,2] Other metal batteries (MBs), such as Na metal batteries (NMBs) and potassium metal batteries (PMBs) also attracted more and more attention due to their abundance in earth crust and low cost.[3,4] Although long cycle life of metal batteries have been demonstrated,[2,5,6] their large-scale applications are still hindered by several barriers. One of the main barriers is the thermal stability of the electrolytes, especially when they are in contact with high voltage cathode. Therefore, development of electrolyte with improved thermal stability is critical for large scale application of metal batteries

In this work, factors affecting thermal stability of electrolytes for Li metal batteries will be discussed. First, electrolyte components should be selected to enable preferential decomposition of its salt rather than solvent so an inorganic rich interphase layer can be formed on electrodes, especially on metal anode to block its continuous reaction with electrolyte. These inorganic rich SEI layers can also enable the formation of large size of metal particles instead of nano powders, therefore minimize the surface area of anode. Formation of a stable SEI layer can not only minimize the formation of powdered metal particles, but also can prevent exposure of large amount of pure metal powder to ambient air in case of mechanical damage of batteries. Second, electrolyte solvents with high boiling point, low vapor pressure, and low reactivity with oxygen species are desired. These features will largely slow down the formation of flammable vapor when the cell is exposed to ambient air. Third, electrolyte should be stable at elevated temperature even at fully charged (high voltage) conditions. In any case, selection of solvent properties should not compromise electrochemical property es of the electrolytes. At last, examples of novel electrolytes based on these design principles will be reported in this work.

Prediction of Electrode-Electrolyte Degradation through Data-Driven Massive Reaction Networks Kristin A. Persson[1,2]; [1]UC Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Despite decades of work, there is still considerable uncertainty regarding the major components of the solid-electrolyte interface (SEI) and its dynamic formation mechanism as a function of electrolyte and anode composition. Here we present a new data-driven first-principles framework using a combination of high-throughput calculations, reaction networks, machine learning and microkinetic modeling. Our automated methodology is based on a systematic generation of relevant species using a general fragmentation/recombination procedure which provides the basis for a vast thermodynamic reaction landscape, calculated with density functional theory. We explore this landscape using stochastic methods and shortest pathfinding algorithms, which yield the most likely reaction pathways which are then refined with transition state calculations and kinetic information. The results of the framework show promise in being able to automatically recover previous insights on single reaction pathways, as well as successfully predicting the early dynamics and competitive nature of the SEI formation. As examples, we present i) formation mechanisms of LEMC as compared to LEDC, ii) decomposition mechanisms of the lithium hexafluorophosphate salt and iii) recover the Peled-like separation of the SEI into inorganic and organic domains resulting from rich reactive competition. By conducting accelerated simulations at elevated temperature, we track SEI evolution, confirming the postulated reduction of lithium ethylene monocarbonate to dilithium ethylene monocarbonate and hydrogen gas. These findings furnish fundamental insights into the dynamics of SEI formation and demonstrate a path forward toward a predictive understanding of electrochemical passivation.

SESSION ES04.03: Li Metal—Characterization and Mechanism

Wednesday Morning, April 24, 2024
Room 422, Level 4, Summit

8:15 AM ES04.03.01
Ultrafast Deposition of Faceted Lithium Polyhedra by Outpacing SEI Formation Xintong Yuan, Bo Liu, Matthew Mecklenburg and Yuzhang Li; University of California, Los Angeles, United States

Electrodeposition of lithium (Li) metal is critical for high-energy batteries. However, the simultaneous formation of a surface corrosion film termed the solid electrolyte interphase (SEI) complicates the deposition process, which underpins our poor understanding of Li metal electrodeposition. Here we decouple these two intertwined processes by outpacing SEI formation at ultrafast deposition current densities while also avoiding mass transport limitations. By using cryogenic electron microscopy, we discover the intrinsic deposition morphology of metallic Li to be that of a rhombic dodecahedron, which is surprisingly independent of electrolyte chemistry or current collector substrate. In a coin cell architecture, these rhombic dodecahedra exhibit near point-contact connectivity with the current collector, which can accelerate inactive Li formation. We propose a pulse-current protocol that overcomes this failure mode by leveraging Li rhombic dodecahedra as nucleation seeds, enabling the subsequent growth of dense Li that improves battery performance compared with a baseline. While Li deposition and SEI formation have always been tightly linked in past studies, our experimental approach enables new opportunities to fundamentally understand these processes decoupled from each other and bring about new insights to engineer better batteries.

8:30 AM *ES04.03.03
Integrating Multi-Functionality that enables *In-Situ* TEM probing of Solid Electrolyte Interphase Characteristics Chongmin N. Wang; Pacific

Northwest National Laboratory, United States

For better battery performances, solid electrolyte interphase (SEI) layer is expected to possess three ideal characteristics: electrically insulative, ionically conductive, and constant thickness. These three characteristics are interactively correlated, typically, the thickness of SEI layer is controlled by the electrical properties of SEI layer. However, SEI layers do not seem to behave the ideal characteristics, rather the thickness of the SEI continuously increases during charge-discharge cycling and shelf storage, indicating that the SEI does not behave as an electrical insulator. We use in-situ bias transmission electron microscopy to directly measure the electrical properties of SEI. We discover that the current-voltage characteristics of SEIs resemble certain electrical conductance, rather than electrical insulation as conventionally assumed. We further demonstrate by tailoring the solvation sheath of the electrolyte, the electrical properties of the SEIs can be readily tuned, which inherently correlate to electrochemical properties. The work highlights the significance of electrical properties of the SEI layer and their tuning towards the enhanced performance of an electrochemical cell.

9:00 AM *ES04.03.04
Real- and Reciprocal Space Characterization of Advanced Solid State Batteries Kelsey B. Hatzell; Princeton University, United States

New and re-imagined energy materials play a critical role in decarbonizing a range of industries related to transportation, chemical fuels, separations, power production and beyond. Transportation accounts for approximately 23% of energy related carbon dioxide emissions and electrification approaches are widespread for personal vehicles. Batteries currently play an outstanding role in a range of applications including electric vehicles and portable electronic applications and there is a growing interests in expanding the frontier for batteries. Applications such as electric aviation, batteries in space applications, and undersea propulsion all present unique engineering and scientific challenges for electrochemical energy storage systems. In this talk I will discuss emerging battery systems which move ions (e.g. charge carrier) in a solid rather than a liquid. I will also discuss the materials and chemo-mechanical principles which impact ion transport and electron transfer reactions in this class of material systems. Understanding how to engineer materials for coordinated and/or concerted transport is critical achieving reversible operation of these materials and devices. Using real- and reciprocal- space techniques I will show how we can measure and visualize material utilization and reaction heterogeneity in solid state batteries in space and time. The talk will conclude by exploring emerging applications for energy and climate materials through highlighting some of our team's emerging directions that focus on batteries for space applications and novel moisture-swing direct air capture processes.

9:30 AM BREAK

10:00 AM ES04.03.05
Quantifying and Understanding Electron-Beam Radiation Induced Degradation of Lithium Battery Materials Shuang Bai; Unversity of California, San Diego, United States

The investigation of the solid electrolyte interphase (SEI) in Li metal batteries is crucial for advancing battery technology, improving safety, extending battery lifespans, and unlocking the full potential of Li metal as an anode material. Spatially resolved techniques, such as transmission electron microscopy (TEM), are widely applied to understand the continuous composition and structure evolution of SEI during battery cycling. However, electron beam-induced damage poses challenges to accurate data interpretation. In this study, we quantify the beam dosage limit for commonly reported SEI components, including Li_2CO_3, LiF, Li_2S, LiOH, LiH, and Li_2O, demonstrating their chemical and structural evolution under electron beam irradiation. Our results reveal that these components exhibit varying susceptibility to electron beam damage, with Li_2CO_3 being the most easily damaged and Li_2O the least. The observed effects of repeated electron beam irradiation include surface atomic displacement, mass loss, and chemical reactions. To preserve pristine chemical environments, minimizing electron beam damage becomes crucial, and cryogenic protection during imaging proves to be an effective approach. Moreover, our study highlights the potential misinterpretation of experimental results due to electron beam damage, providing examples of SEI formed in two different electrolytes. This calls for special attention to ensure accurate characterization of SEI in Li metal batteries.

10:15 AM ES04.03.06
Mechanical Properties and Deformation Behavior of Lithium Metal Lara C. Pereira dos Santos[1,2] and Robert Spatschek[1,3]; [1]Forschungszentrum Jülich, Germany; [2]RWTH Aachen University, Germany; [3]JARA-Energy, Germany

Lithium metal is the ideal candidate as anode material for reaching higher energy densities. However, comprehensive and reliable research on its complex mechanical deformation remains scarce, hindering an in-depth understanding of Li-based solid-state batteries. Lithium mechanical properties vary widely depending on length scale, orientation, strain rate and temperature. Besides, lithium is extremely reactive, creeps at room temperature and has a strong anisotropy, making experimental characterization a considerable challenge. This work aims to study the mechanical properties and deformation of lithium using a combination of experimental and modeling tools. On the theoretical side, techniques such as first-principles, molecular dynamics and effective medium theory are applied. Information not only from the elastic parameters, but also from the plastic regime is obtained. Simulations are carried out for different temperatures, specimen sizes and crystal orientations. On the experimental side, micro-indentation is performed and the hardness of lithium foils is evaluated. With this study, we expect to support investigations regarding the size and orientation dependency of Li mechanical properties. Additionally, we aim to contribute to bridging the gap between theory and experiments, as well as understanding plasticity on small scales, high strain rates and high homologous temperatures.

10:30 AM *ES04.03.07
Liquid Madelung Potential as The "Beyond Debye-Hückel" Concept Validated for Several Metal Electrodes Atsuo Yamada, Norio Takenaka, Atsushi Kitada, Seongjae Ko and Hinata Koyamada; The University of Tokyo, Japan

Achievement of carbon neutrality requires the development of electrochemical technologies suitable for practical energy storage and conversion. In any electrochemical system, electrode potential *E* is the central variable that regulates the driving force of redox reactions. However, quantitative understanding of the electrolyte dependence of *E* has been limited to the classic Debye-Hückel theory that approximates the Coulombic interactions in the electrolyte under the dilute limit conditions. Therefore, accurate expression of *E* for practical electrochemical systems has been a holy grail of electrochemistry research for over a century. Here we show that the "*liquid Madelung potential*" (E_{LM}) based on the conventional explicit treatment of solid-state Coulombic interactions enables quantitatively accurate expression of the electrode potential, with the E_{LM} shift obtained from molecular dynamics reproducing a hitherto-unexplained huge experimental shift for the several metal electrode. Thus, a long-awaited method for description of the electrode potential in any electrochemical system is now available. Examples of battery system optimization based on this new concept will be demonstrated.

11:00 AM *ES04.03.08
First-Principles Modeling of Deposition Processes at Metal Anodes Axel Gross[1,2]; [1]University of Ulm, Germany; [2]Helmholtz Institute Ulm (HIU), Germany

Metal anodes in batteries of the rocking chair type promise to lead to high energy densities as they yield the lowest possible binding energy for the metal atoms and require no host material. On the other, they are often rather reactive causing the decomposition of many commonly used electrolyte components. This may lead to the formation of a passivation layer known as the solid electrolyte interphase (SEI). A better understanding of these reaction mechanisms can lead to an improved electrolyte and substrate design to achieve highly reversible metal anodes. In this contribution, recent purely computational [1] and joint theoretical-experimental [2.3] studies addressing the most likely decomposition products of electrolyte components at a number of alkaline metal anodes are presented. It will be demonstrated how the analysis of the first-principles electronic structure calculations based on density functional theory (DFT) allows to identify the crucial steps in the decomposition reactions.

In addition, metal anodes also play a crucial in batteries using anionic charge carriers such as chloride. Based on periodic DFT calculations, the initial steps in the conversion of a Mg anode to a magnesium chloride salt will be analyzed [4] which represents the driving force in the operation of such Cl-ion batteries.

Unveiling Lithium Metal Anode Behavior through The Advancements and Applications of Titration Gas Chromatography Y. Shirley Meng[1,2] and Wurigumula Bao[1]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

In the realm of energy storage technologies, lithium metal batteries have gained significant attention due to the global shift toward renewable energy systems. Accurate diagnosis and understanding of the attenuation mechanism of batteries are therefore essential for the development direction. Titration Gas Chromatography (TGC) is an effective tool for quantitively understanding the anode materials' cycling behavior. The dead Li in the cycled Lithium metal anode consists of trapped Li (Li^0) and Solid electrolyte Interphase (SEI) Li^+, in which only trapped Li can react with the protic solvent to generate the hydrogen (H_2), while SEI (Li^+) does not. The ideal protic solvent, therefore, must meet specific criteria: 1) exclusively reacting with Li^0 to generate H_2 gas; 2) displaying chemical inertness with SEI components or refraining from producing H_2 gas. Adhering to these conditions, quantifying H2 allows for the differentiation and quantification of trapped Li0 and SEI (Li^+). With the optimal solvent selection, our investigations encompassed: 1) assessing corrosion effects on electrochemically deposited Li metal anode; 2) quantifying Li inventory in practical Li metal batteries3. We demonstrate the importance of using TGC techniques in quantitatively examining the Li inventory changes of the anode under various operating conditions. Beyond that, the results offer unique insights into identifying critical bottlenecks that enhance battery performance development.

SESSION ES04.04: Li Metal—Structure and Substrate
Session Chairs: Wu Xu and Yirui Zhang
Wednesday Afternoon, April 24, 2024
Room 422, Level 4, Summit

1:30 PM ES04.04.01
Lithium Planar Deposition by Microstructural Design. Alexey Rulev[1] and Artur Braun[2]; [1]Empa, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Lithium metal is the most energy-dense electrode material for Li-ion batteries. However, its application is limited by the extensive whisker growth during the charging process. Despite a variety of proposed solutions to the problem, stable Li metal anode was not achieved yet. Partially it could be explained by the fact that the mechanism of such morphological instability is still relatively unclear.
Previously we have proposed the mechanism of lithium whisker growth [1] that explains root-based growth (i.e. by insertion of atoms to the base of growing whisker) of lithium whiskers, which was later observed experimentally. The mechanism focuses on the rapid mass-transfer within the electrode (i.e., self-diffusion of metal lithium) that leads rapid whisker growth. The key elements for this mechanism are presence of the passivating film on top of the electrode and relatively fast solid-state self-diffusion. Both are inherent properties of lithium: the first is the always existing SEI layer; the second is best illustrated by room temperature being about 2/3 of lithium melting point, a point at which solid-state atomic mobility becomes sufficient.
The proposed mechanism also suggests the possibility of relatively smooth deposition of lithium without significant whisker growth. In this work we have used advanced techniques to demonstrate how and where lithium can deposit without loss of morphological stability. We deposited lithium on the idealized model electrodes and then, using focused ion beam (FIB) cross-sectioning and electron back-scatter diffraction (EBSD) on metal lithium we have shown that lithium deposits into the inclined grain boundaries just below the surface of the electrode. This way, the inclined grain boundaries have a certain "capacity" of lithium they can accommodate. Further we show how and to what extent this capacity may be increased by the microstructure engineering. Lithium itself is a fusible metal, which means that it would very easily recrystallize, making traditional ways of controlling the metal microstructure like quenching very limited. We used eutectic alloying with Ga as a way to reduce the size of Li grains. This way we significantly increase the areal density of shallow inclined grain boundaries on the surface of the electrode, this way increasing its "capacity" to accommodate lithium. We demonstrate that it lead to relatively smooth deposition of lithium for an extended time, which was much longer than for pure metal lithium electrodes. It should be noted that, in contrast to other alloy electrodes, like tin of silicon, here lithium constitutes 80 mass % of the electrode, and the deposition proceeds in form of pure metal.

Vertically Orientated TiO_2 1D Lepidocrocite Nanoflakes as Scaffold for Enhanced Li-Metal Anodes Neal A. Cardoza, Mary Qin Hassig, Taber Yim, Michel Barsoum and Vibha Kalra; Drexel University, United States

Lithium metal anodes have long been the ideal anode for a variety of cell chemistries owing to their high gravimetric capacity. Dendrite growth, during cycling, however, restricts their practical deployment. Here, a new class of nanomaterials TiB_2 derived 1-dimensional lepidocrocite quasi two-dimensional

nanoflakes (1DL) are used as basis for creating a Li scaffold, that can be used as an anode-free setup. The 2D nanoflakes comprised of 1DL nanofilaments are synthesized with a bottom-up reaction, directly from commercial 3D-bulk solids at near ambient temperatures and pressures[1,2]. The morphology of the 1DL is highly tunable based on processing parameters and can be intercalated with a variety of cations[3,4]. Here 1DLs are orientated vertically to guide Li-metal deposition and serve as a Li metal scaffold. This is achieved with a control freezing of an aqueous blade cast slurry. Freeze-drying results in an organized vertically oriented structure. These vertical-1DLs enable easier Li nucleation, with lower overpotentials compared with bare Cu or a normal cast slurry of 1DLs. The vertical-1DL shows an overpotential of -0.06 mA vs -0.08 mA for Cu, a 25% reduction. Leading to a more spatially uniform deposition of Li. Further, 1DL flakes can be intercalated with lithiophilic cations to further improve Li metal deposition and nucleation. Lastly, the -OH rich surface groups on the 1DL NFs surfaces help improve the formation of a uniform solid-electrolyte interphase. These properties enable 1DL nanoflakes that are orientated vertically to serve as a Li-scaffold in an anode-free setup.

Microstructural Design Principles for Achieving Stable Metal Anode Interphases with Liquid and Solid-State Electrolytes David Mitlin; The University of Texas at Austin, United States

Lithium metal battery systems (LMBs) are being sought as an ultimate replacement to LIBs, potentially increasing the cell energy by over fifty percent due to the high capacity and low voltage of the metal anode. Analogous improvement in energy is possible with sodium metal batteries (NMBs) and with potassium metal batteries (KMBs), where existing ion insertion anodes can be replaced by plating/stripping metal. However, in all three cases safety and performance are compromised by an unstable solid electrolyte interphase (SEI) that consumes metal ions and electrolyte, and ultimately leads to dendrites. This presentation provides a series of case studies derived from the group's LMB, NMB and KMB liquid and solid-state research on the microstructural design principles that provide for long-term cycling and fast-charge stability of metal anodes. The approaches may be categorized as the following: a) design of plating/stripping supports and templates with tuned geometry and functionality; b) design of secondary interlayers placed between the metal anode and the separator; and c) design of multifunctional hybrid separators to replace the conventional polymer separators employed with LIBs. It is demonstrated that despite appearing distinct, the efficacy of each in enabling electrochemical stability originates from three fundamental features that are directly interrelated. The wetting behavior of the electrolyte on the anode must be optimized, the wetting/stripping behavior of the metal anode on the current collector must be controlled, and a geometrically and chemically modified SEI must be established. Simultaneously achieving all three leads to stable plating/stripping, while missing even one leads to rapid dendrite growth. Cryogenic FIB cross sections and cryo-TEM are combined to yield new insight regarding film wetting behavior and early dendrite formation in optimized versus baseline specimens, analyzing growth in several representative electrolytes.

Interfacial Pressure Improves Calendar Aging of Lithium Metal Anodes Katharine Harrison[1], Kimberly Bassett[2], Kathryn Small[2], Daniel Long[3], Laura C. Merrill[2] and Benjamin Warren[2]; [1]National Renewable Energy Laboratory, United States; [2]Sandia National Laboratories, United States; [3]Air Force Research Laboratory, United States

Lithium metal is a very attractive anode material because its theoretical specific capacity is approximately 10 times higher than conventional graphite anodes. Despite great promise, Li anodes suffer from capacity fade due to instabilities with the electrolyte as well as stranding of active Li. We have previously shown that applied interfacial pressure improves Li anode cycling because the pressure reduces the propensity for Li isolation and enables easier reconnection. Many researchers have also shown that calendar aging can lead to Li capacity loss and this has been attributed to either electrolyte decomposition with concurrent Li corrosion or to the formation of stranded Li. Our prior research focused on calendar aging during cycling suggests the mechanism for calendar aging is largely related to stranding of Li during rest and reconnection of the stranded Li upon further cycling, evidenced by similar average Coulombic efficiencies and Li loss in cells with and without rest. Because our calendar aging studies suggest Li stranding as a major cause of Coulombic efficiency drops and our Li cycling studies suggest this can be mitigated partially through applied interfacial pressure, we hypothesized that applied pressure would improve calendar aging by reducing stranded Li and enabling reconnection.

We systematically varied applied pressure (0-1000 kPa) on Li metal anodes during cycling tests with and without intermittent calendar aging periods. Though the Coulombic efficiency decreases during aging periods, the lost capacity is recovered during subsequent cycles, as shown though average Coulombic efficiency and cumulative Li capacity loss analysis. We find that application of pressure partially mitigates calendar aging, in accordance with our hypothesis that calendar aging is caused by Li standing and can be mitigated to some degree with interfacial pressure. This is further supported by our results showing that the average Coulombic efficiency and cumulative Li capacity losses are similar over 50 cycles for cells that were continuously cycled and cells with periodic calendar aging periods. This result indicates that the losses during aging are reversible, which is consistent with Li stranding and reconnection. We show that pressure is one mitigation technique that helps reduce Li calendar aging in this study, but our finding that calendar aging is primarily governed by the stranding and reconnection of dead Li has wider implications. This research suggests that other mitigations which have been shown to prevent dead Li formation or encourage reconnection during cycling would also likely be successful for the purpose of improving calendar aging.

Stress-Driven Diffusion of Lithium into Copper Current Collectors during Plating and Stripping Kurt Hebert; Iowa State University, United States

Stresses in lithium metal anodes determine their stability during inevitable volume changes experienced upon cycling. Lithium deformation during cycling in liquid cells can initiate surface morphological instabilities which lead to capacity loss, e. g. whiskers and moss (1-3). Evidence suggests that whiskers grow by solid-state diffusion to the whisker base (3), and that whiskers relieve compressive stress in the metal generated by electrodeposition (4,5). While quantitative characterization of these processes is challenging, diffusion accompanying morphology instabilities can be detected when lithium is deposited directly on copper current collectors (6,7). Lv et al. reported operando neutron depth profiling (NDP) measurement measurements of Li diffusion into Cu during plating-stripping cycles in pouch cells (7).

A model is presented for lithium diffusion in copper current collectors during cycling in a liquid cell. Diffusion is driven by gradients of elastic stress in the current collector, induced by the combination of misfit strain due to diffusing Li atoms and bending of the copper film due to the Li concentration gradient (8). The Li diffusion flux at the copper surface (inward and outward during plating and stripping respectively) is assumed to be a small constant fraction of the plating or stripping rate, consistent with the NDP measurements. We show that the model quantitatively accounts for all aspects of the measured concentration distributions. In particular, the model captures the unique "wave-like" concentration profiles revealed by NDP, in which the maximum lithium concentration is always at the copper surface, even when lithium diffuses out of the metal during stripping.

The constant flux boundary condition is justified by a model for surface morphology evolution, in which the lithium surface is covered by spheroidal protrusions that grow and contract, respectively, during plating and stripping (3,9). We show that plating on the spheroids through an intact solid-electrolyte interphase (SEI) layer generates inward stress-driven diffusion and outward creep within the protrusion. At the base of the spheroid, the diffusion flux continues into the substrate. This flux represents a small fraction of the plating rate, and thus accounts for the diffusion inferred from analysis of NDP measurements. Therefore, surface morphology evolution appears to be driven by stresses due to plating/stripping through an intact SEI layer.

The Influence of Copper Current Collector Crystal Orientation on Long and Short Term Lithium Metal Plating Josefine McBrayer, Alexander Heusser, Cooper Bryan and Noah Schorr; Sandia National Laboratories, United States

Lithium metal is a practical anode of choice for beyond lithium ion battery technologies due to its high capacity and low potential. However, recharging (plating) lithium metal has proven difficult because of the formation of lithium dendrites and an unstable solid electrolyte interphase (SEI). Both are root causes of poor performance and safety issues such as internal short circuits, fire, and thermal runaway. To mitigate these undesirable qualities of lithium anodes for secondary battery applications, more uniform lithium plating is necessary. Here we investigate the performance and lithium morphology on single crystal (111, 100, and 110) and polycrystalline copper current collectors to control Li plating, especially in early cycles. The 111 orientation was determined by cryo scanning electron microscopy (with focused ion beam cross sections) and energy-dispersive X-ray spectroscopy to lead to a more compact lithium morphology and uniform SEI. Platting/stripping experiments supported that this improved morphology also manifested in a greater coulombic efficiency in early cycles in lithium-copper cells.

Low-Cost Carbonaceous Metal-Free Wetting Layer as Sodiophilic Treatment for Solid and Molten Na Batteries J Mark Weller[1], Hyungkyu Han[1], Eugene Polikarpov[1], Kee Sung Han[1], Keeyoung Jung[2], David Reed[1], Vincent Sprenkle[1], Vaithiyalingam Shutthanandan[1], Yilin Wang[1] and Guosheng Li[1]; [1]Pacific Northwest National Laboratory, United States; [2]Research Institute of Industrial Science and Technology (RIST), Korea (the Republic of)

Sodium-metal batteries are a promising alternative to Li-metal batteries due to the natural abundance of Na, especially for grid scale energy storage where the cost premium of Li puts strain on the economic feasibility of scalable renewables-plus-storage. Low temperature Na-metal batteries, like their Li-based counterparts, suffer from Na-dendrite formation and dangerous cell failure upon extended cycling or plating at high current densities. Also like their Li-metal counterparts, Na-metal solid-state batteries (SSB) are unable to prevent dendrite intrusion without careful engineering of the Na-metal/solid-electrolyte interface. An alternative approach is to use elevated temperature batteries with a molten anode, which can enable categorically higher current densities with no dendrite issues. Where classically molten Na-batteries such as high temperature Na-S or 'ZEBRA' batteries operate well above 200 °C, it is desirable to reduce operating temperatures to unlock lower cost materials of construction and increase energy efficiency by reducing thermal losses. Unfortunately, it is well known that molten Na has poor wettability in contact with common solid electrolytes like sodium beta-alumina solid-electrolytes (Na-ß"-Al_2O_3, "BASE") or NaSICON (Na-Superionic Conductor) ceramic electrolytes.

Various wetting agents and interface modification strategies have been employed to improve wettability of molten Na and reduce interface resistance in Na-SSBs. Some rely on sputter deposition of a suitable metal such as Sn or deposition of metal precursors from solution followed by a heat treatment to form pure metals such as Pb, Sn, or Bi. Some strategies utilizing exotic phases of carbon such as graphene or carbon nanotubes have also been employed. Still others rely on high temperature annealing to drive off surface contaminants under vacuum or inert atmosphere. All of these strategies lack one or more crucial components such as low-cost, non-toxicity, simplicity, or scalability. This has motivated the development of a 'metal-free wetting layer' (MFWL)

based purely on low-cost carbon sources, that can be applied via scalable processes such as spin-coating, spray-coating, or even drop-casting from solution. Our MFWL shows excellent uniformity when applied to a suitable solid-electrolyte such as BASE or NaSICON, and facilitates excellent wetting of molten Na as low as the melting point of Na. The meso/microstructure of MFWLs and mechanism of Na-wettability will be discussed in detail. Symmetric Na-Na cell data confirm that cells with low specific resistance and excellent cycling stability can be obtained at elevated temperature (T > 100 °C), forming extremely intimate contact between Na and the underlying solid-electrolyte. Further, the utility of this MFWL can be extended to solid-state symmetric Na-Na cells, showing that even without applied pressure, initial experiments with BASE electrolytes treated with MFWL demonstrate a critical current density of ~ 0.5 mA cm^{-2} at 30 °C. This simple, inexpensive, and scalable interfacial modification strategy shows great promise for enabling pure Na-anodes across solid-state and elevated temperature batteries.

Advanced Hybrid Polymer/Ceramic PEO-SnF_2 Protective Mechanism for Sodium Metal Anodes Roya Damircheli, Binh Hoang and Chuan-Fu Lin; Catholic University of America, United States

In the face of mounting global energy requirements and pressing environmental issues, the scientific community turned to lithium-metal batteries, celebrated for their superior capacity and efficiency. However, challenges arising from the scarcity and increasing costs of lithium have redirected research efforts towards sodium batteries. Sodium metal anodes, with their remarkable theoretical specific capacity of ~1166 mAh/g, low anode potential of -2.714 V vs standard hydrogen electrode, and cost benefits, are increasingly recognized as the promising candidate for conventional energy storage systems. Notwithstanding their advantages, the unstable and fragile solid electrolyte interphase (SEI) due to the spontaneous reaction between metallic Na and a liquid electrolyte remains a significant limitation. As this SEI layer expands, it hinders ion transport, causing increased polarization and diminishing the battery's energy efficiency. Specifically, during the plating process, Na ions are deposited beneath the SEI layer, causing significant expansion. This expansion fractures the fragile SEI, allowing dendrites to grow through these defects. As these dendrites grow, they can pierce the separator, posing a risk of short-circuiting the battery. While numerous studies have proposed designs for protecting sodium metal interphase, to overcome these challenges, this study amalgamates mechano-electrochemical protective strategies to enhance sodium metal anode stability, offering groundbreaking solutions to these challenges.
Central to our exploration were tin fluoride (SnF_2) and silicon nitride (Si_3N_4), both established as effective in generating robust artificial SEI layers on the sodium metal surface. These layers, rich in NaF and Na_xN respectively, demonstrated a notable improvement in cycling performance, effectively suppressing dendrite growth and enhancing the battery's cycling stability by nearly 3.5 times compared to bare sodium anodes.
Building upon these foundational insights, a novel approach was conceptualized: a hybrid protective mechanism combining polyethylene oxide (PEO) with the presence of SnF_2 as an additive, is particularly efficacious. This combination was specifically chosen to provide chemical stability, morphological conformality, and mechanical flexibility to accommodate the mechano-electrochemical instability upon sodiation/desodiation processes. Through this novel strategy, we aimed to amalgamate the strengths of both components, ensuring optimal outcomes. This composite artificial SEI under a 0.25 mA/cm^2 current density, delivering a cycling performance 10 times superior to bare sodium metal, and survived up to 1800 hours of cycling. Impressively, at a high current density of 0.5 mA/cm^2, the hybrid system still performed much better than its untreated counterpart and continued cycling for up to 800 hours of cycling. The synergy of PEO and SnF_2 remarkably minimized electrolyte decomposition, inhibited dendrite formation, and stabilized Na plating/stripping processes, all of which consolidating its promise for sodium metal battery technology.

Cryogenic Focused Ion Beam Milling of Intact Na Metal Battery Stacks Reveals Separator Infiltration and Delamination Failure Mechanism Kevin Matthews and Jamie Warner; The University of Texas at Austin, United States

Metal anodes are the next frontier of high-energy-density rechargeable batteries. Sodium (Na) metal batteries are particularly promising due to the widespread abundance and low cost of Na precursors. The structure, composition, and function of the solid-electrolyte-interphase (SEI) as well as the metal growth mechanisms must be understood to improve and commercialize Na metal batteries. We developed a cryogenic workflow utilizing a cryogenic sample transfer system to prepare intact electrode:separator:electrode stacks, allowing us to probe the intrinsic structure and composition of undisturbed battery interfaces. By milling with a gallium ion beam at cryogenic temperatures, we produced clean milled surfaces of the electrodes and separator with minimal beam-induced artifacts allowing for high resolution imaging, spectroscopic mapping, and 3D reconstructions generated from serial milling and imaging. Using these techniques, we studied how the Na electrode, SEI, and separator evolve during cycling in both symmetric and asymmetric cells with a tri-layer porous polymer separator and either a carbonate- or ether-based electrolyte.
Though often discarded before characterization, we find that the separator is a crucial piece of the puzzle when investigating battery performance and failure. We found overwhelmingly that cells begin with a conformal interface between the Na metal and the electrolyte-filled polymer separator instead of being separated by a layer of electrolyte. After extended cycling, Na metal infiltrates the separator pores, growing towards the opposing electrode. At the interfaces between the tri-layers, the Na can grow laterally, delaminating the separator layers. High resolution imaging and electron dispersive X-ray spectroscopy (EDS) mapping capture the Na metal in-between and within the polymer layers. 3D reconstructions of the electrodeposited Na and SEI suggest that the robustness of the SEI and the heterogeneity of its distribution (or lack thereof) relates to the ability of the Na to grow into the porous network of the separator. We combine these results to suggest a new failure model that relies on short-circuiting via the formation of a conductive pathway of Na templated by the porosity of the separator, rather than a penetration of the separator by discrete dendrites.

Weakly-Coordinating Cyclic Ether-Based Electrolytes Improve Potassium Metal Battery Cycling Stability and Capacity Retention Austin Choi[1], Zheng Li[2,1] and Vilas Pol[1]; [1]Purdue University, United States; [2]University of Maryland, United States

As the scientific community holistically seeks alternative energy sources to traditional fuels such as coal and natural gas, attention has turned towards renewable energy generation such as wind and solar. In tandem, methods of storing energy are also being developed as a way to mitigate the intermittent nature of such methods of energy generation. Among these, electrochemical energy storage solutions are of particular promise given their flexibility and performance, allowing them to suit the needs of an increasingly growing number of industries such as chemical production and automotive manufacturing that are trending towards electrification. Lithium-ion batteries (LIBs) especially have become a mainstay in this space owing to their portability, high energy densities, and cycle lifetimes, and are the principle driving force for the growth of the global battery market to beyond US $100 billion today.

The “holy grail” anode material for LIBs is lithium metal itself, offering an excellent theoretical capacity of 3860 mAh g-1, yet the scarcity and uneven distribution of lithium in the Earth’s crust precludes its more widespread utilization. Hence, “Beyond Li-ion” batteries featuring more readily available charge carriers are also being thoroughly investigated to address this concern. Potassium-ion batteries (KIBs) in particular are suitable alternatives as potassium is available globally and at roughly 1000 times the abundance of lithium. Similar to Li metal, K metal is seen as a promising anode material for KIBs, but its proliferation is hindered by the propensity for dendritic growth, difficulty in maintaining a robust solid electrolyte interphase (SEI), and loss

of material in the form of “dead potassium.” Further, the larger ionic radius of potassium ions as compared to lithium ions further strains the SEI and corresponding cathode electrolyte interphase (CEI) during repeated cycling. Strategies to mitigate these effects are thus of paramount importance in successful realization of K metal anodes for KIBs.

As the SEI is derived primarily by decomposition of the electrolyte, electrolyte-based methodologies are the most direct avenue for improving SEI stability and performance. Specifically, the formation of a mechanically robust inorganic SEI and CEI is key in protecting the electrolyte from further degradation throughout repeated plating/stripping on the metal anode and (de)intercalation of the cathode. Specifically, components such as KF that are produced via the decomposition of the fluorine-containing salt are instrumental in the composition of an SEI/CEI that are resistant to internal stresses. Thus, electrolyte solvents that enable preferential salt decomposition rather than organic solvent decomposition are preferred. Such behavior is governed by the solvation structure around the dissolved cations in the electrolyte, where maintaining the presence of salt anions in the solvation shell is critical for development of an inorganic SEI/CEI and is influenced by a variety of factors including the solvent dielectric constant ε and steric effects.

As compared to conventional carbonate-based electrolytes, ether-based electrolytes have been shown to promote such behavior to an increased degree in LIBs, but this effect remains comparatively unexplored in KIBs, especially paired with the K metal anode. This work demonstrates the efficacy of two cyclic ethers in enabling increased cycling stability and Coulombic efficiency against a K metal anode with regards to plating/stripping performance when compared against a typical carbonate-based electrolyte system. Further, these benefits extend to KIBs with a conventional Prussian blue cathode and K metal anode. These performance enhancements are correlated with the corresponding solvation structures, establishing a framework by which electrolyte solvents can be assessed with metal anodes and presents opportunities for further electrolyte design in other metal anode systems.

Probing The Redox -Mediation of Transition Metal Phthalocyanine in Metal-Air Battery Subhankar Mandal and Aninda J. Bhattacharyya; Indian Institute of Science, India

Metal air batteries have garnered significant attention as a potential alternative to Li-ion batteries due to their high theoretical energy. In lithium-air batteries, during the oxygen reduction reaction (ORR), O_2 is reduced to solid insulating LiO_2, Li_2O_2 and in the reverse charge process, which is the oxygen evolution reaction (OER), discharge products convert back to O_2 and Li^+. However, the practical implementation of Li-O_2 batteries has been hindered by several challenges, primarily due to the sluggish kinetics of ORR and OER. In recent times, a liquid-based redox mediator (@ electrocatalyst) has been demonstrated as an effective approach to increase battery efficiency and modify the reaction pathways to alleviate side reactions. In this presentation, we have systematically explored the solution-based redox mediation behaviour of first–row transition metal phthalocyanines for lithium-oxygen batteries. Our findings, based on experiment and theory, convincingly demonstrate that d^5 (Mn), d^7 (Co), and d^8 (Ni) configurations function better compared to d^6 (Fe) and d^9 (Cu) in redox mediation of the discharge and charge step. The d^{10} configuration (Zn) and non-d analogs (Mg) do not show any redox mediation because of the inability to binding to O_2. During the discharge process, the Li_2O_2 coordinate with metal phthalocyanines and leads to a solution phase reaction pathway and reverse process controlled by the RM, thus confirming a bifunctional redox mediator. Apart from the reaction pathways predicted based on thermodynamic considerations, density functional theory calculations also reveal interesting effects of electrochemical perturbation on the redox mediation mechanisms and the role of the transition-metal centre. In addition, to account for the interaction between RM mediator and the discharge products (KO_2(LiO_2), Li_2O_2) and parasitic products (Li_2CO_3 and LiOH), further spectroscopic and theoretically investigations were conducted. Our finding reveals that discharge/parasitic product coordinated to metal centre with the unfilled d orbital and oriented in between to M-N bond.in the case of filled d system, the discharge/parasitic products along the M-N bond and interacting with the imidazole moiety of the phthalocyanine ring leads to the poisoning the catalytic activity in battery performance.

Low-Coordinating Borate Electrolytes for Metal Batteries Tianbiao Liu; Utah State University, United States

Metal batteries (LMBs) are promising alternatives to state-of-the-art Lithium-ion batteries (LIBs) to achieve higher energy densities. I will present our effort in developing novel borate based electrolytes to enable stable, reversible metal deposition. I will first share our results in Mg borate electrolytes as one of the first examples of Cl-free electrolytes for Mg deposition. Borate anion designs can be extended to other metal ion electrolytes because of their structural tunability. I will discuss our recent results on developing Li and Ca based borate electrolytes for Li and Ca metal batteries. This presentation emphasizes the interplay of ion solvation and ion pairing in turning interfacial chemistry between a borate electrolyte and a metal anode.

Computational Insights Elucidating The Effect of Additives on The Stability and Reversibility of Rechargeable Mg-Ion Batteries (RMBs) Rishabh D. Guha[1], Chang Li[2], Linda F. Nazar[2] and Kristin A. Persson[1,3]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of Waterloo, Canada; [3]University of California, Berkeley, United States

In the ever-evolving landscape of energy-storage, lithium-ion batteries (LIBs) have been the traditional workhorse since their launch in 1991; an event that ushered in the personal electronics revolution. However, as the demand for high-performance storage systems continues to surge, factors such as limited volumetric energy densities, finite global resources, and the environmental and human costs associated with lithium extraction underscore the urgent need for the development of alternative technologies for “next-generation” batteries. In theory, multivalent batteries employing Mg^{2+}or Ca^{2+} can achieve high-energy densities with metallic anodes, but the bottleneck with these systems is the discovery of compatible electrolytes which allows reversible intercalation and plating/stripping at the respective positive and negative electrodes. If we specifically look at Mg-ion batteries, the higher charge per-ionic center inhibits ionic mobility in the electrolyte and often leads to the formation of solvated species which are prone to decomposition at the electrode/electrolyte interface. The commercial deployment of RMBs relies on the development of novel and accessible electrolyte systems that minimize these parasitic reactions and exhibit stable, reversible cycling at normal operating conditions.
Utilizing computational insights from classical molecular dynamics (MD) and density functional theory (DFT), this presentation delves into the atomistic-scale phenomenon contributing to the overall poor performance in commercial non-aqueous magnesium electrolytes. It then outlines design strategies for developing novel electrolyte systems that address these shortcomings, emphasizing the impact of solvation structures on efficient Mg^{2+} desolvation and electrolyte decomposition at the anode. The simulations reveal that the introduction of electronegative additives emerges as the key to tailor the solvation structures for enhanced stability. We then discuss the experimental development of an organic electrolyte with an easily accessible magnesium salt which

corroborates these computational takeaways and demonstrates stable plating/stripping for a remarkable period of 8.3 months at a practical areal capacity of 2 mAh cm^{-2}. The presentation will be concluded with some brief highlights on a cost-effective electrolyte system where solvent engineering enables outstanding coulombic efficiency (99.96%) and fast electrodeposition of pure magnesium on copper substrates.

First Principles Investigation into The Dynamics at Ca Anodes and Electrolyte Interfaces Hashan C. Peiris and Manuel Smeu; Binghamton University, The State University of New York, United States

Motivated by recent experimental progress, we have utilized an approach combining density functional theory (DFT) and ab initio molecular dynamics (AIMD) to gain atomistic perspectives into the dynamic processes governing anode-electrolyte interactions. First principles based molecular dynamics allow one to capture the bond-breaking/forming processes, and interfacial interactions between the anode and the electrolyte, while preserving theoretical accuracy independent of empirical parameterizations. The DFT approach allows one to study the charge transfer during reactions energetics, capture transition states, and evaluate the potential energy landscapes in detail.

The transition to sustainable energy systems is predominantly influenced by the effectiveness of energy storage technologies. While Li-ion batteries have been the industry standard, there is a growing interest in multivalent ion battery systems. These alternatives offer advantages such as higher storage capacities, abundant material resources, and reduced geopolitical risks. Specifically, Ca-ion batteries garner attention as a promising option for high-energy density, low-cost batteries. Still at a nascent stage of development, understanding the interactions between the electrolyte and the Ca anode at the interface is crucial for optimizing the performance of these emerging battery technologies.

To gain insights into the initial formation of the solid−electrolyte interphase (SEI) at the interface, we first looked into the decomposition of pure ethylene carbonate (EC) and an EC/$Ca(ClO_4)_2$ electrolyte on a Ca metal surface. We found that $CaCO_3$, CaO, and $Ca(OH)_2$ are the most common byproducts of the initial interfacial reactions. A fast two-electron reduction reaction producing CO_3^{2-} and C_2H_4 is found to be thermodynamically and kinetically favorable, while a reaction producing $C_2H_4O_2^{2-}$ and CO takes precedence when multiple EC molecules are considered. Investigating the EC-based electrolyte decomposition at Li, Ca, and Al anode interfaces, we found that pure EC only decomposes to CO and $C_2H_4O_2^{2-}$ species on each surface. However, upon the introduction of a salt molecule into the electrolyte, a second EC decomposition route resulting in the formation of CO_3^{2-} and C_2H_4 begins to occur. Li and Ca surfaces are more active in EC breakdown than Al due to the rate of charge transfer being much faster due to lower electronegativity and ionization energies.

Thereafter, we looked at the use of preformed solid electrolyte interphase (SEI) using Al_2O_3 to retard the interfacial reactions with the electrolyte (EC) in Ca anodes. The amorphous oxide layer was found to be thermodynamically stable while allowing for the diffusion of Ca through the layer. The oxide coating remained insulating up to the equilibrium stoichiometry. More significantly, the calcinated oxide layer slowed or prevented the decomposition of solvent molecules.

Lastly, we examined the ether and ester electrolyte stability on Ca anodes with different solvent and salt combinations. Tetrahydrofuran (THF) was observed to be the most stable relative to EC, even in a highly reductive environment. We attribute this to the charge distribution in THF on its backbone while the EC concentrates charge on its ester oxygens and carbonyl carbon, resulting in decomposition. We find $Ca(BH_4)_2$ and THF to be the most stable solution in our investigation, corroborating experimental evidence of its suitability as a CIB electrolyte.

More recently, inspired by the recent advances in machine learning-assisted techniques for computational materials research, we have been actively investigating the interactions of Ca metal anodes with S-based cathodes. We report on our current progress in modeling the Ca anode interactions with polysulfides.

Investigating Large Deformation and Amorphous Intermediates in Sb Electrodes Ananya Renuka Balakrishna and Tao Zhang; University of California, Santa Barbara, United States

The key objective is to provide insight into how amorphous intermediates that form in high-capacity anodes during electrochemical cycling accommodate large volume changes and prevent microcracking in Antimony (Sb) electrodes. The electrochemical cycling of alloy anodes introduces an abrupt crystalline to amorphous structural transformation (in Na-based electrodes). This transformation, in turn, is accompanied by anisotropic volume expansion (>100%), abrupt changes to elastic stiffness, and an alteration to the Na-diffusion kinetics and alloying-reaction pathways. We hypothesize that these sudden changes to intrinsic material properties alter local stress distributions and phase transformation pathways in high-capacity anodes, which contributes to their characteristic mechanical response. We are developing a theoretical framework to understand the energy dissipation and deformation mechanism in large-volume change electrodes and to use these mechanistic insights to guide materials design.

1:45 PM *ES04.06.02
Quantifying Li Plating on Graphite during Fast Charging of Li-Ion Batteries Bryan D. McCloskey; University of California-Berkeley, United States

Li-ion battery fast charge is limited due to challenges posed by lithium plating on the graphite anode, whereby the large overvoltage necessary to drive high Li^+ insertion rates instead results in favorable thermodynamic conditions for Li metal deposition on the graphite surface. Li plating is difficult to detect, particularly in small quantities, and results in safety risks and capacity fade due to lithium metal's high reactivity with conventional electrolytes. Here, we present our efforts to develop both chemical and electrochemical methods to precisely quantify Li plating and detect the state-of-charge (SOC) onset of lithium plating on graphite electrodes during constant current fast charging. We will discuss titration mass spectrometry (TiMS), a highly sensitive (~20 nmol resolution, or 0.5 mAh of plated Li) chemical analysis where gases evolved from harvested graphite electrodes immersed in acid are used to quantify various solid electrolyte interphase species, including electrically isolated (inactive) Li metal.[1] TiMS is then used to determine the precise onset of Li plating and to distinguish between the various capacity fade mechanisms that arise during fast charge.[2] We then will discuss the use of simple

electrochemical cycling techniques to quantify irreversible Li plating in Li|Graphite half-cells as a function of energy density (electrode thickness), charge rate, temperature, and SOC.[3] Similar methods are developed to quantify in-situ Li plating for commercially relevant Graphite|$LiNi_{0.5}Mn_{0.3}Co_{0.2}O_2$ (NMC) cells. In combination, all of these techniques provide a highly accurate measure of the onset of Li plating and quantitative insight into capacity losses during fast charging.

Reaction and Ionic Migration at The Electrode-Electrolyte Interface in Solid State Batteries from Machine Learning Molecular Dynamics
Jingxuan Ding, Albert Musaelian, Yu Xie, Menghang (David) Wang, Laura Zichi, Anders Johansson, Simon L. Batzner and Boris Kozinsky; Harvard University, United States

Atomistic-level understanding of the chemical reactions forming the solid-electrolyte interphase (SEI) in solid-state lithium batteries has remained challenging, primarily due to the limited resolution in experimental techniques and the insufficient accuracy in large-scale simulations. In this work, we combine on-the-fly active learning based on Gaussian Process regression (FLARE) with local equivariant neural network interatomic potentials (Allegro) to construct a machine-learning force field (MLFF) to perform large-scale long-time explicit reactive simulation of a complete symmetric battery cell with ab initio accuracy. The MLFF is validated with experimental values of mechanical properties of bulk lithium and diffusion coefficient of solid electrolyte. For the symmetric battery, we observe prominent fast reactions at the interface and characterize the dominant reaction products along with their evolution time scales, using unsupervised learning techniques based on atomic geometry descriptors. Our simulation reveals the kinetics and the passivation involved in the chemical reaction responsible for the SEI formation. The methods in this study are promising for acceleration analysis of atomistic mechanisms in complicated heterogeneous systems and provide design insights for the development of solid-state batteries.

2:30 PM ES04.06.04
Understanding Lithium Plating from Solid and Liquid Electrolytes Using Dynamic Impedance Spectroscopy Robert L. Sacci[1], Zhiao Yu[2], Ritu Sahore[1], Andrew S. Westover[1] and Zhenan Bao[2]; [1]Oak Ridge National Lab, United States; [2]Stanford University, United States

A potential strategy for increasing energy density of lithium batteries is to implement the so-called anode-free design. Here, the lithium metal anode is solely sourced from the cathode, traveling through the electrolyte. However, such Li batteries suffer from short cycle life due to lithium loss from passivation layer formation (solid-electrolyte interphase), which require multiple cycles to stabilize. Anode-free batteries are required to have high Li metal coulombic efficiencies over the whole cycling life, particularly during the initial activation cycles. A holistic approach to electrolyte design, mechanism understanding, and battery engineering is needed to fulfill these requirements.

We used dynamic electrochemical impedance spectroscopy (dEIS) to probe the formation and evolution of the SEI during Li plating and stripping on copper current collectors. dEIS superimposes a multisine waveform atop the applied charge and discharge current. We applied a sliding window fast Fourier transform protocol that converts the complex ratio of the measured potential and current signals into complex impedance. We will discuss two Li platting systems, Lipon (an amorphous ceramic) and a liquid electrolyte with stabilizing additives. We observed drastic changes in the cells' impedance during plating and stripping. We will show how the passivation layer's impedance continues to evolve during Li cycling and accounts for a significant amount of the overall cell resistance. This knowledge enables us to predict the relative length of cycle life without long term continual measurements.

The US Department of Energy's Energy Efficiency and Renewable Energy Vehicles Technologies Office provided funding for this work under the US-German Cooperation on Energy Storage: Lithium-Solid-Electrolyte Interfaces program.

Designing Stable Li Metal as Anode Electrode in Lithium Metal Batteries Junjie Niu; University of Wisconsin--Milwaukee, United States

Rapid increasing demand on electrical vehicles and portable electronic devices place expectation of battery with energy density at 400-500 Wh/kg or higher. Developing stable Li metal anode for both liquid and solid-state electrolyte based battery systems is critical to achieve this goal. Metallic lithium has the highest theoretical specific capacity of 3860 mAh/g and lowest electrochemical potentials of -3.04V versus the standard hydrogen electrode. However, the uncontrollable solid electrolyte interphase (SEI) and growth of mossy/dendritic Li induced safety concerns as well as low columbic efficiency. Several strategies on stabilizing the Li metal-electrolyte interface have been reported such as adding electrolyte additives, constructing Li host for uniform Li deposition and regulating Li ion flux, and developing artificial SEI for Li metal-electrolyte interfacial stabilization.
Here I will talk about our recent progress in designing stable Li metal anode electrode by using a series of surface modifications. A polymer functionalized monolayer MXene shows better lithium regulation during plating and stripping process. Meanwhile, a dual-layer interphase that consists of an *in-situ* formed lithium carboxylate organic layer and an ultra-thin BF_3-doped monolayer MXene on Li metal surface was designed. The honeycomb-structured organic layer increases the wetting of electrolyte due to the large surface area, leading to a thin SEI. As a comparison, the MXene stacks coated on thin Li via rolling process also displayed uniform Li deposition/dissolution and suppressed dendrite growth. The battery displayed a high capacity retention under lean electrolyte condition. These results indicate that a reliable Li metal anode with dendrite suppression can be achieved by coating well-functionalized 2D materials.

Proximity Matters: Interfacial Solvation Dictates Solid Electrolyte Interphase Composition Solomon Oyakhire[1,2], Yi Cui[1] and Stacey F. Bent[1]; [1]Stanford University, United States; [2]University of California, Berkeley, United States

The composition of the solid electrolyte interphase (SEI) plays a crucial role in controlling lithium-electrolyte reactions, yet the underlying cause of SEI composition differences between electrolytes remains unclear. Many studies have correlated SEI composition with the bulk solvation of Li ions in electrolytes, but this correlation does not fully capture the interfacial phenomenon of SEI formation. In our work, we present a direct mechanistic relationship between SEI composition and Li-ion solvation by forming SEIs using polar substrates that modify interfacial solvation structures. We avoid the deposition of Li metal by forming the SEI above the Li^+/Li redox potential. Using theory and spectroscopy, we demonstrate that an increase in the probability density of anions near a polar substrate enhances anion incorporation within the SEI, establishing a direct correlation between interfacial solvation and SEI composition. We demonstrate the generalizability of this SEI-solvation correlation using three distinct classes of electrolytes. Finally, we employ this concept to generate stable, anion-rich SEIs, leading to high-performance lithium metal batteries. In summary, our work clarifies the mechanistic relationship between electrolyte solvation and SEI composition, resulting in a discovery that can be applied to the design of improved lithium metal batteries.

3:45 PM ES04.06.07
Stabilizing Anode/Electrolyte Interface in Li-O_2 Batteries by Molecular Sieves Huiping Wu, Xinbin Wu, Shundong Guan and Liangliang Li; Tsinghua University, China

Lithium-oxygen (Li-O_2) batteries with an ultra-high theoretical specific energy (3500 Wh kg^{-1}) has recently attracted enormous attention. Due to the difficulty in decomposing discharge product Li_2O_2, the charging overpotential of Li-O_2 batteries is high, which provokes parasitic reactions and worsens the cycling stability of the batteries. Redox mediators (RMs) are widely used to decrease the charging overpotential by altering the electrochemical processes in Li-O_2 batteries. However, unwanted side reactions between RMs and Li metal anode may severely damage both the anode and the RMs; therefore, it is necessary to suppress the shuttle effect of RMs to extend the lifespan of Li-O_2 batteries. To improve the interfacial stability of the Li anode, 4A zeolite, a molecular sieve with a narrow aperture size of ~ 0.4 nm, was used to restrain the diffusion of RMs in this work. A polymer membrane containing 4A zeolite was synthesized to evaluate the performance of the molecular sieve. With the membrane, the Li-O_2 batteries with 2,2,6,6-tetramethylpiperidinyloxy (TEMPO) as the RM showed greatly improved performance. The charging overpotentials were kept at low levels and the cycle life of the batteries was extended eight times. The results from Raman spectroscopy indicated that the small pores of 4A zeolite physically blocked the movement of TEMPO, thus stabilizing the interface between the Li anode and the electrolyte. Furthermore, lithiated 4A zeolite was directly coated on the surface of the Li anode to study its effectiveness in suppressing the shuttle effect of RMs. The protective layer composed of lithiated 4A zeolite not only suppressed the shuttle effect of TEMPO, but also reduced the formation of Li dendrites. As a consequence, the cycle life of Li-O_2 batteries was prolonged more than ten times and the full-discharge capacity of the batteries at room temperature was greatly enhanced. In summary, with the assistance of 4A zeolite-typed molecular sieves, it is promising to fabricate interface-stable, high-energy-density, and long-cycle-life Li-O_2 batteries.

Spatially Resolved *Operando* Synchrotron Studies of Li Metal Anode Stripping and Plating - Heterogeneity and Correlations with Cathode Performance Peter Khalifah[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Operando high energy lateral mapping (HELM) synchrotron diffraction studies have been used to carry out spatially resolved studies of the stripping and plating of Li metal anodes during battery cycling. Although it is very challenging to directly quantify the signal from Li metal layers that are only a few microns thick, this can be accomplished when the data collection is carried out in a carefully designed experiment at a modern synchrotron source and the subsequent Rietveld refinements are performed with suitably constrained structural models. In this manner, we have been able to interrogate the heterogeneity that develops during the cycling of “anode-free” pouch cell batteries with different metals used as the current collector. Furthermore, our data has enabled us to identify correlations between the heterogeneity in the anode and the cathode as well as to better understand the effect of this heterogeneity on the local current densities at different regions of the anode. Our synchrotron measurements probe local variations in electrochemical performance that cannot be resolved through traditional electrochemical testing, thereby providing novel insights into processes contributing to the loss of capacity and the reduction in the lifetime of pouch cell batteries.

4:30 PM ES04.06.09
Materials Processing to Create Fibrous Structures and its Application to Battery Manufacturing Jae Chul Kim; Stevens Institute of Technology, United States

We have developed electrospinning-based manufacturing processing applicable for battery systems that involve metallic lithium. With manufacturing feasibility, electrospinning is a widely used to create nano- and micro-porous layers of functional fibers. The electrospinning-produced layers can afford a wide variety of functionalities applicable to biomedical templates, separation membranes, and energy storage by tailoring fiber compositions. However, its manufacturing capability is limited at producing randomly-oriented fibrous structures. Topology and tortuosity of the electrospun fibers are poorly controlled, making it difficult to systematically investigate structure-property relationships for any given applications, especially electrochemical systems.

In this presentation, we will demonstrate how to we have obtained precise geometrical control of fiber construction by advancing the electrospinning method. Unlike conventional electrospinning, our approach employs a mobile stage that allows alignment of fibers. Produced fibrous structures will be used to construct the anode current collectors of an anode-free battery, one of the most promising energy-dense batteries beyond the Li-ion. While incorporating Li metal has proven difficult due to uncontrolled dendrite growth upon repetitive Li plating and stripping, we found that the anode current collector reinforced by the three-dimensional fibrous structure enhances Li storage efficiency over the extended number of cycles, compared to the planar current collector. We will discuss the effect of fiber compositions and controlled geometrical configurations on stabilizing Li plating and stripping morphologies to suppress Li dendrite growth. We will also provide a cell design principle to fundamentally extend the cycle life of anode-free batteries. Significantly, we consider that battery manufacturing advanced by this work will offer a systematic strategy to develop next-generation energy storage systems for a sustainable energy future.

5:00 PM ES04.07.01
Excellent Reaction Kinetics and Low-Temperature Adaptability of Zinc Batteries Enabled by Water-Acetamide Symbiotic Solvation Sheath Shuyun Wang[1], Shengmei Chen[1], Yiran Ying[2], Gang Li[3], Haipeng Wang[4], Ka Kiu Keith Cheung[1], Qingjun Meng[5], Haitao Huang[2], Longtao Ma[6] and Juan Antonio Zapien[1]; [1]City University of Hong Kong, Hong Kong; [2]The Hong Kong Polytechnic University, China; [3]Northwestern Polytechnical University, China; [4]Yantai University, China; [5]Shaanxi University of Science and Technology, China; [6]South China University of Technology, China

Although rechargeable aqueous zinc batteries are cost effectiveness, intrinsic safety, and high activity, they are also known for bringing rampant hydrogen evolution reaction and corrosion. While eutectic electrolytes can effectively eliminate these issues, its high viscosity severely reduces the mobility of Zn^{2+} ions and exhibits poor temperature adaptability. Here, we infuse acetamide molecules with Lewis base and hydrogen bond donors into a solvated shell of $Zn[(H_2O)_6]^{2+}$ to create $Zn(H_2O)_3(ace)(BF_4)_2$. The viscosity of 1ace-1H_2O is 0.032 Pa s, significantly lower than that of 1ace-0H_2O (995.6 Pa s), which improves ionic conductivity (9.56 mS cm^{-1}) and shows lower freezing point of -45 , as opposed to 1ace-0H_2O of 4.04 mS cm^{-1} and 12 , respectively. The acidity of 1ace-1H_2O is ~2.8, higher than 0ace-1H_2O at ~0.76, making side reactions less likely. Furthermore, benefiting from the $ZnCO_3$/ZnF_2-rich organic/inorganic solid electrolyte interface, the Zn||Zn cells cycle more than 1300 hours at 1 mA cm^{-2}, and the Zn||Cu operate over 1800 cycles with an average Coulomb efficiency of ~99.8%. The Zn||PANI cell cycles over 8500 cycles, with a specific capacity of 99.8 mAh g^{-1} at 5 A g^{-1} at room temperature, and operated at -40 with a capacity of 66.8 mAh g^{-1}.

5:00 PM ES04.07.02
Carbide-Mediated Catalytic Hydrogenolysis: Defective Carbonaceous Lithium Host for Liquid-Electrolyte and All-Solid-State Lithium Metal Batteries Namhyeong Kim[1] and Hyungyeon Cha[2]; [1]Pukyong National University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Commercial lithium-ion batteries based on intercalation carbonaceous anodes are reaching their limit in energy density due to the limitation of theoretical capacity of electrode materials. In this regard, lithium metal is an ideal anode owing to its high specific capacity. However, the practical use of the Li metal is still challenging. The Li metal anode suffers from dendrite formation, volume change, and severe side reactions, which lead to fatal safety issues and cell degradation.
Here, we propose a defective graphene shell grown on a carbon matrix as a stable lithium metal host via carbide-mediated catalytic hydrogenolysis. Unlike conventional carbon hydrogenolysis, the carbide-mediated hydrogenolysis provides not only channelling reaction but also the graphene shell with defects. These defects and nano-channels effectively mitigate the Li nucleation overpotential and achieve a stable cycle life with a comparable volume change with that of commercial graphite. Due to these features, the host exhibits good cycle stability (87.2% after 500 cycles) and low dimension variation (9 μm) in carbonate electrolyte full-cell evaluations. In addition to its good performances in the carbonate electrolyte, our versatile Li host, acting as a Li-ion flux regulating interlayer, also achieves an improved cycling performance in the argyrodite Li_6PS_5Cl based high energy density all-solid-state battery full-cell configuration.

5:00 PM ES04.07.03
Regulation of Outer Solvation Shell toward Superior Low-Temperature Aqueous Zinc-Ion Batteries Qianyi Ma, Zhongwei Chen and Aiping Yu; University of Waterloo, Canada

Aqueous Zn-ion batteries are well regarded among the next-generation energy storage technologies due to their low cost and high safety. However, the unstable stripping/plating process leading to severe dendrite growth under high current density and low temperature impedes their practical application. Herein, we demonstrate that the addition of 2-propanol can regulate the outer solvation shell structure of Zn^{2+} by replacing water molecules to establish a “eutectic solvation shell,” which provides strong affinity with the Zn (101) crystalline plane and fast desolvation kinetics during the plating process, rendering homogeneous Zn deposition without dendrite formation. As a result, the Zn anode exhibits promising cycle stability over 500 hours under an elevated current density of 15 mA cm^{-2} and a high depth of discharge of 51.2%. Furthermore, remarkable electrochemical performance was achieved in a 150 mAh Zn|V_2O_5 pouch cell over 1000 cycles at a low temperature of -20 °C. This work offers a new strategy to achieve the excellent performance of aqueous Zn-ion batteries under harsh conditions. It reveals electrolyte structure designs that can be applied in related energy storage and conversion fields.

RF Sputtered Tungsten Oxide Based Electrochromic Devices for Energy Efficient Smart Window Applications Sang Ji Kim[1], Usha Krishnan Sundaram[1], Jin Young Hwang[2], Hyeon Dong Kim[1] and Sangyeol S. Lee[1]; [1]Gachon University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

In light of the global energy crisis and increasing environmental problems, reducing building energy consumption has become more important than ever. About 30 to 40% of the world's primary energy is used for heating, cooling, ventilation, and appliances in buildings. A smart glass window an electrochromic device, which works on electrochromism is a promising way to convert and save renewable energy because they have a high chromatic contrast, are affordable and are environmentally benign. Tungsten oxide based thin films were fabricated on ITO precoated substrate via RF magnetron sputtering technique. The film exhibited a maximum transmittance of 83%. SEM analysis revealed the uniform, and crack-free surface, revealing the low roughness of the thin film. The film exhibited smooth morphology with fine grains distributed evenly over the surface. Based on the electrochromic analysis, WO_3 thin films, showed larger optical modulation (ΔT) of 76%. We hope that this research sets the stage for developing high-performance electrochromic smart windows.

N, S-Doped Graphene Quantum Dots for Affordable and High-Performance Aqueous Zinc-Ion Battery Anna Chen[1], Qianyi Ma[2], Tingzhou Yang[2] and Michael Fowler[2]; [1]Laurel Heights Secondary School, Canada; [2]University of Waterloo, Canada

The exorbitant costs linked to cutting-edge energy storage technologies, exemplified by lithium-ion batteries, present formidable obstacles to the widespread adoption and maintenance of new energy vehicles. As a result, there is an urgent call to expedite the development of the next generation of energy storage technology—one marked by both low cost and high performance. Aqueous zinc-ion batteries (AZIBs) have emerged as promising

candidates, offering an enticing blend of affordability and superior performance, positioning them as pivotal contenders for next-generation energy storage solutions. Nevertheless, the practical application of AZIBs faces significant challenges due to spontaneous surface corrosion and uncontrolled dendrite growth.
In pursuing a pragmatic solution while upholding cost efficiency, we propose a design strategy that involves N, S-doped graphene quantum dots (GQDs) derived from lemons and kitchen soda sources. This innovative approach aims to fabricate high-performance AZIBs. The introduction of GQDs serves a dual purpose: 1. it promotes the uniform distribution of zinc flux across the anode surface. 2. it mitigates the side reaction between the Zn anode and electrolyte. This optimization technique has the potential to substantially enhance the appeal and cost-effectiveness of the new high-performance battery energy storage technology.
Keywords: energy storage, nanomaterials, GQDs, aqueous Zn ion batteries

5:00 PM ES04.07.06
Enhancing Lithium-Ion Battery Safety in Hybrid Energy Systems: The Role of Triphenyl Phosphate (TPP) in Electrode/Solvent Dynamics and Fire Mitigation Fernando Soto; The Pennsylvania State University, United States

Lithium-ion batteries (LiBs) are key in sustainable energy solutions such as Power-to-X (P2X). Their high energy density, long cycle life, and declining costs have made them especially appealing for broader deployments (1). However, with these advantages come inherent risks, particularly those associated with thermal runaway and potential fire hazards (2-3). Recent advances and the push for higher energy densities have led to the introduction of new materials and chemistries within LiBs (4). But these modifications, while enhancing performance, can sometimes exacerbate the underlying risks, especially when exposed to real-world conditions like extreme temperatures or physical damage.

This research focuses on Triphenyl Phosphate (TPP) as a flame retardant to enhance LiBs safety in hybrid energy systems. TPP's potential in mitigating fire risks without significantly impacting battery performance is examined. The study utilizes density functional theory (DFT)-based molecular dynamics simulations to explore the interactions of TPP with lithium surfaces and the implications for the Solid Electrolyte Interphase (SEI) layer. We present three computational models to analyze TPP's influence on LiB safety at high temperatures, simulating scenarios with and without TPP. The results reveal TPP's potential in stabilizing thermal degradation products and reducing gas evolution during thermal stress. The study also investigates TPP's impact on the SEI layer's formation and structure, critical to LiBs performance and safety.

The findings suggest that TPP could serve as an effective additive in LiBs, particularly in complex, interconnected hybrid energy systems, offering a safer and more reliable energy storage solution. This research bridges knowledge gaps about TPP's role in LiBs and paves the way for designing safer batteries in the context of evolving energy storage demands.

5:00 PM ES04.07.07
Free-Standing Conversion-Type Ceramic Nanowire Interlayers towards Stable Lithium Metal Batteries Kaixi Chen[1], Wenbin Fu[1,2], Fujia Wang[1] and Gleb Yushin[1,2]; [1]Georgia Institute of Technology, United States; [2]Sila Nanotechnologies Inc., United States

Today, the growing demand for electric vehicles and consumer electronics necessitates the development of batteries with higher energy efficiency and lower costs [1]. Utilizing lithium metal anodes allows lithium batteries to provide a substantially higher energy density (3860 mAh g^{-1}) compared to those built with conventional anodes. However, crucial issues associated with Li metal anodes remain unresolved. Particularly, a major challenge is the development of lithium dendrites, which have the potential to induce short circuits and present significant safety risks [2].

To mitigate this issue, we introduce a novel design featuring a self-supporting conversion nanowire membrane, serving as a transformative interlayer to modulate lithium deposition, facilitating the development of stable and secure lithium metal batteries. This conversion interlayer is capable of producing a LiF-rich interface *in-situ* to guide heterogeneous lithium nucleation, fuse deposited lithium and suppress lithium dendrite growth regardless of electrolyte. When this interlayer is incorporated, Li metal full cells coupling with both $LiFePO_4$ (LFP) and $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ (NMC 811) cathodes exhibit substantially reduced capacity deterioration compared to those with bare Cu. Our results demonstrate that using a conversion nanowire interlayer offers significant promise for creating safe and high-energy lithium metal batteries.

Laminated Tin–Aluminum Anodes to Build Practical Aqueous Aluminum Batteries Beier Jia and Qingyu Yan; Nanyang Technological University, Singapore

Aqueous aluminum metal batteries (AAMBs) have emerged as promising energy storage devices, leveraging the abundance of Al and their high energy density. However, AAMBs face challenges such as unsuccessful Al deposition during charging or poor anode reversibility, passivation layer formation, and the competing hydrogen evolution reaction (HER). A promising approach to alleviate these issues is introducing foreign metals to interact with Al. In this study, Sn is selected for its appropriate standard reduction potential (−0.13 V), work function (4.42 eV), and compatibility with Al, facilitating Al underpotential deposition and enhancing anode reversibility. We first determine the feasibility of Al deposition on Sn substrate after three-electrode testing, which, however, results in low capacity. To increase the contact interface between Sn and Al and thereby improve capacity, we employ a scalable folding and rolling method to prepare Sn–Al laminate electrodes (Sn@Al). The Sn@Al heterostructure can effectively suppress Al passivation, reducing internal resistance. The Sn@Al electrodes demonstrate stable cycling for over 900 h in symmetric cells and superior performance in full cells when coupled with Al_xMnO_2 or KNHCF cathodes. To further enhance Sn@Al anodes, a polymer coating is applied to suppress HER. After 700 cycles, the p-Sn@Al||KNHCF cell shows 82% capacity retention compared to the 10th cycle. This study presents a strategy for designing effective and low-cost anodes for AAMBs and may provide insights into developing metal anodes for other aqueous batteries.

Facile Solvothermal Synthesis of Binder Free 1T-VS2/MXene Hybrid Electrode Materials for Li-Ion Batteries Rahul S. Ingole[1], Kwangjun Kim[1], Minwook Kim[1], Yongtae Kim[1], Snehal L. Kadam[2] and Jong G. Ok[1,1]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

The development of high-capacity batteries has become crucial to meet the growing demands for modern electric applications like electric vehicles, smartphones, and various smart wearable devices. However, their widespread adoption of Li-ion batteries is hindered due to the limited capacity, low energy density, poor cycling stability, and high cost of traditional electrode materials. To resolve these challenges continuous design and development of novel electrode materials are required. Due to their unique properties, transition metal chalcogenides (TMCs) and MXene hybrid composite materials have emerged as promising electrode materials for high-capacity Li-ion batteries. In this study, we explore the facile solvothermal synthesis of binder-free 1T-VS_2/MXene hybrid electrode materials for high-capacity Li-ion battery applications. The facile solvothermal synthesis offers several advantages, including simplicity, binder-free, cost-effectiveness, and scalability. It involves the simultaneous growth of 1T-VS_2 and MXene nanosheets within a single reaction vessel, resulting in a homogeneous growth of 1T-VS_2 on the MXene sheets. This method eliminates the need for separate synthesis and post-deposition steps, restructuring the fabrication process and improving the efficiency of electrode materials. The 1T-VS_2 decorated MXene serves various roles in the hybrid composite, firstly they act as conductive pathways, facilitating electron transport and reducing internal resistances. This results in enhanced charge/discharge rates and improved power density of the electrode material. Additionally, MXene provides mechanical stability to the fragile VS_2 nanoparticles, preventing agglomeration and ensuring long-term stability. The electrochemical properties of the binder-free 1T-VS_2/MXene hybrid electrode materials were systematically investigated using several techniques such as voltammetry, galvanostatic charge-discharge, C-rate, stability, and electrochemical impedance spectroscopy. The results demonstrated significant improvements in electrochemical performance compared to pure VS_2 electrodes. The hybrid composite electrodes revealed high capacity, improved rate performance, and excellent cycling stability. The bonder-free 1T-VS2/MXene hybrid electrode materials' enhanced electrochemical performance can justify the VS2 and MXene synergistic effects. The MXene provides high conductivity, efficient ion diffusion, and structural stability, while the VS_2 nanoparticles offer large redox sites and high energy density. The amalgamation of these properties results from a well-balanced electrode material with improved Li-ion battery performance.
Keywords: 1T-VS_2/MXene hybrids, facile solvothermal, high-capacity, Li-ion battery

Ag-Loaded Hollow Carbon Framework for Stable Anode-Free Li Metal Batteries Jong Hun Sung and Jong-Sung Yu; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Anode-free lithium (Li) metal batteries are recognized as one of the most efficient battery systems with full merits of high capacity (3860 mAh g^{-1}) and low operating potential (-3.04 V vs standard hydrogen electrode) of Li. Removing the Li anode from rechargeable batteries can increase energy density and lower production costs. However, without continuous Li supply in the anode side, the anode-free design encounters huge challenges against high cycle stability. Herein, an N-doped hollow carbon framework (HCF) derived from zeolitic imidazolate framework (ZIF) is loaded with silver (Ag) as a lithiophilic element, and the resulting Ag@HCF casted on a copper (Cu) current collector (Ag@HCF/Cu) is proposed for stable Li deposition to achieve the long-term cycle life in anode-free batteries. The HCF has several advantages of N-doping, low weight, high specific surface area, and high electrical conductivity, which can help provide uniform Li nucleation and plating reaction and minimize energy density loss. In addition, Ag@HCF can effectively suppress the Li dendrite growth through uniform distribution of electrons. In this study, the Ag@HCF/Cu, which is prepared using in-situ Li plating reaction delivers the low nucleation overpotential, reduced voltage hysteresis, and high average coulombic efficiency (ACE) at high current density up to 4 mA cm^{-2} under 4 mAh cm^{-2}. Furthermore, in a full cell system which is assembled with $LiNi_{0.5}Co_{0.2}Mn_{0.3}O_2$ (NCM) cathode of 4 mAh cm^{-2} scale, Ag@HCF/Cu||NCM cell reveals superior capacity retentions of 80.9% for 100 cycles and 66.0% for 300 cycles, which can become an effective cornerstone for stable anode-free Li metal batteries.

5:00 PM ES04.07.12
Enhancing Zn-Ion Battery Performance with Thioacetamide Electrolyte Additive Minji Yeo[1], Yujin Kim[1], Jihoon Kim[1], Sukeun Yoon[1] and Kuk Young Cho[2]; [1]Kongju National University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Zn-ion batteries (ZIBs) are emerging as a next-generation energy storage solution, characterized by enhanced safety, cost-effectiveness, and a more abundant resource base compared to their flammable, naturally occurring counterparts. Distinctively, ZIBs employ a Zn-metal anode and a Zn-ion (Zn^{2+}) storage cathode, resulting in a substantial theoretical capacity (820 mAh g^{-1} or 5850 mAh cm^{-3}) and a low redox potential of −0.76 V versus the Standard Hydrogen Electrode (SHE). Nevertheless, ZIBs confront several challenges, including limited charge-discharge reversibility attributed to the formation of Zn dendrites via the hydrogen evolution reaction (HER), uneven Zn electrodeposition, and the presence of electrochemically inert by-products such as ZnO, $Zn(OH)_2$, and $ZnSO_4[Zn(OH)_2]_3$-xH_2O. To resolve these issues, a range of methodologies has been explored, encompassing innovations in Zn electrode design, separator development, and the exploration of electrolyte additives.
In this study, the electrochemical characteristics and transformations on the Zn-metal surface were investigated by employing Thioacetamide (TAA) as an electrolyte additive within the aqueous liquid electrolyte of Zn-ion batteries. The primary objective of this research is to reduce the formation of the aforementioned Zn dendrites and byproducts while aiming to achieve a uniform Zn-metal surface deposition. TAA, characterized by primary amine functional groups, is recognized for its electrochemical activity, primarily attributable to the sulfur (S) present in the thioamide species, which tends to actively participate in electrochemical reactions. Furthermore, TAA undergoes hydrolysis within the electrolyte, resulting in the generation of weak acid by-products such as hydrofluoric acid and acetic acid, thereby facilitating the removal of impurities and contributing to a smooth deposition process. Consequently, TAA emerges as a promising functional additive capable of controlling the Zn electrodeposition process.

5:00 PM ES04.07.13
Functional Carbon-Based Zn Host Assisted with Ultra-Thin Hydrophilic ZnO Layer for Practical Aqueous Zn-Metal Batteries Jung Been Park and Dong-Wan Kim; Korea University, Korea (the Republic of)

Eco-friendly aqueous Zn-metal batteries (AZMBs) is considered a promising candidate for grid-scale energy storage system owing to its high theoretical capacity (5,854 mAh cm^{-3}), low standard reduction potential (–0.76 V vs. Standard Hydrogen Electrode), and high compatibility with aqueous electrolyte. However, the inevitable dendritic Zn growth and side-reactions (hydrogen evolution reaction (HER) and Zn corrosion) during continuous cell operation block the practical utilization of AZMBs. Hence, we effectively ameliorate the growth of Zn dendrite and the side reactions of Zn-metal anode by developing the zincophilic porous carbon host (top layer) and ultra-thin ZnO layer (bottom layer) originating from native-oxide of metallic Zn. The functional carbon host provides many zincophilic Zn nucleation/growth sites due to its large specific surface area and oxygen doping effect, which inhibits Zn dendrite growth and volume expansion, as well as inhibits sides reactions due to its low HER properties stemming from hydrophobicity of carbon. Also,

the hydrophilic ultra-thin ZnO layer (~10 nm) facilitates hygroscopicity of the aqueous electrolyte to the host to prevent “top accumulation” of Zn deposits on the carbon host, compensating low wettability of hydrophobic carbon host. Thus, the resonance between these two layers layer stably maintains low overpotential (~50 mV) even at ultra-high current density and high capacity (10 mA cm^{-2} and 5 mAh cm^{-2}, respectively) during repetitive Zn plating/stripping. Furthermore, when combined with a MnO_2 cathode, the full-cell exhibits superior cyclability over 1,000 cycles at a low negative-to-positive electrode capacity ratio (~7.3), approaching practical AZMBs.

ACKNOWLEDGEMENTS

Colloidal Synthesis and Defect Engineering of Vanadium Selenide: A High-Performance Anode Material for Li-Ion Batteries Chaeheon Woo and Jae-Young Choi; Sungkyunkwan University, Korea (the Republic of)

Defect engineering is essential for enhancing the performance of lithium-ion batteries (LIBs), particularly in transition metal chalcogenides (TMCs). Vanadium selenide, known for its outstanding electrochemical performance, has been extensively studied. In this study, we successfully synthesized Mo-doped V_2Se_9 at the nano-scale using a liquid-phase process. The resulting Mo-doped V_2Se_9 anode enhances reactive sites, facilitates Li^+ ion transport, and exhibits high electronic conductivity. With these advantages, a reversible capacity of 1309.45 mAh g^{-1} at 100 mA g^{-1} was confirmed even after the 100th cycle. Furthermore, Mo-doped V_2Se_9 exhibits non-anomalous behavior, demonstrating a 30.34% increase in capacity after 100 cycles compared to the initial cycle. Herein, we elucidate the variation in capacity with doping concentration and provide insights into the reasons for the capacity increase. This study presents an expandable strategy for synthesizing doped TMCs, contributing to the enhancement of the lithium-ion battery anode performance in other TMCs.

5:00 PM ES04.07.15
First-Principles Study on The Interfacial Reaction of Cathode Coating with Organic Additive for Aqueous Zinc-Ion Batteries Moonwon Lee[1,2], Jin Hong Lee[1], Kyu-nam Jung[1] and Kanghoon Yim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of)

Aqueous zinc-ion batteries (AZIBs) are gaining great attention as a potential post-lithium-ion battery technology due to the advantages in safety and cost. However, numerous challenges still need to be addressed to improve the energy density and cycle stability for the commercialization of AZIBs. As an example, Mn-based cathodes which are widely used for aqueous ZIBs face a significant issue of Mn^{2+} dissolution into the electrolyte. To address this concern, various strategies are under investigation such as extra addition of Mn^{2+} into the electrolyte and crystal structure modification. In this work, we have utilized MnO_2 as the cathode material and introduced an organic additive to the electrolyte. The organic additive formed a protective coating on the cathode surface, effectively inhibiting Mn^{2+} dissolution and resulting in an enhanced battery performance. To understand the effect of organic coating and the atomistic mechanisms governing the formation of the coating film on the cathode and its role in surface protection, we employed density functional theory (DFT) calculations to theoretically investigate the interfacial reactions on the cathode surface and identify the origin of inhibition of Mn^{2+} dissolution.

Electrochemical Study of The Ti-V-Ni-A(A=Fe,Mn,Al) Alloy used as Anode in Nickel-Metal Hydride Batteries Gulhan Cakmak[1], Hakan Yüce[1] and Eli Grigorova[2]; [1]Mugla University, Turkey; [2]Bulgarian Academy of Science, Bulgaria

While the energy crisis is on its way to becoming a crisis for the whole world, this problem and the storage of energy also emerge as an important problem. Although there are many energy storage methods, rechargeable batteries are of great importance. Accordingly, the development of highly efficient energy storage and conversion devices is more important than at any time in this century. Ni-MH batteries come first among these rechargeable batteries. In this direction, various alloys have been developed and continue to be developed to be used as anode materials in these batteries. Among these alloys, studies have shown that Ti-V-based alloys are especially useful for NiMH batteries and show critical technology advantages such as superior safety, environmental friendliness and excellent high/low temperature performance, and show a great development potential, especially in the field of low-temperature batteries. The electrode properties of AB alloys Continuous efforts are being made to develop and use new, high-performance versions for anode materials. Body-centered cubic (BCC) Ti or V-based alloys have an effective hydrogen storage capacity of more than 2 wt% and the pressure-composition (P-C) for absorption and desorption) shows a suitable plateau pressure in the isotherm curve and has been observed to be suitable for use as an anode material in Ni-MH batteries. This alloy electrode will be prepared by melting in a vacuum arc melting furnace under argon atmosphere and with the help of SPEX Ball Mill the alloy will be reduced below 45 microns and then Ti-V-Ni-A The crystallographic properties of the (A=Fe,Mn,Al) alloy will be examined. The electrochemical results are aimed at performing charge/discharge tests on NiMH batteries using potentiostat/galvanostat and collecting electrochemical impedance spectrum (EIS) data on the cell.

Characterization of Mg0.5Al0.25Cr0.25Ni0.25A0.25 (A=Nb,Ta,Co) Alloys as Anode Materials for NiMH Batteries Gulhan Cakmak[1], Hakan Yüce[1], Fatih Piskin[1], Berke Piskin[1] and Eli Grigorova[2]; [1]Mugla University, Turkey; [2]Bulgarian Academy of science, Bulgaria

Hydrogen energy is becoming an important part of a viable solution to worldwide climate change and atmospheric pollution. In this regard, hydrogen storage materials direct the research of rechargeable batteries.High entropy alloys containing Mg consist of an attractive system because Mg is light, cheap, and abundant, and has a high absorption capacity. Mg-containing alloys are an attractive candidate for solid-state hydrogen storage and can be further applied in electrochemical systems where the hydrogen atoms occupy the interstitial forming metal hydride (MH). A Ni/MH battery is composed of a Ni(OH) 2 positive electrode, a metal MH negative electrode and an alkaline electrolyte (KOH solution). The family of hydrogen storage alloys based on transition metals (TM) – Mg – Ni has attracted increasing attention in recent years. They can meet the general electrochemical performance requirements by exhibiting high discharge capacity, long durability, good rate capacity, admirable discharge capacity at low temperature and low self-discharge characteristics. In this direction, it is aimed to add these properties to Mg-based alloys by adding transition metals to Mg-based alloys. In this direction, it is aimed to produce Mg0.5Al0.25Cr0.25Ni0.25A0.25 (A=Nb,Ta,Co) alloys.This alloy electrode will be prepared by melting in a vacuum arc melting furnace under argon atmosphere and with the help of SPEX Ball Mill the alloy will be reduced below 45 microns and then The crystallographic properties of the Mg0.5Al0.25Cr0.25Ni0.25A0.25 (A=Nb,Ta,Co) alloy will be examined. The electrochemical results are aimed at performing charge/discharge tests on NiMH batteries using potentiostat/galvanostat and collecting electrochemical impedance spectrum (EIS) data on the cell.

Do Protons released from DRX Cathode Surfaces Initiate Decomposition of Ethylene Carbonate Electrolyte in Lithium-Ion Batteries? Rohith Srinivaas Mohanakrishnan[1,2], Sudarshan Vijay[1,2], Jordan Burns[1,2] and Kristin A. Persson[1,2]; [1]University of California Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The cathode-electrolyte interphase (CEI) is a critical, but not fully understood component of Li-ion batteries (LIBs). Ethylene Carbonate (EC), a commonly used electrolyte in LIBs, starts to decompose at approx. 3.8 V vs Li/Li+ to form this CEI [1]. One of the initial products formed due to this decomposition is vinylene carbonate (VC) which has been experimentally observed by in-situ FT-IR(Fourier Transform Infrared Spectroscopy) measurements at potentials as low as 3.8 V vs Li/Li+[2]. In this talk, we explore the feasibility of this reaction occurring through a mechanism involving transition metal ions on the cathode surface through density functional theory calculations performed under realistic surface conditions. Previous ab initio studies on the EC decomposition on NMC surfaces have been performed[3,4,5]. As a prototype for next generation cathode, we study Disordered Rocksalt(DRX) surfaces as cathodes and explore the equilibrium between EC,VC and abstracted hydrogen as a function of the potential. We find that surface adsorbed hydrogen is released as protons at a potential of 3.7 V vs. Li/Li+, which drives the conversion of EC to VC. We study the thermodynamics of proton release from the DRX surface at different lithiation stages from ab initio calculations to understand the potential dependence of proton release and further understand the thermodynamics of EC to VC decomposition. This will allow us to better understand the reactions occurring at the cathode electrolyte interface as well as crosstalk between anode and cathode materials.

5:00 PM ES04.07.19
Computational Study on a Variety of Lithium Diffusion Pathways Yevgeniya Kondratyeva and Artem Sergeev; N.N.Semenov Federal Research Center for Chemical Physics, Russian Federation

Lithium metal batteries are promising storage systems with better electrochemical characteristics than ubiquitous Li-ion. Lithium anode is the key to creating high-power batteries and the main challenge at the same time. One of the main flaws of using lithium as anode material is the formation of heterogeneous deposits on lithium surface during charge process. The most common type of such deposits is whiskers. Understanding of whiskers' formation and growth mechanism is required for solving this problem. Last studies have shown that solid-state processes run the whole show in the whiskers' formation processes.
In this study we investigated and compared different pathways of lithium diffusion within metal electrode: diffusion of point defects in the metal bulk, self-diffusion through grain boundaries and the influence of Li-Li_2O interface on the point defects. Due to high reactivity of lithium, we weren't able to provide all these investigations in chemical lab, we had to estimate diffusion processes with computational methods: Molecular Dynamics (MD) and DFT.
We have chosen MD for modeling all-lithium-systems (LAMMPS package) because this method can handle a relatively large system size and time scale. For avoiding inaccuracies, we have compared several force fields firstly. One of them was Machine-learning Interatomic Potential (MLIP), which we had trained ourselves. The results obtained with MLIP have shown DFT-level of accuracy. For instance, we calculated melting parameters and point defect energies obtained with 5 different potentials and compared these data with the published experimental and DFT data. Thus, we revealed the superiority of MLIP over other potentials and the possibility of using it to simulate large systems such a grain boundary with DFT-accuracy.
Further we simulated lithium grain boundary and calculated lithium diffusion coefficient from mean squared displacement slopes. Simulation cell consist of two lithium slabs rotated at a certain angle, which was chosen based on coincidence site lattice. We showed that the boundary is 3-5 atomic layers thick and is amorphous at room temperature. The mobility of grain boundary atoms was found to be extremely high and only 5 times lower than it is in supercooled molten lithium.
For comparison of the diffusion coefficients in the grain boundary and bulk we had to estimate self-diffusion value in solid lithium bulk. We investigated the mobility of point defects (vacancy and self-interstitial atom) in the lithium bulk and discovered an anomalous phenomenon. Temperature dependence of vacancy diffusion coefficient corresponds to Arrhenius law, simultaneously this dependence of self-interstitial atom does not correlate with Arrhenius law and even demonstrates an inverse dependence, i.e. diffusion coefficient decreases with the temperature increasing. We have further demonstrated that this anomaly is due to the interplay between ballistic motion of interstitial defect along <111> direction and its rotation which obeys to Arrhenius law.
There is the third way for lithium diffusion. It would be surface diffusion for any less reactive metal, but for lithium this way is not available due to presence of SEI. It is considered that the closest to lithium layer of SEI consists of lithium oxide, so we simulated Li-Li_2O interface using DFT (VASP) and estimated the behavior of point defects at the heterogeneous interface. We have studied the influence of space-charge at the interface on the defect energetics and mobility along the interface.
Eventually, we have been able to consider all possible mass-transfer pathways within the electrode to build a complete picture of processes during lithium deposition. We have discovered that solid-state diffusion along grain boundaries and Li-SEI interfaces is sufficient to realize the proposed mechanism of whiskers' formation and growth.

Ionic Peltier Effect in Concentrated Carbonate and Ether-Based Li-Ion Electrolytes Yu-Ju Huang, David Cahill, Zhe Cheng and Peilin Lu; UIUC, United States

Understanding the Li+ transport and solvation behaviors in electrolytes is crucial for electrolyte selection to optimize cell performance. The ionic Peltier effect is the phenomenon of heat generation or absorption at the interface of electrodes during a reversible electrode reaction. It can provide us with information on the solvation thermodynamics of Li-ion electrolytes. By using the temperature difference metrology developed by our group, we expand our ionic Peltier coefficient measurements and study more ether-based and carbonate-based electrolytes. The magnitude of Peltier coefficients of ether-based electrolytes is -70-80 kJ/mol, almost 2 times larger than that of carbonated-based electrolytes, around -20-30 kJ/mol. This difference indicates a larger change in partial molar entropy between the Li electrode and electrolyte at the interface in ether-based electrolytes. In addition, we also observe a decrease in the magnitude of the Peltier coefficient in ether-based electrolytes with increasing concentration, the same as in carbonate electrolytes. For carbonate

electrolytes, the binary mixture (EC/DMC) electrolyte has a Peltier coefficient between the values of pure solvents, EC and DMC. Peltier coefficients of different Li salt concentrations, from 0.5M to 3M, are slightly temperature dependent by being more negative with increasing temperature. Combining with the present Li solvation thermodynamic properties and the structures of different electrolytes, we provide information on the interaction between Li ion-solvent, and its correlation with solvent physical properties.

Increasing The Cycle Life of Zinc Metal Anodes and Nickel-Zinc Cells Using Flow-Through Alkaline Electrolytes Shuhua Shan[1], Mihir Parekh[2], Rong Kou[1], Donghai Wang[1] and Chris Rahn[1]; [1]Pennsylvania State University, United States; [2]Clemson University, United States

Alkaline electrolyte flow through porous Zn anodes and $Ni(OH)_2$ cathodes can overcome diffusion limits, reduce dendrite growth, and improve cycle life. Zinc deposition morphology improves with low flow rates for KOH/ZnO electrolytes at current densities near the diffusion-limited regime. Zinc dendrites present without flow are suppressed by micrometer-per-second flow at concentrations ranging from 0.2 to 0.6 M ZnO dissolved in 6 M and 10 M KOH solutions. Zn-Cu asymmetric cell tests reveal that flowing electrolyte increases the lifespan by more than 6 times in the diffusion-limited regime by suppressing gas evolution and dendrite formation. Ni-Zn cell tests show that a flow-assisted battery cycles 1500 times with over 95% Coulombic efficiency (CE) at 35 mA/cm^2 current density and 7 mAh/cm^2 charge capacity, increasing the battery lifespan by 17 times compared with a stagnant electrolyte Ni-Zn cell. Flow-through electrolyte also stabilizes the Zn electrode in the over-limiting regime, achieving approximately 4 times increased lifespan and 297 cycles with over 90% CE at 52 mA/cm^2.

Mimicking Ion and Water Management in Poultry Breeding for Highly Reversible Zinc Ion Batteries Zhi Li; University of Alberta, Canada

Aqueous Zn-ion chemistry has emerged as a promising energy storage technology yet suffers from severe irreversibility due to poor management of water and Zn2+ flows, leading to dendrite formation, parasitic reactions, and structural collapse of many cathode materials. To address these challenges, we turned to eggshell membranes (ESM), which have evolved over millions of years to regulate water and Ca2+ flows, ensuring the formation of well-defined hard shells and protecting chicken embryos during incubation. We discovered ESM, especially after denaturation, can effectively retard water, regulate Zn2+ flow, and self-concentrate Zn2+ at the electrode interfaces, thus achieving dendrite-free Zn plating/striping at a Coulombic efficiency of ~99.8% over 500 cycles, steady charge/discharge beyond a half year, and capacity retention of 90.1% over 10,000 cycles for Zn-V full cells. To demonstrate scalability, we fabricated prototyped ESM-based papers, showing dual-electrode protection capability and long-term stability. This work also inspires bionic structures in batteries and beyond.

Two Architected Battery Electrodes are Better than One! Debra R. Rolison[1], Jeffrey W. Long[1], Ryan H. DeBlock[1], Christopher N. Chervin[1], Samuel Kimmel[2,1] and Christopher Rhodes[2]; [1]U.S. Naval Research Laboratory, United States; [2]Texas State University, United States

Having removed the roadblock to rechargeable aqueous alkaline batteries by architecting the zinc in a sponge form factor, thus thwarting formation of cell-shorting zinc dendrites, our team at the US Naval Research Laboratory has turned to improving the performance of the opposing electrode. To do so, we again bring an architectural perspective to the positive electrode. Keeping the zinc sponge anode as a constant factor, we demonstrate two classes of Zn-based alkaline cells that derive improved discharge areal capacity and capacity retention, namely Ni–Zn and Zn–air, when the respective cathodes adopt either an architected form factor or deploy architected catalysts. We nucleate and grow Al(III)-substituted α-$Ni(OH)_2$ onto carbon nanofiber paper and achieve 1.5 electrons per Ni rather than the 1 electron per Ni characteristic of Ni cathodes. Using the 3D electron-wired cathode, the cell retains that extra per Ni capacity without fade over 80 cycles. To catalyze oxygen reduction (ORR) and evolution (OER) in the air electrode, we use aerogels as the design architecture. By blending aerogel versions of an excellent ORR catalyst (the 2×2 tunneled polymorph of MnO_2, cryptomelane) with an excellent OER catalyst (nickel ferrite) in a powder-composite electrode structure, we attain high areal capacity (mAh per geometric area) while achieving state-of-the-art low voltage hysteresis (700 mV) and charging voltage <2 V.

9:15 AM ES04.08.04
Advancements in Zinc Sponge Anode Fabrication for Scale-up, Manufacture and Battery Performance Jeffrey W. Long, Ryan H. DeBlock and Debra R. Rolison; Naval Research Laboratory, United States

Zinc (Zn) anodes were historically prone to shape change, short-inducing dendrite formation, and suboptimal redox utilization in aqueous battery systems, particularly when subjected to extensive charge–discharge cycling. The Naval Research Laboratory introduced a 3D-architected Zn “sponge” design that mitigates many of the historic limitations of Zn anodes [1]. Over several years of development, the fabrication routes to Zn sponges have continued to evolve from early proof-of-concept examples with specialized chemicals and multistage thermal processing toward a more recent focus on methods that are fast, low-cost, readily scalable, and energy efficient. The latest protocols use simple inorganic porogens such as sodium chloride and potassium carbonate in conjunction with chemical sintering and simplified heating steps to produce robust Zn sponges in varied monolithic forms (discs, plates, cylinders) and scales (up to 20 cm on a side). We will discuss the latest advances in the fabrication, materials characterization, and electrochemical evaluation of Zn sponges as directed toward their use as anodes in aqueous batteries (alkaline to mild-pH).

9:30 AM ES04.08.05
Colossal Capacity Loss during Calendar Aging of Zn Battery Chemistries Bo Liu, Xintong Yuan and Yuzhang Li; University of California, Los Angeles, United States

Whereas previous research efforts in Zn battery chemistries have primarily focused on extending their cycle life, calendar aging has largely been neglected and is poorly understood. Here, we discover that Zn metal anodes lose 12-37% of their capacity after only 24 hours of calendar aging, which is more than

an order of magnitude greater than any other battery chemistry previously studied. We find that this large capacity loss occurs regardless of electrolyte chemistry, substrate composition, and calendar aging time, suggesting that the losses cannot be accounted for by corrosion alone. By leveraging titration gas chromatography, we distinguish corrosion losses from losses due to electrically disconnected Zn ("dead" Zn) and quantify dead Zn as the main contributor to capacity loss during Zn battery aging. More broadly, this study shows that large instabilities in seemingly non-reactive metals (e.g., Zn) can occur, highlighting the importance of understanding their underlying degradation mechanisms.

Characterization of Iron Anodes for Rechargeable Aqueous Batteries Xiao Zhao[1,2], Evan Carlson[1] and William C. Chueh[1]; [1]Stanford University, United States; [2]Lawrence Berkeley National Laboratory, United States

Metallic iron is an attractive anode material for aqueous batteries, particularly if the full 3-electron redox between Fe and Fe (III) can be accessed reversibly. However, oxidation of Fe (II) to Fe (III) causes drastic morphology change and irreversible formation of highly resistive phases. Yet, it remains unclear how these phases form at the nanoscale and, crucially, how they might be avoided. To achieve fully reversible Fe anodes, it is critical to obtain a mechanistic understanding of nanoscale morphology and phase evolution during electrode cycling. Here we investigated the electrochemical transformation pathways between Fe (II) and Fe (III) oxides using both ex-situ and operando techniques, including SEM, Raman, AFM, Infrared Nanospectroscopy (nano-FTIR) and Scanning Transmission X-ray Microscopy (STXM). Correlating the morphology evolution during this transformation to local Fe oxidation state and phase would offer fundamental insight into Fe (II)/(III) conversion and inspire novel engineering of the Fe anode to achieve higher capacity and cyclability.

Peptide Gel Electrolytes for Stabilized Zn Metal Anodes Yizhou Wang and Husam N. Alshareef; KAUST, Saudi Arabia

The rechargeable aqueous Zn ion battery (AZIB) is considered a promising candidate for future long-duration energy storage due to its intrinsic safety features and low cost. However, Zn dendrites and side reactions (*e.g.*, corrosion, hydrogen evolution reaction, and inactive side product (Zn hydroxide sulfate) formation) at the Zn metal anode have been serious obstacles to realizing satisfactory AZIB performance. The application of gel electrolytes is a common strategy for suppressing these problems, but the normally used highly crosslinked polymer matrix (*e.g.*, polyacrylamide (PAM)) brings additional difficulties for battery assembly and recycling. Herein, we have developed a gel electrolyte for Zn metal anode stabilization, where a peptide matrix, a highly biocompatible material, is used for gel construction. Various experiments and simulations elucidate the sulfate anion-assisted self-assembly gel formation and its effect in stabilizing Zn metal anodes. Unlike polymer gel electrolytes, the peptide gel electrolyte can reversibly transform between gel and liquid states, thus facilitating the gel-involved battery assembly and recycling. Furthermore, the peptide gel electrolyte provides fast Zn ion diffusion (comparable to conventional liquid electrolyte) while suppressing side reactions and dendrite growth, thus achieving highly stable Zn metal anodes as validated in various cell configurations. We believe that our concept of gel electrolyte design will inspire more future directions for Zn metal anode protection based on gel electrolyte design.

10:45 AM ES04.08.09
Understanding, Quantification and Mitigation of Hydrogen Evolution Reaction for Aqueous Zinc Metal Batteries Kingshuk Roy; Purdue University, United States

The study delves into the hurdles faced by aqueous zinc metal batteries (AZMBs), including challenges like the unwanted hydrogen evolution reaction (HER), corrosion of the zinc substrate, and dendrite growth, all of which hinder the overall effectiveness of these batteries. To thoroughly understand HER, the study introduces the use of in-situ electrochemical mass spectrometry (ECMS) for precise real-time monitoring of HER during zinc electrodeposition. It is highlighted that even a minute fraction (0.3%) of the total charge attributed to HER has a detrimental impact on the long-term cycling performance of AZMBs. The study establishes a significant platform by introducing a method to accurately determine the faradaic efficiency in zinc electrodeposition. This advancement becomes a valuable tool in evaluating additives and modifications aimed at enhancing the stability of AZMBs and suppressing the HER. Moreover, the text introduces a thoughtful approach to improving AZMBs by employing tetraalkylsulfonamide (TAS) additives. This additive is designed to tackle challenges like dendrite formation, HER, and ZnO passivation on the anode, which have historically impeded the development of AZMBs. Through various techniques such as nuclear magnetic resonance spectroscopy, mass spectrometry, and density functional theory studies, we demonstrate that TAS molecules displace water from Zn2+ solvation. This alters the solvation matrix, disrupting the hydrogen bond network in free water. The study reports promising outcomes with TAS additives, including suppressed dendritic growth and HER, along with a remarkable ~25-fold cycle life improvement—from approximately 100 hours to over 2500 hours—at a current density of 1 mA/cm2. Techniques such as X-ray diffraction and X-ray photoelectron spectroscopy reveal impressive suppression of insulating side products and the formation of ion-conductive solid electrolyte interphase components. Post-cycling analysis further illustrates uniform, planar zinc growth in the presence of TAS, in contrast to the inhomogeneous, void-containing clusters observed in its absence. In conclusion, the findings from this study suggest that TAS additives offer a comprehensive framework for realizing robust zinc metal batteries, presenting a promising alternative to lithium-ion batteries.

11:00 AM ES04.08.11
The Preparation of Moldable Zinc-Ion Batteries Using Graphene Oxide Doughs Min-Yen Tsai, Han-Shiuan Lin and Che-Ning Yeh; National Tsing Hua University, Taiwan

The increasing demand for electric vehicles has ignited a pursuit to enhance their energy density while simultaneously reducing manufacturing costs. Compared with Li-ion batteries, aqueous Zn-ion batteries show tremendous potential due to their attractive characteristics of having a high theoretical capacity (820 mAh g^{-1}) and a low potential (-0.76 V vs SHE). Furthermore, coupled with its safety and environmental friendliness advantages, this renders it with significant potential for large-scale applications. In this work, we use graphene oxide (GO)/carbon nanotube (CNT)/cellulose nanofibrils (CNF) composite dough as the 3D scaffold for the electrode. The composite dough is a binder-free and self-sustaining structure with moldable features. The characteristics of arbitrary shapes, highly processable and tunable microstructures endow it with significant potential for diversified applications. The composite dough combines the advantages of three different carbon materials. GO possesses a large surface area and, after annealing, maintains structural integrity to prevent collapse. CNT prevents the aggregation of GO after reduction and enhances the ionic conductivity of the composite. CNF improves the mechanical strength of the composite and its abundant hydroxyl groups enable the dough to maintain the viscoelastic state at high water content up to 90 wt%. The composite dough is then transformed into an electrode scaffold characterized by high porosity, excellent conductivity, and a large surface area. The anode features Zn powders (ZPs) integrated into the composite dough-based electrodes, which enhances control over the N/P ratio. However, zinc anodes normally suffer from issues including hydrogen evolution and corrosion. Coating TiO_2 nanoparticles onto the surface of the dough not only protects the ZPs from side reactions but also suppress dendrite growth. In addition, TiO_2 can also enhance the electrode's hydrophilicity, zincphilicity, and facilitate Zn ion diffusion. On the cathode side, α-MnO_2 is used as the active material and is incorporated into the composite dough. Our results indicate that the

MnO_2@composite dough-based electrode has higher gravimetric capacity and cycle stability compared to the MnO_2@carbon paper. The improved contact between MnO_2 and composite scaffold leads to enhanced charge transfer. The ZPs/TiO_2@composite||MnO_2@composite dough-based cell exhibits more stable cycle performance and higher discharge capacity than those of ZPs@carbon paper||MnO_2@carbon paper cell. This work offers an alternative approach for fabricating 3D and moldable electrodes, broadening the horizons for 3D electrodes in high-performance energy storage devices.

11:15 AM ES04.08.12
Promoting Room Temperature Aluminum Deposition Through Rapid Ligand Exchange Complexes Dan Thien Nguyen[1,2], Venkateshkumar Prabhakaran[1,2], Ying Chen[1,2], Karl Mueller[1,2] and Vijayakumar Murugesan[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]Joint Center for Energy Storage Research (JCESR), United States

Unlocking room temperature aluminum (Al) electroplating stands as a promising avenue for advancing multivalent energy storage systems and pioneering surface coating methods, pivotal in driving a zero-emission economy. Despite its potential, challenges such as electrolyte-induced parasitic reactions during Al deposition, high flammability risks, suboptimal Coulombic efficiency, and the costliness of organic-based electrolytes have persisted. Addressing these challenges necessitates reducing activation energy and expediting kinetics for the electrochemical reduction of aluminum cations in organic electrolyte solutions. This is pivotal for achieving efficient, reversible room temperature electrodeposition of Al. In our study, we introduce a novel electrolyte material—a highly concentrated aluminum chloride ($AlCl_3$) solution within weakly coordinating dialkyl-ether and sulfone compounds.[1] These solvents swiftly form ligand exchange complexes with $AlCl_3$, enabling rapid Al electrodeposition at a minimal 0.2 V overpotential. Additionally, they effectively suppress the solvent's parasitic reaction, particularly in the low voltage regime. Our research delves into the intricate interactions between solvents and solutes in weakly coordinating environments, shedding light on their influence on electrolyte solution electrochemistry. This foundational understanding is pivotal for future electrolyte design and optimization, benefiting both electroplating and rechargeable batteries.

Room 422, Level 4, Summit

1:30 PM ES04.09.01
Anthraquinone-Based Silicate Covalent Organic Frameworks as Solid Electrolyte Interphase for High-Performance Lithium-Metal Batteries Chen Li; The Hong Kong University of Science and Technology, China

Lithium (Li)-metal batteries (LMBs) possess the highest theoretical energy density among current battery designs and thus have enormous potential for use in energy storage. However, the development of LMBs is severely hindered by safety concerns arising from dendrite growth and unstable interphases on the Li anode. Covalent organic frameworks (COFs) incorporating either redox-active or anionic moieties on their backbones have high Li-ion (Li^+) conductivities and mechanical/chemical stabilities, so are promising for solid-electrolyte interphases (SEI) in LMBs. Here, we synthesized anthraquinone-based silicate COFs (AQ-Si-COFs) that contained both redox-active and anionic sites via condensation of tetrahydroxy-anthraquinone with silicon dioxide. The nine Li^+ mediated charge/discharge processes enabled the AQ-Si-COF to demonstrate an ionic conductivity of 9.8 mS cm^{-1} at room temperature and a single-ion-conductive transference number of 0.92. Computational studies also supported the nine Li^+ mechanism. We used AQ-Si-COF as the solid electrolyte interphase on the Li anode. The LMB cells with $LiCoO_2$ cathode attained a maximum reversible capacity of 188 mAh g^{-1} at 0.25 C during high-voltage operation. Moreover, this LMB cell demonstrated suppressed dendrite growth and stable cyclability, with its capacity decreasing by less than 3% up to 100 cycles. These findings demonstrate the effectiveness of our redox-active and anionic COFs and their practical utility as SEI in LMB.

1:45 PM ES04.09.02
Modifying Li+Transport and Interface Chemistry via Citric Acid-Treated Silica Carrier in Nanoparticle Colloidal Electrolyte toward Stable Li-Metal Batteries Minhong Lim and Hongkyung Lee; DGIST, Korea (the Republic of)

Tailoring the lithium ion (Li+) microenvironment is essential for achieving rapid ionic transfer and a mechanically strong solid-electrolyte interphase (SEI). This is key to the stable cycling of lithium-metal batteries (LMBs). Beyond the conventional approach of adjusting salt and solvent compositions, this study introduces a novel method. It involves simultaneous modulation of Li+ transport and SEI chemistry through a citric acid (CA)-modified silica-based colloidal electrolyte (C-SCE). The CA-tethered silica (CA-SiO2) provides more active sites for attracting complex anions. This leads to a greater dissociation of Li+ from these anions, resulting in a high Li+ transference number (approximately 0.75). The intermolecular hydrogen bonds formed between solvent molecules and CA-SiO2, along with their migration, serve as nano-carriers. These nano-carriers are responsible for transporting additives and anions to the lithium surface, thereby strengthening the SEI through the co-implantation of SiO2 and fluorinated components. Notably, C-SCE has shown promise in suppressing lithium dendrite formation and enhancing the cycling stability of LMBs. This is a significant improvement over the CA-free SiO2 colloidal electrolyte. The study highlights that the surface properties of nanoparticles play a crucial role in the dendrite-inhibiting capabilities of nano colloidal electrolytes.

2:00 PM ES04.09.03
Revitalizing Native Lithium-Metal Electrode Surfaces through Hydrohalic Acid-Assisted Pre-Halogenation Jiyeon Seo, Jaeho Lee and Hongkyung Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Lithium metal anodes (LMAs) represent the ultimate choice for advancing beyond traditional Li-ion batteries due to their remarkable attributes, including a high capacity of 3860 mAh g–1 and a low working potential of –3.04 V vs. SHE. However, the inherent challenges associated with LMA usage, such as their exceedingly high surface reactivity, uncontrollable dendritic plating, and unbounded volume expansion, have long hindered the development of practical lithium-metal batteries (LMBs). The primary culprit behind these issues is the formation of a non-uniform solid-electrolyte interphase (SEI) layer, arising from byproducts within the electrolyte and the inherent surface characteristics of LMAs. In light of these challenges, achieving uniform passivation of LMAs and the formation of a homogeneous SEI layer during the initial stages are imperative. Such uniformity is crucial to enable consistent Li^+ ion flux. Additionally, the integration of halogenated SEI components holds great promise, offering enhanced mechanical strength, insulation properties, and thermodynamic stability.

In this study, we introduce a straightforward LMA treatment technique utilizing hydrohalic acids (HXs, X = F, Cl, Br, and I) to rejuvenate the native passivation layer (NPL) found on as-manufactured LMAs. This treatment ensures an even distribution of halogenated compounds across the LMA surface. A key aspect of this process involves the dissolution of existing inorganic Li-compounds, such as Li_2O, LiOH, and Li_2CO_3, present in the NPL by water molecules from aqueous HXs. This results in chemical reactions between HXs and pure Li, ultimately enriching the NPL with LiX compounds. A comparative analysis was conducted to identify the most advantageous LiX compounds for stabilizing the LMA surface and enhancing the cycling stability of LMBs. Furthermore, we elucidated the critical role played by LiX compounds in interfacial reactions when employing localized high-concentration electrolyte (LHCE) as an advanced electrolyte in LMBs. Through this comparative study, it was demonstrated that the establishment of a LiCl-rich SEI layer during the initial stages effectively lowers the energy barrier for Li nucleation and reduces interfacial resistances. This leads to significant enhancements in cycling performance for LMBs, even under practical operating conditions.

2:15 PM ES04.09.04
Tracking Dendrites and Solid Electrolyte Interphase Formation in Composite Electrolyte using Solid State NMR Spectroscopy Ayan Maity, Asya Svirinovsky-Arbeli, Yehuda Buganim, Chen Oppenheim, Brijith Thomas, Arava Zohar and Michal Leskes; Weizmann Institute of Science, Israel

Solid-state lithium batteries have garnered significant attention in recent years as they are a promising technology with immense potential for development with diverse applications. Utilization of solid electrolytes is particularly appealing as it enables the use of lithium metal anodes and thus offer superior energy density with enhanced safety compared to traditional liquid electrolytes. Among the different types of solid-state batteries, polymer-based electrolytes are attractive due to their flexibility and non-flammable nature [1]. However, the practical implementation of polymer electrolytes in rechargeable batteries for high-energy applications faces challenges. These include limited room temperature Li-ion conductivity and formation of lithium dendrites at high current densities. To address these issues, one potential approach is to incorporate solid-state ceramic particles into the polymer matrix. However, there is still a limited understanding as to how ceramics incorporation impacts dendrite formation and propagation, as well as the composition and properties of the solid electrolyte interphase (SEI). The SEI plays a crucial role in the battery chemistry and gaining insights into its atomic-level structure and composition has the potential to transform the development of composites, enhancing their ability to suppress dendrite formation [2]. Unfortunately, there is a shortage of analytical tools capable of precisely identifying the SEI's chemical constituents at the atomic scale, and even more so, of understanding how these constituents affect ionic transport across the SEI. Here we introduce an innovative approach which allows to (i) quantify dendrites formation, (ii) determine SEI composition and its properties which allows us to (iii) determine the dendrite's propagation path within the composite electrolyte.
Using Li NMR spectroscopy, we successfully quantified the formation of dendrites in the cycled composites. Remarkably, we find a consistent rise in dendrite formation by increasing ceramic content up to 40 wt. %, when using $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP) and $Li_{6.4}Al_{0.2}La_3Zr_2O_{12}$ (LLZO) as ceramic fillers in polyethylene oxide. To determine the effect of ceramic content on dendrites formation, we employed dynamic nuclear polarization (DNP) [3], a method in which the high electron spin polarization is used to increase NMR sensitivity, to selectively enhance the SEI signal [4]. We make use of the inherent conduction electrons of the dendrites for DNP, enabling us to identify the chemical components and structure of the SEI, as well as the SEI permeability to Li-ions. We determined the chemical components of the SEI formed on dendrites in a pure polymer electrolyte and with the addition of varying content of LAGP and LLZO. Surprisingly, we found that SEI structures significantly differ not just with varying ceramic types but also with different ceramic contents, suggesting the nature of possible interaction of the dendrites with ceramic and polymer matrix. Furthermore, analysis of the SEI composition allows us to trace the dendrite propagation within the composite. We showed that in composites with 40 wt. % LAGP, dendrites chemically react with LAGP, hindering their growth towards the opposite electrode and impacting battery lifespan. Conversely, with 40 wt. % LLZO, dendrites are physically blocked without any chemical reaction. In summary, our study offers valuable insights into the SEI's composition, structure, and its correlation with dendrites and ceramic components. The approach can be used to identify the optimal ceramic material to reduce dendrite formation and enhance SEI's Li-ion permeability for improved battery performance.

Nondestructively Visualizing and Understanding Li Dendrite 'Soft Short' and Bulky Li Creeping in All-Solid-State Batteries Hongli Zhu; Northeastern University, United States

All-solid-state Li metal batteries (ASLMBs) represent a significant breakthrough in the quest to overcome limitations associated with traditional Li-ion batteries, particularly in energy density and safety aspects. However, widespread implementation is stymied by the complex challenges surrounding ASLMBs. An essential part of the solution lies in a profound understanding of the complex mechano-electro-chemical behavior of Li metal in the ASLMBs. In this study, we leverage advanced techniques, operando neutron imaging and X-ray computed tomography (XCT), to nondestructively visualize Li behavior within ASLMBs. This novel approach gives us a unique window into real-time Li evolution, both pre- and post- the occurrence of a "soft short". Our utilization of two-dimensional neutron radiography, complemented by three-dimensional neutron tomography, enables us to chart the terrain of Li metal deformation operandoly. Concurrently, XCT offers a rich, three-dimensional insight into the internal structure of the battery following a "soft short". Despite the manifestation of a "soft short", we observe the persistence of Faradaic processes. To study the elusive 'soft short' behavior in solid electrolytes, we have coupled phase-field modeling with electrochemistry and solid mechanics theory. This has enabled us to simulate Li dendrite growth under varying external pressures. Our research unravels how external pressure plays a significant role in curbing dendrite growth, potentially leading to dendrite fractures and thus uncovering the origins of both "soft" and "hard" shorts in Li metal batteries. Furthermore, by harnessing finite element modeling, we dive deeper into the mechanical deformation and the fluidity of Li metal.

3:00 PM BREAK

3:30 PM ES04.09.06
Enhancing Lithium Stripping Efficiency in Anode-Free Solid-State Batteries through Self-Regulated Internal Pressure Hongli Zhu; Northeastern University, United States

Anode-free all-solid-state lithium metal batteries (ASLMBs) promise high energy density and safety but suffer from low initial coulombic efficiency and rapid capacity decay, especially at high cathode loadings. Using operando techniques, we concluded these issues to interfacial contact loss during lithium stripping. To address this, we introduce a conductive carbon felt elastic layer that self-adjusts pressure at the anode side, ensuring consistent lithium-solid electrolyte contact. This layer simultaneously provides electronic conduction and releases plating pressure. Consequently, the first coulombic efficiency dramatically increased from 58.4% to 83.7% along with over tenfold improvement in cycling stability. Overall, this study reveals an approach to enhance

anode-free ASLMB performance and longevity by mitigating lithium stripping inefficiency through self-adjusting interfacial pressure control enabled by a conductive elastic interlayer.

3:45 PM ES04.09.07
Exploring Wet SEI Layer Dynamics and Stability in Lithium-Ion Batteries Through Salt Concentration: An *Ab-Initio* Molecular Dynamics and Machine Learning Study Fernando Soto; Penn State University-Greater Allegheny, United States

The Solid-Electrolyte Interphase (SEI) layer plays a key role in the performance and longevity of lithium-ion batteries (LiBs) (1), with its stability being crucial for efficient reversible operation of LiBs. This study focuses on the dynamics of the 'wet SEI' – an inorganic layer in contact with electrolyte solution (2), comprising components such as lithium fluoride (LiF), lithium oxide (Li_2O), and lithium carbonate (Li_2CO_3). A combination of *ab-initio* molecular dynamics (AIMD) simulations and machine learning models is employed to identify a 'goldilocks' salt concentration that optimizes the stability of the SEI layer, a critical factor in enhancing battery performance.

The study provides a comprehensive analysis of the interaction dynamics of LiF, Li_2O, and Li_2CO_3 in various electrolyte environments. The changes in cluster stability, surface area, and bond dynamics are explored, particularly focusing on the effects of varying salt concentrations on these parameters. The goal is to characterize an optimal salt concentration that yields an ideal inorganic SEI layer, enhancing the layer's protective qualities and improving overall battery safety and efficiency.

The findings of this study are significant for advancing the understanding of wet SEI layer formation and its optimization in LiBs. The implications of achieving an optimal SEI layer are profound, potentially leading to batteries with higher energy density, longer cycle life, and improved safety profiles.

Unraveling The Impact of Pectin on Transport and Mechanical Properties of EC-LITFSI Electrolytes Sipra Mohapatra and Santosh Mogurampelly; Indian Institute of Technology Jodhpur, India

Biocompatible electrolytes are becoming attractive alternatives for the existing counterpart technology for battery electrolytes, as they are sustainable, renewable, and easily degradable. We used all-atom molecular dynamics simulations to study the transport and mechanical characteristics of a new class of battery electrolytes containing ethylene carbonate (EC), Li-TFSI, and pectin at different weight percentages. Pectin is a polysaccharide exhibiting high ion solvating capability, making it a potential candidate for battery electrolyte applications. Our simulation results demonstrate that pectin reduces the coordination numbers of lithium ions surrounding the counterions (and vice versa) as a result of the strong lithium-pectin interactions in comparison to lithium-TFSI interactions. We observed that smaller ionic clusters are favored over larger ones due to strong ion-polymer interactions, which is different from the trend observed in conventional electrolytes. Moreover, the ion association probability shows an increase in free ions, which indicates an enhancement in the overall ionic conductivity of pectin EC-LiTFSI electrolytes. Interestingly, TFSI ionic diffusivities show a strong correlation with the ion-pair relaxation timescales, with a relationship of $D_{TFSI} \sim \tau_c^{-0.95}$. On the other hand, the diffusivities of lithium ions follow a different pattern, with $D_{Li} \sim \tau_c^{-3.1}$, suggesting a unique transport mechanism for lithium ions. Consequently, the Nernst-Einstein conductivities scale with the ion-pair relaxation timescales as $\sigma_{NE} \sim \tau_c^{1.85}$. Furthermore, the increase in viscosity and ion-pair relaxation timescales show that pectin can also enhance the mechanical stability of the electrolytes.

Organic Electrode Materials for Li-Ion Batteries Dwight Seferos; University of Toronto, Canada

Organic materials hold promise as less-scarce materials for electrodes in a range of emerging battery technologies. Despite this, they have significant hurdles to overcome in terms of capacity, stability, and conductivity. Here, I will discuss our efforts in the rational design of organic materials as electrodes, both anodes and cathodes, for Li-ion batteries. First, I will discuss functional groups to maximize theoretical capacitance. Second, I with discuss the arrangement of these functional groups as macromolecules that render them insoluble, which is a requirement for any electrode in both the charged and discharged state. And in both, synthetic strategies for developing the functional group chemistry and macromolecules will be discussed. We consider both linear and 2D/3D type macromolecular designs for this purpose. Finally, I will share some insight into designs that have afforded very high capacity as anodes, where the lithium intercalation exceeds the expected 1 Li per 6 carbon units. Overall, this presentation will describe chemical structures and electrochemical properties and then aim to rationalize performance at the molecular level.

Molecular Engineering toward Highly Stable Redox Flow Batteries with High Energy Density Dawei Feng; University of Wisconsin--Madison, United States

An increasing amount of renewable energy sources are being integrated into the electric grid in the US and around the world. However, as intermittent wind and solar begin to approach more than a quarter of grid energy production, significant energy storage technology must be employed as well to mitigate the unbalanced energy production and demand in the grid. To meet the emission targets in an economically viable manner, low-cost grid-scale energy storage technology must be developed. This talk will compare different battery technologies and describe our efforts in development of new generation of inexpensive redox active species for redox flow batteries (RFB) that can offer extraordinary energy density and cycling stability. This involves identification of critical needs for redox couple design in RFB and development of simplest yet effective synthetic routes towards redox active molecules with desired performance.

9:00 AM *ES05.01.02
Ion-Coupled Electron Transfer of Naphthalene Diimide for Organic Redox Flow Batteries Hye Ryung Byon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Organic redox flow batteries (RFBs) have been investigated for future energy storage systems (ESSs). Tailoring organic redox-active molecules tunes solubility, redox potential, and chemical stability, which gives the promise to enhance energy density, cyclability, and calendar life in RFBs. Numerous studies focused on increasing molecular solubility to satisfy Econo-technical levels. In addition, introducing electron-donating and withdrawing groups to the redox-active core modulated redox potentials to negative and positive shifts, respectively. The most effective way to multiply raising energy density is to find a redox-active core undergoing multiple electron-transfer processes. Quinone is the representative one providing a single two electrons transfer in an aqueous electrolyte solution. Fast redox kinetics and chemical stability are achieved by H^+ coupling; The reduced form, hydroquinone, promoted the following electron transfer in the acidic solution. A similar concept is applied for non-aqueous electrolyte solutions and using cations of supporting electrolytes. However, such an ion-coupled electron transfer was rarely studied to date.
Here, we demonstrated naphthalene diimide (NDI) and Li^+ coupled electron transfer in acetonitrile (MeCN). The NDI is an excellent model for the stepwise two-electron transfer process. Its low solubility by the strong p-stacking interaction was surmounted by introducing ammonium cationic substituents to the NDI via simple condensation and *N*-alkylation. As a result, two ammonium-tethered NDI and bistriflimide ($TFSI^-$) as the counter anion showed 0.9 M solubility in MeCN. Two cathodic events made an anionic radical and dianionic NDI core, respectively. The received electron is delocalized over the NDI core and also stabilized by pairing it with the cation. Cyclic voltammograms showed ~120 mV of potential difference from two cathodic waves with Li^+ of LiTFSI electrolyte in MeCN, which was narrower than ~370 mV with K^+ of KTFSI. It suggested that the Li^+ possessing high charge density was closely coupled with the anionic radical NDI, expediting the second electron-transfer process. The process was also dependent on non-aqueous solvents. High donor-number (DN) solvents widened the potential difference with Li^+ because a thick solvation shell of Li^+ weakened the ion coupling. We applied this system for non-aqueous RFBs. Unlike two distinct galvanostatic plateaus appearing with K^+, the ammonium-introduced NDI with Li^+ showed almost a single overlaid plateau caused by the rapid reduction of the anionic radical. The ammonium-tethered NDI/Li^+ in MeCN cells performed high cyclability and low crossover through an anion exchange membrane, showing a capacity fading rate of 0.0089% for 1000 cycles in RFBs.

9:30 AM ES05.01.03
Water Self-Regenerative and Non-Flammable High-Performance Hydrogel Electrolyte with Anti-Freeze Properties and Intrinsic Redox Activity for Energy Storage Applications Nageh K. Allam; American University in Cairo, Egypt

Hydrogel electrolytes are essential components of a plethora of functional devices due to their flexibility and high electronic and ionic conductivity. However, they suffer from poor water retention (dehydration) during operation. Consequently, the overall performance of the hydrogel-based devices is severely declined as a result of conductivity fading of the hydrogel with poor self-regeneration. To this end, the rational tailoring of hydrogel electrolytes with high conductivity, self-regeneration, non-flammability, anti-freezing ability, stability, and intrinsic redox activity is necessary to enable the fabrication of highly durable devices. Herein, we demonstrate the design and synthesis of highly ionic conductive LiBr@PVA-based electrolytes. Upon the use of the synthesized hydrogel electrolytes in supercapacitor devices, they revealed intrinsic redox activity with outstanding water retention capability and self-regeneration characteristics. The mechanism of regeneration and water retention is thoroughly investigated. Also, the devices showed an improved self-discharge potential (SDP) rate compared to those previously reported using polymeric electrolytes with redox additives. Moreover, the synthesized LiBr@PVA-based electrolytes exhibited high anti-freezing properties with stable electrochemical performance before and after regeneration. Our study provides a universal method to fabricate large-scale hydrogel electrolytes with unique properties and opens the door to fabricating high-performance solid state devices.

Systematic Design of Active Materials and Membrane Separators for All-Organic Non-Aqueous Redox-Flow Batteries Gan Chen[1], Wenhao Zhang[2,1], Yiping Li[1,2], Kaushik Dey[1], F. Dean Toste[2,1] and Brett A. Helms[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Redox-flow batteries employ dissolved active materials separated by a semi-permeable membrane to store energy. Cell life and capacity are maximized when active materials can be sequestered in their respective cell compartments at high concentration. Here, I will discuss how the design of the semi-permeable membrane must be considered alongside that for the active materials, whose infinite miscibility with non-aqueous electrolytes allow for high volumetric capacity. The oligomeric design of these active materials makes them sufficiently large to be excluded by a microporous membrane, while maintaining substantially faster electron transfer kinetics than competing polymeric and colloidal active materials. I will discuss how these design features influence charge transfer with the electrode and other attributes that impact the efficiency of the flow cells as they relate to emerging applications in grid-scale energy storage.

U.S. DOE Initiatives Advancing Flow Battery Manufacturing Innovation Changwon Suh; U.S. Department of Energy, United States

The Department of Energy's Advanced Materials and Manufacturing Technology Office (AMMTO) continues to invest in energy storage research, development, demonstration, and deployment (RDD&D) to help stakeholders improve efficiency, cut costs, and make materials, devices, and systems with superior performance. Despite recent promising advances, manufacturing capabilities are still necessary to meet the expected demand for energy storage as we move toward a clean energy economy. Strengthening the domestic manufacturing supply chains is also another important task to pursue in parallel.

AMMTO funded projects through Battery Manufacturing funding opportunity announcement and national laboratory call to address technical and manufacturing challenges in U.S. flow battery production, specifically targeting the optimization of flow batteries across commercial, industrial, and utility applications. These projects aim to and improve the manufacturability of flow batteries and reduce the cost of manufacturing battery components and systems by implementing advanced designs and processes.

In this talk, the status and accomplishments of the projects will be highlighted. In addition, there will be a robust discussion of a wide variety of AMMTO's efforts in the context of technical and manufacturing challenges regarding scale-up and performance that still prevent the flow battery community from achieving cost targets and commercial viability.

11:00 AM *ES05.01.06
Innovative Metal Complex Catholytes for Aqueous Redox Flow Batteries Yu Zhu; University of Akron, United States

Aqueous Redox Flow Batteries (RFBs) have been recognized as potential candidates for large-scale grid energy storage. Nonetheless, commercial RFBs face material limitations, primarily due to the toxicity and cost of current active materials. To address this, there's an urgent need for next-generation RFBs that harness earth-abundant active materials, characterized by high solubility, optimal redox potential, and electrochemical stability. While organic and hybrid materials have been explored as alternatives, they present their own set of challenges, particularly when functioning as catholyte materials. This research will present a strategic design of metal complex catholytes for aqueous RFBs. By altering the symmetry of these metal complexes, we've achieved notable advancements in tackling solubility and crossover issues. Furthermore, our recent scattering experiments revealed the discovery that these materials form self-assembled particles in solution, paving new avenues for the design of active materials with enhanced water solubility.

SESSION ES05.02: Flow Based Energy Storage II

Embedded, Micro-Interdigitated Flow Fields for Flow-Based Electrochemical Desalination and Beyond Kyle C. Smith; University of Illinois-Urbana Champ, United States

The delivery of fluids to porous electrodes is essential to the efficient functioning of flow-based electrochemical devices. To date this has been accomplished in flow batteries and fuel cells by using flow fields that employ millimetric channels embedded in ~1 cm thick bipolar plates that abut porous electrodes. Here, we demonstrate novel flow fields that use interdigitated microchannels less than 100 μm wide, embedded within porous intercalation electrodes for the purpose of water desalination [1]. We subsequently use these electrodes containing Prussian blue analog nanoparticles to achieve seawater-level salt removal (~500 mM NaCl) for the first time in a flow-based symmetric Faradaic deionization (FDI) device, while previous work had relegated such devices to brackish water desalination having >5X lower salinity. Physics-based modeling shows that the patently low hydraulic permeability of these intercalation electrodes (<0.5 μm^2) induces perpendicular flow within the electrode material between adjacent microchannels to promote reaction uniformity, despite parallel flow within electrode material being realized for the hydraulic permeability of flow battery and fuel cell electrodes (~10 μm^2). We fabricate these microfluidic patterns using laser engraving. Here, electrode wetting prior to laser engraving is shown to produce enhanced microchannel resolution and smoothness while maintaining the chemical and microstructural integrity of electrodes by suppressing the propagation of heat affected zones via the low thermal diffusivity and high latent heat of water. The resultant patterned electrodes exhibit as much as 100-fold increased apparent permeability relative to unpatterned electrode material, resulting in decreased pumping pressure and energy requirements. Consequently, simulated brackish water (~100 mM NaCl) and simulated seawater (~500 mM NaCl) solutions were desalinated to near-potable water with thermodynamic energy efficiencies (TEEs) of 40% and 7%, respectively. While TEEs show room for significant improvement relative to the thermodynamic limit, brackish TEE is at parity with reverse osmosis neglecting energy recovery. Such efficiency also shows the promise of embedded, micro-interdigitated flow fields for flow-based electrochemistry using low-permeability porous electrodes, such as those that contain nanomaterial conductive additives, catalysts, or active materials.

electrodes towards seawater desalination and beyond, Energy Environ Sci. 16 (2023) 3025–3039.

1:45 PM *ES05.02.02
Manufacturing Electrodes with Tailored Structures for Efficient Mass Transport in Flow Batteries: Challenges and Opportunities Ana Jorge Sobrido, Michael W. Thielke, Carlos Julando Junior Mingoes and Luis M. Murillo Herrera; Queen Mary University of London, United Kingdom

Deep and rapid decarbonisation of the global energy systems require the wholesale replacement of fossil fuels with renewable resources (e.g., wind, solar). However, these resources are intermittent and unpredictable challenging the existing grid infrastructure which is based on the just-in-time dispatchable generation enabled by combustion of fossil fuels. As such, flexible energy management systems, including electrochemical energy storage technologies, are urgently required to enable reliable electricity delivery from the variable assets. Among them, redox flow batteries (RFBs) are excellent candidates for large-scale, long duration energy storage due to their flexible design, long service life, high reliability, and environmental friendliness. Nevertheless, this technology is still in its infancy in terms of optimisation of materials and battery design that can lead to improvement in performance and cost. Our research seeks to improve upon one of their performance-determining components: the electrodes. In my talk, I will present our work on the use of electrospinning to produce self-supporting materials highly conducting and consisting of fibres of 500nm - 1micron diameter. I will also introduce our approach to replace commonly employed petrol-derived materials with biomass-waste carbon electrodes via electrospinning. Electrospinning is a versatile technique that allows the production of freestanding fibrous materials with tailored properties, including fibre diameter, surface chemistry and alignment of fibres. Finally, I will summarise the main challenges and opportunities to the development of efficient electrodes with optimised mass transport and charge transfer for redox flow batteries.

2:15 PM ES05.02.03
Designer Novel Deep Eutectic Electrolytes for Vanadium Redox Flow Batteries Luis M. Murillo Herrera, Carlos Mingoes, Michael W. Thielke and Ana Jorge Sobrido; Queen Mary University of London, United Kingdom

Deep eutectic solvents (DES) are binary or ternary mixtures of Lewis acids and bases that exhibit significantly lower melting points than those of the original components. The application of these neoteric solvents in energy storage have recently started to gather attention due to is promising properties as low toxicity, high biodegradability, cost-effectiveness, high solubility for metal salts, conductivity and designer capability, which means that the DES can be specifically formulated for a desired application from among 10^6 possible combinations approximately.
Within the classification of DES, the second family composed of metal halides and quaternary ammonium salts has been applied to Li, Fe, and Al batteries, whereas DES of the third family made of quaternary ammonium, phosphonium or sulphonium halides and hydrogen bond donors have been recently applied as supporting electrolytes for redox flow batteries (RFB). Despite their huge structural flexibility, the application of DES to RFBs have been narrowed to mixtures of choline chloride with ethylene glycol, glycerol and urea, the three main archetypes of the third family. The chemistries studied so far are All-V(acac) and Fe/V. Although promising, these electrolytes suffer from high viscosities and low conductivities, which in consequence produces high cell polarisation resistance, low efficiencies, high pressure drop and small operational currents.
The overarching objective of this work is to transcend the prevailing DES archetypes to design and evaluate novel DES formulations tailored specifically for vanadium RFB applications based on family III DES. In the organic salt department, particular relevance is placed on the influence of the cation and the hydrogen bond donor in properties like cathodic window, viscosity/conductivity and vanadium solubility. Different counter anions are analysed in terms of anodic window, hygroscopicity, vanadium solubility and the potential to develop redox-actives DES (RADES), *e.g* bromide-based DES. In the hydrogen bond donor department, the impact of adjacent DES properties as pH, polarity and ionic strength on vanadium redox mechanisms is being under scrutiny.
The most common separator technology studied for DES-based RFBs are proton-exchange membranes, which are not ideal for non-aqueous systems. As part of this project, the compatibility of DES with other membrane technologies as anion-exchange are explored, including membrane-less designs based on differences in negolyte and posolyte polarity.
Finally, new vanadium (III) complexes with electron-donating ligands capable of displacing V(II)/V(III) redox potential towards more cathodic values, while synergistically interacting with the web of intermolecular interactions of the solvents are proposed to leverage the larger cathodic windows of DES compared to aqueous electrolytes, thus increasing the active species concentration and the cell potential.

2:30 PM *ES05.02.04
Automated Electrochemical Characterization for Redox Flow Batteries Using The Electrolab: Molecules, Polymers, Electrolytes and their Complex Interactions Zirui Wang, Michael A. Pence and Joaquin Rodriguez-Lopez; University of Illinois at Urbana Champaign, United States

Designing superior redox flow batteries (RFBs) requires advanced electrochemical characterization techniques that elucidate manifold transport, reactivity, stability, and interactive properties of molecules, electrolytes, and other materials present in these systems. The modularity of many RFB designs enables significant flexibility in the choice of experimental conditions, thus making it imperative to swiftly identify those that lead to improved properties. This not only requires the ability to carry out many experiments in a timely fashion, but also to use electroanalytical approaches in a comprehensive and clever way. To accomplish these objectives, our group has recently introduced The Electrolab, an automated electrochemical platform that combines hardware, software, a dispensing robot, and custom designed e-chips which altogether enable characterization campaigns with minimal supervision while maximizing diagnostic power. The Electrolab is sufficiently versatile to enable both relatively simple but tedious experiments such as determining diffusion coefficients, to systematic experiments incorporating titrations, to more sophisticated measurements of lifetime of redox species using microelectrode e-chips.
In this presentation, we will first describe new opportunities in the use of redox-active polymers for the construction of redox flow batteries. Unlike small molecules, polymeric redox active materials exhibit dynamics that are highly dependent on aspects such as electrolyte concentration and type. I will then explain how the Electrolab incorporates functions to systematically explore these dependencies, including automated robotic titrations which enable to rapidly identify limiting factors. Finally, I will describe how a different type of redox titration experiment based on scanning electrochemical microscopy can be developed and automated to understand charge transfer performance between redox mediators and charge storage media such as redox polymers. Putting together automated electrochemistry, advanced techniques based on microelectrodes, and new concepts for energy storage based on polymeric materials, promises new directions in the identification of RFB systems.

SESSION ES05.03: Poster Session: Flow Based Energy Storage
Session Chairs: Ertan Agar and Ruozhu Feng
Wednesday Afternoon, April 24, 2024
Flex Hall C, Level 2, Summit

5:00 PM ES05.03.01
Using Covalent Modification to Create Phenyl-, Butyl- and Fluorine-Modified Active Material for Deployment in Redox Flow Batteries Robert Serrano[1,2], Jennifer Bolibok[1] and Patrick Cappillino[1]; [1]University of Massachusetts, Dartmouth, United States; [2]Arizona State University, United States

In the United States, 13.6% of the country's power now comes from the two leading contenders for new sustainable energy projects: wind and solar. Since these two methods of generation are intermittent, it has been the prevailing thought that grid-level energy storage would be needed to balance when electricity is generated and when it is demanded. For this purpose, integrated battery technology such as lithium-ion manganese oxide (LMO) and lithium iron phosphate (LFP) have been adapted from the advancement of electric vehicle development in recent years, but can be expensive, require active thermal management, face longevity issues from deep cycling, and are not suitable for extreme temperatures. Redox- flow batteries have been proposed to solve these issues, but low energy density has been a limiting factor for wide-scale adoption. Using covalent modification, we are seeking to increase the energy density of a metal-organic compound for use as a non-aqueous redox-flow battery active material. Alpha substituted bromoacetic acids were used to synthesize the ligand of a vanadium complex in order to fine tune chemical properties of the complex, with α-bromophenylacetic acid and 2-bromohexanoic acid exhibiting great promise. The resulting ligands were characterized via NMR — specifically HSQC — which will be presented.

5:00 PM ES05.03.02
Investigation of The Dynamics of Extreme Redox-Active Molecule and Electrolyte Concentrations Relevant for Nonaqueous Redox-Flow Batteries Anton S. Perera[1,1], Nathan Stumme[2], Sashen Ruhunage[1,1], Andrew Horvarth[2], Scott Shaw[2] and Chad Risko[1,1]; [1]University of Kentucky, United States; [2]The University of Iowa, United States

Organic redox-active molecules have been explored for many uses including, acting as the active material in energy-storage systems for redox flow batteries (RFBs) and providing overcharge protection in lithium-ion batteries (LIBs). The concentration of the redox active species and the supporting electrolyte in an RFB play a significant role in determining the energy density of a battery. Nevertheless, at very high concentrations, the physicochemical relationship between the redox active molecule, electrolyte salt, solvent, and the electrochemical performance of an RFB has not yet been well studied. Herein we present a molecular-level understanding of the effect of concentration on physical properties of the redox-active solution to complement experimental observations using molecular dynamic (MD) simulations. To examine this relationship, we explored the redox-active molecule 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO) and tetrabutylammonium hexafluorophosphate ($TBAPF_6$) electrolyte salts varied across concentrations of 1 mM to over 1000 mM in acetonitrile. We observed relationships between the transport properties of these solutions that were primarily based on solvation and ion-pairing effects. Furthermore, we also provide suggestions on obtaining optimum performance in such systems based on our theoretical insight.

5:00 PM ES05.03.03
Surface Decorated 3D Printed Electrodes as Viable Options for High Performance Redox Flow Batteries Carlos Mingoes, Michael W. Thielke, Luis M. Murillo Herrera and Ana Jorge Sobrido; Queen Mary University of London, United Kingdom

In an era marked by rapid urbanization and industrialization, accompanied by increased demands for energy availability and utilization, the need for more large-scale application of reliable and sustainable energy sources has never been more pressing. As we take on the challenges of climate change and resource depletion, the need for efficient and scalable energy storage systems has emerged as crucial for the transition to a cleaner and more resilient energy landscape. Due to the intermittent nature of sustainable energy sources (Solar, wind...), energy storage systems are needed to bridge the temporal and geographical gaps that they impose.

Among the various energy storage technologies, Redox Flow Batteries (RFBs) has emerged as a particularly promising solution. A system wherein power and energy are decoupled affording the ability to scale each independently, rendering the system very flexible; different flow battery systems can be designed for different purposes, with different energy and power combinations.

In the quest to optimize flow battery technology, to make it more cost efficient and cost competitive, lots of research has been focused into enhancing the power density and efficiency of the electrochemical cell. This translates to refined engineering and in-depth study of electrode materials and structures to ascertain what characteristics makes them ideal for flow cells. Carbon based electrodes with porous structures are the standards in this regard. Providing large electrochemically active surfaces for the electrochemical reactions and having porous structures that facilitate mass, charge, and heat transport. Some conventional porous electrodes are carbon felts, cloths and papers, all electrodes composed of carbonized fibres and are prepared by methods, such as electrospinning, and weaving.

Recently, there has been increased interest in the potential of 3D printed electrodes for RFB. It is a very scalable manufacturing method, with numerous printing techniques and various material precursor types to choose from. In the scope of electrode designs, this method presents the ability to readily fabricate intricately designed custom electrodes, with well tune electrolyte transport channels for efficient mass transport. Depending on precursor type, printing method and thermal treatment steps, the structural, electrochemical and mechanical properties of the electrodes can be tuned. However, as demonstrated in other studies, preparing electrodes with high electrochemical surface area via this method can be challenging and thus surface decoration with other high surface area materials, such as carbon nanotubes and nanoparticles is a desirable option to increase this necessary characteristic for RFB electrodes.

In our work we aim to demonstrate the potential of surface decorated 3D printed electrodes to be a viable option in high performance RFB. 3D printed electrodes are thermally treated to induce conductivity and are subsequently surface decorated with nanomaterials to produce surface decorated 3D printed electrodes.

5:00 PM ES05.03.04
Architecting Electrospun Carbon Fibres for Redox Flow Batteries and The Influence of Fibre Size and Alignment Michael W. Thielke[1], Luis M. Murillo Herrera[1], Carlos Mingoes[1], Alexander H. Quinn[2], John N. Vergados[2], Fikile Brushett[2] and Ana Jorge Sobrido[1]; [1]Queen Mary University of London, United Kingdom; [2]Massachusetts Institute of Technology, United States

As one of the promising uprising technologies in the field of stationary energy storage, redox flow batteries are in focus for the future storage of sustainable energy harvesting. The carbon fibre-based electrodes in these batteries are a crucial component in achieving high efficiency and performance, which is significantly influenced by the composition and morphology of the utilized carbon fibres. Our work is based on the fabrication of carbon fibres by using electrospinning, a potential alternative to replace commercial carbon felts with higher performance based on the outstandingly high surface-to-volume ratio. This also allows the effective fabrication of doped and decorated fibres by an in situ doping of the fabricated fibre with catalytically active metal nanoparticles or through heteroatom-based doping of the fibre material itself.
Electrospinning has been proven to be a highly versatile technique to fabricate submicron carbon fibres and can be performed with alternative polymeric materials to synthesize carbon fibres, including biopolymers from renewable sources, such as lignin, opening the possibility of a fully sustainable future of

energy storage, without any dependence on petrol-derived resources. In recent years, different approaches to implementing bioderived carbon into the electrode have been reported, most commonly by using an additive method to enhance the commercial carbon felt with biomass-derived carbon particles, or by using given fibrous biomaterials from fibrous structure.
The versatility of the electrospinning process allows the fabrication of different fibre architectures. By modifying the collector of the electrospinning process to a rotating drum, the fibres can be collected in alignment with the rotation which can then be installed parallel or perpendicular to the flow field of a redox flow battery. The orientation can lower the pressure within the system and significantly influence the current density during the operation of the battery. To optimize the balance between pressure and performance, the degree of orientation of the fibres was gradually controlled through the rotation speed of the drum.
Another important factor that influences the performance of a redox flow battery is the fibre diameter, which can be controlled by changing the parameters of the electrospinning process. While electrospun carbon fibres are generally used due to their electrochemical active surface area compared to commercial felts, the process itself has the potential to form fibres in different sizes, in this case in the magnitude starting from 220 nm and up to 850 nm.
Changing the size of the fibres is a trade-off between the available performance through the higher surface area of the smaller fibres and lowering the pressure of the flow and favouring the mass transport of the larger fibres.

5:00 PM ES05.03.05
Gas Diffusion in Catalyst Layer of Flow Cell for CO_2 Electroreduction Toward C2+ Products Nageh K. Allam; American University in Cairo, Egypt

The use of gas diffusion electrode (GDE) based flow cell can realize industrial-scale CO_2 reduction reactions (CO_2RRs). Controlling local CO_2 and CO intermediate diffusion plays a key role in CO_2RR toward multi-carbon (C_{2+}) products. In this work, local CO_2 and CO intermediate diffusion through the catalyst layer (CL) was investigated for improving CO_2RR toward C_{2+} products. The gas permeability tests and finite element simulation results indicated CL can balance the CO_2 gas diffusion and residence time of the CO intermediate, leading to a sufficient CO concentration with a suitable CO_2/H_2O supply for high C_{2+} products. As a result, an excellent selectivity of C_{2+} products ~ 79% at a high current density of 400 $mA.cm^{-2}$ could be obtained on the optimal 500 nm Cu CL (Cu500). This work provides a new insight into the optimization of CO_2/H_2O supply and local CO concentration by controlling CL for C_{2+} products in CO_2RR flow cell.

5:00 PM ES05.03.06
1D Borophosphates for Use as Electrolyte Membranes in Solid Acid Fuel Cells Brian Chaloux, James Ridenour, Michelle Johannes and Albert Epshteyn; US Naval Research Laboratory, United States

Although they are relatively new players in the field of hydrogen energy conversion, solid acid fuel cells (SAFCs) demonstrate several advantages compared to their more well-developed counterparts: polymer electrolyte membrane fuel cells (PEMFCs) and solid oxide fuel cells (SOFCs). The elimination of water as the proton carrier in solid acid electrolytes allows operation at intermediate temperatures (e.g., 200–350 °C), simultaneously improving catalytic activity and removing the need to manage liquid water while avoiding the high-cost, refractory materials required for operation under SOFC conditions. However, higher operational temperatures necessitate the discovery, design, and manufacture of electrolyte materials with improved thermal stability compared to PEMs.

Cesium hydrogen sulfate ($CsHSO_4$) and cesium dihydrogen phosphate (CsH_2PO_4, CDP) are two well-studied examples of solid acids: protic materials which remain solid at operational temperature while exhibiting proton conduction. CDP demonstrates particular promise as a SAFC electrolyte, as a superprotonic transition from a low-temperature monoclinic phase to a high-temperature cubic phase dramatically improves its proton conductivity above 225 °C. However, active humidification of the CDP electrolyte is required to prevent thermal decomposition (i.e., dehydration) below the superprotonic transition temperature, limiting the practical operational window of CDP-based SAFCs to 225–260 °C.

We synthesize and explore an isostructural family of one-dimensional inorganic polyelectrolytes, the “BOB” borophosphates – empirical formula $M_{5-x}H_x[BOB(PO_4)_3]$ where M is a monovalent cation – as alternative proton conducting solid acids to commercially available membrane materials including PEMs and CDP. Comparing the previously described $Rb_3H_2[BOB(PO_4)_3]$, $Na_5[BOB(PO_4)_3]$, and the novel $(NH_4)_3H_2[BOB(PO_4)_3]$, we find that the rubidium borophosphate (RbBOB) strikes an attractive balance between temperature- and humidity-dependent ionic conductivity and thermal stability. Exhibiting stability under air, inert atmosphere, and hydrogen up to 400 °C and exhibiting ionic conductivity up to 10^{-4} S cm^{-1} under active humidification at elevated temperature, RbBOB is an exciting new solid acid for SAFC electrolyte membranes.

10:00 AM *ES05.04.03
Accelerate Material Discovery and Expand Chemistry Space for Aqueous Organic Redox Flow Batteries Wei Wang; Pacific Northwest National Laboratory, United States

Aqueous organic redox active materials have recently shown great promise as alternatives to transition metal ions as energy bearing active materials in redox flow batteries for large-scale energy storage due to their structural tunability, cost effectiveness, availability, and safety features. However, development to date has been limited to a small palette of aqueous soluble organics. This presentation will provide an overview of a data-driven approach to accelerate the discovery and development of aqueous organic redox-active molecules for flow batteries, including database curation, structure-property correlation, and automated property characterization and performance testing. This presentation will also use fluorenone as an example to showcase how a natively redox-inactive molecule can be tuned to possess two-electron redox reversibility through hydrogenation and dehydrogenation.

10:30 AM ES05.04.04
Understanding The Principles of Charge Transfer to Realize High Capacity Utilization in Redox Targeting Flow Batteries Sam Kopfinger, Hongyi Zhang, Thai Boonme, Garrett Grocke and Shrayesh Patel; The University of Chicago, United States

Redox targeting systems represent a promising path for flow batteries, circumventing the solubility constraints encountered by various organic redox compounds. Yet, the pivotal challenge remains the attainment of high capacity utilization of the target within flow cell systems and a deeper comprehension of the mediator-target interplay. In addressing this gap, we present the development of a high solids accessibility redox targeting flow battery, alongside the formulation of an advanced yet clear thermodynamic model to unravel the intricacies of the mediator-target relationship. Our approach involves a ferrocene bearing insoluble polymer that is synthesized for use as a redox target and matched with different mediator systems: one with a single molecule that has a nearly identical potential and the other with a dual molecule system that has mediators with a voltage offset to encourage charge transfer. These two systems were then tested in a catholyte limited flow cell to determine the capacity accessibility of the mediator-target system. The single molecule system was able to increase the cell's capacity by 90% of the redox target's capacity and the dual molecule system was able to increase the capacity by >95% of the redox target's capacity. To better understand the thermodynamics of each system they are modeled using a Nernst analysis. For the single molecule system, this analysis builds on prior work to suggest that not only is a small voltage offset extremely important, but that the mediator's accessible state of charge range will determine the redox target's thermodynamic accessibility limits. For the dual molecule system, the model suggests that a medium voltage offset is ideal as it allows for high amount of charge transfer in the preferred direction with enough potential overlap to assist charge transfer in the reverse direction. In summary, our work not only demonstrates the achievable high accessible capacity of redox targeting systems within flow cells but also provides a comprehensive thermodynamic model to elucidate their operational mechanisms and crucial design considerations.

10:45 AM *ES05.04.05
Redox-Mediated Electrified Chemistry for Carbon-Neutral Energy Applications Qing Wang; National University of Singapore, Singapore

Redox reaction involving charge transfer at the electrode-electrolyte interface represents an essential process for various electrochemical energy conversion and storage applications, such as fuel cells, electrolyzers and batteries, etc. As a result, the operation (*i.e.*, cell voltage, current density, number of charges, etc.) of the above devices is inherently dictated and constrained by the redox reactions at the electrode-electrolyte interface. The redox-mediated process — a chemical reaction between an electrolyte-borne redox species electrochemically generated on electrode and a material (generally insoluble in electrolyte) away from the electrode, provides additional flexibility in circumventing the constraints intrinsically confronted by the conventional electrochemical devices. One example is the redox targeting of energy storage materials for flow batteries. The redox-mediated reactions of high-capacity solid material stored in the tank with redox electrolyte flowing through it considerably boost the energy density of redox-flow battery without compromising its salient features of operation flexibility and scalability. Another example is the redox-mediated water electrolysis for spatially decoupled hydrogen production. The electrochemical-chemical cycle enables continuous reaction between an electrolyte-borne redox mediator and an HER or OER catalyst loaded in a fixed-bed reactor spatially separated from the cell, which is believed to be advantageous to enhanced safety and on-demand hydrogen production. So, with the assistance of redox mediators shuttling between the electrode compartment and reactor tank, the border of the conventional electrochemical reaction is spatially extended beyond the electrode compartment, which endows the system with intriguing features for various innovative energy applications.

10:30 AM *ES06.01.01
Lithium-Metal Stabilization through Tellurium Chemistry in Lithium-Sulfur Batteries Arumugam Manthiram; University of Texas at Austin, United States

Lithium-sulfur (Li-S) batteries are appealing owing to the high specific capacity (1672 mA h g^{-1}) and low cost of sulfur. Lithium-sulfur cells involve a solid-liquid-solid conversion of sulfur species, from S to intermediate lithium polysulfides to the end discharge product Li_2S, which results in a sluggish reaction kinetics due to the insulating nature of S and Li_2S. Furthermore, the dissolution of ploysulfides and their migration from the cathode to the anode severely hamper the reversible plating and stripping of lithium-metal anode. These problems impede the practical application of Li-S batteries. Numerous efforts have been devoted to overcoming these challenges, but the intrinsically low stripping and plating efficiency of Li and the corrosion from polysulfides necessitate excess Li and electrolyte.

This presentation will focus on the exploitation of the chemistry of tellurium, which lies in the same group as sulfur in the periodic table. The addition of a small amount of tellurium into sulfur cathodes helps enhance the cycle life of Li-S cells. However, due to the poor utilization of Te, a significant amount of Te is required to improve cell cycling performance, resulting in an increase in cost. To overcome this challenge, we have adopted two approaches: (i) use of tellurium nanowires (TeNW) synthesized *via* a hydrothermal method and (ii) incorporation of $LiTe_3$ synthesized by a one-step process as an additive into the electrolyte.

Coating TeNW onto the separator greatly enhances Te utilization and a significant improvement in cell cycle life. The versatility of TeNW is further demonstrated by utilizing it with carbon nanotubes as the anode substrate. The exceptional performance of TeNW is due to its high-surface area nanostructure and excellent conductive network, facilitating efficient electron transfer during cell cycling.

On the other hand, $LiTe_3$ reacts rapidly with polysulfides and functions as a redox mediator to significatly improve the cathode kinetics and the utilization of active material in the cathode. The formation of a Li_2TeS_3/Li_2Te-enriched interphase layer on the anode surface enhances ionic transport and stabilizes Li deposition. By regulating the chemistry on both the anode and cathode sides, the $LiTe_3$ additive enables a stable operation of anode-free lithium-sulfur cells with only 0.1 M concentration in conventional ether-based electrolytes. With a high utilization of Te, the additive enables significantly longer cycle life of anode-free pouch full-cells under lean electrolyte conditions.

Lithium Sulfur Batteries - What is The Future of this Battery Chemistry? Y. Shirley Meng[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

The research and development of lithium sulfur batteries have been decades, yet we still do not see its commericalization success. In this talk, I will give an examination of the literature and discuss the remaining scientific hurdles and technical chanllenges. With the advancement in all solid state batteries, our group has develped an unique apporach in enabling lithium sulfur electrochemistry with solid state electrolytes. The progress made was enabled by fundamental understanding of the interfacial sciences and new scientific tools such as cryogenic micrsocopy and advanced spectroscopy.

11:30 AM *ES06.01.03
Design Interface Reactions in All-Solid-State Batteries Xin Li; Harvard University, United States

Solid state battery is a mechanically more coupled device than the commercial liquid electrolyte Li-ion batteries. Mechanical constriction effect strongly modulates the electrochemical stability at all interfaces in a solid-state battery. This effect introduces some unique dynamical evolution of interface reactions upon battery cycling, understanding of which is challenging but also giving us an opportunity to design the battery performance beyond commercial Li-ion batteries. The talk will discuss the design of such a dynamic process at the electrolyte-electrode interfaces for a stable cycling of solid state batteries. The importance of the self-limiting interface reactions due to dynamic voltage stability will be emphasized.

1:30 PM *ES06.02.01
A Long Cycle Li-S Battery with Minimum Shuttle Effect - Catalytic Disproportionation of Dissolved Polysulfide to Elemental Sulfur Deyang Qu, Dantong Qiu and Dong Zheng; University of Wisconsin Milwaukee, United States

A Long cycle-life Li-S battery pouch cell with high sulfur loading (5 mg per cm^2) is reported with the mitigation of the shuttle-effect. The performance was achieved with a bifunctional carbon material with three unique features. The carbon can catalyze the disproportionation of dissolved long-chain polysulfide

ions to elemental sulfur; the carbon can ensure homogenous precipitation of Li sulfide on the host carbon and the carbon has honeycomb porous structure which can store sulfur batter. All the features will be demonstrated experimentally and reported.
Through an ex-situ, postmortem analysis in which a Li-S cell was disassembled after many cycles, few dissolved polysulfides were found in the electrolyte of the Li-S cell made with the bifunctional carbon in comparison with a control Li-S cell. A HPLC was used to determine the distribution of dissolved elemental sulfur and polysulfide ions in the electrolyte of the Li-S batteries during cycling. Only dissolved elemental sulfur was detected in the cell with the bifunctional carbon, while a distribution of polysulfide ions of various -S-S- chain length was observed in the control Li-S cell. A catalytic polysulfide disproportionation reaction mechanism was proposed, in which polysulfide ions can be catalytically disproportionate to elemental sulfur and Li_2S_2 and/or Li_2S precipitates. Since the dissolved polysulfides are the engine driving the shuttle effect, the detrimental shuttling in a Li-S cell can be mitigated through the removal of dissolved polysulfide ions in the electrolyte during the discharge and recharge.
The unique porous structure of the bifunctional carbon which was made from a raw silk was revealed by a SEM and a N_2-absorption isotherm. The pore structure was believed to store sulfur uniformly and ensured the homogeneous deposition of Li_2S_2 and/or Li_2S. The N-containing functionalities that were introduced to carbon from the amino acids of raw silk can catalyze the disproportionation of the dissolved S_n^{2-} to solid S_8 at the cathode side, thereby mitigating the shuttle effect. In addition, the hierarchical honeycomb porous structures generated by a carbonization process can physically trap high-order lithium polysulfides and sustain the volume change of sulfur. With the synergistic effects of the unique structures and characteristics of the carbon, the sulfur/carbon composite using delivers a high reversible capacity of over 1000 mAh g^{-1} and over 600 mAh g^{-1} with a sulfur content of 1.2 mg cm^{-2} 5 mg cm^{-2} in a pouch cell, respectively.

2:00 PM *ES06.02.02
SPAN and Beyond: Sulfur-Based Cathodes Free of Polysulfides Ping Liu; University of California, San Deigo, United States

Li-S battery is a highly desirable technology featuring high energy density and low-cost materials. However, the challenges with the technology are also well documented. In ether-based electrolytes, the redox of sulfur goes through a soluble polysulfide mechanism, which facilitates the reaction kinetics but greatly impacts the cycle life and practical energy density due to the need for elevated amount of electrolytes. Sulfurized polyacrylonitrile, SPAN, in contrast, does not involve the polysulfide mechanism. Instead, the material goes through a solid-solid conversion process. Coupled with the presence of a robust cathode electrolyte interface (CEI), the material has demonstrated exceptionally long life, well over 1000 cycles.

SPAN's limitation lies in its limited sulfur content (~ 43 wt%) and specific capacity (< 700 mAh/g). These values put a practical limit for the energy density of Li-SPAN battery at around 300 Wh/kg. In order to increase the capacity, we have embarked on a study to understand the structure and the capacity-limiting mechanism. During the first cycle, lithiation leads to a loss of H_2S which in turn improves the degree of conjugation and electronic conductivity. Both sulfur and the nitrogen on the pyridine ring are involved in the charge storage during the subsequent cycles. Recently, we have focused on further raising sulfur contents in SPAN by introducing sulfur species that resist the formation of long-chain polysulfide in the solid state. Structural analysis reveals the critical roles played by the nitrogen in facilitating the redox reaction of the additional sulfur. More than 20% improvement in capacity is obtained without the introduction of soluble polysulfide process. We will discuss in detail the reaction mechanisms of these high-sulfur SPAN materials and the pathway towards their implement in high energy density batteries.

2:30 PM ES06.02.03
Multifunctional Heterostructures for High-Energy-Density Lithium-Sulfur Batteries Viet Phuong Nguyen[1,2], Jae-Hyun Kim[1,2] and Seung-Mo Lee[1,2]; [1]University of Science and Technology (UST), Korea (the Republic of); [2]Korea Institute of Machinery & Materials (KIMM), Korea (the Republic of)

A dense electrode with high sulfur loading is a straightforward approach to increasing the energy density of lithium-sulfur batteries, but the development of dense electrodes suffers from both fabrication challenges and electron/ion transport limitations. In addition, the shuttle effect of soluble lithium polysulfides and sluggish reaction kinetics cause declined utilization efficiency of the active material and poor cycling stability. In this study, we demonstrated that a novel heterostructure in the form of TiS_2 nanoribbons decorated with TiO_2 could function as an effective sulfur host to tackle these issues. We observed that TiO_2 with high adsorption capability anchors the lithium polysulfides, and TiS_2 with high electrical/ionic conductivity and catalytic activity can accelerate the charge transportation and enhance the kinetics of sulfur evolution reactions. Benefitting from these synergistic effects, the lithium-sulfur batteries using TiO_2@TiS_2 heterostructures exhibited high gravimetric and volumetric energy densities of 331 Wh kg^{-1} and 730 Wh L^{-1}, respectively, as well as superior cyclability at a high sulfur mass loading of 7.5 mg cm^{-2} and lean electrolyte of 2.5 µL mg^{-1}. The electrochemical performance was comparable to or even superior to the lithium-ion and lithium-sulfur batteries reported in the literature. This work provides an effective strategy for designing stable and high-energy-density lithium-sulfur batteries for practical energy storage applications.

2:45 PM ES06.02.04
Carbon Nanofoam Papers as Electrode Architectures for Chalcogens in Lithium- and Sodium-Based Batteries Jeffrey W. Long[1], Zachary G. Neale[2], Matthew J. Lefter[2], Debra R. Rolison[1], Megan B. Sassin[1] and Rachel E. Carter[1]; [1]Naval Research Laboratory, United States; [2]U.S. Naval Research Laboratory, United States

Sulfur has emerged as a promising charge-storage material for advanced rechargeable batteries based on the high capacity of the sulfur/sulfide redox reaction and earth-abundance of this element. The main limitations of sulfur-containing electrodes are the poor conductivity of sulfur and the propensity for release of soluble polysulfides into the electrolyte during redox cycling. These challenges can be mitigated by incorporating sulfur into porous, conductive carbon substrates to form cathodes for nonaqueous lithium- and sodium-based batteries. We find that carbon nanofoam papers (CNFPs) are highly effective materials for such purposes, providing the advantages of tunable pore size distributions (nm to µm), scalability in area (many cm^2) and thickness (100s of µm), and plug-and-play form factors for efficient battery construction [1]. Vapor deposition is a convenient route to coat the interior and exterior surfaces of CNFPs with nanometers-thick sulfur at effective weight loadings of up to 60 %; selenium and sulfur–selenium blends are also deposited in a similar fashion. We investigate the interplay of CNFP structure and chalcogen loading and composition with electrochemical performance in coin cells and pouch cells. In situ characterization with such techniques as optical microscopy and X-ray absorption spectroscopy provides additional details on redox mechanisms and associated side reactions.

3:30 PM ^ES06.02.05
Unraveling Mechanisms and Enhancing Kinetics in All-Solid-State Lithium-Sulfur Batteries Hongli Zhu; Northeastern University, United States

All-solid-state lithium-sulfur batteries (ASSLSBs) hold promise for high energy density and improved safety compared to conventional lithium-sulfur cells using liquid electrolytes. However, low utilization of active sulfur caused by sluggish reaction kinetics has greatly hindered ASSLSB development.

Achieving efficient sulfur electron/ion accessibility in the cathode structure is critical. Porous carbon hosts, widely used in liquid cells, have been proposed to address these challenges. However, conventional porous carbons with buried pores are ineffective for ASSLSBs, as the non-mobile solid electrolytes cannot penetrate the pores to access enclosed sulfur. An ideal porous carbon should maximize surface area for sulfur while restricting pores to only the exterior surface. Despite works applying porous carbons in ASSLSBs, the optimal structure has not been well elucidated. Here, we pioneer discussion on the ideal carbon structure and develop polyacrylonitrile-derived porous carbon fibers (PPCF) with a unique core-shell morphology. A microporous shell on a dense core provides high surface area with accessible pores for electrolytes and sulfur. Consequently, ASSLSBs with PPCF show outstanding performance.
Furthermore, we grow MoS2 nanosheets on carbon fibers. The chemical and electrochemical compatibility of MoS2 with sulfur and sulfide solid electrolytes greatly improves cathode stability and ion/electron transport. Metallic 1T MoS2 enables electron transfer, while the layered structure facilitates Li intercalation. This significantly enhances kinetics and relieves electrolyte decomposition. Our optimized ASSLSB delivers an ultrahigh initial capacity of 1456 mAh/g with high coulombic efficiency and 78% retention after 220 cycles.
Finally, we reveal the Li-S redox reaction undergoes a two-step transformation, producing polysulfide intermediates. Kinetic limitations can cause incomplete conversions, leaving polysulfides like Li2S2. Our mechanistic insights guide design principles for ASSLSBs.

4:00 PM ES06.02.06
Unravelling The Synergistic Effect of Cross-Linked Aqueous Binder and a Transition Metal Sulfide-Based Catalyst in High-Performance Lithium-Sulfur Batteries S B Majumder[1], D. Chatterjee[1], S Sahoo[2] and Suprem R. Das[2,2]; [1]Indian Institute of Technology, Kharagpur, India; [2]Kansas State University, United States

Commercial lithium-ion batteries (LIBs) generate a significant carbon footprint during the procurement of relatively scarce raw materials such as Li, Co, Ni, etc., manufacturing of cells, and their recycling. Lithium-sulfur batteries are far more environmentally friendly as they use only scarce lithium, have significantly higher specific energy density than LIBs, and easier to recycle. A facile one-step scalable process has been developed to increase the loading and conductivity of sulfur; retard long-chain polysulfides shuttling, tackle volumetric fluctuation of active particles and inhibit the lithium anode corrosion together with its dendritic growth during discharge-charge cycles. In the quest for this single-step scalable process, we have formulated a binder EA-PAA which can effectively anchor the polysulfides but is unable to escalate the conversion of low-order polysulfides to end discharge product-Li_2S_2/Li_2S, at a satisfactory level. The EA-PAA-based cathode delivers a capacity of 845 mAh/g, which decays to 539 mAh/g after 100 cycles. In order to augment the sluggish conversion kinetics of low order polysulfides, the catalytic effect is found to be a powerful solution. As a result, numerous catalysts have been developed and proved to exhibit catalytic effects in recent years. Unfortunately, none of them have been found to be as effective as using a catalyst alongside a polysulfide anchoring binder. Moreover, the polysulfide anchoring behavior could be facilitated in an alternative way by regulating the shape of sulfur particles by introducing polar capping agents such as PVP, which could additionally buffer the volume changes upon the conversion of sulfur to Li_2S. This would facilitate both anchoring the polysulfides while enhancing the conversion of low order polysulfides, in a single research study. So herein we are proposing a chalcogenide-based catalyst (e.g., ZnS) alongside the EA-PAA binder to formulate a cathode with high sulfur (>75%) content, which can deliver high discharge capacity (>1100 mAh/g) at C/2, with superior cycling ability (>85 % capacity retention at C/2 after 500 cycles), with high Coulombic efficiency (>90%) & rate performance (perform at 1C).

4:15 PM ES06.02.07
Binder-Free Manganese Iron Nitrides/N-Doped CNT Cathode for Lithium-Sulfur Batteries Yi-Jie Wang, Bo-Dong You and Che-Ning Yeh; National Tsing Hua University, Taiwan

Lithium-sulfur batteries (LSBs) hold promise due to their high energy density for commercialization. However, in lab-scale research, sulfur loading has typically remained below 2 mg cm^{-2}, far below the practical application requirements. The pressing need to increase sulfur loading inevitably intensifies a host of challenges, including poor conductivity, volume expansion, and notably, the shuttle effect. In this work, we present an innovative approach to address these formidable challenges. Our strategy involves the utilization of a composite composed of manganese iron nitrides and reduced graphene oxide (rGO). Manganese and iron are selected as host elements for their cost-effectiveness and substantial potential for cathode modification. Fe-N co-doped carbons demonstrate high adsorption–catalysis effectiveness for long-chain polysulfide reactions (LPR), while Mn-(O, N) coordination exhibits a strong adsorption effect for short-chain polysulfide reactions (SPR) and reduces charge-transfer resistance for Li_2S. Manganese iron nitrides are prepared by deriving the manganese-iron bimetallic metal-organic framework (MOF), which possesses high surface area and abundant active sites to adsorb the polysulfide and catalyze the conversion reactions. These bimetallic nitrides are assembled on a low tortuosity reduced graphene oxide (rGO) aerogel. The rGO aerogel, created through directional freeze drying, offers flexibility to accommodate volume expansion, high porosity to house sulfur, and creates direct pathways for fast charging of ions. By employing this directional rGO aerogel as the sulfur scaffold, manganese iron nitrides significantly mitigate the shuttle effect associated with various states of the polysulfides. Through the implementation of the S/rGO aerogel without additives as the cathode for LSBs, we can achieve a higher areal capacity while simultaneously preserving cycle stability. This advancement holds the potential to expedite the realization of LSBs for real-world applications.

4:30 PM ES06.02.08
Synergistic Effect of Anatase/Rutile Nanoparticle and Nitrogen Doping on NH_2-MIL-125(Ti)-Derived Porous Carbon as High Performance Lithium-Sulfur Battery Cathodes Seoyeah Oh[1], Seokhee Lee[2] and Jiwon Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Lithium-sulfur (Li-S) batteries have garnered significant attention as a future energy storage systems owing to their high theoretical capacity, energy density, and abundance of sulfur in nature. However, their development has been hindered by the polysulfide shuttle effect, which adversely affects the cycling stability of Li-S batteries. Various approaches – such as designing the pore structure of porous carbon, or introducing heteroatoms and/or metal oxides into the porous carbon – have been applied to address these issues. For instance, Yang et al. controlled the polysulfide adsorption on the porous carbon cathodes which depends on the phase of titanium dioxide (TiO_2) particles (*i.e.*, anatase or rutile) introduced in the electrodes[1]. Furthermore, Kim et al. improved the retention of Li-S battery via coupled effects of nitrogen (N) vacancies and the rutile phase of TiO_{2-x}[2]. However, the synergistic effects from the correlation among these factors (*e.g.*, heteroatom doping and phase type of TiO_2 particles) have not yet been systematically studied.
In this work, we present a micro-sized NH_2-MIL-125(Ti) metal organic framework (MOF)-derived porous carbon (*micro*-cNMT) as a host material of sulfur for Li-S battery cathodes. *micro*-cNMT possesses a hierarchical micro-/meso-porous structure, N heteroatoms, and mixed phases of TiO_2 nanoparticles (*i.e.*, both anatase and rutile). These parameters collectively enhanced the performance of Li-S batteries through their synergistic effect. Specifically, *micro*-cNMT enhanced the prevention of polysulfide shuttle effects by the cooperation of physical and chemical adsorptions, facilitated by its hierarchical porous structure and N/TiO_2 nanoparticle doping, respectively. Porous structure of *micro*-cNMT not only accommodated active sulfur and its volume transition, but also facilitated Li-ion diffusion, which is confirmed by both cyclic voltammetry (CV) at various scan rates and Randles-Sevcik equation. Anatase and rutile phases of TiO_2 nanoparticles preferentially adsorbed short-chain polysulfide and long-chain polysulfide, respectively, preventing the loss of active sulfur throughout the entire discharging process. The long-chain polysulfide adsorption was confirmed by direct visualization of Li_2S_6 migrating from electrolyte to the *micro*-cNMT. Furthermore, scanning electron microscope (SEM) images of cathodes after 100 cycles of

discharge-charge and operando X-ray diffraction (XRD) measurement during the first discharge demonstrated that the *micro*-cNMT enhances short-chain polysulfide adsorption, thereby facilitating sulfur reduction reactions from polysulfide to Li_2S. As a result, the *micro*-cNMT cathode improved cycling stability owing to a synergistic effect from N and mixed phases of TiO_2 (0.39% decay at 0.1 C for 100 cycles), compared to the control group without N or with a single phase of TiO_2 nanoparticles (either anatase or rutile only).

Synthesis, Electronic Structure and Redox Chemistry of Li2MnP2S6, A Candidate High-Voltage Cathode Material Yi-Ting Cheng[1], Fujii Yuta[2], Yu Nomata[2], Madhulika Mazumder[1], Nataly C. Rosero-Navarro[2], Aichi Yamashita[3], Yoshikazu Mizuguchi[3], Chikako Moriyoshi[4], Takao Mitsudome[5], Kiyoharu Tadanaga[6], Akira Miura[2] and Chris Bartel[1]; [1]University of Minnesota, United States; [2]Hokkaido University, Japan; [3]Tokyo Metropolitan University, Japan; [4]Hiroshima University, Japan; [5]Osaka Metropolitan University, Japan; [6]Osaka University, Japan

While significant efforts have been made to harness the large capacity of sulfide-based cathodes, there has been limited focus on increasing their voltage. Here, by a novel iodide-assisted synthesis route, we successfully synthesized lithium metal thiophosphates $Li_2MP_2S_6$ (M = Mn, Fe, and Co), of which $Li_2Mn_{0.902}P_2S_6$ is a new compound. Electrochemical cycling revealed $Li_2FeP_2S_6$ and $Li_2MnP_2S_6$ can both be cycled at an equilibrium voltage of ~3 V, significantly higher than other sulfide-based cathodes. Despite the similar voltages, these two materials were found to operate by very different redox mechanisms. Density functional theory calculations show that while $Li_2FeP_2S_6$ exhibits traditional cationic redox, $Li_2MnP_2S_6$ involves participation and rehybridization of coupled Mn-S and S-S states. This work reinforces the promise of high-voltage sulfide-based cathodes for Li-ion batteries with the potential for significant capacity by combining both cationic (transition metal) and anionic (sulfur) redox.

SESSION ES06.03: Poster Session: Sulfur and Sulfide Chemistry for Electrochemical Energy Storage
Session Chairs: Dongping Lu and Hui Wang
Tuesday Afternoon, April 23, 2024
Flex Hall C, Level 2, Summit

5:00 PM ES06.03.01
Enhancing Aqueous Zinc Sulfur Battery Performance with a Novel Hybrid Electrolyte Yuqi Guo[1], Rodney Y. Chua[1], Yingqian Chen[2], Yi Cai[1], Ernest Tang[1], Nicholas J. Lim[1], Thu Ha Tran[1], Vivek Verma[1], Ming Wah Wong[2] and Madhavi Srinivasan[1]; [1]Nanyang Technological University, Singapore; [2]National University of Singapore, Singapore

Rechargeable aqueous Zn/S batteries hold significant promise due to their high capacity and energy density. However, their long-term cycling stability is hindered by sulfur side reactions and the growth of Zn anode dendrites in the aqueous electrolyte. In response, this research explores a simultaneous solution to these challenges through the development of a unique hybrid aqueous electrolyte incorporating ethylene glycol as a co-solvent. This innovative electrolyte design strategy facilitates the fabrication of Zn/S batteries with exceptional performance metrics on capacity, energy density and cycling stability under a high current rate. In addition, the investigation of the cathode charge-discharge mechanism reveals a multi-step conversion reaction. During discharge, elemental sulfur undergoes sequential reduction by Zn, ultimately forming ZnS. On charging, ZnS and short-chain polysulfides are oxidized back to elemental sulfur. This study not only offers a novel electrolyte design approach but also sheds light on the unique multi-step electrochemistry of the Zn/S system, paving the way for improved Zn/S batteries in the future.

5:00 PM ES06.03.02
Ultra Lean-Electrolyte Li–S Batteries Realized by Highly Solvating Electrolyte Design Zixiong Shi and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

Lowering electrolyte usage is a key to attaining high energy density lithium–sulfur (Li–S) batteries. However, this remains a tremendous challenge in the conventional ether-based electrolytes with moderate polysulfide solubility. Highly solvating electrolytes, which can facilitate polysulfide dissolution, are considered a promising strategy to overcome this issue. They can also elevate sulfur utilization via altering reaction pathways and expediting redox kinetics. Nonetheless, mechanistic probing and kinetic evaluation on the complicated Li–S chemistry are still lacking. Herein, we design a highly solvating electrolyte via synchronous solvent and additive engineering. Spectroscopic investigations uncover that high-donor-number component can enable S_3^- radical-directed reaction path and three-dimensional Li_2S precipitation. Additionally, it has been revealed that ammonium ions promote the dissociation and dissolution of Li_2S by means of the H-S^{2-} bond. Benefiting from high polysulfide solubility and favored redox reaction, Li–S batteries with a low electrolyte and sulfur (E/S) ratio of 5 μL mg_s^{-1} achieve a high capacity of 1092 mAh g^{-1}. Even at a harsh E/S ratio of 3 μL mg_s^{-1}, they still deliver an admirable capacity of 923 mAh g^{-1} and sustain a stable operation over 40 cycles. Our work elucidates the polysulfide speciation and reaction mechanism in highly solvating electrolytes, which opens a new avenue for achieving pragmatic lean-electrolyte Li–S batteries.

5:00 PM ES06.03.03
Structural Properties and Ion Diffusion Pathways in Molybdenum Sulfide Materials of Interest for Li-S Batteries Sahar Bayat[1], Keerthan R. Rao[1], Taohedul Islam[2], Saiful M. Islam[2] and Chad Risko[1]; [1]University of Kentucky, United States; [2]Jackson State University, United States

Rechargeable battery systems, such as lithium-sulfur batteries, have garnered significant attention due to their high specific energies, lightweight form factors, and cost. However, challenges such as polysulfide shuttling and limited recharge cycles remain as shortcomings. Molybdenum sulfide-based chalcogels demonstrate potential to address these limitations as they show enhanced kinetics of lithium diffusion and the ability to mitigate polysulfide shuttling in lithium-sulfur (Li-S) systems. Here we are interested in developing structure–function relationships of molybdenum sulfide structures identified in the chalcogels through density functional theory (DFT) calculations and first-principles molecular dynamics simulations. We explore diverse sampling trajectories to extract structural factors, pair distribution functions, and bond structures to identify models that closely align with experiment. We then aim to elucidate ion diffusion pathways within the different molybdenum sulfide structures. The results of these studies provide fundamental understanding of the relationships among the composition, structure, and ion diffusion pathways in molybdenum sulfide-based chalcogels with the goal of delivering insights for future materials development.

5:00 PM ES06.03.05
Optimizing Lithium-Sulfur Battery Performance by The Integration of MgO Additive Sunny Choudhary[1], Nischal Oli[1], Rajesh K. Katiyar[1], Balram Tripathi[2], Gerardo Morell[1] and Ram Katiyar[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]S S Jain Subodh P.G.(Auto.) College, India

This study focuses on mitigating polysulfide dissolution in lithium-sulfur batteries by employing magnesium oxide (MgO) nanoparticles. We successfully incorporated MgO nanoparticles with sulfur through a commercially viable approach using a planetary ball mill. When integrated into the sulfur electrode, MgO led to improved capacity retention in the lithium-sulfur cell, surpassing the performance of cells with unaltered sulfur electrodes. This enhancement in cycling stability can be attributed to the robust chemical bonding between MgO and lithium polysulfide entities. This interaction effectively curtailed the shuttle effect of lithium polysulfides, thereby augmenting the utilization of the active sulfur material. The uniform dispersion of MgO nanoparticles on the surface of the sulfur demonstrates their effectiveness as additives for trapping lithium polysulfides. This research showcases the potential of MgO nanoparticles as a viable solution for the challenges associated with polysulfide dissolution in lithium-sulfur batteries. Our primarily data exhibits stable reversible capacity more than ~ 600 mA h g^{-1} over 100 cycles at 0.1C, surpassing a coulombic efficiency of ~99%. During the conference, we will present our insights into structural examination and electrochemical analysis.

5:00 PM ES06.03.06
Improving Low-Pressure Performance of Silicon Anodes in All-Solid-State Batteries using Ag Eunsuh Lee, Seunggoo Jun and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

All-solid-state batteries (ASSBs) have emerged as promising alternatives to conventional lithium-ion batteries (LIBs), offering enhanced safety and superior energy density. Similarly to LIBs, Si stands out as an attractive anode candidate for ASSBs, owing to its high theoretical capacity (3580 mA h g^{-1}) and low voltage (<0.4 V vs. Li/Li^+). However, it has been well documented that Si faces a significant challenge in LIBs; its immense volume change (>300%) during charge-discharge cycles leads to substantial pulverization and consequent electrical isolation of Si particles. In LIBs, this issue is often mitigated by combining Si with nanostructured carbonaceous materials, such as carbon nanotubes and graphene. Yet, in ASSBs, these same additives can consume Li^+ sources and generate byproducts that exhibit poor Li^+ conductivity. Recent advancements have demonstrated notable performance improvements in Si-based ASSBs by excluding SEs and carbon additives, albeit with minimal binder content and operation at 50 MPa. Nevertheless, from practical application, it is critical to evaluate and ensure performance sustainability at substantially reduced operating pressures.
Herein, we provide a comparative analysis of the performance of Si ASSBs at varying operating pressures, emphasizing the significance of assessments at low pressures. We also introduce our approach to enhancing low-pressure performance through interfacial modification using metallic Ag. Lastly, we offer a series of complementary analytical results that delve into the underlying mechanism contributing to performance enhancement.

Electrochemistry of Deep Eutectic Fluorinated Ether Electrolyte in Li-SeS_2 Batteries Julio Zamora; Washington State University, United States

Lithium-Selenium disulfide (Li-SeS_2) batteries are a promising electrochemical system with much higher energy density compared to current Li-ion batteries. However, Li-SeS_2 batteries with conventional ether-based electrolytes undergo rapid performance degradation due to the “shuttle phenomena” associated with the formation and dissolution of polysulfide/selenide intermediates during battery cycling. Deep Eutectic Solvent (DES) electrolyte promises wide thermal stability and cost effectiveness compared to conventional commercial electrolytes. However, at high lithium salt concentrations, the high viscosity of DES hinders interfacial lithium-ion transport, and it can passivate Li-metal anodes. Dilute fluorinated ether has been implemented to improve bulk lithium-ion transport in other battery systems. In this study, we have designed novel, DES-based fluorinated ether electrolyte and investigated their thermal stability and lithium-ion solvation structure. Implementing novel DES-based electrolytes in Li-SeS_2 battery, we were able to reduce the performance degradation, retaining (>92%) of initial discharge specific capacity after high-rate cycling, achieve high coulombic efficiency (>99%), and achieve good battery cycling performance. This work provides new strategies for developing highly stable liquid electrolytes for high-energy Li-SeS_2 batteries.

5:00 PM ES06.03.08
Inorganic Porous Nanostructures Prepared by The Breath Figure Mechanism and Their Application in Lithium-Sulfur Batteries. Shu-Hao Chang and Yi-Jing Tsai; Chung Yuan Christian University, Taiwan

Lithium-sulfur batteries, recognized for their high theoretical capacity and plentiful sulfur source, are potential candidates for future energy storage devices. One significant challenge to commercialization is the polysulfide shuttle effect, which reduces the cycling stability and battery lifespan. We solved this issue by incorporating porous nanostructured metal sulfide into the battery's separator. We prepared metal sulfide nanoparticles through a simple hydrothermal synthesis and subsequently developed a porous thin film using the breath figure approach. Variables like substrate choice, temperature, and humidity were adjusted to refine the nanostructures. These modifications helped curb the shuttle effect by trapping the mobile polysulfides, thereby enhancing battery efficiency. The electrochemical attributes of these upgraded devices are elaborated upon in this research.

5:00 PM ES06.03.09
Hafnium Trisulfide Nanoribbons as a Promising Anode for High-Performance Lithium-Ion Storage Wei Shuangying; University of Chemistry and Technology, Prague, Czechia

Exploring the electrochemical characteristics of low-dimensional van der Waals materials is crucial for advancing novel rechargeable energy-storage devices, such as lithium-ion batteries (LIBs). Given their diverse band gaps, anisotropic conductivity, and high specific capacity, materials within the extensive family of transition metal trichalcogenides (TMTCs), including hafnium trisulfide (HfS_3), have garnered increased attention in recent years. Despite numerous theoretical and experimental studies focusing on the synthesis and physicochemical attributes of hafnium trisulfide, there remains a scarcity of experiments delving into its lithium-ion storage properties. Hence, HfS_3 material with a quasi-1D structure was applied as anode material for lithium-ion batteries. HfS_3 micro-belts were prepared using a simple solid-state reaction. Upon performing the relevant electrochemical tests, after 100 cycles, the HfS_3 electrode exhibits a high reversible capacity of 221.7 mAh g^{-1} at a current density of 100 mA g^{-1} and a great rate capability of 157.5 mAh g^{-1} at the 101st cycle at a high current density of 800 mA g^{-1}. The excellent lithium storage performance can be related to the lithiation amorphization process, surface-controlled pseudocapacitive behavior, and low charge transfer resistance. The promising electrochemical characteristics of HfS_3 may shed new light on the design of transition metal trichalcogenides as viable anode materials for lithium storage. Nevertheless, the lithium storage behavior of ZrS_3 flakes is thus largely unexplored due to its low electronic conductivity and the challenges associated with its exfoliation.

5:00 PM ES06.03.10
Nickel-Based Sulfide Decorated Hydroxides as Cathode Materials for Hybrid Supercapacitors Ziwei Gan, Xiaohe Ren, Mengxuan Sun, Zhijie Li and Chunyang Jia; University of Electronic Science and Technology of China, United States

Due to their outstanding electrochemical properties, transition metal sulfides and hydroxides are often used as high-performance electrode materials for supercapacitors. The Mn-doped $Co(OH)_2/Ni_3S_4$ electrode material in this study, due to the synergistic reaction mechanism among $Co(OH)_2$ and Ni_3S_4 and the increased active sites by the addition of Mn, the Mn-$Co(OH)_2/Ni_3S_4$ exhibits excellent electrochemical property. The electrochemical performance of the Mn-$Co(OH)_2/Ni_3S_4$ hybrid electrode was measured in an electrode cell made of 2 M KOH solution, showing a superior specific capacitance of 1107.0 C g^{-1} at 0.5 A g^{-1}, in addition to the excellent capacity retention rate at 10 A g^{-1} is 72.7 % of that at 1 A g^{-1}. The performance of the hybrid supercapacitor (HSC) assembled with Mn-$Co(OH)_2/Ni_3S_4$ compound and activated carbon (AC) was measured under the same electrolyte conditions, anwell-specificific capacity (157.2 F g^{-1} at 0.5 A g^{-1}) was achieved, along with superior long-term stable charge/discharge capability (88.9 % of the original specific capacity after 35,000 cycles at 8 A g^{-1}). Meanwhile, the most practical application is when the power density of 410.4 W kg^{-1}, the assembled HSC device has an energy storage capacity of 58.8 W h kg^{-1}, revealing that the developed Mn-$Co(OH)_2/Ni_3S_4$ has great application potential for supercapacitors in the future.

5:00 PM ES06.03.11
Hybrid Nanoarchitectures of $Zn_{0.76}Co_{0.24}S$ Nanoparticles@$Co(OH)_2$ Nanosheets for High-Performance Supercapacitor with Excellent Energy Density Xiaohe Ren, Ziwei Gan, Mengxuan Sun, Chunyang Jia and Zhijie Li; University of Electronic Science and Technology of China, China

It is a great challenge to achieve both high specific capacity and high energy density of supercapacitors by designing and constructing hybrid electrode materials through a simple but effective process. In this paper, we proposed a hierarchically nanostructured hybrid material combining $Zn_{0.76}Co_{0.24}S$ (ZCS) nanoparticles and $Co(OH)_2$ (CH) nanosheets using a two-step hydrothermal synthesis strategy. Synergistic effects between ZCS nanoparticles and CH nanosheets result in efficient ion transports during the charge-discharge process, thus achieving a good electrochemical performance of the supercapacitor. The synthesized ZCS@CH hybrid exhibits a high specific capacity of 1152.0 C g^{-1} at a current density of 0.5 A g^{-1} in 2 M KOH electrolyte. Its capacity retention rate is maintained at ~70.0% when the current density is changed from 1 A g^{-1} to 10 A g^{-1}. A hybrid supercapacitor (HSC) assembled from ZCS@CH as the cathode and active carbon (AC) as the anode displays a capacitance of 155.7 F g^{-1} at 0.5 A g^{-1}, with a remarkable cycling stability of 91.3% after 12,000 cycles. Meanwhile, this HSC shows a high energy density of 62.5 Wh kg^{-1} at a power density of 425.0 W kg^{-1}, proving that the developed ZCS@CH is a promising electrode material for energy storage applications.

SESSION ES06.04: Sulfide-Based Solid-State Batteries—Electrolyte and Anode

Progress Towards New Sodium Mixed Oxy-Sulfide-Nitride Glassy Solid Electrolytes Steve Martin, Madison Olson, Alec Wakefield, Nicholas Oldham and Noah Riley; Iowa State University of Science and Technology, United States

While Lithium batteries are currently the most popular battery for grid scale energy storage, the rapidly increasing demands for Lithium to electrify transportation will soon outpace available geological reserves. For this reason, sodium batteries, with their comparable volumetric energy storage density, yet orders of magnitude lower cost, have been of interest for more than 50 years. The lack of a high conductivity, low cost, and electrochemically stable solid electrolyte has been a central reason for the current lack of a commercially available Na battery. In this talk, I will describe our more recent progress in developing new chemistries of Na-based glassy solid electrolytes that can be formed as thin films and in characterizing the many thermal, chemical, electrochemical, and mechanical properties needed of them.

9:00 AM *ES06.04.02
Thermal Runaway Behavior of Sulfide-Based Solid Electrolytes for All-Solid-State Batteries Taehun Kim, Kanghyeon Kim and Kyu Tae Lee; Seoul National University, Korea (the Republic of)

Lithium-ion batteries, which contain flammable liquid electrolytes, are susceptible to explosions when subjected to mechanical and thermal stress. Consequently, all-solid-state batteries (ASSBs), featuring solid electrolytes in place of liquid counterparts, have gained increasing attention as a promising alternative to current Li-ion batteries due to their potentially superior safety profile. Among these, thiophosphate-based solid electrolytes are considered particularly promising due to their high Li^+ ion conductivity and suitable mechanical flexibility, resulting in improved electrochemical performance for ASSBs. However, regrettably, the safety of sulfide-based ASSBs remains uncertain, as their thermal stability has primarily been assessed under specific, mild conditions, such as low state-of-charge (SOC) levels. In this presentation, we demonstrate the safety concerns associated with various solid electrolytes used in all-solid-state batteries with Ni-rich layered oxide cathode materials, particularly in the context of thermal and mechanical stress. Additionally, we propose not only the mechanisms responsible for the thermal degradation of solid electrolytes in the presence of Ni-rich layered oxide cathode materials but also the key factors that determine the thermal runaway of solid electrolytes. This discovery provides a deeper insight into the failure modes of all-solid-state batteries, shedding light on the broader understanding of their potential challenges and safety considerations.

9:30 AM ES06.04.03
Sulfide Solid Electrolyte with Better Safety and Cost Reduction Benoit Fleutot, Fabien Nassoy, Emmanuelle Garitte, Alexis Perea, Sergey Krachkovskiy, Steve Duchesne, David Rozon, Karine Tremblay and Chisu Kim; Hydro-Québec, Canada

All-solid-state batteries are viable alternatives to conventional batteries employing organic electrolytes because of their benefits, i.e., high power density, high energy density, long-life operation and safety. These advantages stem from the great features of inorganic solid electrolytes, which are single ion conductor, so a high lithium-ion transport number, and no-liquid nature. Solid oxide or sulfide are largely studied to allow the emergence of all-solid state batterie based on solid electrolyte ceramic. In particular, the sulfide-based solid electrolytes possess favorable mechanical properties, high ionic conductivity comparable to liquid electrolytes but suffer of moisture exposure that could induce H_2S generation and very expensive precursor. Sulfide-based solid-electrolytes can potentially be employed in conjunction with a lithium metal negative electrode and 5V-class high voltage positive electrode material. Different families of sulfide electrolyte as glass ceramic, thio-LISICON, LGPS, argyrodites are synthetized by similar precursor as Li_2S-P_2S_5 and other component in function of composition. The composition must be designed to create stable passivating interface with lithium metal. In

parallel, the sulfide solid electrolyte reacts with all components constituting the positive electrode as active material, electronic conductor, binder, current collector… Hence, the optimal composition is a key issue. To hope for an emergence of this type of materials within all-solid batteries, it is necessary to avoid the use of heavy and expensive elements but also to improve the resistance of these materials towards humidity. This is possible thanks to the studies carried out on surface modification of sulfide electrolyte or the use of oxy-sulfide in the literature. Nevertheless, all these materials are based on the same precursor: Li_2S: very expensive and unsafe material. The ideal sulfide material would be one that is stable at high potential and low potential with lithium metal, a strong resistance to humidity allowing the handling of the material as well as its safe use in batteries with a low cost synthesis method in a minimum of steps using the minimum of expensive precursors.
In this field and since a few years, Hydro-Quebec has decided to conduct specific research on all-solid ceramic batteries and especially in the field of sulfide-based ceramic electrolytes. A specific study has been carried out to (1) optimize the composition of sulfide solid electrolyte with cheaper precursors to maintain or increase the properties as ionic conductivity and electrochemical stability, (2) better understand the reactivity at various dew points. Safety being in Hydro-Québec's DNA, emphasis has been placed on safety with a minimum step process as well as precise monitoring of H_2S generation of the precursors and the final material depending on temperature and humidity level. The complementarity between synthesis process, compositions, NMR analyses, XRD analyses, ionic conductivity, electrochemical stability, and safety measurements will be presented for the first time on sulfides prepared at Hydro-Quebec.

9:45 AM ES06.04.04
A High-Throughput Platform for Combinatorial Synthesis and Characterization of Thiophosphate Solid Thin-Film Electrolytes Andrea Crovetto; Technical University of Denmark, Denmark

Research in thin-film battery materials is scarce, and reports of sulfur-based solid electrolytes and battery electrodes in thin-film form are particularly few. Even if we disregard the possible practical applications of thin-film materials in bulk solid-state batteries, dedicated work on sulfide battery materials in thin-film form would be highly beneficial for a very simple reason. Bulk synthesis of sulfide solid electrolytes is not amenable to parallelized, high-throughput experimentation by combinatorial methods. Conversely, an appropriately designed thin-film deposition system is an ideal platform for rapid exploration of new battery materials.

In this contribution, I will present our recently acquired, highly customized thin-film synthesis platform dedicated to air-sensitive sulfides, thiophosphates and related materials containing sulfur and phosphorus. To the best of my knowledge, this is the only synthesis platform in the world where it is possible to deposit thin-film thiophosphate superionic conductors of any elemental composition in a high-throughput, combinatorial fashion. Our thin-film deposition setup is designed to easily obtain compositional gradients (e.g., a P/S ratio gradient in one direction and a Li/Ge ratio in the perpendicular direction). Together with the automated, mapping-type characterization instruments in our laboratories, these combinatorial methods enable fast screening of multicomponent phase diagrams of sulfides (as well as process parameters at constant composition) in the search for optimal properties in emerging or completely new battery materials. Materials of interest can be either electrodes or solid electrolytes.

As a material scientist within the optoelectronics field specializing in sulfides, I hope that this contribution will promote discussion and potential future collaboration with sulfide battery experts.

10:00 AM BREAK

10:30 AM *ES06.04.05
Comparative Study of Oxides and Sulfides in Terms of their Dendrite Resistance: The Impact of Internal Defects and Interlayers Yue Qi; Brown University, United States

The key challenge for the Li-metal electrode is to maintain a smooth surface at the microscopic scale during cycling. During lithium plating, it was found that the bandgap, tunneling barriers, and electron localization on internal defects, such as pores and crack surfaces and grain boundaries play a more important role in Li-dendrite nucleation and growth. A combined DFT and phase-field method was developed to demonstrate these effects. Several oxides (cubic Li7La3Zr2O12 (c-LLZO), Li1.17Al0.17Ti1.83(PO4)3 (LATP), and Li2PO2N) and sulfide (β-Li3PS4 and Argyrodite Li6PS5Cl) electrolytes and their interlayer materials (Li_2O vs. Li_2S) were compared.
For the bulk solid electrolytes, the oxides tend to show much smaller bandgaps on the surface and grain boundaries than the corresponding bulk materials. While LLZO showed the most significant excess electrons on the surface and grain boundaries, β-Li3PS4, and argyrodite showed no such behavior. This is consistent with the observed trend and morphology of Li dendrite growth in different solid electrolyte materials.
Further, the Li_2O and Li_2S interface layers showed different lithium metal wettability. A combined density functional theory (DFT) and kinetic Monte Carlo (KMC) interface evolution simulations showed that the lithiophilic interface (Li/Li_2O) repels vacancies into the bulk Li, so Li atoms can quickly fill the Li vacancies near the interface and maintain a smooth Li surface. In contrast, the more lithiophobic interface (e.g. Li/Li_2S) traps Li vacancies toward the interface, and the accumulated Li vacancies form voids causing interface delamination. The appropriate alloying and stack pressure were predicted to avoid interface delamination at Li/Li_2S interface during the stripping process.

11:00 AM *ES06.04.06
Unveiling Lithium-Solid Electrolyte Interface Evolution in All-Solid-State Batteries through *Operando* Characterizations Yan Yao; University of Houston, United States

All-solid-state lithium metal batteries are projected to offer one of the highest specific energy among rechargeable batteries, positioning them as a front-runner for electric vehicle applications. Lithium metal anodes outperform conventional graphite anodes in terms of cell-level energy density. However, ensuring a conformal metal–electrolyte contact is a great challenge. In this presentation, I will illustrate the use of operando tools to understand issues like void formation and contact loss at the Li–electrolyte interface in all-solid-state batteries. I will first showcase a study where the Li-Mg alloy anode suppresses void growth. Operando scanning electron microscopy reveals voids coalescing into a gap at the pure-Li–electrolyte interface, but large voids split into smaller voids and collapse to ensure contact between Li-Mg alloy anode and solid electrolyte. This behavior is further supported by density function theory calculations, emphasizing the role of strong Mg-S interaction at the electrolyte interface in repelling vacancies and mitigating void formation. In the second example, I will introduce an interlayer strategy optimizing contact between the solid electrolyte and lithium metal, which enhances stripping/plating uniformity and suppress lithium dendrite formation.

11:30 AM ES06.04.07
Interfacial Evolution of Surface Modified Li Metal Anodes in All-Solid-State Batteries Yoon Seok Jung; Yonsei University, Korea (the Republic of)

For decades, the pursuit of solidifying electrolytes using inorganic solid electrolytes (SEs) that display high mechanical strength has been regarded as a "Holy Grail" in the quest to enable Li metal anodes. Sulfide SE materials such as Li argyrodite (e.g., Li_6PS_5Cl) are particularly attractive due to their

mechanical sinterability and high ionic conductivities, making them subjects of extensive research for practical ASSBs. However, these materials encounter a critical limitation: their electrochemical instability in contact with Li metal. This instability leads to the reductive decomposition of sulfide SEs, producing byproducts like Li_2S, which substantially escalate interfacial impedance. More critically, Li metal tends to grow through the SE layers, inducing catastrophic short circuits. To address these challenges, various surface modification techniques have been explored. Inorganic materials (e.g., LiF) and alloying elements (e.g., Ag) have received considerable attention. However, despite advances in enhancing the performance of Li metal ASSBs, there is a noticeable gap in our understanding on the interfacial evolution, particularly concerning factors associated with cell fabrication methods and/or operating conditions.
In this presentation, we report our strategies for stabilizing Li metal anodes in ASSBs that use Li_6PS_5Cl, specifically through the incorporation of electroless-plated In or MgF_2 interlayers. Our findings indicate that neither intermetallic nor simple inorganic interlayers maintain stability throughout cell fabrication or operation. In contrast, MgF_2 interlayers exhibit substantial enhancements in these aspects. Furthermore, comprehensive analytical techniques, including operando electrochemical pressiometry, to probe the interfacial evolution in Li metal ASSBs, are also presented.

11:45 AM ES06.04.08
Insights into the Chemo-Mechanics of Sulfur Conversion Electrodes via *Operando* Acoustic Transmission for Lithium Batteries Kerry Sun[1,1], Gunnar Thorsteinsson[1,1], Alexandra Stiber[1,1,1], Libby Katzman[1,1], Wesley Chang[2], Richard May[1,1] and Daniel Steingart[1,1,1]; [1]Columbia University, United States; [2]Drexel University, United States

The chemo-mechanics of the lithium-sulfur battery are unique in Li-ion batteries due to the sulfur electrode undergoing two first-order phase changes during discharge and charge. However, dissolution of sulfurous species in liquid electrolytes is a primary degradation mode in Li-S systems. Here, we use acoustic transmission to track the mechanical phasing of the sulfur electrode. We show that acoustic time of flight (or sound speed) is directly correlated to sulfur's physio-chemical phase dynamics. This is because the acoustic sound speed is a composite property dependent on the density and elastic modulus of the medium. By accounting for cell dilation, we show that inter-cycle and intra-cycle sound speed changes in time of flight are due to the sulfur dynamics alone. This understanding is linked with ex-situ techniques like XRD and TGA to track the effect of polysulfide shuttling.

SESSION ES06.05: Sulfide-Based Solid-State Batteries—Li Anode and Interface

1:30 PM ES06.05.01
High Performance MOF Separator for Li-S Battery using Langmuir-Blodgett Technology Seoyoung Yoon, Geonho Kim and Jiwon Kim; Yonsei University, Korea (the Republic of)

Lithium-sulfur (Li-S) batteries have been widely emphasized as alternatives to commercial lithium-ion batteries not only for their higher theoretical capacity (1,675 mAh/g) but also for abundance of sulfur in nature and being safe. However, the shuttle effect of lithium polysulfide limits long cycle life of batteries, and separators have been modified to effectively control reaction intermediates. For example, polymer-based separators have been coated with oxide or carbon in order to enhance filtration via pore or electrical attraction/repulsion. In particular, metal-organic frameworks (MOFs) as coating materials have advantages of porosity and electrochemical property which can be easily adjusted by the composition of metal clusters and ligands. However, most traditional coating techniques such as chemical vapor deposition (CVD) and vacuum filtration coating methods require heating process and produce relatively thick layer (at least microscale), thereby limiting its applicability.
Herein, we synthesized two types of MOF (i.e. MOF-5 and IRMOF-3) nanosheets using Langmuir-Blodgett (LB) technique to functionalize Li-S battery separator. A modified separator was uniformly formed (3.27 Å for R_a; roughness average) by depositing five molecular monolayer films (total thickness of ~47.5 Å) at room temperature, while zinc acetate dihydrate and (2-amino-)terephthalic acid were used as MOF precursors. To note, polysulfide permeation test in H-cell revealed that a LB-coated MOF separator had comparable degree of filtration to a slurry-coated MOF separator despite of its thin thickness (c.a. 4,000 times thinner than slurry-coated one). Moreover, Li-S battery with a IRMOF-3 coated separator exhibited 1.13 times higher cycle stability (retention of 54.26% after 100 cycles) compared to one with non-coated separator (retention of 48.83% after 100 cycles). This suggests that heteroatom (i.e. nitrogen in IRMOF-3) and pore structure of MOF coating layer contribute to enhanced filtration ability of separators. Consequently, we can improve the cycle stability of Li-S batteries by applying a nanoscale MOF modification layer to separators via LB, which can further pave a way for commercialization of Li-S batteries.

1:45 PM ES06.05.02
Towards a Sealed Rechargeable Li-SO_2 Battery: Overcoming Slow Diffusion Kinetics and Side Reactions Gayea Hyun, Myeong Hwan Lee, Haodong Liu, Shen Wang, Victoria Petrova and Ping Liu; University of California San Diego, United States

Rechargeable lithium-sulfur dioxide (Li-SO_2) batteries are potentially of low-cost and high-energy density. The high SO_2 solubility in organic solvents has enabled cell operation under non-pressurized conditions. For example, superior electrochemical stability has been observed in carbonate-based electrolytes. However, most of the reports so far employ an “open cell configuration”, where continuous SO_2 supply is provided. The needed accessories, such as gas diffusion layers and Swagelok-type cell construction with heavy steel frames, and gas handling systems, greatly impede the development of practical high-energy-density batteries.
Herein, we report our progress on understanding the behavior of electrolytes containing SO_2 within a closed system and to maximize the utilization of the active material. In comparison to other redox-active gases, SO_2 molecules, with their relatively high molecular weight (twice as heavy as O_2) and polarity, not only suffer from slow diffusion (~0.7 times lower diffusion coefficient compared to that of O_2) within the electrolyte but also exhibit a peculiar reverse osmotic behavior. When SO_2 is consumed in the electrolyte volume between the two electrodes, dissolved SO_2 in electrolyte outside the current path does not diffuse in. Instead, organic solvents are driven into the current path, leading to an evolution of SO_2 gas outside a cell stack. Our investigation confirmed that this behavior is driven by the molecular interactions between SO_2 and the organic solvents.
Based on the above insights, we have designed electrochemical cells to strategically place all SO_2 containing electrolyte within the current path, leading to maximize utilization. Our optimized bobbin-type battery, in which the electrolyte containing SO_2 is entirely contained within the cell stack, has proven highly effective in maximizing discharge capacity. This configuration allowed us to achieve exceptional utilization (~73%) of SO_2 along with an acceptable E/C ratio (~13 g/Ah, with discharge capacities of 2639 mAh/g_{KB} and 7.9 mAh/cm^2). To further enhance the performance, we have developed a nanoporous lithium protective layer made of a composite of Nafion and alumina nanopowder, capable of retaining SO_2 reactant within the cell stack while minimizing continuous reactant loss from undesirable reactions with Li metal anode. In addition, we have achieved remarkable cycling stability by identifying catalysts

to reduce side reactions and polarization on the cathode. This research sheds new light on the working mechanisms of the Li-SO_2 chemistry and points to its potential as a low-cost, sustainable battery.

2:00 PM *ES06.05.03
Alloy Anodes in Sulfide-Based Solid-State Batteries Matthew McDowell; Georgia Institute of Technology, United States

Alloy anodes offer high theoretical capacity, but they typically exhibit fast capacity decay in lithium-ion batteries because of excessive solid-electrolyte interphase growth. Here, we investigate a variety of alloy anodes in sulfide solid-state batteries, and we show that they can exhibit significantly improved interfacial stability and enhanced cyclability when engineered effectively. *In situ* measurement of stack pressure evolution during cycling shows that the volume changes of alloy anodes can lead to large pressure swings within the solid-state battery cell, giving insight into electrode composite evolution. We further investigate the fundamental electrochemical behavior of 12 different foil-based alloy anode materials in solid-state batteries, and we find that lithium trapping by the delithiated phase can play a key role in limiting performance. Based on these insights, we present a new design for dense foil aluminum-based alloy anodes with multiphase microstructure that offers significantly improved performance due to retained transport pathways within the foil. This design offers a paradigm that does away with slurry coating, potentially reducing manufacturing costs. In addition, we investigate solid-state dealloying of foil anodes to understand the interplay between densification and interfacial contact evolution at different stack pressures. Taken together, these findings show the importance of controlling chemo-mechanics and interfaces in alloy anodes for sulfide-based solid-state batteries for improved energy storage capabilities.

2:30 PM *ES06.05.04
Tuned Reactivity at The Lithium Metal – Argyrodite Solid State Electrolyte Interphase David Mitlin; The University of Texas at Austin, United States

Thin intermetallic Li_2Te–$LiTe_3$ bilayer (0.75 mm) derived from 2D tellurene stabilizes solid electrolyte interphase (SEI) of lithium metal and argyrodite (LPSCl, Li_6PS_5Cl) solid-state electrolyte (SSE). Tellurene is loaded onto standard battery separator and reacted with lithium through single-pass mechanical rolling, or transferred directly to SSE surface by pressing. State-of-the-art electrochemical performance is achieved, *e.g.* symmetric cell stable for 300 cycles (1800 hours) at 1 mA cm^{-2} and 3 mAh cm^{-2} (25% DOD, 60 mm foil). Cryo-FIB sectioning and Raman mapping demonstrate that Li_2Te–$LiTe_3$ bilayer impedes SSE decomposition. The unmodified Li–LPSCl interphase is electrochemically unstable with geometrically heterogeneous reduction decomposition reaction front that extends deep into the SSE. Decomposition drives voiding in Li metal due to its high flux to the reaction front, as well as voiding in the SSE due to the associated volume changes. Analysis of cycled SSEs found no evidence for pristine (unreacted) lithium metal filaments/dendrites, implying failure driven by decomposition phases with sufficient electrical conductivity that span electrolyte thickness. Density Functional Theory (DFT) calculations clarify thermodynamic stability, interfacial adhesion, and electronic transport properties of interphases, while mesoscale modeling examines interrelations between reaction front heterogeneity (SEI heterogeneity), current distribution and localized chemo-mechanical stresses.

SESSION ES06.06: Sulfide-Based Solid-State Batteries—Cathode and Devices
Session Chairs: Dongping Lu and Yang Zhao
Thursday Morning, April 25, 2024
Room 432, Level 4, Summit

8:30 AM *ES06.06.01
Hot-Pressed FeS_2 Cathodes with Oxysulfide Solid-State Electrolyte for All-Solid-State Batteries Hernando J. Gonzalez Malabet[1], Hayden Cunningham[2] and Thomas A. Yersak[1]; [1]General Motors Global R&D, United States; [2]Optimal Inc., United States

The performance of all-solid-state batteries (ASSBs) is limited by poor interfacial contact between active material (AM) and solid-state electrolyte (SSE) particles. At the cell level, poor interfacial contact manifests as difficult operating specifications (e.g. high stack pressure, elevated temperature, or slow charge rate), or poor cell durability. This seminar investigates how an advanced processing technique can better consolidate electrode composites. It will be shown that the electrochemical performance of FeS_2/InLi ASSBs was improved when the cells were hot-pressed at a temperature > 200 °C. When cycled at 25 °C, a cold-pressed (CP) FeS_2/InLi ASSB delivered negligible capacity whereas a hot-pressed (HP) FeS_2/InLi ASSB delivered a 1st cycle discharge capacity in excess of 600 mAh g^{-1}. The improved performance is attributed to better interfacial contact between AM and SSE. This result was achieved by selecting thermally stable FeS_2 active material and highly processable $Li_7P_3S_{9.75}O_{1.25}$ (LPSO) SSE.

9:00 AM *ES06.06.02
Tailored Ni-Rich Cathodes for All-Solid-State Batteries Torsten Brezesinski; Karlsruhe Institute of Technology, Germany

Bulk-type solid-state batteries hold promise as an enabling technology for high density electrochemical energy storage. Especially layered (Ni-rich, low-Co or Co-free) oxide cathode materials [e.g., $LiNi_xCo_yMn_{1-x-y}O_2$ (NCM or NMC) and $LiNiO_2$ (LNO)] and superionic lithium thiophosphate solid electrolytes are being considered for high energy density solid-state battery applications. However, electro-chemo-mechanical degradation occurring during cycling is a major obstacle towards development of stable and long-lived cells. In this presentation, I will highlight the importance of tailoring Ni-rich cathodes for increasing performance of pellet-type and slurry-cast electrodes. In addition, I will show recent findings on the effect that protective surface coatings have on interfacial side reactions and mechanical degradation in thiophosphate-based cells.

9:30 AM ES06.06.03
Functional Surface Modification of Ni-Rich Cathode for All-Solid-State Lithium-Ion Batteries Employing Sulfide Solid Electrolytes Jun Pyo Son and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

Intensive research and development efforts have been directed towards lithium-ion battery (LIB) for electric vehicle applications. However, conventional LIBs utilize flammable organic liquid electrolytes, which pose inherent safety risks, including a propensity for fire-related incidents. These safety concerns have spurred heightened interests in all-solid-state batteries (ASSBs), which utilize inorganic solid electrolytes (SEs) instead. For ASSBs to meet the practical demands of high energy density, the use of Ni-rich layered oxide cathode active materials (CAMs), denoted as $LiMO_2$ (M = Ni, Co, Mn, and/or Al), which are prevalent in LIBs, is essential. However, a significant change arises with sulfide SEs, known for their high ionic conductivity but poor electrochemical stability. This instability necessitates the application of an insulating buffer layer on Ni-rich CAMs. Furthermore, Ni-rich CAMs are prone

to structural instability, leading to internal cracking and significant degradation, notably an irreversible H2-H3 phase transition when in high states of charge. To address the structural stability issues inherent in Ni-rich CAMs, metal doping techniques have been commonly employed.
In this presentation, we propose a comprehensive strategy that addresses not only the poor electrochemical stability of sulfide SEs but also the detrimental phase transition of Ni-rich CAMs. This approach involves the development of multi-component functional coatings. Along with significantly enhanced electrochemical performance, interfacial evolutions probed by complementary analyses are presented.

9:45 AM ES06.06.04
In-*Operando* FTIR Study on The Redox Behavior of Sulfurized Polymers as Cathode Material for Li-S Batteries Vibha Kalra; Cornell University, United States

Sulfurized polymers are an attractive cathode active material, promising to overcome the intransigent polysulfide shuttle effect sulfur cathodes face via the anchoring of sulfur by a carbon-sulfur (C-S) bond. Both sulfur-diisopropenylbenzene copolymers (SDIB) and sulfurized polyacrylonitrile (SPAN) contain C-S bonds which should function in this way, however, their performance in ether electrolytes still exhibit capacity fade associated with the polysulfide shuttle. We investigate this anchoring effect using in-operando ATR-FTIR spectroscopy to develop a molecular level understanding of the polysulfide speciation reaction in sulfurized polymers and cathode level molecular changes. We find that in SDIB copolymers with sulfur wt % of 80 and 30 wt %, the C–S bond is not active in the voltage window of Li–S batteries (1.8-2.6V vs Li/Li+). In SPAN, however, we found that the C-S bond is active in the typical voltage window (1-3V vs Li/Li+) contributing to the evolution of polysulfide species in electrolyte with low concentrations of lithium nitrate (LiNO3), however this effect is mitigated when higher concentrations of LiNO3 are used. We attributed the mitigation of the polysulfide shuttle to the formation of a cathode electrolyte interface (CEI), composed of lithium fluoride, established via ex-situ XPS studies on cycled cathodes. Additionally, we observed the reversible behavior of the C-S bond in IR at ~680 cm-1 in electrolytes with high concentration of LiNO3, as opposed to the irreversible behavior of the bond in electrolyte with low concentrations of LiNO3. Moreover, we observed the lithiation of the cyclized PAN backbone, identified by the elimination of the aromatic region of the IR spectrum after the first cycle.

10:00 AM BREAK

10:30 AM *ES06.06.05
Polymeric Materials for Scalable, Reliable Sulfide-Based All-Solid-State Batteries Jang Wook Choi; Seoul National University, Korea (the Republic of)

Sulfide-based all-solid-state batteries (ASSBs) are considered to be a next-generation energy storage concept that offers enhanced safety and potentially high energy density. Despite considerable progress in the development of materials, sulfide-based ASSB technology still remains at research stage without solution-based scalable manufacturing schemes having been established because of the incompatible polarity of binder, solvent, and sulfide electrolyte during slurry preparation. In this talk, I will introduce a novel binder design based on protection-deprotection chemistry, which resolves the tricky issue of polarity compatibility among the three electrode components (solvent, binder, and SE) in the slurry solution. Protection by the tert-butyl group allows for homogeneous dispersion of the binder in the slurry based on a relatively less polar solvent, with subsequent heat-treatment during the drying process to cleave the tert-butyl group. Upon deprotection, the polar carboxylic acid group is exposed, which enables hydrogen bonding interaction with the high-nickel layered oxide active material. Deprotection strengthens the electrode adhesion drastically, even beyond the levels of commercial LIB electrodes, and the key electrochemical performance parameters are improved markedly in both half-cell and full-cell settings. This study highlights the potential of sulfide-based ASSBs for scalable manufacturing and also provides insights that protection-deprotection chemistry could generally be used for various battery cells that suffer from polarity incompatibility among multiple electrode components.

Self-Templated 3D Porous Sulfide Solid Electrolytes for Solid-State Sodium Metal Batteries Xiaolin Guo, Yang Li and Hui Wang; University of Louisville, United States

Rechargeable solid-state sodium (Na) batteries have gained great attention for their high-safety, high energy density and low cost. However, due to the high reactive Na anode, poor electrolyte/electrode interfaces compatibility is the biggest obstacle for inorganic sulfide solid electrolytes (e.g., Na_3MS_4, M=P, Sb) to achieve high performance batteries. Thus, it is necessary to design the nanostructure of sulfide solid electrolyte (SE) and modify interface to address that challenge on the electrochemical instability. In this talk, we will introduce a facile and simple synthesis to prepare Na_3SbS_4 (NSS) sulfide solid electrolyte with 3D porous framework, which can be further infiltrated with a phase transition polymer to form a composite solid electrolyte. The Na_3SbS_4-based composite (NSSC) exhibits enhanced interface stability towards Na metal compared with pristine NSS. The fabricated cells with structure of Na|NSSC|TiS_2 shows excellent cycling stability for 200 cycles wit decent capacity retention. This result demonstrates great promise of achieving high-energy sodium metal batteries with sulfide solid electrolytes.

11:15 AM ES06.06.07
Investigating The Electro-Mechano-Chemical Coupling Phenomena of an Electrolyte in All Solid-State Battery Kethsovann Var[1,2], Christel Laberty Robert[1], Sofiane Maiza[2], David Sicsic[2] and Damien Bregiroux[1]; [1]Sorbonne Universite - Laboratoire Chimie de la Matière Condensée de Paris, France; [2]Renault Group, France

Lithium-ion technology's energy density is constrained by negative electrode intercalation. The integration of lithium metal into solid-state batteries shows promise for a substantial enhancement of energy density. It would increase energy density from 372 mAh/g to 3862 mAh/g. However, several challenges persist, including cycling pressure, dendrite growth, and volumetric electrode variations that can lead to detachment and cracks in the electrodes, ultimately causing premature battery degradation.
This study primarily focuses on understanding the intricate relationships between electrochemical and mechanical properties within solid-state batteries. The chosen material is the argyrodite (Li_6PS_5Cl), which exhibits high ionic conductivity (10^{-3} cm^{-1}), comparable to that of liquid electrolytes. This material can be easily compacted through cold pressing due to its favorable mechanical properties. According to literature results, the material has a relatively low Young's modulus [E] 25-40 GPa [1,2], classifying it as a soft material, in contrast to oxide families.
The material's intrinsic properties (such as Young's modulus, hardness, viscoelasticity, etc.) were investigated using nanoindentation. In order to overcome the reactivity issues related to air and humidity, we have designed a specific device, inspired by Hikima [2] to conduct nanoindentation test in ambient atmosphere. Young's modulus values for the pure material were around 16 GPa which is lower than literature. The inconsistency in these results is attributed to the shaping process which introduces factors like porosity and surface inhomogeneity, necessitating refinement.
On the other hand we shown that the material has small elastic range, corresponding to its reversible deformation. It becomes evident that expanding the material's elastic range is imperative to accommodate electrode volumetric variations. We studied mechanical properties of argyrodite by a) modifying the particle size to manipulate macrostructural defects, and b) modifying the material's stoichiometry $Li_{6+x}PS_{5-x-y}O_yZ$ by introducing elements like (F, Cl, Br, I). This modification is intended to affect the strength of chemical bonds, consequently influencing the Young's modulus.

Simultaneously, on a macroscopic scale, a testing cell is developed to monitor pressure variations during cycling. The $Li_4Ti_5O_{12}$ / Li_6PS_5Cl | Li_6PS_5Cl | Li_6PS_5Cl / NMC811 (single or polycrystalline) system is the primary focus. The nearly negligible volumetric variation of LTO allows for the examination of pressure changes specifically at the positive electrode. Using this system, we were able to monitor the impact of electrolyte particle size on the pressure variation. Moreover, a composite with polymer is studied to accommodate volume variation and reduce pressure variation at macroscale.
The ultimate goal of this research is to enhance our understanding of the intricate mechanisms involved in the electro-mechano-chemical coupling and the degradation processes within solid-state batteries.

Bioinspired Multifunctional Nanocomposites for Energy Storage Applications Ahmet Emre, Emine Turali-Emre and Nicholas A. Kotov; University of Michigan, United States

Bioinspired ion transport membranes have been extensively researched for energy storage applications. Sulfur, due to its natural abundance, low toxicity, high theoretical specific energy density (2600 Wh/kg), and high specific capacity (1675 mA/g), is attracting significant attention as an alternative battery system to replace traditional lithium-ion batteries that have limitations in terms of safety, capacity, and energy density in various applications. However, polysulfide dissolution and shuttling pose challenges that prevent the mass commercialization of metal sulfur batteries. We have developed a practical and comprehensive approach for developing high-performance metal sulfur batteries inspired by biological ion transport mechanisms. We used aramid nanofiber (ANF)-based composite ion transport membranes that prevent dendrite formation and confine polysulfides on the cathode side[1]. ANF composite battery separators provide diverse and opposing properties, including high mechanical properties, high ionic conductivity, and high thermal/chemical stability. These biomimetic separators have highly selective ion-sieving properties that make the batteries safe and high-performing. It is crucial to fabricate such biocompatible, affordable, flexible, and high-energy-density batteries to power next-generation EVs.

8:00 AM *ES06.07.01
Characteristic Analysis of Single Particle Cathode Materials for Sulfide-Based All Solid State Batteries Jiwon Jeong[1,2], Kyoung Eun Kim[1,3], Mingony Kim[1,3], Sang Ok Kim[1,3], Woo Young Yoon[2], Ji-Young Kim[1] and Kyung Yoon Chung[1,3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]KIST School, Korea University of Science and Technology, Korea (the Republic of)

All Solid State Batteries (ASSBs) have great attraction as next generation energy storage technology due to their nonflammable solid electrolytes (SE) and high energy density compare to commercial Li-ion batteries. However, there are still some issues that need to be addressed to move beyond lithium-ion batteries (LIB)..
One of the troublesome challenges is the unstable contact between active material and SE. A typical cause of unstable interface contact is unwanted side reactions between active material and SE. In particular, among solid electrolytes, sulfide-based solid electrolytes with high reactivity and a narrow operating voltage accumulate ions and electrons at the interface in contact with the cathode active material, causing many side reactions. In order to prevent such a side reaction, there have been an efforts to such as coating the surface of the cathode material with stable polymer, metal oxide, and lithium metal oxide.
Another cause of interfacial contact loss is volume change. Whether ASSB or LIB, volume changes occur due to intercalation and deintercalation of lithium in the active material. In particular, materials that achieve higher capacities have larger volume changes because more lithium is accommodated. For this reason, composite anodes containing high-nickel NCMs in ASSB exhibit rapid capacity decline because it is difficult to restore contact between the cathode and the electrolyte once separated. To suppress volume changes, various methods are used, such as controlling the shape of active materials, surface coating using hard materials, and improving the physical properties of solid electrolytes.
Here, we adopt a method of strengthening physical properties of a material and suppress volume changes by growing a cathode active material as a single particle. The single particle cathode material was synthesized by growing the primary particles of the polycrystalline cathode precursor into large sizes. For performance comparison based on physical properties, poly and single particle cathode material is applied to a sulfide based ASSBs. The details will be discussed at the meeting.

8:30 AM *ES06.07.02
Sulfide Solid Electrolyte for Lithium/Sulfide All-Solid-State Batteries Xiayin Yao[1,2]; [1]Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China; [2]Center of Materials Science and Optoelectronics Engineering, University of Chinese Academy of Sciences, China

All-solid-state lithium batteries are considered as the most promising next generation electrochemical energy storage devices because of their high safety and energy density[1]. Among all solid electrolytes, sulfide solid electrolytes have attracted increasing attention due to their high ionic conductivities and favorable interface compatibility with sulfur-based cathodes.

In the past decade, different sulfide solid electrolytes with room temperature ionic conductivity of 10^{-3} ~ 10^{-2} S/cm have been successfully synthesized. The moisture stability can be improved with oxide or halogen doping[2]. Besides, accroding to process of water molecule adsorption and dissociation reactions, LiF-coated core–shell solid electrolyte can reduce the adsorption site, thus resulting in superior moisture stability when exposing in moist air[3]. Meanwhile, the interfacial compatibility between solid elctrolyte and lithium anode can also be enhanced. In order to reduce the sulfide solid electrolyte particle size, a liquid/solid fusion technology is developed to synthesize high ionic conductivty sulfide solid electrolyte with reduced particle size[4]. Based on the high ionic conductive sulfide solid electrolyte powder, thin film can be obtained by cold press solid electrolyte with surface modification[5], dry film method[6] and wet coating approach[7]. The obtained $Li_{5.4}PS_{4.4}Cl_{1.6}$ sulfide solid electrolyte membrane possesses a high ionic conductivity of 8.4 mS cm^{-1} with a thin

thickness of 30 μm.[6] And the thickness of sulfide solid electrolyte film can be further reduced with relative high ionic conductivity above 1 mS cm^{-1}[7].

Due to similar chemical potential, sulfide cathodes show excellent interface compatibility with sulfide solid electrolytes. A series of transition metal sulfides or sulfur-based materials are employed as electrodes for all-solid-state rechargeable batteries based on intercalation/deintercalation and conversion reaction mechanisms. Nevertheless, transition metal polysulfides, such as FeS_2[8], VS_4[9], and MoS_6[10], exhibit typical anionic redox driven electrochemical processes. Combination of electronic conductive carbonecious materials and sulfide solid electrolyte coating can realize three-dimensional electronic/ionic conduction networks at the triple solid-solid contact interface. The well-designed transition metal polysulfide MoS_6 nanocomposite delivers a high reversible energy density of 1640 Wh kg^{-1} based on the active material at 0.1 A g^{-1}[10].

Although bright prospect of all-solid-state lithium batteries, there are still many challenges for their pratical application. More attentions should be concerned on the high ionic conductivity and high chemical stable sulfide solid electrolytes, reducing the solid electrolyte thickness, electronic/ionic conduction network construction in the electrode layer, high specific areal capacity as well as allievateing stress/strain and volume changes.

Iron Sulfides as High Energy Density Lithium Battery Cathodes Liping Wang[1], Zhendong Li[2], Jian Zou[1] and Hong Li[3]; [1]University of Electronic Science and Technology of China, China; [2]Tianmu Lake Institute of Advanced Energy Storage Technologies, China; [3]Institute of Physics, Chinese Academy of Sciences, Beijing, China

Conversion-type cathodes for lithium metal batteries are considered long-term targets due to their low cost and high energy density. However, they suffer from poor cycling life. In this talk, we present various interface engineering strategies, such as designing topotactic reactions and constructing a 3D ionic-electronic network to overcome this challenge. We demonstrate that micro-sized FeS_x cathode achieves an long cycling life at a high areal capacity (> 4 mAh/cm2) at high current rates. Meanwhile, we also demonstrate Li-FeSx pounch cell prototype with an energy density up to 390 Wh/kg at room temperature without adding external pressure. It reveals the potential of conversion cathodes, even in micro-size, for practical applications.

Irreversibility and Structural Distortion in Organic and Inorganic Fullerenes Arising from Electrochemical Cycling of Alkali-Metal-Ions. Arijit Roy, Sonjoy Dey, Shakir Bin Mujib and Gurpreet Singh; Kansas State University, United States

While large interlayer spacing allows for Na^+ and K^+ ion storage in transition metal dichalcogenide (TMD) based electrodes, side reactions, and volume change leading to pulverization of crystalline structure are persistent challenges for employing these materials in next-generation devices. Here in this study, we first investigate if irreversibility due to structural distortion resulting in poor cycling stability is also apparent in the case of quantum confined organic and inorganic (TMDs; such as MoS_2) fullerenes. To address these problems, we propose upper and lower voltage cut-off experiments to limit specific reactions. Differential capacity curves and derived surface plots highlight the continuation of reactions when a high upper cut-off technique is applied, indirectly suggesting the restriction of structural dissolution. Furthermore, structural preservation in half-cell electrodes during Li^+, Na^+, or K^+ storage delivered better capacity retention with stable performance and higher coulombic efficiency, laying the ground for future works.

4:00 PM *MF01.01.01
Biomaterials and Bioprinting to Enable Personalized Tissue Mimics Sarah C. Heilshorn; Stanford University, United States

Each individual is unique, yet pharmaceutical companies design the same therapies for all of us using lab mice. In the future, the biofabrication of personalized tissue mimics offers the exciting possibility of individualized therapies. However, current biofabrication methods are greatly hampered by a lack of materials that are simultaneously biofunctional and reproducible. A cell's behavior is directly influenced by its surrounding microenvironment; thus, ideally each cell type would be cultured in its own customizable biomaterial. To fulfill this need, my lab designs bespoke biomaterials that can be tailored to fit a range of applications. In one demonstration, I present a family of biomaterials that support the growth of patient-derived organoids, i.e. three-dimensional cell aggregates that demonstrate emergent, tissue-like behavior. While organoid cultures have the potential to revolutionize our understanding of human biology, current protocols rely on the use of Matrigel, a complex, heterogeneous material with large batch-to-batch variations. In contrast, our double-network hydrogels are formulated with recombinant biopolymers that can be fine-tuned to display a reproducible properties including printability. In a second example, I present a new "pick-and-place" 3D bioprinting strategy for the spatial positioning of organoids within a hydrogel support matrix. Using this method, we can fabricate large tissue structures composed of multiple organoids that fuse together. We demonstrate potential applications in the fabrication of neural "assembloids" composed of dorsal- and ventral-patterned neural organoids together with patient-derived brain cancer spheroids. We envision that these two technologies will be used together in the future to create personalized tissue models of individual patients.

4:30 PM *MF01.01.02
Orthogonal, Synergistic and Cooperative Precision Photochemistry for Multi-Wavelength Additive Manufacturing Christopher Barner-Kowollik[1,2]; [1]Queensland University of Technology, Australia; [2]Karlsruhe Institute of Technology, Germany

Over the last decade, our laboratory has employed monochromatic tunable laser systems to reveal a fundamental mismatch between the absorptivity of a chromophore and its photochemical reactivity in the vast majority of covalent bond forming reaction as well as specific bond cleavage reactions. Our data overturns the long-held paradigm that effective photochemical reactions are obtained in situations where there is strong overlap between the absorption spectrum and the emission wavelength. The lecture will demonstrate how a detailed action-plot driven precision mapping of photochemical reactivity enables the design of advanced multi-colour network formation and 3D printing modes with never-before-seen precision, exploiting wavelength orthogonal, synergistic, cooperative, and antagonistic photochemical reaction systems.

SESSION MF01.02: Advances in Light-Based Printing / Multimaterial Printing II
Session Chairs: Emily Davidson and Daryl Yee
Tuesday Morning, April 23, 2024
Room 325, Level 3, Summit

10:30 AM *MF01.02.01
Multimaterial Actinic Spatial Control (MASC) 3D Printing Andrew Boydston; University of Wisconsin–Madison, United States

Creation of multimaterial parts with complete 3-dimensional geometric freedom is a considerable challenge with potentially game-changing potential for manufacturing capabilities. Various approaches within the additive manufacturing and 3D printing communities have relied on equipment modifications that enable segregation of build materials and then selective deposition of different materials (from separate reservoirs) during printing. We propose a chemical approach to multimaterial parts fabrication that allows for a breadth of compositional diversity through orthogonal reaction mechanisms that can be mediated by different wavelengths of light. In this way, we are able to create multimaterial parts from single resin reservoirs (or vats) and control compositional gradients, heterogeneity, feature sizes, and colour without requiring complex compatibilization of vastly disparate build materials. Our published results already confirmed the ability to create soft-stiff materials combinations from a mixture of acrylate- and epoxide-based monomers. Our unpublished preliminary results have now confirmed the ability to create metallic components in the final parts, using photoredox catalysed reduction of soluble metal salts. Additionally, we have introduced some exciting resin features such as the ability to permanently alter colour through modulation of local pH via application of light, and a class of acrylate resin that produces soluble thermoplastics after photocuring. Specific targets of our program thus include: 1) creation of composite structures and open cell foams entirely via liquid-to-solid photocuring (no solids required in the resin feed), 2) creation of organic-inorganic combinations in multimaterial parts (e.g., circuitry, flexible electronics, antennae metamaterials), and 3) access to multicolor materials including custom camouflage patterns throughout a 3D part from a single resin composition.

11:00 AM MF01.02.02
Multi-Material Volumetric Additive Manufacturing of Hydrogels Using Gelatin as a Sacrificial Network and 3D Suspension Bath Morgan Riffe[1], Matthew Davidson[2], Gabriel Seymour[1], Abhishek Dhand[3], Megan Cooke[2], Hannah Zlotnick[2], Robert McLeod[1,1] and Jason Burdick[1,2,3]; [1]University of Colorado Boulder, United States; [2]University of Colorado-Boulder, United States; [3]University of Pennsylvania, United States

Volumetric additive manufacturing (VAM) is an emerging layerless method for the rapid processing of reactive resins into 3D structures, where printing is much faster (seconds) than other lithography and direct ink writing methods (minutes to hours). As a vial of resin rotates in the VAM process, patterned light exposure defines a 3D object and then resin that has not undergone gelation can be washed away. Despite the promise of VAM, there are challenges with the printing of soft hydrogel materials from non-viscous precursors, including into multi-material constructs. To address this, we used a sacrificial gelatin matrix to modulate resin viscosity to support the cytocompatible VAM printing of macromers based on poly(ethylene glycol), hyaluronic acid (HA), and polyacrylamide. After printing, gelatin and unreacted resin are removed by washing at an elevated temperature (37°C). These constructs are soft due to the low polymer concentration and would be difficult to print in other types of additive manufacturing. Cell viability of various cell types (bovine mesenchymal stromal cells (MSCs), chondrocytes, and meniscal fibrochondrocytes) was also confirmed over 7 days of culture with an average viability of 96.4%. To print multi-material constructs, the gelatin-containing resin is also used as a shear-yielding suspension bath (including high molecular weight HA to further modulate bath properties) where an ink (also containing gelatin and high molecular weight HA) with a different photoreactive monomer can be extruded into the bath to define a multi-material resin that can then be processed with VAM into a singular defined object. Multi-material constructs of methacrylated HA (MeHA) used as the bath and gelatin methacrylamide (GelMA) used as the ink are printed (as proof-of-concept) with encapsulated MSCs, where the local hydrogel properties define cell spreading behavior with culture. After 1 day of culture, the cells spread in the GelMA regions and stayed rounded in the MeHA regions, due to the adhesion ligands and degradability present in GelMA. In future studies, this process can be applied to tissue engineering to help recapitulate the heterogenous nature of complex tissues such as the meniscus.

11:15 AM ^MF01.02.03
Upconversion-Enabled Volumetric 3D Printing Dan Congreve[1,2], Tracy Schloemer[1,2], Sam Sanders[2], Qi Zhou[1], Arynn Gallegos[1], Hao-Chi Yen[1], Mahesh Gangishetty[2], Daniel Anderson[2], Michael Seitz[1,2] and Chris Stokes[2]; [1]Stanford University, United States; [2]Rowland Institute at Harvard University, United States

Triplet fusion upconversion, the manipulation of excited states in molecules to convert two low energy photons into one higher energy photon, has shown tremendous potential for a wide range of applications. Here, I will discuss how we can use this process to enable volumetric 3D printing, including the chemical, material, and optical designs required to do so and recent progress in pushing towards exciting applications.

11:45 AM MF01.02.04
Continuous Volumetric 3D Printing: Xolography in Flow Lucas Stüwe[1], Matthias Geiger[1], Franz Röllgen[1], Thorben Heinze[1], Marcus Reuter[2], Matthias Wessling[1,3], Stefan Hecht[4,2,3] and John Linkhorst[5,1]; [1]RWTH Aachen University, Germany; [2]XOLO GmbH, Germany; [3]DWI–Leibniz Institute for Interactive Materials, Germany; [4]Humboldt-Universität zu Berlin, Germany; [5]Technische Universität Darmstadt, Germany

Various printing techniques have emerged since Charles Hull's introduction of commercial 3D printing in 1980, with vat polymerization and technologies like stereolithography (SLA) and digital light processing (DLP) standing out with high resolution and fine surface finish. Despite impressive resolutions of up to 600 nm for SLA and about 75 µm for DLP, a fundamental trade-off between resolution and printing speed persists, limiting the applicability of 3D printing in high-throughput scenarios like scaffolds in bottom-up tissue engineering. For growing specific tissues on centimeter scale, millions of biocompatible building blocks with controllable micron-sized porosity are required to enable cell interpenetration and nutrient supply. Traditional AM methods that rely on the layer-by-layer approach, are not yet able to close the gap between high production rates and high resolution.
The next step in rapid additive manufacturing is represented by volumetric 3D printing, such as xolography. Unlike traditional layer-by-layer approaches, volumetric printing directly polymerizes a defined resin volume, allowing for arbitrary geometries while maintaining high resolution at rapid printing speeds. Xolography is a linear volumetric 3D printing method that utilizes dual-color polymerization for precise volumetric curing. A photoswitchable photoinitiator switches from a dormant to a latent state by illumination with the first wavelength in the UV-light spectrum. Upon illumination with the second wavelength, polymerization is initiated. Based on this principle, the polymerized volume can be set by projecting an image of the second wavelength onto a UV-light sheet. By moving the resin through the UV-light sheet and synchronizing a sequence of images with this movement, complex 3D geometries can be produced in seconds to minutes.
Xolography emerges as a possible choice for medical applications like tissue engineering, owing to its ability to achieve high printing speeds while maintaining high resolution, even with marginal photoinitiator concentrations (0.01wt%) - which can be a safety concern in biomedical contexts - and the use of high-viscosity resins, making it compatible with biodegradable high-molecular photopolymers.
In this study, Xolography is transformed from a batch process into a continuous fabrication method by vertically flowing resin through the UV-light sheet. The sequence of the projected images is synchronized to the resin velocity at the area of both intersecting wavelengths. The flow profile is visualized by computational fluid dynamic simulations. By designing a symmetrical flow cell with four inlets, the flow profile can be adjusted by the ratio of the volume flow through each inlet and is subsequently flattened in the intersecting area of both wavelengths for an enhanced printing resolution.
A second prerequisite for continuously printing objects via xolography is the circumvention of unwanted polymerization by the UV-light only. At increased radiant fluxes, polymerization occurs without the second wavelength. This is particularly the case at the glass-resin boundary where the resin velocity is reduced, and the radiant flux received by the resin is maximized. By integrating oxygen-permeable side windows to the flow cell, oxygen can

diffuse into the resin, quench the photoinitiator in the boundary layers and thus prevent unwanted curing.
With these modifications, the continuous xolography process achieves recognizable feature sizes of up to 10 µm in x/y and 25 µm in z-direction. Objects can be printed in parallel at a minimum object distance of 80 µm to utilize the entire printing area with constant resolution and print speed, showcasing the flexibility and potential for upscaling continuous volumetric 3D printing via xolography. This innovative approach closes the gap between high volume generation rate at high resolutions and holds great promise for biomedical applications.

SESSION MF01.03: Bioapplications
Session Chairs: Emily Davidson and Emily Pentzer

A Molecular Approach to Additive Manufacturing Medical Devices for Use in The Clinic Matthew L. Becker; Duke University, United States

The emergence of additive manufacturing has afforded the ability to fabricate intricate, high resolution, and patient-specific polymeric implants. However, the availability of biocompatible resins with tunable resorption profiles remains a significant hurdle to clinical translation. In this presentation, I will outline our strategies for synthesizing highly functional oligomeric resins that can be photochemically printed into a variety of structures possessing unique mechanical, chemical and degradation properties. I will also describe their use in a number of pre-clinical applications.

2:00 PM MF01.03.02
Materials Development for Additive Manufacture of Magnetic Resonance Imaging (MRI) Phantoms Brian Derby; University of Manchester, United Kingdom

Magnetic resonance imaging (MRI) is an important non-invasive probe used extensively for medical diagnostics. Phantoms are manufactured devices of controlled specific composition, dimensions and shape that are used for: instrument calibration, to provide common reference samples to allow the calibration of multisite research collaborations, they can act as replacements for human volunteers or live animal models during operator training or technique development. Additive manufacture is an attractive method for the production of phantoms with better physiological shape reproduction, if appropriate printable materials can be developed that provide the appropriate imaging contrast to mimic healthy and diseased tissue.
Phantoms are more difficult to develop for MRI applications than other medical imaging techniques, such as X-Ray or ultrasonic imaging, because the imaging contrast is provided by the relaxation times, T1 and T2) of the nuclear magnetic resonance excitation of protons in biological systems. These relaxation times (T1 and T2) in biological tissue are much longer than in conventional polymeric materials because of the presence of water and the soft matter gel nature of biological tissue. Hence, conventional MRI phantom materials are either aqueous solutions or weak gels of biologically extracted hydrogels such as agarose gels, carageens and alginates, possibly doped with paramagnetic ions to further tune the relaxation times. These phantoms have a very limited shelf-life and are normally formulated prior to use and disposed of afterwards. They are not particularly stable and the relaxation may be affected by the local environment, e.g. humidity, ambient temperature or oxygen pressure (altitude of the site).
Here we demonstrate a family of printable materials that have been developed using formulations of silicone resins that can access the T1 and T2 parameter space that encompasses most medically important organs and tissues. This tunability can be achieved using conventional silicone formulations and commercially available resins usi.ng simple variation of polymer and oligomer molecular weight and cross-linking density. A second strategy is also presented that uses a multiphase or composite approach with blends of immiscible materials. These formulations are shown to have the rheological properties appropriate for extrusion additive manufacturing methods. Simple demonstrator structures have been produced that show good imaging quality and stability.

2:15 PM MF01.03.03
3D Printed Core-Shell Structured Scaffolds with NIR-Triggered Dual Release for Cancer Therapy and Uterine Tissue Regeneration Shangsi Chen, Zhaohe Xu and Min Wang; The University of Hong Kong, Hong Kong

Gynecologic cancers and uterine fibroids can cause dysfunction of the uterus and hence result in female infertility. Various treatment options, including surgical resection, radiation therapy, chemotherapy and hormone therapy, are available for treating gynecologic cancers and uterine fibroids, aiming to restore fertility for women of the child-bearing age. Surgical resection is one of the most used treatments for cancerous tissues and uterine fibroids. However, insufficient clinical intervention can result in tumor recurrence, and the residual defective tissue after surgery can cause intrauterine adhesion (IUA) and further affect women's reproductive ability. Therefore, new and novel treatments that can effectively kill residual tumor cells and at the same time, regenerate new and healthy uterine tissues should be developed. In the current study, a dual drug/biomolecule release system, with the release being triggered by a near-infrared (NIR) laser that would deliver anticancer drug and biomolecules (for promoting uterine tissue regeneration) in a chronological manner, was designed and fabricated for the affected uterus. Specifically, gelatin (Gel) hydrogel/poly(L-lactide-*co*-trimethylene carbonate) (PLLA-co-TMC, "PTMC" in short) core-shell structured scaffolds with NIR-triggered dual releases of anticancer drug doxorubicin hydrochloride (DOX) and hormone estradiol (E2) were constructed via 3D printing for providing cancer therapy and for promoting uterine regeneration for postoperative females. DOX is a commonly used antineoplastic agent for treating many cancers and has been clinically used for uterine cancers. E2 is an estrogen steroid hormone extensively used to facilitate uterine regeneration. In our fabrication, Gel and DOX were homogeneously mixed first and 3D printed to form Gel-DOX scaffolds. E2-containing polydopamine (PDA@E2) microspheres were synthesized and homogeneously dispersed in PTMC-dichloromethane (DCM) solution. Gel-DOX scaffolds were then soaked in the PTMC-PDA@E2 solution for fabricating Gel-DOX/PTMC-PDA@E2 core-shell structured scaffolds. It was observed that the PTMC-PDA@E2 coating layer significantly enhanced mechanical properties of the scaffolds, making them comparably strong with the native uterine tissue. Furthermore, the coating layer protected the Gel-DOX core from rapid biodegradation and thus inhabited the burst release of DOX. Moreover, Gel-DOX/PTMC-PDA@E2 scaffolds could release DOX and E2 in a chronological manner, firstly delivering DOX together with photothermal therapy (PTT) to effectively kill Hela cells used in the *in vitro* experiments and then sustainably releasing E2 over 28 days of the experiment duration to promote uterine tissue regeneration. The *in vitro* experiments showed that DOX could be quickly released in 3 days and that the core-shell scaffolds exhibited excellent anticancer ability through the synergy of DOX release and hyperthermia cancer cell ablation. E2 via controlled release over the 28 days promoted the proliferation of bone marrow-derived mesenchymal stem cells (BMSCs) and induced their differentiation. The novel Gel-DOX/PTMC-PDA@E2 core-shell scaffolds have shown their high potential for postoperative management for female patients.

2:30 PM *MF01.03.04
An Ultrashort Aliphatic Self-Assembling Peptide Platfom Supports Automated 3D Bioprinting for Large-Scale Tissue Constructs and 3D Tissue

Differentiation Charlotte A. Hauser; King Abdullah University of Science and Technology, Saudi Arabia

Bioprinting is increasingly relevant for various applications in regenerative medicine. However, automated printing of stable large-scale constructs under physiological conditions with high shape fidelity and long-term cell survival are challenges that most existing bioinks cannot solve. Additionally, the required chemical or UV-cross-linking processes of current printing approaches compromise the encapsulated cells, resulting in restricted structure complexity. Rationally designed ultrashort self-assembling peptides are a promising class of biomaterials with different biomedical applications. We have rationally designed three self-assembling tetrapeptides as bioinks and demonstrated their potential for automated 3D bioprinting of large-scale cell constructs and their differentiation. The peptide bioinks overcome severe limitations in current bioprinting procedures, avoiding cell-compromising abrasive conditions such as chemical treatments or UV-cross-linking during the printing process. Using these peptide bioinks as a suitable body-like but synthetic material, we demonstrate an instant solidifying cell embedding printing process via a sophisticated extrusion procedure under true physiological conditions. Our printed large-scale cell constructs and the chondrogenic differentiation of printed mesenchymal stem cells point to the strong potential of the peptide bioinks for automated complex tissue fabrication.

Room 325, Level 3, Summit

3:30 PM *MF01.04.01
Solvent-Cast 3D Printing with Multi-Material Inks to Independently Control Biochemical and Physical Properties Lesley W. Chow; Lehigh University, United States

The biochemical and physical properties of a polymer-based biomaterial are commonly tailored to drive desired cellular responses for specific applications. However, modifying one property can lead to unwanted changes to another that make it difficult to fine-tune cell-material interactions. For example, surface chemistry can be controlled by changing composition, but this also impacts mechanical properties. Scaffold stiffness can be tuned without changing polymer type by changing porosity, but pore size and shape also affects cellular infiltration and nutrient and oxygen exchange. To address these challenges, we developed a versatile solvent-cast 3D printing platform using inks containing different polymer MW ratios and/or end-functionalized polymer conjugates to independently control surface chemistry, stiffness, and architecture. Blending different MW ratios of the same polymer allow us to change scaffold stiffness while the end groups of the conjugate become displayed on the surface during fabrication. In addition, using multiple printer heads enable us to spatially deposit different inks to organize biochemical and physical cues within the same construct. This talk will describe our platform and how we are 3D printing heterogeneously organized scaffolds to regenerate complex tissues like the osteochondral interface.

4:00 PM MF01.04.02
3D-Nanomaterials Printing for Tailorable Sensing and Flexible Electronics Rahim Esfandyarpour; University of California, Irvine, United States

Over the past decade, three-dimensional (3D) printing technology has fundamentally transformed traditional fabrication and manufacturing, particularly for micro-scale structures, models, and devices. Recent advancements in 3D printing, especially in the domain of nanomaterials, offer benefits such as ease of operation, cost-effectiveness, rapid prototyping, high resolution, and the capability to tailor designs and fabricate sensors customized to specific model requirements, individual needs, or disease diagnostics. Notably, with the rising emphasis on in-situ real-time health monitoring, the demand for wearable sensors is surging. However, to achieve widespread adoption of wearable biosensors for large-scale population monitoring, there's a need for swift, reliable, cost-effective, and high-throughput integration of these platforms.

In this study, we demonstrate our innovative approach to 3D printing of nanomaterials, successfully producing multiplexed, cost-effective, and mechanically flexible wearable bioelectronic sensing patches. These patches comprise 3D-printed nanomaterial-based flexible sensors and flexible wearable microfluidic sample-handling units, all integrated within just a few hours.

Further, we demonstrated the mechanical and electrical robustness of these patches under repeated bending cycles. We characterized the performance of the sensing units ex situ with various target ion samples across a spectrum of concentrations. Negative control experiments further showcased the patches' capability for selective ion detection. Additionally, we highlighted the potential of our 3D-printed nanomaterial patches for continuous health monitoring. This was evidenced by the simultaneous in situ monitoring of multiple ions (e.g., H+, Na+, K+, and Ca2+) present in sweat.

Our work represents a significant stride towards enabling personalized health monitoring practices, deploying 3D nanomaterial printing technology for the facile and affordable development of tailored, integrated wearable, and flexible biosensing platforms, optimized for the noninvasive and continuous monitoring of individual health parameters.

4:15 PM *MF01.04.03
Room-Temperature 3D Printing of Super-Soft and Solvent-Free Elastomers Christopher Bates; University of California, Santa Barbara, United States

This talk will discuss versatile strategies for designing new 3D-printable resins to efficiently access materials with unique properties.

4:45 PM MF01.04.04
Directed Self-Assembly of Thermoplastic Elastomers via 3D Printing for Mechanically Tailored Soft Architectures Alice Fergerson, Ben H. Gorse and Emily C. Davidson; Princeton University, United States

Many biological systems utilize self-assembled hierarchically ordered structures to achieve complex functional properties. However, current methods cannot scalably achieve this level of control over structure and function across multiple length scales in synthetic systems. Here, we make progress towards bridging this gap by demonstrating the use of material extrusion 3D printing to induce tunable alignment of a commercial cylinder-forming polystyrene-*b*-poly(ethylene-*co*-butylene)-*b*-polystyrene (SEBS) thermoplastic elastomer along a controlled print path. We demonstrate that the extent of nanostructure alignment and resulting anisotropy can be tuned via the shear and extensional forces applied to the material during 3D printing. In addition, we show that

post-printing thermal annealing plays a critical role in maximizing domain alignment via relaxation of trapped stresses. Ultimately, we have demonstrated the ability to induce up to 85x greater tensile modulus along the print direction compared to perpendicular to the print direction. By designing custom print paths for these soft and mechanically anisotropic materials, we enable fabrication of soft architectures with tailored macroscopic mechanical behavior such as controlled localization of strain upon deformation.

SESSION MF01.05: Poster Session I: Materials Development
Session Chairs: Alice Fergerson and Daryl Yee
Tuesday Afternoon, April 23, 2024

5:00 PM MF01.05.01
Development of Binding System for Metal Fused Filament Fabrication of AlSi10Mg Alloy Gustavo M. Delfino[1,2], Kaue R. dos Santos[1,2], Leandro J. de Camargo[3], Haroldo C. Pinto[2] and Tamires d. Nossa[1]; [1]Federal Institute of Education, Science and Technology - IFSP, Brazil; [2]University of São Paulo, Brazil; [3]Federal Institute of Education, Science and Technology of São Paulo - IFSP, Brazil

Additive manufacturing technology through 3D printing can efficiently produce parts with complex geometries using smaller, portable equipment. 3D printing plays a significant role in manufacturing polymer prototypes and products in various areas. One promising area of research involves incorporating metal powder into polymer filaments for 3D printing, aiming to expand the versatility of the technique and provide an alternative to conventional approaches such as Fused Filament Manufacturing (FFF). The binder polymer formulation plays a crucial role in the success of the manufacturing process. This study presents the development of a specific binding system for the 3D printing of AlSi10Mg filaments. The binder includes low-density polyethylene (LDPE) and thermoplastic starch (TPS). LDPE contributes to structural integrity during binder dissolution, reduces viscosity, and increases strength and stiffness. Meanwhile, TPS, besides being biodegradable, provides flexibility to the filaments. The study included an analysis of the shape and size distribution of metallic powder particles before their incorporation into the polymeric matrix. The composite filaments were produced using reactive extrusion (REX), being mechanically characterized and evaluated for their homogeneity. The reactive extrusion method demonstrated effectiveness in the production of homogeneous composite filaments in relation to the metallic filler incorporated into the thermoplastic polymer blend. Although extruded filaments exhibit inferior mechanical properties compared to thermoplastics generally used in FFF additive manufacturing, the method has potential for application in the manufacture of new composite filament compositions using LDPE and TPS blend matrix as a binding for application in 3D printing.

5:00 PM MF01.05.02
Different Strategies for Developing an Electrically Conductive and Flexible Composite by DLP 3D Printing Luca Montaina[1], Rocco Carcione[2], Francesca Pescosolido[1,3], Silvia Orlanducci[1], Silvia Battistoni[4] and Emanuela Tamburri[1,3]; [1]University Tor Vergata, Italy; [2]ENEA, Italy; [3]University of Tor Vergata, Italy; [4]National Research Council, Italy

Additive manufacturing (AM), or 3D printing, is one of the main elements in the development of Industry 4.0, which can increase plant productivity and improve product quality. Indeed, thanks to the layer-by-layer manufacturing approach, AM opens up the possibility of mass customization of products by achieving complex designs, with minimal material waste. However, despite the several advantages of AM, the widespread usage of this technology is still limited by several factors, such as surface finish, standardization, and lack of materials. In this context, the primary contribution of this work involves the design and synthesis of a flexible and electroconductive composite, being the flexibility and conductivity essential properties in various industries, spanning from electronics, to sensors, and wearable technology. In particular, we are focusing our research on different strategies for including a conductive polymer, i.e. polyaniline (PANI), into a poly(ethylene glycol) diacrylate (PEGDA) matrix by using a Digital Light Processing (DLP) [et1] 3D printer. Such printing technique typically makes use of a light to selectively cure a thin layer of a photosensitive ink. However, the 3D printing technology for CPs is still in its early stages and faces many challenges, mainly related to poor solubility and printability of CP systems. In this context, we report two different protocols for producing PEGDA-PANI items by means of a DLP 3D printer. In the first, an in-situ approach is exploited to synthetize PANI inside a printed PEGDA substrate, by combining 3D printing with a subsequent chemical oxidation process. Conversely, the second approach exploits the printer UV light to start the photopolymerization of aniline monomers directly during a PEGDA printing process. The PEGDA-PANI systems produced by both the methods show suitable morphological and structural features, as well as electrical and electrochemical performances, making them potentially useful for various soft electronics applications.
The two distinct production methods developed highlight the versatility and adaptability of 3D printing in producing electroconductive materials. Moreover, the possibility to produce flexible and customizable electronics provides broader implications for various industries, as an expanded list of available materials for AM opens doors to novel product designs and functionalities.

5:00 PM MF01.05.03
Material-Process-Property Relationships for Direct-Ink-Writing of Ceramic Matrix Composites Caitlin Grover[1], Irmak Sargin[2], Scott Beckman[1] and Arda Gozen[1]; [1]Washington State University, United States; [2]Middle East Technical University, Turkey

Ceramic matrix composites (CMCs) consist of a reinforcing secondary material phase within a ceramic matrix. These material systems can resist corrosive/oxidizing environments and have high hardness even at high temperatures. Among the two types of CMCs, ones featuring chopped fiber reinforcements offer simpler processing compared to the ones continuous fiber reinforcement systems. However, chopped fiber CMCs remain inferior to their continuous fiber counterparts in terms of mechanical and thermal properties [1]. This is primarily because the conventional processing methods generally lack control over the part microstructure and produce a randomly distributed reinforcement phase, limiting the achievable property enhancement. Emerging material extrusion-based additive manufacturing methods such as Direct-ink-writing (DIW) offer an exciting potential to address this issue. In DIW, highly viscous inks including ceramic matrix powders and reinforcing fibers are deposited layer-by-layer as they are extruded out of small capillaries. It has been shown that the high shear and extensional stresses experienced by the inks during this process can align the reinforcing particles along the printing direction [2,3], providing means to control final part microstructure.

This study aims to understand the material-process-property relationships for DIW of CMCs including aluminum oxide matrix and chopped silicon carbide fiber reinforcements. Here, we formulate inks by combing aluminum oxide powder and silicon carbide fibers with a liquid phase polymer which is a precursor to silicon carbide. Through a custom DIW print head with integrated capillary rheometry [4] capability, we characterize the shear rates experienced by the inks during the printing process. We then examine the density, microstructure and mechanical properties of the printed and sintered CMCs to understand the influence of the DIW process on these outcomes. We expand the analysis to cover various ink compositions and nozzle sizes to explore the key material and process parameters to achieve microstructural control.

5:00 PM MF01.05.04
Dehydration Methodology for Poly (ethylene glycol) Diacrylate Hydrogels Using Silica Gel Samaher Shaheen[1], Sam Lloyd-Harry[1], Ozgul Yasar-Inceoglu[1] and Ozlem Yasar[2]; [1]California State University, Chico, United States; [2]The City University of New York, United States

Poly (ethylene glycol) diacrylate (PEGDA) hydrogels have been proven to be a promising material in bone tissue engineering applications due to their remarkable capacity for the precise control of mechanical properties. The 3-dimensional structures of hydrogels play an important role in their biological efficiency and mechanical properties. Analysis of these nanoscale structures often requires the imaging of dehydrated hydrogels. The dehydration process is traditionally performed using freeze-drying or thermal techniques, which can be costly or cause damage to the nanostructures. This study uses silica gel to analyze a cost-effective dehydration methodology for PEGDA hydrogels. The 80% concentration hydrogels were prepared with an 85:15 PEGDA to PDMS volume ratio via sonication and subsequent UV light exposure. After photolithography, the weight and dimensions of the cured specimen were recorded. Then, a comparative dehydration study was initiated: one common method involving oven dehydration (190 to 200 F) and a narrative technique surrounding the specimen with dry silica gel beads inside a sealed container. Both dehydration methods were performed on multiple samples over (24, 48, and 72 hours). Post-dehydration, the specimens were measured and weighed. Characterization methods such as FTIR, SEM, XRD, Raman spectroscopy, compression testing, and hardness testing were performed. The preliminary findings of this study show that the silica gel method was more successful at preserving the 3-D structure and pore sizes than the thermal method. Furthermore, this study establishes that the silica gel dehydration method is a promising cost-efficient technique for preparing PEGDA hydrogel specimens for different types of analyses and can potentially extend the accessibility of tissue engineering materials research.

5:00 PM MF01.05.05
A Temperature-Dependent Framework of The Curing of Silicone Elastomers for Additive Manufacturing Te Faye Yap, Jasmine Klinkao, Anoop Rajappan, Marquise D. Bell, Barclay Jumet and Daniel Preston; Rice University, United States

Silicone elastomers offer a wide range of desirable mechanical properties, from extreme softness to high strain, that are not typically exhibited by additively manufactured parts. Direct ink writing (DIW) and vat photopolymerization (VP), two of the most commonly used layer-by-layer additive manufacturing methods for polymers, remain limited to materials with specific properties that allow for processing; for example, in DIW, the extruded inks should hold their shape post-printing, and in VP, photocurable thermosets are required. The additive manufacturing of parts from new materials, such as thermally polymerizable silicone elastomers, has only begun to be explored with layer-by-layer fabrication techniques, and the formation of elastomeric parts has largely remained limited to casting [1].

Development of new methodologies to allow for thermally polymerized silicone elastomers to enter the additive manufacturing design space must rely on a fundamental understanding of how temperature affects the rate of curing of these elastomers. Furthermore, the adhesion between layers in layer-by-layer printing processes must be well-understood. Recent work has shown examples of VP and DIW fabrication of parts using silicone elastomers, and the authors note the importance of considering the role of adhesion between layers in the performance of the final printed part; however, the adhesion strength between layers was not characterized or studied comprehensively [2, 3].

To facilitate development of future additive manufacturing processes, we developed an analytical model based on an Arrhenius framework that describes the rate of crosslinking as a function of temperature for commercially available platinum-catalyzed silicone elastomers. Our model, validated with experiments, serves as a guideline to determine the duration required for curing these silicone elastomers at any given temperature. For example, we show that the curing speed doubles with each ~10 °C increase in temperature. Furthermore, we highlight that the curing behavior exhibits self-similarity—using a nondimensional reaction coordinate, we can predict the extent of curing even for arbitrary spatiotemporal heating conditions. The nondimensional reaction coordinate serves as a powerful tool that allows us to study the adhesion strength between layers as a function of the curing time and temperature. Using the reaction coordinate, we are able to characterize the regimes where layer-to-layer adhesion would result in adhesive (versus cohesive) failure, and we can predict the adhesive or cohesive strength at different extents of curing. This work provides a framework to describe the relationship between temperature, the extent of the curing reaction, and the adhesion strength between layers, which will broaden the design space for the additive manufacturing of silicone elastomers and extend their processing beyond conventional casting.

Temperature Dependent Hygromechanical Behavior of Additively Manufactured Nylon (polyamide 6) and ULTEM (polyetherimide) Continuous Carbon Fiber Composites Madeline A. Morales, Bradley D. Lawrence and Todd C. Henry; DEVCOM Army Research Laboratory, United States

Fused deposition modeling (FDM) is used extensively for rapid prototyping with 3D printed thermoplastic materials. Nylon (polyamide 6) is a popular filament material; however, the mechanical properties are known to degrade in the presence of moisture and/or elevated temperature. In contrast, ULTEM (polyetherimide) has higher strength/stiffness and resistance to moisture/temperature but is more expensive. This work compares the impact of

hygrothermal conditioning on the flexural strength and modulus of Markforged Onyx (Nylon + chopped carbon fiber) and ULTEM 9085 samples with and without the addition of continuous carbon fibers printed using a Markforged FX20 3D printer. Samples for bend testing were conditioned at 90% RH at 22°C for 26 days, and mass/dimension increase was recorded. 3-point bend testing according to ASTM D7264 was conducted while varying temperature from 22°C (room temperature) to 50°C using an Instron load frame with an environmental testing chamber. The rate of flexural strength/modulus decrease with increasing temperature was compared for the four different materials (Onyx, Onyx + continuous carbon fiber, ULTEM, ULTEM + continuous carbon fiber) in the as-printed and conditioned state. Ductile vs. brittle failure mechanisms are discussed considering the polymer moisture content and microstructure. Fiber-polymer interfacial bonding is also discussed. The results will help inform end users of the optimal material to use given the operating load, moisture, and temperature conditions for their specific application.

5:00 PM MF01.06.01
Additive Manufacturing of 3D Microchambers for Cell Culture Aman Singhal[1], Tejas Y. Suryawanshi[1], Arun Jaiswal[2], Shobha Shukla[1] and Sumit Saxena[1]; [1]Indian Institute of Technology Bombay, India; [2]The University of Sydney, Australia

Two-photon polymerization (TPP) has been developed as a direct laser writing technique for the preparation of complex 3D structures with resolution beyond the diffraction limit. Its remarkable characteristics, such as precise 3D fabrication, sub-diffraction resolution, material flexibility, and mild processing conditions, have made it suitable for several applications in biosciences. One such application is the fabrication of microchamber scaffolds for cell culture, which are three-dimensional structures that provide mechanical support and a three-dimensional environment for cells growth and differentiation. Here, we report the fabrication of 3D square microchambers scaffold using TPP technique. Fabricated scaffolds are made up of microchannels and microchambers interconnected to create a porous structure that mimics the extracellular matrix (ECM) of natural tissues that can provide a suitable environment for cell growth and differentiation. These scaffolds can be used in tissue engineering and regenerative medicine applications.

5:00 PM MF01.06.02
Carboxymethylation of Silk Fibroin and Injectable Microgel Assembly Prepared from Thereof Yeonwoo Yu, Seonghyeon Jo, Yehee Lee and Ki Hoon Lee; Seoul National University, Korea (the Republic of)

Silk fibroin (SF) from silkworm cocoons is a fibrous protein and found its application in various fields such as tissue engineering, drug delivery, soft electronics, etc., owing to its biocompatibility. SF can be fabricated into various different forms, such as films, macro-to-nano fibers, scaffolds, and hydrogels. Among these forms, SF hydrogel can be made by physical and chemical crosslinking. Physical crosslinking of SF is based on the formation of β-sheet structure, which results in a brittle mechanical behavior of the hydrogel. On the other hand, chemical crosslinking of SF through enzymatic crosslink or photo-crosslink results in elastic SF hydrogel. In 3D printing, various kinds of natural polymers are used as ink, and, in many cases, 3D constructs are formed upon the gelation of the polymer right after its extrusion. SF was also considered as a candidate natural polymer in 3D printing, but the inherent low viscosity of SF aqueous solution and its slow gelation kinetic were the technical hurdles. Therefore, blending with other 3D printable polymers or introducing photo-crosslinkable functional groups were suggested as a solution for SF. Meanwhile, microgel assembly has been applied in the 3D printing field. Microgels can be assembled into a macro-sized hydrogel through various interactions between the microgel particles. If the microgel assembly was formed by a reversible dynamic bonding, such microgel assembly can flow upon shear stress and recover back into a viscoelastic solid state when the stress is removed.
The aim of this study is to prepare a suitable SF microgel assembly for 3D printing. Many previous studies have been reported on preparing SF microgels, but they had to dissolve the SF fiber. However, large amounts of chemicals are required during this dissolution, and time-consuming dialysis should be followed. We have skipped this step by conducting direct modification of SF in its fiber state. Carboxymethylation was performed directly on the SF fiber, which resulted in a rod-like microgel. The carboxymethylation has been done primarily on the tyrosine of SF. The negative charges of carboxymethyl groups allowed high water uptake and swelling by the repulsive forces, but the dissolution was prevented by the intact β-sheet structure working as a physical crosslinker. By controlling the concentration and the degree of carboxymethylation of SF microgel, optimum conditions for microgel assembly formation were established. Rheological studies confirmed the injectability of SF microgel assembly, in which gel-like behavior under a low shear rate but flowability under a high shear rate. Finally, we have successfully built a standalone 3D construct of SF microgel assembly by extrusion 3D printer. The prepared SF microgel would have high potential in tissue engineering, and enhancing the structural stability of the 3D construct of SF microgel is currently underway.

Optimizing Collagen Bioprinting for Mechanically Strong and Resilient Ligament/Tendon Engineering Grace Hu[1], Karla Cebrero[2], Nandita Venkataraman[2], Zeqing Jin[2], Zev J. Gartner[1,3,4] and Grace Gu[2,1]; [1]University of California, Berkeley & San Francisco, United States; [2]University of California, Berkeley, United States; [3]University of California, San Francisco, United States; [4]Chan Zuckerberg Biohub, United States

Ligaments and tendons coordinate and stabilize our body's movement, but damage to these soft tissues has been an enduring problem accounting for 30% of musculoskeletal clinical cases every year.[1] While athletes who play contact sports are most commonly prone to sprains or ruptures of the anterior cruciate ligament (ACL), people can experience ligament and tendon injuries through falls, twists, or overuse. Traditional surgical interventions involve graft replacement from elsewhere in the patient's body, which often requires months of recovery and fails to achieve enthesis healing or true regenerative capabilities. Promisingly, the development of synthetic biomaterials that mimic the native hierarchical structure of ligaments/tendons can facilitate tissue repair.[2]
The overarching goal of our work is to optimize how type I collagen, the main component of tendons and ligaments, can be 3D-printed to serve as artificial implants. Our novel approach combines both a computational and experimental framework to iterate upon the bioprinted collagen. Numerical simulations are first implemented to characterize the swelling behavior of collagen, which are then compared to experimental testing.[3] With an eye towards translation and ease-of-use, we utilize the commercially-available CellInk BioX bioprinter to control infill density, concentration, nozzle diameter, and heating duration throughout printing, observing vastly different mechanical properties in the resultant hydrogels. Secondly, we aim to fabricate gradient materials with directionally varying stiffnesses so that the printed collagen can achieve enhanced integration as a connective tissue. Overall, this synergistic approach will enable customizable, on-demand printing of ligaments and tendons for regenerative medicine.

Stimuli-Responsive Microscale Mechanical Logic Abhinav Parakh, Caitlyn C. Krikorian (Cook), Elaine Lee and Widianto P. Moestopo; Lawrence Livermore National Laboratory, United States

To overcome the operational limitations of conventional electronics, equivalent logic circuits composed of precisely fabricated mechanical systems have shown promise as a viable alternative. Here, we develop microscale, battery-free mechanical sensors in which stimuli-responsive materials are paired with micro-scale mechanical circuits to enable high mechanical computing power within a sensor system. We utilize additive manufacturing with micron-scale precision to fabricate structures that respond to thermal and chemical changes, and we perform computation by applying these stimuli. By integrating multiple stimuli-responsive actuators to mechanical logic gates, we demonstrate proof-of concept computation of environmental cues in the microscale without electrical power. Our exploration of signal propagation dynamics in microscale mechanical logic circuits actuated by materials with different stimuli responsivity will accelerate the development of smart, active, and sentient materials that can interface with extreme environments and respond to external changes without needing batteries. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 (LLNL-ABS-850674). Support from LDRD Exploratory Research 22-ERD-030 and LDRD Feasibility Study 24-FS-018 are gratefully acknowledged.

5:00 PM MF01.07.02
Investigation of Mechanical Performance of Composites Based on 'Hat' Aperiodic Monotile Structures Jiyoung Jung, Ailin Chen and Grace Gu; UC Berkeley, United States

Disordered structures, as oftentimes found in nature, have the potential to have unique behaviors and higher mechanical performance in terms of stiffness, strength, and toughness compared to ordered structures. However, such a disordered structure increases the complexity of design and fabrication process, which can be resolved if the infinite plane can be aperiodically covered with a single unit cell (i.e. aperiodic monotile). With the long efforts of the mathematics community, a hat-shaped aperiodic monotile structure was recently discovered. This study proposes new composite designs using an aperiodic monotile structure and investigates mechanical performance and mechanisms. For tensile loading, aperiodic monotile composites consisting of stiffer material for core areas and softer material for boundaries are considered varying volume fractions of each phase. On the other hand, for compressive loading, the composites composed of stiffer material forming boundaries and softer material as filling are examined with different size of unit cells. The specimens are fabricated using multimaterial polyjet additive manufacturing processes. To probe further into the mechanisms, phase field modeling based fracture simulations are conducted for tensile loading cases and explicit dynamic fracture simulations are conducted for compressive loading cases. Simulations show that aperiodic monotile structure enables high strength and toughness compared to a honeycomb structure under tensile loading. In addition, the aperiodicity of the aperiodic monotile structure allows superior performance under compression compared to the periodic structure. This study shows that the aperiodic monotile composite structure can be next generation of composite structure showing superiority to other conventional composite structures in terms of stiffness, strength, and toughness.

5:00 PM MF01.07.03
Xerographic 3D Printing with Periodic Patterns Hyung Ju Ryu, Hadi Moeinnia, Omar Nemir, Sami Khan and Woo Soo Kim; Simon Fraser University, Canada

3D Printing, a form of additive manufacturing (AM) has gained widespread popularity for the fabrication of intricate structures. It is recognized as an innovative solution to overcome the limitations associated with traditional subtractive manufacturing methods. It also offers cost efficiency, design flexibility, rapid prototyping, and environmentally friendly attributes. In this research, we explore the Xerographic 3D printing method. The objective is to fully harness the potential of AM, capitalizing on the high productivity of the well-established Xerographic 2D digital printing techniques. In addition to the core electrostatic interactions underpinning the Xerographic dry copying process, our work introduces hydrophobic interactions between fluoropolymer particles and interim and final substrates, thus contributing to the formation of 3D structures by a transfer method. To implement this approach, we use a surface micro-texturing technique to create periodic structures on metal substrates followed by surface functionalization, which subsequently impacts hydrophobic properties. Thus, our research reveals that the supplementary hydrophobic effects substantially improve the fidelity and precision of 3D structures produced through Xerographic 3D printing. Our study is poised to advance the utilization of Xerographic 3D printing by providing a more efficient avenue for 3D structure fabrication while also deepening our understanding of the interaction mechanisms within the Xerographic setup.

5:00 PM MF01.07.04
Materials Design guided by Defects in Liquid Crystals Jeremy R. Money[1], Fakhreddin Emami[1], Andrew Gross[1], Jose A. Martinez-Gonzalez[2] and Monirosadat Sadati[1]; [1]University of South Carolina, United States; [2]Universidad Autónoma de San Luis Potosí, Mexico

Architected cellular materials represent a growing body of materials research encompassing a broad classification of materials, from open celled foams to sheet-based lattices. Comprised of unit cells of varying geometries and tessellation patterns, these material systems give rise to unique properties attributed primarily to their unit cell geometry as opposed to their bulk material chemistry. Enabled by additive manufacturing technologies, architected cellular materials are increasingly making their way into commercial design and production, offering solutions to many challenges faced by industries such as biomedicine and personal protective equipment and energy. However, additional barriers to ubiquity such as the stiffness/toughness tradeoff of lattice based architected cellular materials present opportunities for the development of novel unit cell geometries with tunable topological features. Current areas

of design inspiration are drawn from the intricate patterns displayed by nature or solid atomistic crystals. However, the opportunity for novel approaches to unit cell design presents a frontier ripe for exploration.

One such approach exists in the study of the behavior of liquid crystals and their interpenetrating networks of defects or disclination lines. This fascinating state of matter possesses the long range orientational ordering of solid crystals while retaining the fluidlike properties and response to confining geometries possessed by liquids. These material systems exhibit self-assembly of their constituent molecules, or mesogens, into interesting mesostructures which pack together forming 3D periodic arrangements. This behavior has been extensively investigated for its optical response; however, little is understood about the mechanical properties of the resultant disclination architectures. Through utilization of Landau-de Gennes guided simulations, these architectures can be readily predicted at the nanoscale and then upscaled for design and fabrication as promising candidates for architected cellular materials. Of the unique geometries which arise from the disclination arrangements in liquid crystal systems, is the interpenetrating double diamond lattice that shows promise for structural applications. Study of the mechanical response of these geometries indicate potential toughening mechanisms induced by contact between the bicontinuous lattice networks. In addition to its variable strut diameter and reinforced nodal regions, the relative density of these structures can be adjusted rapidly using the liquid crystal's scalar order parameter. The exploration of these disclination lattices offers a promising avenue for the enhancement of architected cellular materials, with tunable design parameters unique to the behavior of liquid crystal systems.

Dual-Function Hydrogel-Based Smart Wearables: AI-Driven Temperature Responsiveness & UV Index-Indicative Color Monitoring Mohamed Elnemr and Haider Butt Butt; Khalifa University of Science and Technology, United Arab Emirates

The integration of smart wearable technology with daily life necessitates materials that are not only responsive but also robust and user-friendly. This work introduces an advancement in smart wearables crafted from hydrogel composites, employing Digital Light Processing (DLP) 3D printing to achieve a level of durability comparable to conventional plastics. The enhanced hydrogels uniquely incorporate thermochromic & photochromic capabilities, allowing for a dynamic color response to temperature & UV light variations.
These color transitions are not merely aesthetic; they are intricately linked to an artificial intelligence (AI) model specifically trained to decode these hues into precise temperature measurements, providing a non-invasive method for monitoring personal thermal environments. In contrast, the photochromic aspect of the wearables acts as a visual sentinel against UV exposure, autonomously signaling when protective measures are advisable, bypassing the need for AI intervention.
These transformative hydrogel wearables challenge existing perceptions of material capabilities. With direct colorimetric feedback for UV protection and AI-assisted temperature monitoring, they offer practical, immediate environmental responsiveness in a user-friendly format.

5:00 PM MF01.08.02
Manufacturing Electrostatic Chucks via Ceramic 3D Printing: Formulation of Photopolymer Resin and Simulation-driven Structural Optimization Munseong Kim, Jihoon Kim and Sukeun Yoon; Kongju National University, Korea (the Republic of)

The electrostatic chuck is utilized to hold objects such as silicon wafers and LCDs securely. As advancements in related industries continue, research interest in electrostatic chucks is on the rise. Traditional manufacturing processes for these chucks primarily rely on APS (atmospheric plasma spraying) coating, a method that poses limitations in shape flexibility and consumes high energy. To overcome these challenges, this study introduces a method employing photopolymerization 3D printing, which combines ceramics with photopolymer resins. This 3D printing technology stands out for its exceptional precision and rapid production speeds. By integrating ceramic composite resin, it not only allows for the emulation of the physical properties of various ceramic materials but also vastly enhances design flexibility. To produce a ceramic composite resin tailored for photopolymerization 3D printing, a photopolymerization resin was formulated using two monomers: 1,6 hexanediol diacrylate (HDDA) and Trimethylpropane triacrylate (TMPTA). The resin's printing attributes and performance were assessed by monitoring the curing properties in response to varying monomer ratios. Following this, BaTiO3 (BTO) powder was added in concentrations ranging from 0 to 30 vol.% to the best-performing resin to create a high dielectric constant BTO photopolymerization resin. To determine the optimal wavelength by evaluating the printability of the manufactured resin according to the optical characteristics of BTO, the curing characteristic behavior was analyzed according to the changes in the three wavelength bands of 385nm, 405nm, and 415nm. The dielectric properties of the 3D-printed BTO composite layers were evaluated to optimize the BTO content for peak dielectric performance, emphasizing both a high dielectric constant and breakdown strength. Based on this material insight, bipolar-type electrostatic chuck models were designed. Their structural optimization and corresponding chucking performance were enhanced using finite element analysis through COMSOL. In this study, by applying ceramic composite resin to photopolymerized 3D printing technology, we were able to fabricate electrostatic chucks with exceptional chucking performance through 3D ceramic printing.

5:00 PM MF01.08.03
Development of Conductive Aerogels for DLP-3D Printed Sensors Diana Cafiso[1,2], Federico Bernabei[1,3], Matteo Lo Preti[1], Ignazio Roppolo[2], Candido Fabrizio Pirri[2] and Lucia Beccai[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Torino, Italy; [3]Scuola Superiore Sant'Anna, Italy

The growing demand for versatile soft sensors has propelled the research on novel materials and the use of technologies that ensure broad design flexibility, e.g., 3D printing [1]. Digital Light Processing (DLP) 3D printing is a promising approach for fabricating sensors with elaborate and scalable architectures due to the excellent resolution of the printed structures [2]. Still, developing printable and deformable materials is mandatory to fully harness the advantages of this technology for soft sensing.
In this work, we combined DLP 3D printing and lyophilization to manufacture conductive and soft aerogels featuring intricate morphologies. Hydrogels made of an insulating Polyethylene Glycol Diacrylate (PEGDA), poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT: PSS) and a photoinitiator were 3D-printed via DLP. Subsequently, the hydrogels were lyophilized to obtain conductive aerogels. The dual-step process limited the collapse of the printed samples during the solvent removal, leading to the fabrication of aerogels possessing elaborate 3D geometries with a remarkable resolution of 200 µm.
The aerogels' electrical, morphological and mechanical properties could be finely controlled by adjusting the chemical composition of the precursor hydrogels. The content of PEDOT: PSS was changed from 50%wt to 10%wt, and samples with tunable electrical conductivity were successfully fabricated.

The solvent ethylene glycol was used to further decrease the electrical resistivity from 70 kΩ*cm to 35 kΩ*cm. Moreover, SEM analysis of the obtained aerogels revealed a closed-cell porous morphology. The porosity increased with the amount of PEDOT: PSS from 58% to 96%, and the size of the pores ranged from 5 μm to 60 μm. The adjustable porosity played a crucial role in enhancing the deformability of the material and in tailoring the elastic modulus from 0.26 kPa to 1 MPa. Moreover, the softer aerogels endured repeated loading and unloading cycles.
A reactive diluent was added to the formulation to optimize the material's properties for force-sensing applications. The decrease in the crosslinking density and the formation of larger pores improved the deformability of the so-modified aerogels. Consequently, the electrical resistance under the application of compressive force decreased, demonstrating the suitability of these aerogels for the development of 3D force sensors. Different porous aerogel architectures were fabricated and tested, revealing the influence of the geometrical features on force sensitivity and paving the way for soft sensors with programmable design and performance.
Finally, despite their hydrophilicity, the samples exhibited remarkable stability upon humidity (up to 70% of relative humidity), proving their suitability for various working environments.
These results highlight the potential of the proposed material for developing 3D-printed soft structures with tailorable architectures and electro-mechanical properties, thus offering significant opportunities and versatility for soft sensing.

5:00 PM MF01.08.04
Adaptive 3D-Printed Pressure Sensor Hadi Moeinnia, Danielle Agron and Woo Soo Kim; Simon Fraser University, Canada

Pressure sensors have garnered considerable attention across a range of domains, including robotics, healthcare, and sports applications. Various pressure sensor designs have been proposed to enhance sensitivity and broaden the pressure detection spectrum. Nonetheless, creating a highly sensitive sensor capable of accommodating a wide range of pressure loads often demands the use of specialized clean rooms and costly equipment. In this study, we introduce a fully 3D-printed architectural pressure sensor equipped with a shape programmability feature. Leveraging the customizable 3D design capabilities of 3D printing, we fabricate pressure sensors tailored to individual patients. The pressure transduction mechanism relies on capacitance. Both experimental and simulation results affirm the precise adjustability of the sensor's detection range, spanning from 70 to 2,500 kPa. Sensitivity levels range from 0.01 1/kPa to 0.0002 1/kPa, with a remarkable response time of 800 milliseconds. Importantly, the cost of fabricating the entire sensor is under 5 cents per unit. The 3D architecture pressure sensor can be deployed in an array configuration for pressure mapping purposes, making it valuable in biomedical and robotic applications.

5:00 PM MF01.08.05
Controlling Dielectric Constant and Breakdown Voltage for Optimizing Chucking Force in 3D-Printed Electrostatic Chucks: A Combined Simulation and Experimental Investigation Yujin Kim, Jihoon Kim and Sukeun Yoon; Kongju National University, Korea (the Republic of)

Electrostatic chuck (ESC) is used to adsorb objects such as semiconductor wafers and LCD panels using electrostatic force and is attracting great attention as a device that can compensate for the shortcomings caused by mechanical clamps or vacuum chuck. The ESC is composed of an insulating layer (body), a dielectric layer, and an electrode in which the electrode is formed in a bi-polar type and interdigitated pattern. The chucking force is known to be enhanced by maximizing the dielectric constant and breakdown voltage of the dielectric materials. However, it is difficult to find a single material that simultaneously exhibit both required characteristics. In this study, distinct materials were selected for the body and dielectric layer of the ESC. Two different ceramic composite resins were formulated by varying the contents of $BaTiO_3$ (BTO) and Al_2O_3 (Alumina) between 0 to 30 vol% within a photocurable resin. BTO, which has a relatively high dielectric constant ($\varepsilon_r \sim 23$) but a lower breakdown voltage (7 kV/mm), was used for the dielectric layer. In contrast, alumina, with a lower dielectric constant ($\varepsilon_r \sim 6$) but a higher breakdown voltage (43 kV/mm), was chosen for the body. Using the DLP (Digital Light Process) 3D printing technique, a body comprising alumina with an interdigitated electrode pattern was created. Subsequently, this body was coated with a dielectric layer composed of BTO. The structural dimensions of the ESC were optimized through finite element simulation (COMSOL) to achieve the maximum chucking force. The simulation result and the measured chucking force of the fabricated ESC were compared and analyzed. The ESC made of a combination of alumina (body) and BTO (dielectric layer) exhibited superior performance compared to ESCs made solely of alumina or BTO for both body and dielectric layer. Additionally, these findings were consistent with the simulation results. In this study, using FEA-optimized structures and selective material choices, we successfully fabricated an ESC through 3D printing methods.

5:00 PM MF01.08.06
Printing of Micro-Lens Encapsulation Using Siloxane/Silica Nanocomposites for Highly Efficient Micro Light-Emitting Diode Arrays Byung Jo Um, Hyungshin Kweon, Junho Jang and Byeong-Soo Bae; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Nowadays, micro-scale light-emitting diodes (μLEDs) have attracted tremendous attention as next-generation displays. Encapsulating materials are essential to protect μLEDs from external environments and to increase light extraction efficiency (LEE) [1]. Conventional encapsulating materials face challenges in terms of thermal stability, and refractive index, limiting the long-term reliability and efficiency of μLEDs [2]. To overcome these challenges, highly stable siloxane hybrid materials containing phenyl groups have been studied, suggesting that the phenyl group can improve optical performance [3]. In addition, lens-shaped encapsulation has been identified as a way to increase the light extraction efficiency of Chip-On-Board LEDs, but the existing method is complicated such as manufacturing unique supports on the substrate, making it difficult to apply to μLEDs [4].
Herein, we have developed the highly stable μLED encapsulating material with high refractive index (RI) and thixotropic index (TI), which greatly improved LEE and reliability of μLED. To obtain μLED encapsulating material, we fabricated phenyl-based siloxane hybrid (PSH) of thermal-induced hydrosilylation reaction of sol-gel synthesized linear vinyl-phenyl siloxane (LVS) and linear hydrogen-phenyl siloxane (LHS) resins. By using two phenyl-based siloxane resins, we can induce the high phenyl group contents in matrix, which lead to high RI of matrix. Polydimethylsiloxane-terminated hydrophobic fumed silica nanoparticles (FSNs) were dispersed in PSH that act as giving thixotropic properties for the formation of lens-shape and inducing scattering effect for the increment of LEE. We studied trade-off relationship among optical transparency, thermal stability, and TI of PSH by varying amount of FSN in matrix. Through optimization of FSN contents in PSH, we achieved excellent optical and rheological properties (RI: ~1.59 @ 486 nm, and TI: 3.96 from 0.1 to 100 s^{-1}) of PSH with 1.5wt% of FSN. Furthermore, the fabricated PSH with 1.5wt% of FSN showed the high thermal stability at 130 °C for 700 hours. After encapsulating μLED arrays with PSH@FSN, the optical performance improved by 29.86% compared to the bare μLED arrays. Furthermore, we confirmed the reliability of PSH@FSN-encapsulated μLEDs under 85 °C/85% relative humidity, which exhibited almost similar luminous flux (86.4% retained) after 60 days aging.

Wednesday Morning, April 24, 2024
Room 325, Level 3, Summit

8:30 AM MF01.09.01
3D Printed Stretchable Soft Electronics with Metamaterials-Inspired Electromagnetic Architecture LeiBin Li, Dwipak Sahu, Jared Anklam, Samuel H. Hales, Samannoy Ghosh and Yong Lin Kong; University of Utah, United States

The integration of electronics with soft and stretchable materials can enable active functionalities on the otherwise passive constructs. Previous works have demonstrated exciting success in imparting stretchability with geometrical designs but often require challenging microfabrication processes. Here, we propose a 3D printing approach that can create freeform electronics by selectively annealing micro-extruded nanomaterials *in situ* using a metamaterials-inspired electromagnetic architecture. This enables the creation of microscale three-dimensional interconnects and electronics with a desktop-sized platform that can resist strain and flexing – allowing the integration of stretchable active components on a soft substrate. We are also studying the integration of printed electronics into a broad range of soft materials by leveraging soft matter physics phenomena. Overall, we envision that this approach can enable new fabrication methodologies that lead to strategies that not only improve device compatibility and durability but also enable new classes of 3D-printed soft electronics.

8:45 AM MF01.09.02
3D Printing of Polyvinyl Alcohol Hydrogels (PVA) Enabled by Aqueous Two-Phase System (ATPS) Michinao Hashimoto; Singapore University of Technology and Design, Singapore

The synthesis of PVA hydrogels (PVA-Hy) requires a high-concentration alkali solution (*e.g.*, sodium hydroxide, NaOH, 4.2 M), and the rapid physical crosslinking of PVA makes it challenging to ensure layer-to-layer adhesion for 3D printing. This work demonstrated the three-dimensional (3D) printing of PVA hydrogels in benign conditions (NaOH, 0.3 M) using a two-phase system (ATPS). Salting out of PVA to form ATPS allowed temporal stabilization of 3D-printed PVA structures while it was physically crosslinked by moderate alkaline conditions. Crucially, the layer-by-layer printing of PVA was enabled by delayed reaction at low alkaline concentrations. To verify this principle, we studied the feasibility of direct ink write (DIW) 3D printing of PVA inks (5 – 25% w/w, m = 0.1 – 20 Pa s, and MW = 22000 and 74800) in aqueous embedding media offering three distinct chemical environments: (1) salts for salting out (*e.g.*, Na_2SO_4), (2) alkali hydroxides for physical crosslinking (*e.g.*, NaOH), and (3) mixture of salt and alkali hydroxide. The presence of the salt did not compromise the stretchability and durability of PVA-Hy. Overall, our method demonstrated a unique concept of embedded 3D printing enabled by ATPS for temporary stabilization of the printed structures to facilitate 3D fabrication.

9:00 AM MF01.09.03
A Digital Exploration of The Mechanical Property Space of Self-Stabilizing Dynamic Printable Foams Brett A. Emery[1], Daniel Revier[2], Kelsey Snap[3], Jeff Lipton[1] and Keith Brown[3]; [1]Northeastern University, United States; [2]University of Washington, United States; [3]Boston University, United States

Foams are versatile by nature, and are used ubiquitously in applications ranging from padding and insulation to acoustic dampening. Previous work established that foams additively manufactured via Viscous Thread Printing (VTP) are capable of enabling a greater degree of control over many of the key mechanical properties of conventional foams such as Young's modulus, fracture characteristics, and toughness while eliminating the need for chemical foaming agents. However, the relationship between input parameters and output properties is currently only accomplished via iterative empirical testing which limits generalizability and predictive control of desired output properties. Our work addresses this by combining high-throughput automated experimentation with machine learning to identify a subspace able to predict material behavior down to the stress-strain curve level. We identify a self-stabilizing microstructure trend in the VTP process, amplifying confidence in achieving desired output properties. Evidence for this self-stabilization is demonstrated by introducing various print height perturbations during the print process and measuring layer thickness as a function of the number of layers before restitution. This predictive mapping was developed utilizing data collected from thermoplastic polyurethane (TPU) specimens before being generalized by applying assumptions inherent to filament-based additive manufacturing to VTP's core physical models. This generalization was then validated using polylactic acid (PLA) and Nylon suggesting inherent compatibility with any material suitable for filament-based 3D printing.

9:15 AM MF01.09.04
Temperature-Responsive Dynamic Granular Hydrogels for 4D Printing Applications Keisuke Nakamura, Nikolas Di Caprio and Jason Burdick; CU Boulder, United States

4D printing is an emerging technology to fabricate dynamic objects that can change their shape and properties in response to external stimuli (e.g., temperature). Such 4D printed materials have a wide range of potential applications, including soft robotics, active drug delivery systems, and pharmaceutical models. Granular hydrogels, comprised of jammed microgels, are promising as 3D printable materials due to their shear-thinning and self-healing properties, as well as unique micropore structure. By introducing stimuli responsiveness (e.g., volume transitions) into individual microgels, we anticipated that printed granular hydrogels would exhibit dynamic macroscopic and micropore structures; such dynamic granular hydrogels remain largely unexplored. To investigate this, we developed temperature-responsive microgels and assembled them into granular hydrogels to explore their application for 4D printing. Specifically, temperature responsiveness was achieved by crosslinking norbornene-modified hyaluronic acid (NorHA) with dithiol-terminated poly(N-isopropyl acrylamide) (DTPN) via a thiol-ene reaction, which showed a low critical solution temperature (LCST) transition. To form microgels, an emulsion of NorHA, DTPN, and photoinitiator was formed in stirring mineral oil and crosslinked via UV irradiation, which produced microgels with an average diameter of ~155 μm at room temperature (rt) after washing from the oil. Microgel diameters decreased by ~20% when heated (41°C), which was reversible when cooled back to rt. Granular hydrogels were prepared by centrifuging microgels, with structures exhibiting porosity and pore sizes of ~18 % and ~5360 μm^2, respectively, at rt. The porosity and the pore sizes significantly increased (~28 % and ~10300 μm^2, respectively) when heated (41°C), presumably due to microgel shrinkage and disconnection. To enhance the stability of granular hydrogels toward 4D printing, inter-particle photocrosslinking was introduced using a tetra-arm PEG thiol in the presence of a photoinitiator and light. Post-crosslinked granular hydrogels were stable and exhibited a bulk volume decrease by ~23% when heated. Interestingly, unlike granular hydrogels without post-crosslinking, increased temperatures reduced pore sizes (5848 μm^2 to 4283 μm^2) within post-crosslinked granular hydrogels. This is likely because there is no disconnection between the covalently crosslinked microgels during heating, resulting in isotopic shrinkage of micropores. Finally, control granular hydrogels (i.e., non-responsive to

temperature) were used as suspension baths (i.e., shear-yielding and self-healing materials) to receive temperature-responsive granular hydrogel inks to create multi-material objects that actuate in response to temperature based on patterned responsivity. We envisage that our findings will facilitate the rational design of dynamic hydrogels that respond to various stimuli based on an innovative 4D printing approach that exploits the benefits of granular hydrogels.

9:30 AM *MF01.09.05
3D Printing-Assisted Casting of Soft Electronic Materials Yue (Jessica) Wang; University of California, Merced, United States

It is challenging to balance architectural complexity, electrical conductance, and material generality for the 3D printing of soft electronic materials. In this talk, I will discuss our efforts on 3D printing-assisted casting to alleviate this trade-off. Light-based 3D printing is used to create hollow molds, providing structural complexity and design freedom, whereas the casting nature imparts material versatility. The casting molds are made of superabsorbent polymers and printed in a partially hydrated state. Their dehydration provides significantly enhanced feature resolution and excellent thermal and mechanical properties, making them versatile for casting. After casting and curing desired materials within the mold cavity, over-hydration of the molds facilitate their energy-efficient removal. Using a polymeric conductor, poly(3,4-ethylenedioxythiophene) (PEDOT), as a model system, complex architectures such as octet and truncated octahedron can be achieved. Compositing silver flakes with PEDOT through a thermal injection process leads to prints with conductivity over 6000 S/cm. This method can also be applied to other hard-to-print soft materials and composites, and potentially enable multi-material structures through sequential casting.

10:30 AM *MF01.10.01
The Practical Application of Additive Manufacturing for Extreme Environments Melissa A. Smith and Bradley Duncan; MIT Lincoln Laboratory, United States

In the automotive, aerospace, and defense industries, there is need for additively manufactured components that cannot only withstand extreme environments but to also be capable of multiple functions or enhanced capabilities. Existing material sets for additively manufactured components are often unsuitable for extreme environments, which limit their practical use and implementation. For example, organic or polymeric components are not rugged or suitable for temperature extremes. More rugged materials (metals and ceramics) can be difficult and expensive to process and are constrained in their compatibility to make composites or blends, hindering the fabrication of multifunctional structures. At MIT Lincoln Laboratory, our mission being technology in support of national security, we develop new materials sets to address shortcomings of the existing, well-established material sets. Success in this mission will facilitate not only the adoption of additive manufacturing for demanding or extreme applications, but also to provide a more far-reaching technological advantage. Specifically, this talk will highlight three distinct cases where new materials are implemented for (1) thermal, mechanical, and chemical stability extreme environments by using inorganic glass-based structures, (2) shielding of high energy particles or radiation for the localized protection of electronic components in space systems by designing composite materials consisting of materials with high and low atomic numbers, and (3) for obscuring transmission line designs in radio frequency systems using graded dielectrics. In all cases, the materials and composites were processed using direct write additive manufacturing, which features low processing temperatures and active mixing. Further, we show the ways our methods and materials outperform existing well-established materials. Due to the simplicity of our approach the consequential implications of its use, we expect the wide adoption of these materials and methods and also the increased acceptance of additively manufacture components for real applications (beyond prototyping and structural modelling), especially those in extreme environments.

3D Printed Electromagnetic Wave Absorber based on Carbon Black-Based Load-Bearing Metastructure Jeongwoo Lee[1], Daniel D. Lim[2], Jaemin Lee[1], Dowon Noh[1], Sujin Park[1], Grace Gu[2] and Wonjoon Choi[1]; [1]Korea University, Korea (the Republic of); [2]University of California, Berkeley, United States

As electronic equipment becomes more diverse and miniaturized due to advances in science and technology, addressing the issues of interference shielding and electromagnetic (EM) radiation absorption becomes increasingly important. Carbon-based composites combined with porous metastructures are lightweight, flexible and their EM properties can be modified in a desired frequency band, making them suitable for a variety of applications. However, the low density of these structures intrinsically limits their mechanical properties.
In this study, we report a multifunctional broadband metamaterial absorber (MBMA) with EM wave absorption, energy absorption, and constant relative stiffness using a bending-dominated lattice structure based on Kelvin Foam comprising carbon-black composite polylactic acid (PLA). Using computational simulation, EM wave characteristics are optimized by adjusting structural parameters such as beam diameter and unit cell size, and intrinsic material properties like dielectric constant according to carbon black filler concentration. Then, the optimized structure is additively manufactured for experimental validation to demonstrate the feasibility of actual implementation. The developed MBMA achieves an outstanding broadband (C-Ku band) EM wave absorption rate (>90%, average 95.9%) even at densities as low as cork (200 kg/m^3), with a maximum absorption of 99.1% at 15.8. GHz. Regardless of the layer stacking direction, the relative density-to-relative stiffness ratio is close to 2.0, maintaining the theoretical stiffness of Kelvin Foam. The experimentally measured performances using 3D-printed MBMA are almost identical to the theoretically confirmed simulation results, validating the design and fabrication of the developed structure. This rational design strategy using 3D lattice structures can inspire multifunctionality of mechanical metamaterials including EM wave absorption, enabled by developing various polymer-based materials and unit cell structures.

Responsive 3D Printed Composites for Protective Applications Miaomiao Zou and Sebastian Pattinson; University of Cambridge, United Kingdom

Responsive materials that change their properties depending on their environment could enable diverse new medical, wearable, and other devices with exceptional function and compact form factors. Shear-stiffening gels (SSG) can be flexible but harden in response to rapid impact. This could enable protective devices amongst other applications. However, SSG can be easily deformed under external force and cannot recover its original shape, which limits its potential applications. In this work, we develop a 3D-printed elastic shear-stiffening composite to achieve shear-stiffening behavior alongside shape recovery. We find that the composite displays good anti-impact properties better than pure SSG, as well as shape recoverability. We also describe initial results describing further applications for these structures enabled by complex 3D printed geometries.

11:30 AM MF01.10.04
Digital Light Processing of Stiff yet Tough Single Network Hydrogels Abhishek Dhand[1], Matthew Davidson[2], Hannah Zlotnick[2] and Jason Burdick[1,2]; [1]University of Pennsylvania, United States; [2]University of Colorado Boulder, United States

Wide applicability of hydrogels towards tissue repair, drug delivery, or biomedical devices is often restricted due to weak mechanical properties and an inability to process them into structures that mimic tissue architecture. Conventional strategies to enhance hydrogel stiffness through increased number of crosslinks often result in embrittlement. To resolve the stiffness-toughness conflict, hydrogels with high degree of polymer chain entanglements have been developed, particularly with the use of low initiator concentrations and slow radical polymerization[1]. Unfortunately, this approach is not directly amenable to processing methods such as Digital Light Processing (DLP), which relies on the rapid light-based crosslinking of liquid precursors to form 3D shapes in a bottom-up, layer-by-layer manner[2,3]. To overcome this mechanical performance-processability conflict, we introduce one-step, Continuous curing after Light Exposure Aided by Redox initiation (CLEAR) printing approach towards formation of highly entangled networks. CLEAR printing is a dual-initiating approach that uses light to crosslink and set the shape of the part, while a complementary reaction (via redox initiators) slowly allows complete conversion of any unreacted monomer within the printed part under ambient conditions.

To demonstrate the advantage of CLEAR, we use acrylamide as a model monomer to form 3D printed, water-swollen highly entangled hydrogels with modulus (~250 kPa) and toughness (~600 kJ m^{-3}) values far higher than those (~100 kPa, ~150 kJ m^{-3}) attained with DLP alone. Despite their 85% water content, CLEAR printed hydrogels are also superior in compression and under shear than those printed with DLP alone. Interestingly, we also show that the CLEAR technique outperforms traditional approaches of improving green strength (e.g., light flood cure or thermal post-curing). We next leverage CLEAR to process highly entangled hydrogels into complex shapes with open, interconnected pores (e.g., trabecular structure), hollow channels, and knotted topologies with high print fidelity and resolution. These 3D printed structures can sustain cyclic (tensile or compressive) loading and recover their original shape with minimal hysteresis. Further, we show that CLEAR can be applied to other monomer systems through changing the type of monomer (e.g., N-isopropylacrylamide, acrylic acid) or the type of crosslinker (e.g., polyethylene glycol PEG diacrylate, gelatin methacrylamide) to obtain 3D printed, swollen single network hydrogels with modulus and toughness values as high as 300 kPa and 1.8 MJ m^{-3}. Additionally, we establish the applicability of CLEAR towards 3D printing of highly entangled elastomers with toughness of 30 MJ m^{-3}, nearly 10-fold higher than those printed with DLP alone.

As a potential biomedical application, we demonstrate the use of 3D printed, cytocompatible highly entangled hydrogels towards achieving robust adhesion onto wet tissues (e.g., *ex vivo* porcine heart, lung, stomach, intestine, tendon) with high interfacial toughness values ranging between 300 to 1000 J m^{-2}. We then process these hydrogels into 3D porous patches that can not only conform to curved tissue topology (e.g., heart) but are also compliant with the dynamic movement of native tissues. Finally, we show proof-of-concept hydrogel adhesives with 3D patterns to (i) form microfluidic connections directly onto tissues for delivery of drugs and (ii) metamaterial structures that enable directional, spatially selective adhesive strength.

Fracture Resistant Architected Polymers Using Material and Structural Size Effects Zainab S. Patel, Abdulaziz Alrashed and Lucas Meza; University of Washington, United States

Strength and toughness are both highly desirable properties of structural materials, but they are often thought of as mutually exclusive, i.e., it is difficult to increase one without decreasing the other. Much work has gone toward developing materials that are both strong and tough using different composite architectures and material processing techniques, but they generally ignore the role of length scale and structural size-effects on toughness. In this work, we develop nanoarchitected polymeric materials that utilize heterogeneity and size-affected ductility to enhance their toughness without sacrificing strength. We create specimens with layered architectures in a micro-single edge notch bend configuration using two-photon lithography and various post-processing techniques. Gradually reducing the layer thickness (D) resulted in an increased fracture energy and slower, stable crack propagation, a phenomenon that became pronounced as the layer thickness approached or was smaller than the material fracture process zone (D ≦ FPZ). This energetic size effect is quantified using Bazant's Size Effect Law. The thinnest of these layered structures demonstrated an increase in toughness by 5x from 60 J/m2 to 300 J/m2 as interlayer spacing was increased from 0 to 4 um, a value that is augmented by the creation of heterogeneity along the crack path. Cracks are observed to rapidly propagate in specimens with no interlayer spacing, but then show increasing blunting and deflection in structures with moderately spaced interlayers (~ 3 um). For larger interlayer spacings (>3 um), cracks do not propagate through; rather, deflect along the interlayer even at very large displacements. Notably, these materials do not show an appreciable loss in strength and stiffness up to an intermediate layer spacing despite a ~40% reduction in density. The results of this study not only demonstrate the large degree of tunability in these architectures but also show how to fundamentally utilize size effects to create architected materials with unprecedented properties.

Molecular Control via Dynamic Bonding Enables Material Responsiveness in Additively Manufactured Metallo-Polyelectrolytes Seola Lee, Pierre Walker, Seneca Velling, Amylynn Chen, Zhen-Gang Wang and Julia R. Greer; California Institute of Technology, United States

Metallo-polyelectrolyte Complexes (MPEC) are a class of soft materials that exhibit unique mechanical and physical properties through reversible electrostatic interactions between dynamic crosslinkers (multivalent metal ions) and charged polymer chains. These molecular-level processes give rise to a wide range of material dynamic responses, for example, stimuli-responsiveness, self-healing, and high toughness through enhanced energy dissipation. The current state-of-the-art fabrication method based on the multistep nature of solution-based metallo-polyelectrolyte synthesis produces materials that suffer from poor long-term stability and inhomogeneity or relies on covalent crosslinking as a backstop for indirect synthesis. The range of scales involved in determining the behavior of MPECs (local bond liability, polymer configurations, and macroscale behavior) further presents computational challenges, which limits the broader application of models to guide experimental methods.

In this work, we demonstrate a facile, single-step fabrication method for MPECs via stereolithography, which produces homogeneous, stable, and high-longevity materials using a straightforward synthesis route. Then, aided by the robust fabrication platform, we present a theory-guided, physically-informed multi-scale study of MPECs. We have developed a roadmap that outlines the effect of different chemical species on the additively manufactured MPEC properties which can be used to tailor its functionality and responsiveness at material level. Our fabrication method enables easy compositional tuning by a simple swap of metal salt precursors during the resin formulation, which allows the wide selection of metal ions and produces a variety of metal-coordinated polymers.

We demonstrate the tunability of mechanical response by adjusting metal ion valency and polymer charge sparsity. We find that mono-, di-, and trivalent metal ions afford control of the coordination environment and bond strength, which propagate to the macroscale properties where higher valency ions result in stiffer and tougher materials. Polyanion charge sparsity, regulated by the pH of the precursor photoresin, also impacts the phase behavior of the gels, leading to changes in the mechanical response. Molecular Dynamic (MD) simulations and diverse polymer characterization methods (morphology, thermal and mechanical) demonstrate that the combination of these parameters controls the extent of dynamic crosslinking present in the system and the emerging polymer configurational distribution governing material properties of MPEC gels. We believe the development of a simple synthesis pathway via additive manufacturing, informed and guided by experimental investigation and molecular modeling, provides a comprehensive understanding of the parameter space and enables the selective design of advanced compliant and functional metallo-polyelectrolytes.

Functional Polymers for 4D Additive Manufacturing with High Precision Eva Blasco; Universität Heidelberg, Germany

4D printing has gained much attention during the last years and become a promising tool for the fabrication of dynamic and adaptive structures with potential application in different fields ranging from biomedicine to optics to soft-robotics. The additional fourth dimension refers to the ability of a 3D printed object to change its properties over time. We can imagine it as the addition of “life-like” behavior. While great progress has been made at the macroscale, the continuous miniaturization of todays devices has tremendously increased the demand for manufacturing at the smaller scales. Emerging technologies such as two-photon 3D laser printing have enabled the precise printing of structures at the micro and nanometer scale.

Our group has recently succeeded in the development of new functional materials for laser micro- and nanoprinting. In particular, we have focus on the incorporation of new features such as conductivity, subtractive manufacturing (inks allowing printing and erasing), superresolution and more recently, stimuli response for complex actuation. In this lecture, special attention will be paid to the design of inks based on functional polymers for 3D/4D microprinting. The challenges as well as the potential and perspectives of the field will be highlighted, too.

2:15 PM MF01.11.03
Free-Form Printing and Deformation Control Strategies for Liquid Crystal Elastomers Devin Roach[1,2], Timothy White[3], Jeremy Herman[3] and Bryan Kaehr[2]; [1]Oregon State University, United States; [2]Sandia National Laboratories, United States; [3]University of Colorado Boulder, United States

Fabrication pathways for liquid crystal elastomer (LCE) have remained a topic of intensive research interest in recent years. Photopatterning and two-stage reaction techniques were pioneering methods which enabled molecular patterning and fabrication of LCE networks in few, relatively simple steps. Recently, additive manufacturing (AM), or 3D printing, has become another promising approach for facile production of LCE networks. The combination of 3D printing with responsive materials, such as LCE, has led to a new generation of smart structures that not only possess a static shape but also can change their shape over time. This process is termed 4D printing, with the fourth dimension being time. The focus of this talk will be on the development of new 4D printing techniques to generate a new class of complex, multi-planar LCE geometries. One of the most notable 4D printing methods, direct ink write (DIW), enables simple fabrication of complex LCE structures by coupling the printing process with the LCE alignment step. This occurs due to the shear forces generated during extrusion through the DIW nozzle. By combining this approach with multiple materials, novel shape transformations can be achieved. For example, by combining LCE with the unique properties of another smart material called shape memory polymers (SMP), the shape transformation can be locked in place. Furthermore, LCE/SMP composites offer superior mechanical properties in both the deformed and undeformed state for functional engineering applications. The structures produced using this method, however, can only perform 2D to 3D shape transformations. Many smart structures applications require more complex 3D shapes to be fabricated. For this reason, we will discuss a recently developed printing method called embedded 4D printing. Here, LCE is extruded into a gel matrix to create complex 3D architectures which can generate unique 3D to 3D shape transformations. This approach enables LCE molecular programming in any 3D cardinal direction. The ability to 4D print complex 3D LCE structures without the need for supports opens new avenues for the design and development of functional and responsive systems such as soft robotics, biomedical devices, and advanced materials engineering.

Architected Soft Matter and The 4th Dimension Howon Lee; Seoul National University, Korea (the Republic of)

Stimuli-responsive soft matter promises great potential for autonomous and intelligent engineering systems when precisely manufactured in specific architectures with programmed responses. Emerging pathway to create such dynamic systems involves additive manufacturing of stimuli-responsive and programmable soft matter. This approach has been termed *“4D printing”*, with the 4th dimension being time. In this talk, additive manufacturing of various soft matter using projection micro-stereolithography (PμSL) is presented. PμSL is a micro 3D printing technique that turns light into a complex 3D structure by utilizing digital light processing (DLP) technology. Combining rapid, versatile, and scalable micro 3D printing technique with various

functional soft matter, design principles and mechanics inspired by exquisite motions and morphologies in nature are physically realized. Micro-architectures that can transform and move are demonstrated by programming of dynamic response of various responsive hydrogels. Reconfigurable, deployable, and mechanically tunable lightweight material is created by employing shape memory polymers in mechanical metamaterials. Also presented is printing of liquid crystal elastomers with encoded molecular orientations for programming reversible shape change and soft robotic locomotion.

4:00 PM MF01.11.05
3D Printing of Polyelectrolyte Complexes: From Rheogical Optimization to Biomaterials Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

Polyelectrolytes have a unique property of complexation when oppositely charged paired polymers form films or coacervates. They have found applications in diverse fields, including drug delivery, wastewater treatment, and tissue engineering. With 3D printing, using polyelectrolytes presents an exciting opportunity for precisely fabricating functional materials and devices. However, the strong electrostatic interactions and the complex formation as coacervates are unstable as viscoelastic materials hinder the flow and processability of inks during the direct ink writing (DIW) process. They have been mostly demonstrated by 3D printing in support media. This talk will focus on the use of polyelectrolyte complexes (PECs) suitable for DIW, in air to form complex shapes and objects. To make PEC-based inks amenable to 3D printing in air, a wash-out deplasticizing procedure was developed. Studies on different formulations were developed that meet the printability of polyelectrolyte complexes and their rheological requirements based on the use of nanoparticles, water-soluble polymers, and ampholytes. Our investigation entailed systematically exploring solvent composition, pH conditions, and the incorporation of specific additives. Furthermore, we evaluate how these ink formulations impact the final printed structures' fidelity, mechanical properties, and complexation behavior. The findings have the potential to enlarge the way we design and manufacture PEC functional materials across diverse applications, from biomedicine to electronics by harnessing the properties of polyelectrolyte complexes

4:15 PM MF01.11.06
Multi-Axis Magnetic 3D Printing of Magnetically-Responsive Architecture Brian Elder, Taylor Greenwood, Samannoy Ghosh and Yong Lin Kong; University of Utah, United States

The ability to program magnetic remanence in situ during extrusion-based 3D printing can enable the creation of soft, magnetically responsive architecture. Indeed, in comparison with other methods, such as folding or assembly, this freeform fabrication approach can create highly complex responsive architecture and actuators. Here, towards this goal, we developed a multi-directional magnetic 3D printing process that allows *in situ* programming of the magnetic domains during 3D printing. The multi-axis magnetic field enables the variance of magnetic remanence within a continuous filament, achieving complex deformation even in a single printed filament. This capability increases the range of possible motions, including bending, twisting, and contraction. As a proof of concept, we demonstrated the fabrication of a tunable propeller, magnetic-responsive textiles, and a magnetically-actuated ingestible device. We also demonstrated eight fundamental remanence pairs that produce deformation units, which we envision could enable the future design of tunable soft actuators and robots.

4:30 PM *MF01.11.07
Intelligentsia of Additively Manufactured Hierarchical Materials Julia R. Greer, Seola Lee, Seneca Velling, Wenxin Zhang and Cyrus Fiori; California Institute of Technology, United States

Creation of reconfigurable and multi-functional materials can be achieved by incorporating architecture into material design. In our research, we design and fabricate three-dimensional (3D) nano-architected materials that can exhibit superior and often tunable thermal, photonic, electrochemical, biochemical, and mechanical properties at extremely low mass densities (lighter than aerogels), which renders them useful and enabling in technological applications. Dominant properties of such meta-materials are driven by their multi-scale hierarchy: from characteristic material microstructure (atoms) to individual constituents (nanometers) to structural components (microns) to overall architectures (millimeters and above).
Our research is focused on fabrication and synthesis of nano- and micro-architected materials using 3D lithography, nanofabrication, and additive manufacturing (AM) techniques, as well as on investigating their mechanical, biochemical, electrochemical, electromechanical, and thermal properties as a function of architecture, constituent materials, and microstructural detail. Additive manufacturing (AM) represents a set of processes that fabricate complex 3D structures using a layer-by-layer approach, with some advanced methods attaining nanometer resolution and the creation of unique, multifunctional materials and shapes derived from a *photoinitiation-based chemical reaction* of custom synthesized resins and thermal post-processing. A type of AM, vat polymerization, has allowed for using hydrogels as precursors, and exploiting novel material properties, especially those that arise at the nano-scale and do not occur in conventional materials. The focus of this talk is on additive manufacturing via vat polymerization and function-containing chemical synthesis to create 3D nano- and micro-architected metals, ceramics, multifunctional metal oxides (nano-photonics, photocatalytic, piezoelectric, etc.), and metal-containing polymer complexes, etc., as well as demonstrate their potential in some real-use biomedical, protective, and sensing applications. I will describe how the choice of architecture, material, and external stimulus can elicit stimulus-responsive, reconfigurable, and multifunctional response.

SESSION MF01.12: Sustainable Polymers
Session Chairs: Michinao Hashimoto and Daryl Yee
Thursday Morning, April 25, 2024
Room 325, Level 3, Summit

8:15 AM *MF01.12.01
Bacterial Cellulose-Based Inks: Enabling Mechanical Property Control in Sustainable 3D Printing Kuotian Liao, Mallory Parker, Hareesh Iyer, Aban Mandal, Taylor A. Hilton, Rebekah I. Brain and Eleftheria Roumeli; University of Washington, United States

Advancements in sustainable materials are needed to combat pressing challenges posed by synthetic plastics, such as non-renewable sourcing, environmentally detrimental manufacturing processes, and end-of-life fates. Biopolymers are attractive alternatives to petroleum-derived polymers, offering a reduction in environmental impact across their entire lifecycle. In parallel, additive manufacturing has revolutionized the production of polymer-based materials for numerous applications, particularly those challenging to manufacture using conventional techniques, utilizing sustainability practices such as minimal material usage and limited waste generation. Currently, the materials used in 3D printing applications are rather limited and majority of them are synthetic polymers. There is a clear need to provide more sustainable materials for the ever-increasing 3D printing applications. In this study, we present an entirely biobased material platform designed for direct ink writing (DIW), with the aim of enabling precise control over the mechanical properties of 3D-printed structures, both at the hydrogel and solid foam states. Utilizing polymer network principles, we use lab-cultured bacterial cellulose

(BC) as our primary, load bearing network element. We investigate the effects of chemical treatment with deep eutectic solvents on the BC fiber charge and degree of defibrillation, which ultimately exert a profound influence on ink rheology and hydrogel properties. BC holds particular promise due to its combination of high aspect ratio, molecular weight, and degree of crystallinity, and its capacity for scalable and tunable biosynthesis. Additionally, we explore the impact of introducing other biopolymers (e.g. proteins) and organic small molecules (e.g. lipids) on the rheological properties and mechanical integrity of the printed structures. By incorporating spatially modulated compositions, we open avenues for further fine-tuning of material properties. This comprehensive investigation aims not only to deepen our understanding of the structure-property relationships within BC-based networks but also to pave the way for tailoring the properties of resulting gels and foams for a diverse range of applications. These insights are poised to significantly advance our fundamental understanding of polymer physics and offer innovative solutions for sustainable material development.

8:45 AM MF01.12.02
Additive Manufacturing of Vitrimers with Circularity Sungjin Kim[1,2], Md Anisur Rahman[1], Karen C. Guzman[1], Zoriana Demchuk[1], Jeff Foster[1] and Tomonori Saito[1,3]; [1]Oak Ridge National Laboratory, United States; [2]The University of New Mexico, United States; [3]The University of Tennessee, Knoxville, United States

Over 400 million tons of solid plastics are globally produced annually and only ~9% of those are currently recycled in U.S.. Establishing closed-loop circularity of plastics with a facile manufacturing path is critical for global circular economy. When commodity plastics are upcycled into higher-performance materials with facile processability, a sustainable closed-loop manufacturing would become reality. Additive manufacturing (AM) of such upcycled plastics to custom-designed structures accomplishes energy and resource efficient low-carbon closed-loop manufacturing. We hereby open a circular upcycling of a commodity plastic into a higher-performance vitrimer with fused deposition modeling or direct ink writing, resulting in robust printout properties comparable to crosslinked thermosets. Vitrimer exhibits mechanical robustness and chemical resistance because of its covalent network formation, but it can also be malleable by reconfiguring reversible crosslinks through the associative bond exchange at elevated temperature, making it recyclable. Due to its crosslinked nature, the upcycled vitrimers provide stronger, tougher, solvent-resistant 3D objects and separatable from unsorted plastic waste. Tailoring the vitrimer composition overcomes the major challenge of (re)printing crosslinked materials, allowing multi-cycle printing. This presentation updates our efforts on AM of upcycled commodity plastics, especially upcycled vitrimers.

9:00 AM *MF01.12.03
Sustainability, Biodegradability and Circularity in Photopolymer Resins for 3D Printing Andrew P. Dove; University of Birmingham, United Kingdom

One of the unresolved consequences of the massive global production of plastic is the lack of proper waste management. As a consequence of technological limitations as well as inefficient collection and sorting methods, current recycling schemes are underperforming. In part this is a result of the inherent linear design of our polymer systems, and lack of consideration of waste management and environmental impact of the waste that does escape into the environment, at the polymer design stage. We, among others, are focussing on creating tools that could be applied to design polymers ‘with the end in mind’ – i.e. to incorporate chemical bonding that can be easily processed to make polymers but readily reversed either ‘on demand’ for recycling, or upon exposure to environmental triggers. To this end, one strategy in our research has focussed on the challenge to design photoset materials that can be processed by advanced methods such as additive manufacturing that are sustainably sourced but can be readily circularised. This talk will detail our efforts in this field to improve the sustainability of photopolymer resins through the use of sustainably sourced monomers, plastic upcycling and the development of closed loop recycling of photoset materials.

9:30 AM *MF01.12.04
Mechano-Responsive Protein-Polymer Networks for Sustainable Additive Manufacturing Alshakim Nelson; University of Washington, United States

Bio-sourced and biodegradable polymers for additive manufacturing could enable the rapid fabrication of parts for a broad spectrum of applications ranging from healthcare to aerospace. However, a limited number of these materials are suitable for vat photopolymerization processes. Herein, we report a process to fabricate protein-based constructs using commercially available vat photopolymerization printers. Bovine serum albumin (BSA) is a single-chain nanoparticle that can be chemically derivatized with acrylate and methacrylate functionalities. Aqueous resins were formulated from these materials to produce complex 3D geometrical constructs with a resolution comparable to commercial resins. While BSA is often used in cell culture protocols and diagnostic assays, we demonstrate that BSA can serve as junctions within polymer networks to afford stiff hydrogels and bioplastics with unique physical properties. Protein-based shape-memory objects and engineered living materials were 3D printed and will be highlighted as opportunities for future applications.

10:00 AM BREAK

SESSION MF01.13: Sustainable Polymers / Functional Materials

10:30 AM ^MF01.13.01
Dynamic 3D Printing of Bottlebrush Block Copolymer Photonics Ying Diao; University of Illinois at Urbana-Champaign, United States

Biological systems have evolved to exhibit dynamic, hierarchical structures that confer complex functionality, such as the adaptable, structural color in chameleons that allows them to match their environment. Attaining such dynamic complex structures at the nanoscale have been challenging to achieve in synthetic macromolecular systems. In addition, synthetic colors we use today constitutes one of the biggest environmental pollutants that severely impact human and aquatic life. Developing printable dynamic structure color will not only introduce new functionality that current synthetic color is not capable of, but also help address this urgent environmental issue. Towards this aim, we and collaborators developed a programmable 3D printing process that can modulate nanoscale assembly and structure color of bottle brush block copolymers on the fly. By understanding and controlling the polymer assembly pathways during processing, we demonstrated 3D printing structure color as chameleon patterns without changing the ink material. We and collaborators further unveiled the underlying mechanism by probing polymer assembly pathways via a combination of X-ray scattering, optical spectroscopy, electron microscopy and coarse-grained simulations – the programmable structure color was attained through arresting polymer chain extension and entrapping metastable structures by controlling the assembly kinetics during printing.

11:00 AM MF01.13.02
A 3D Printable Thermally Conductive yet Electrically Insulating Polymer Nanocomposite based on Ag@SiO2 Nanowires Jean-Pierre Simonato[1,2], Antoine Bodin[1,2], Thomas Pietri[1,2] and Caroline Celle[1,2]; [1]Université Grenoble Alpes, France; [2]CEA LITEN, France

What do high density batteries and up-to-date electronic chips have in common?
The problem of heat dissipation.
With the emergence of fast charging technologies, high energy density batteries and new generation microprocessors, the heat generation in such systems while in operation becomes significantly more intense. If this heat is not efficiently dissipated,: a) the risk of thermal runaway in batteries increases and thus threatens the users safety, b) the performance, lifetime and reliability of electronic systems weaken. Improvement of batteries and electronic devices performances is therefore closely linked to the effectiveness of the thermal dissipation of such systems. Besides high thermal conductivity, very good electrical insulation of these structural materials is also expected to avoid issues such as short circuits or higher power consumption.
The use of thermoplastic polymers seems relevant due their intrinsic electrical insulation behavior and simple processability. However, such materials generally present low thermal conductivity (< 0.4 $W.m^{-1}.K^{-1}$). An appropriate strategy for improving thermal conductivity while simultaneously preserving electrical insulation of polymer-based materials is to incorporate thermally conductive yet electrically insulating fillers to the polymer matrix.
In this presentation, we will show that the development of one-dimensional silver-silica core-shell nanowires ($AgNW@SiO_2$) is a relevant route to very efficient heat dissipative nanocomposites. We will present how the fine tuning of the silica nanolayer on silver nanowires is of utmost importance to reach optimized performances.
By adjusting the rheology of the nanocomposite, i.e. limiting the content of the nanofillers to 3 vol%, a proof of concept was 3D printed by FDM (Fused Deposition Modelling). Thanks to the alignment of the 1D nanofillers during the FDM printing process, as observed under various printing patterns, the thermal conductivity of the PC nanocomposite reaches an unprecedented value of 3.48 ± 0.06 W m^{-1} K^{-1} in the printing direction, i.e. a fifteen-fold increase over the thermal conductivity of neat PC.

11:15 AM MF01.13.03
Integration of Thermoplastic Elastomers and Low Melting Point Alloys for 3D Printing of Multifunctional Composites Weinan Xu; University of Akron, United States

Due to the significant differences in physical and chemical properties of polymers and metals, their additive manufacturing is conducted using very different and incompatible methods or conditions. Such incompatibility is a significant limitation for multi-material 3D printing and fabrication of 3D functional composites. We address this issue by creating functional composites composed of thermoplastic elastomers, Field's metal, and graphene; and their 3D printability by fused filament fabrication is achieved. The 3D printable composites have widely tunable internal structures, mechanical, thermal, electrical properties, and full recyclability. Multiphysics modeling was developed to predict and elucidate the structure and properties. The 3D structures can be transformed from insulating to conductive based on the melting and coalescence of Field's metal nanoparticles. The incorporation of graphene bridges the adjacent Field's metal particles and significantly enhances the conductivity. Such 3D-printable polymer-metal hybrid platform will enable new advancements in soft electronics and robotics, and energy storage.

Interface-Modified Liquid Metal Elastomer Composites for Printing Stretchable Conductors Ren-Mian Chin, Youngshang Han and Mohammad H. Malakooti; University of Washington Mechanical Engineering Department, United States

Liquid metal alloys of gallium, such as eutectic gallium-indium (EGaIn), have garnered attention for their distinctive metallic and fluidic properties. These materials have been utilized in a variety of forms and device architectures, ranging from fluidic microchannels to polymer nanocomposites. Additionally, liquid metal can be embedded in the elastomer matrix to synthesize liquid metal elastomer composites (LMEC) which can augment various functional properties. These composites, with tailored material compositions, can also show high electrical conductivity while having excellent elasticity. However, creating a percolating network of liquid metal (LM) in low modulus elastomers, such as Ecoflex 00-30, is quite challenging. This is because the ultrasoft polymer matrix cannot deliver sufficient mechanical forces to the gallium oxide on the surface of the LM droplets. Since the oxide shell causes separation between the micro-sized LM particles, an innovative strategy for breaking this solid barrier is required to achieve conductive LM pathways in the low elastic modulus LMECs.
In this presentation, we will demonstrate how embedded EGaIn microdroplets in Ecoflex can be "mechanically sintered", or called "activated", to become electrically conductive. Surface modification of LM particles is a key for weakening the particle-matrix interface in LMEC, which results in the formation of a percolation network by strain-activation. Furthermore, we will discuss how the formulated composite can be used for printing stretchable conductors. The printed traces can be stretched over 900% tensile strain, and electromechanical testing results indicate minimal changes in electrical resistance under substantial deformations and strain rates. Finally, we will demonstrate the practical application of the formulated printable EGaIn-Ecoflex 00-30 inks in stretchable electronics circuits. Overall, this work highlights the potential of liquid metal elastomer composites for use in functional electronics and provides a promising approach for achieving high electrical conductivity in ultrasoft polymer matrices.

11:45 AM MF01.13.05
Advancing Semiconducting Polymer Patterning: Photothermal Approach for Sub-Micron Feature Fabrication for Electronic NIR Photodetectors Meghna Jha, Joaquin Mogollon Santiana, Megan L. Hong, Harishankar Manikantan and Adam J. Moule; University of California, Davis, United States

The industrial development of Semiconducting Polymers (SPs) faces a significant hurdle in the absence of an inexpensive, rapid, and viable patterning technology capable of producing sub-micron features. In this study, we explore Photothermal Patterning as a promising technique that leverages the solubility characteristics of SPs to address this challenge. The Photothermal Patterning process involves exposing an
SP film to a semi-poor solvent mixture, rendering the polymer insoluble at room temperature. Subsequently, the SP film is exposed to laser radiation at a wavelength that is strongly absorbed by the SP in its solid state. The absorption of photons leads to localized heating, causing the SP to dissolve once the temperature surpasses its dissolution threshold, resulting in the formation of negative patterns. To validate
the feasibility of this approach, we conducted experiments using the Alvéole PRIMO, a commercially available cleanroom equipment. Additionally, we developed a quasi-steady state model to investigate the dissolution behavior of SPs in solvent mixtures induced by a Gaussian laser beam's heating effect. Through our analysis, we successfully determined the depth and width of the patterns obtained and identified the influence of solubility kinetics on heat transfer dynamics. By gaining a comprehensive understanding of the heat transfer effects, we have been able to identify the regime in which these effects dominate, thereby enabling us to modify the shape of the patterns obtained. Leveraging this knowledge, we aim to employ the Photothermal Patterning technique to fabricate P3HT patterns over silver electrodes, with the
goal of obtaining a functional NIR photodetector. This research significantly contributes to the development of a cost-effective and rapid patterning

technology for SPs, opening up new possibilities for their industrial applications in the field of electronic devices.

Direct Laser Writing of Composite Materials towards Bio-Inspired Photonic Actuators Aoife Donohoe, Colm B. Delaney, Jing Qian and Louise Bradley; Trinity College Dublin, The University of Dublin, Ireland

Colour and colour changes play hugely important roles in the natural world, enabling organisms to camouflage, signal, and mimic. These responsive colour changes are a result of a phenomenon known as structural colour. The reflection of colour in these materials is dependent on a high refractive index and ordered structures with feature sizes comparable with wavelengths in the visible range. [1] In nature, this is often achieved through exploitation of naturally occurring crystals of chitin and guanine that can be ordered from the nano to millimetre scales.[2]

Synthetic analogues of structural colour have often been achieved through the use of liquid crystals, colloidal nanoparticles, and sol gel chemistry, resulting in colloidal crystal assemblies and photonic films.[3] Extrinsic structural colour has also been approached through the use of additive and subtractive manufacturing techniques such as etching, e-beam lithography, and nanoimprint lithography, often from dielectric material. [4] The combination of nanocomposite materials and Direct Laser Writing (DLW) using two-photon polymerisation (2PP) has emerged as a route to obtain ordering of a material in both an extrinsic and intrinsic manner mimicking that seen in biology.[5,6]

In this work we present DLW as a method to produce materials with controlled structural properties on the nm and micron scale in a precise manner resulting in a wide gamut of responsive colours through the exploitation of stimuli-responsive nanocomposite materials, to create responsive photonic materials inspired by those in the natural world. This presentation will encompass a range of nanocomposite materials including colloidal particles, liquid crystalline cellulose, polypeptides, and guanine nanocrystals. Upon incorporation into stimuli responsive materials, we present arrays of printed microstructure pixels, exhibiting dynamic structural colour to stimuli such as light, temperature, humidity and concentration. These materials offer a range of applications in technology such as active display technologies, steganography, and polarisation encryption.

Direct-Ink-Write Crosslinkable Bottlebrush Block Polymers for On-The-Fly Control of Structural color Sanghyun Jeon, Yash Kamble, Haisu Kang, Jiachun Shi, Matthew Wade, Bijal Patel, Tianyuan Pan, Simon Rogers, Charles Sing, Damien Guironnet and Ying Diao; University of Illinois at Urbana-Champaign, United States

The biological world offers exquisite examples of how simultaneous control over molecular composition and long-range macroscopic order gives rise to material properties unique to living organisms. One such phenomenon is structural color, found in various animals, arising from the periodic ordering of domains with different refractive indices on the nanometer scale. Structural color presents an eco-friendly alternative to synthetic color, as it avoids the environmental pollution associated with synthetic dyes. Additionally, it offers high brilliance and dynamic properties that are challenging to achieve through synthetic methods. Among various materials, bottlebrush block copolymers (BBCPs) show significant promise in mimicking biological structural color due to their ability to access a wide range of nanoscale morphologies, including lamellar, cylindrical, and spherical structures, resulting in visible-range structural coloration. In this study, we demonstrate "on-the-fly" modulation of structural color during printing by combining a UV-assisted DIW 3D printer with photo-crosslinkable BBCP chemistry. A key innovation is to realize dynamic control of assembly kinetics through programming the rate of photo-crosslinking, which serves to kinetically arrest assembly and lock in desired structural color “on-the-fly”, or as we print. We then validate two key aspects of this hypothesis by combined coarse-grained simulations, rheological characterizations, and experimental structural analysis. First, using the implicit side-chain model developed by our team, we elucidate an evaporation-driven assembly pathway whereby the structural color evolves from blue to red due to backbone extension. This inference is affirmed by scanning electron microscopy and ultra-violet visible spectroscopy. Second, by rheology and in situ imaging, we show that the crosslinking timescale matches with the evaporation-driven assembly timescale, supporting the idea that assembly is arrested by crosslinking during evaporation-driven structural evolution. Enabled by this mechanistic understanding, we program the temporal profile of UV irradiance to demonstrate modulation of structural color “on the fly” as to access much of the visible spectrum and to create color gradients using a single ink material.

2:00 PM MF01.14.03
Additive Manufacturing via Direct Ink Writing: Printing Functional Hydrogels and Ceramics for Medical Applications Philipp Schadte, Leonard Siebert and Rainer Adelung; Kiel University, Germany

Additive manufacturing (AM) also known as 3D printing is a highly versatile set of techniques for processing polymers, metals as well as ceramics into complex shapes. Among all AM techniques Direct Ink Writing (DIW) is the most versatile in terms applicable materials by employing a simple extrusion-based approach. Soft hydrogels, e.g., have been processed for biomedical applications using DIW. These polymeric materials offer not only tunable printing properties but also often show great biocompatibility. In combination with functional particles like ZnO these materials will exhibit advanced functionalities like antibacterial properties. This work presents an ink system for active wound dressings consisting of sodium alginate hydrogel as carrier

and ZnO particles in the shape of micrometer sized crystals (t-ZnO) with a tetrapod geometry. While the sodium alginate adjusts the inks rheological properties, the individual ZnO tetrapod arms penetrate through the hydrogels surface and have direct contact with the wound. This is due to the unique geometry of the t-ZnO as well as the selection of suitable concentrations for the alginate hydrogel and the particles. The penetration of t-ZnO enables to utilize the tetrapod's antibacterial properties. Additionally, rheological investigations have been performed improving the printing the results. The sodium alginate shows a high yield point as well as a shear thinning behavior, which is highly desirable for a 3D printing process. These properties enable to print openly porous wound dressings with an oxygen access directly at wounds surface while the at same time the damaged tissue stays protected from contaminations. In order to improve the wound healing even further the t-ZnO particles can be decorated with a variety of functional proteins. These characteristics have been proven using cell and ex-vivo skin tests.
In contrast to these soft materials, DIW allows also to process hard ceramic biomaterials like zirconia. In combination with water soluble polymers like polyethylene oxide, pastes with high shape retention and strong shear thinning properties can be produced. These pastes are utilized in this work for the 3D printing of dental implant materials. The rheological properties have been tailored by changing the inks pH value allowing to process yttrium stabilized zirconia and reaching a high mechanical strength. In summary, this works presents an AM approach, which allows to manufacture soft hydrogels and polymers in combination with hard ceramic particles enabling the versatility of DIW and showing their great potential for biomedical applications.

2:15 PM MF01.14.04
Tuning Aging, Mechanical and Electrical Properties of Liquid Metal Polymer Composites for Improved Stretchable, Deformable and Robust Electronics and Robotics Amanda Koh[1], Anh Hoang[1], Chanyeop Park[2] and Omar Faruqe[2]; [1]University of Alabama, United States; [2]University of Wisconsin–Madison, United States

Soft, stretchable electronics are a promising platform for wearable devices for monitoring health, movement, infrastructure damage, robotic environments, among many varied applications. While the literature demonstrates a wide range of strategies for achieving soft electronics, the incorporation of electronically active elements into a soft polymer (typically an elastomer for full stretchability) is one of the most successful. To get the most utility out of the elastomer composite, the electronic element must also be able to withstand repeated strain and not degrade the elasticity of the host. Room temperature liquid metal polymer composites (LMPCs) are composites of the metal alloy gallium-indium-tin (galinstan) and an elastomer matrix (most commonly polydimethylsiloxane, PDMS). As galinstan is liquid at room temperature, it inherently has no strain fatigue, and the research in Koh Lab has shown that galinstan can be composited into the matrix at concentrations greater than 70vol% without a dramatic increase in polymer modulus. Simultaneously, the LMPC exhibits dielectric properties with tunable relative permittivity up to and exceeding 160 based on liquid metal loading and polymer molecular weight. To realize the potential of this polymer composite material, it is necessary to fully explore its rheological, electrical, and sensing properties in order to transition it to a functional manufacturing platform. Additionally, it is necessary to understand the dielectric aging and fatigue properties of the composite as made in order to validate the long term utility of the composite as a sensor, wearable, or robotic component. The work presented will show recent data demonstrating how dielectric aging is impacted by LMPC formulation, and how these properties can be simultaneously tuned with mechanical/rheological properties to optimize the system for additive manufacturing or molding. Furthermore, this presentation will include new results related to the spatial homogeneity of the LMPC, which is a property that is both critical to manufacturing (the density of galinstan is greater than six times that of the host polymer) and largely unexplored in the literature. The data presented will demonstrate the boundaries within which spatial homogeneity does or does not impact mechanical, electrical, aging, and sensing properties as well as methods of improving homogeneity if necessary. The work discussed and presented here directly enables ongoing work in the Koh Laboratory to create components for wearable devices, robotic locomotion, and infrastructure hardening that rival and exceed the capabilities of ceramic and thermoplastic polymer dielectrics, expanding the possibilities for such systems.

2:30 PM MF01.14.05
Aggregation-Induced Emission to Visualize and Monitor Progression of Photopolymerization Xiaoxing Xia, Sijia Huang, Elena Belk, Martin De Beer, Abhinav Parakh, Magi Yassa and Johanna J. Schwartz; Lawrence Livermore National Laboratory, United States

Light-induced polymerization is widely used in high-resolution fabrication such as additive manufacturing and photolithography as well as low-cost industrial processes such as UV curable coating and adhesives. Polymer parts made from acrylate-based resins exhibit a large variation in materials properties due to differences and inhomogeneities in the degree of conversion within each part and thus suffer from quality control challenges for high-precision applications. As new photochemistries are being actively developed, it is increasingly important to examine the uniformity of polymerization with high spatial resolution and monitor its progression kinetics with detailed temporal information. In this work, we introduced a class of fluorophores based on aggression-induced emission (AIE) as an additive in the photo-resin formulation; their fluorescence intensity increases as the local rigidity of the cross-linked polymer increases. We conducted systematic ex-situ photo-rheology and FTIR measurements to establish the calibrated relation between fluorescence intensity and polymerization conversion for representative resin formulations. We used fluorescence microscopy and confocal microscopy to demonstrate high resolution grayscale mapping of polymerization conversion in 3D printed parts made by various photopolymerization methods including Digital Light Processing (DLP), Two-Photon Polymerization (2PP), and tomographic Volumetric Additive Manufacturing (VAM). With this unique visualization method, we observed the periodic variation of higher and lower conversion across each printed layer in DLP-printed dog-bone samples, which led to large differences in tensile strength as a function of the printing orientation with respect to the loading direction. Finally, we implemented a fluorescence monitoring setup to a VAM system that actively tracks the conversion of the 3D printed parts as tomographic printing progresses, which offers vast opportunities for real-time in-process metrology and feedback control to improve printing quality.

Bioinspired Hierarchical Composite Hydrogels via Shear-Assembled Direct Ink Writing Technology Wei Zhai, Tian Li and Quyang Liu; National University of Singapore, Singapore

Soft materials, such as hydrogels, have garnered significant attention in fields like wearable electronics, soft robotics, biomedicine, and energy technology, thanks to their unique combination of high electrical conductivity, stretchability, biocompatibility, and self-healing capabilities. Nevertheless, the inherent

brittleness of hydrogels has presented a challenge to their practical application. Biological soft tissues, like tendons and cartilage, exhibit remarkable strength, flexibility, and message-transmission capabilities due to their composite composition and intricate hierarchical structures. Drawing inspiration from nature, we have developed a promising approach—shear-assembled direct ink writing—to strengthen and toughen hydrogels by incorporating secondary-phase fillers and creating bioinspired hierarchical structures. This process involves applying shear-force-induced self-assembly extrusion printing of nanoceramic platelets enhanced hydrogel inks, providing control over nano- to sub-micro scale structures. Additionally, the filaments can be 3D printed into free-form bioinspired architectures, ranging from micro- to macro-scale, such as unidirectionally aligned, Bouligand, and crossed lamellar configurations. By tailoring the composition, nanoceramic alignment, and printing patterns, the composite hydrogel exhibits multiple strengthening and toughening mechanisms across different scales. Through the application of this technology, we have successfully produced flexible and robust nanoceramic-hydrogel composites with high ceramic compositions for creating reconfigurable structures. Furthermore, we have developed flexible bioceramic-hydrogel composites with potential applications in bone tissue engineering, as well as strong and tough conductive composite hydrogels for use in flexible electronics.

3:45 PM MF01.15.02
New Natural Polymer-Based Composite Hydrogels and Their 3D Printing into Scaffolds for Liver Tissue Engineering Xinyang Zhang, Xirui Zeng and Min Wang; The University of Hong Kong, Hong Kong

The liver is an important organ which performs many and diverse tasks in the human body. Chronic or acute liver failure occurs as a result of nonalcoholic fatty liver disease, alcoholic liver disease, hepatocellular carcinoma (HCC), etc. HCC is the fourth leading cause of cancer-related mortality and is also showing an increasing trend globally, with an estimated 500,000 to 1 million new cases annually. The primary treatment for early HCC is surgical resection. But surgery may not provide 100% removal of HCC tissue and hence tumor recurs in the liver in up to 80% of patients. On the other hand, liver transplantation, another main treatment option for HCC, can achieve a high survival rate with a low risk of recurrence. But this strategy has been severely limited in clinics due to the lack of liver donors, immune rejection, surgical complications, etc. Liver tissue regeneration (LTR) using the tissue engineering approach appears to be an important alternative treatment for the patients, and 3D printing provides a powerful platform for fabricating advanced liver tissue engineering (LTE) scaffolds for LTR. For LTR, the scaffolds should facilitate enhanced cell function and survivability, and hence inks/bioinks for 3D printing should closely resemble liver's cell-extracellular matrix (ECM) in composition and possess suitable gelling characteristics for different 3D printing or bioprinting processes. But the progress in 3D printing-based LTE has been hindered by the lack of inks that have adjustable properties and mimic the native environment of liver. Hydrogels based on natural polymers are attractive as printing inks for LTR because they also have the advantages of good biocompatibility and biodegradability. In the current study, we formulated and evaluated natural polymer-based hydrogel inks for 3D printing into LTE scaffolds. Double-bond modified hyaluronic acid and aldehyde-based hyaluronic acid were prepared first. They were then mixed with carboxymethyl chitosan and collagen to form composite hydrogels (designated as CHC hydrogels) for 3D printing. The gel-forming behaviour and effects of carboxymethyl chitosan amount of composite hydrogels (4CHC, 6CHC and 8CHC) were investigated, and the printability of these three composite hydrogels was studied. The hydrogel formation time was less than 1 minute, showing rapid gel formation and convenience for use. Rheological analysis revealed that hydrogel inks had good shear thinning behaviour and thixotropic properties, which would ensure successful 3D printing. Composite hydrogels contained abundant micropores, which are conducive for cell adhesion and proliferation. Compression tests showed that Young's modulus of composite hydrogels was close to that of healthy liver tissue, indicating that the composite hydrogels are biomechanically suitable for LTR. The hydrogels also showed good swelling efficiency and biodegradation properties. In extrusion 3D printing, the 6CHC hydrogel formed smooth filaments and could be printed into 15-layer, grid-type scaffolds with higher shape fidelity than 4CHC and 8CHC hydrogels. After UV crosslinking, printed 6CHC grid-type scaffolds could maintain their shapes without collapsing. Hepatocytes seeded on 3D printed scaffolds proliferated very well, indicating good biocompatibility and scaffold suitability for LTR. The new composite hydrogels appear to be suitable materials for 3D printing into LTE scaffolds which provide appropriate biomechanical and biochemical microenvironments in liver tissue regeneration.

4:00 PM MF01.15.03
Accurate Rheological Characterization of Highly-Filled Direct-Ink Write Pastes Jessica Kopatz, James Griebler, Jonathan Leonard, Alexander S. Tappan and Anne M. Grillet; Sandia National Laboratories, United States

Direct-ink write is an additive manufacturing technique that enables the creation of reproducible and complex hardware by depositing a viscous, shear-thinning liquid onto a substrate in a custom-pattern via extrusion through a syringe. The rheology of these inks is tailored through the addition of various filler materials. To successfully print highly-filled inks, we need to understand the effect of filler morphology, size, loading, and packing fraction on the ink rheology and corresponding printability. More importantly, characterization methods that accurately capture the ink's rheological properties that correlate to resin printability is imperative. Various filler particles and volume loadings of particles were dispersed in Polydimethylsiloxane (PDMS, Sylgard® 182) to investigate the change in zero-shear viscosity, shear- thinning behavior, and plateau modulus. Comparisons between capillary rheometer measurements versus parallel plate rheometer measurements were made. The extrusion force was measured at several volume loadings determine the highest attainable volume loading for printable resins as a function of different filler morphologies. The goal of this work is to understand effects of filler morphology on ink printability while determining adequate characterization techniques that accurately capture the rheological behavior.

Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

4:15 PM MF01.15.04
3D Printed Soft Composites with Tunable Mechanical Properties Kimberlee Hughes and Arda Gozen; Washington State University, United States

The use of soft engineering materials such as silicones has been gaining more traction due to the emergence of technologies such as soft robotics, pre-surgical organ models, and wearable electronics. where compatibility with soft biological systems and the ability to mimic their functionalities are essential. For the continued advancement and broad utilization of these technologies, there is a need for further development of soft engineering materials with properties required in relevant applications. Particularly, the ability to precisely control the mechanical properties, as well as their spatial distribution towards development of functionally graded biomimetic compliant structures is a significant research interest. Additive manufacturing with multi-polymer systems have proven to be an effective method to achieve this goal, however, the commonly used Polyjet approach is highly expensive and limited in material capabilities. Towards addressing this challenge, this work presents novel soft composites, consisting of a silicone matrix and thermoplastic elastomer reinforcements, fabricated through low-cost extrusion-based additive manufacturing. Mechanical properties of these composites are functions of the reinforcement geometry that can be precisely controlled. We use a customized 3D printer with direct ink write (DIW) and fused filament fabrication (FFF) capabilities to print composites with a sinusoidal reinforcement pattern. We demonstrate that changes in the amplitude and frequency of these sine waves led to significant differences in the hyperelastic behavior of the composites. Specifically, decreases in amplitude and frequency led to an overall stiffening of the composite, while increasing these parameters led to a softer stress-strain response that approached that of a non-reinforced silicone sample.

Additionally, changing these parameters independently led to differences in strain-hardening behavior. Finally, we demonstrate the ability of this approach to seamlessly control the spatial compliance distribution of composites, by printing parts with sinusoidal reinforcements of spatially varying amplitude and frequency.

4:30 PM MF01.15.05
Freeform Additive Manufacturing of Carbon Fiber Reinforced Composites Using Dielectric Barrier Discharge-Assisted Joule Heating Smita Shivraj Dasari[1], Aniela Wright[1], Anubhav Sarmah[2], Jacob Carroll[1], Thang Quyet Tran[3] and Micah Green[1]; [1]Texas A & M University, United States; [2]University of Minnesota, United States; [3]Singapore Institute of Manufacturing Technology (SIMTech), Agency for Science, Technology and Research (A*STAR), Singapore

In this work, a novel out-of-oven additive manufacturing (AM) technique to rapidly print and cure thermosetting carbon fiber reinforced composites (CFRCs) using dielectric barrier discharge (DBD)-assisted Joule heating was developed. Conventionally, CFRCs are produced by automated fiber placement machines (AFPs) that use large, cumbersome molds and time-consuming oven/autoclave treatments to cure CFRCs in the desired shapes. Recently, out-of-oven AM has garnered attention as a method to manufacture CFRCs without the use of molds. AM allows for on-the-fly printing and curing of thermosetting CFRCs; however, current out-of-oven AM techniques are limited to UV-curable, low viscosity, or rapid-curing resins. Here, the DBD was used for in-situ heating and curing during AM of continuous CFRCs; this method is resin-agnostic, applying to most commercially available thermosetting resins. As the partially cured composite (prepreg) is deposited, Joule heating induced via a DBD applicator allows the part to cure in the desired shape; this is possible because of the conductive carbon fiber susceptors inside the part. Composites manufactured by this method show properties similar to those manufactured in conventional ovens. With the help of this technique, one can print composites in free space or on stationary and mobile substrates. 2D structures, and 3D multilayered structures can be printed. Automation of this process is also demonstrated. This technology leverages the advantages of AM techniques to enable the printing of high-performance and lightweight materials in any desired shape.

SESSION MF01.16: Composites / Devices / Methods

8:00 AM MF01.16.01
Squeeze Flow Induced Fiber Alignment in Fused Filament Fabrication of Carbon Fiber and PDMS Mixture Hoang Minh Khoa Nguyen and Dong-Wook Oh; Chosun University, Korea (the Republic of)

Fused Filament Fabrication (FFF) represents a significant segment of additive manufacturing processes, mainly known for its ability to fabricate complex structures using various materials. Among these, polymer composites integrated with short carbon fibers have gained immense attention due to their potential to exhibit augmented mechanical and thermal properties, positioning them as ideal candidates for high-performance applications in the aerospace and automotive industries. The optimization of these enhanced properties is intrinsically connected to the alignment of carbon fibers within the extruded filament. As current research indicates, this alignment is not a mere consequence of the filament extrusion but is significantly influenced by many factors. Primary among these are the configuration of the printing nozzle and the interactions occurring at the deposition bed. Despite widespread recognition of the merits of these composites, a conspicuous knowledge gap persists regarding the dynamics of fiber rotation during deposition. This paper seeks to bridge this aspect by incorporating experimental and computational methodologies.
Through flow visualization experiments, we observed fiber orientation in multiple focal planes during the extrusion process. This facilitated an in-depth assessment of the alignment angle, indicative of fiber rotations during extrusion. Initially, we examined the fiber rotations as exiting the nozzle, capturing their trajectory and orientation. This was followed by mapping the alignment angles as the extruded filament after the solidification, offering insights into the end-state orientation of the fibers. To foster a comparative analysis, we further performed a numerical flow simulation inside the nozzle and on the deposition bed. The computational calculation was done in a 2-dimensional incompressible Newtonian flow model, which provided velocity information within the filament. The flow field calculation paired with the Advani-Tucker orientation tensors was compared to the fiber orientation obtained from the flow visualization experiment.
We also varied configurations of the nozzle and the deposition bed design configurations. Specifically, by adjusting the gap between the nozzle tip and deposition bed, we introduced different squeeze flows, allowing us to delineate their impact on fiber rotation. Additionally, we varied in-nozzle flow geometries. By comparing the "straight channel" against the "orifice-embedded" nozzles, we manipulated flow fields, and each impacted fiber alignment during the extrusion and deposition process. Nozzle geometry significantly influenced the alignment of carbon fibers in the printed filament. The utilization of a "straight channel" nozzle led to fibers aligning parallel to the heating bed, while the "orifice-embedded" nozzle resulted in fibers aligning perpendicular to it. Moreover, the computational calculation revealed that squeeze flow introduced an additional factor to fiber alignment during the deposition process. In conclusion, our findings regarding nozzle gap, in-nozzle geometry, and squeeze-flow phases play a significant role in the fiber alignment within the printed filament. This study provides insights into the mechanics of fiber alignment in FFF and highlights advancements in customizing polymer composite materials, signaling a significant shift in additive manufacturing material science.

8:15 AM MF01.16.02
Customizable Flexible Pressure Sensors with Enhanced Performance via Ink Optimization and Microdome Integration Sina Hassanpoor, Kaliyah Shearod and Taeil Kim; Baylor University, United States

This research presents an extensive exploration of the development of customizable flexible pressure sensors through the application of Direct-Ink-Writing 3D printing technology. It places a primary focus on the optimization of ink formulations, varying filler ratios of carbon nanotubes (CNT) and silicon dioxide (SiO_2) in polydimethylsiloxane (PDMS) matrix. The research systematically examines how these optimized ink formulations offer precise control over the electrical and hyperelastic properties of the printed sensors and explains their influence on key sensor characteristics such as conductivity and sensitivity. The optimization process of ink formulation is at the core of this research. By adjusting the proportions of CNT, SiO_2, and PDMS, the printability of inks and the electrical properties of sensors could be effectively manipulated. This fine-tuning is essential for ensuring that the sensor operates efficiently in a wide range of environments and applications. Concurrently, the hyperelastic properties of the sensors, which encompass flexibility and elasticity, can be tailored to meet specific requirements. A crucial aspect of this research is the effect of these controlled modifications on the sensors' performance characteristics. The paper delves into how these adjustments can significantly impact the linearity and sensitivity of pressure sensors. Examining these attributes provides a comprehensive understanding of how customizability can enhance the sensors' precision and suitability for various applications. The integration of microdomes with various sizes and differing ink ratios as printed structures atop a flat printed layer introduces a dynamic

dimension to the pressure sensor design. These microdomes are meticulously tailored to function as responsive elements, each uniquely tuned for specific applications. When subjected to varying levels of pressure, these microdomes exhibit an array of behaviors, allowing the sensor to capture detailed data. This multifaceted approach enhances the adaptability of the sensor, making it well-suited for a wide range of applications where precise pressure sensing is imperative, such as touch-sensitive screens, medical devices, or robotic grippers. This adaptability and sensitivity are particularly relevant in healthcare and biomedical applications. Pressure sensors with these attributes can have a meaningful impact on patient care, providing accurate data for diagnosis and treatment. Moreover, integrating microdomes onto the sensor surface, each designed for specific functions, enhances the sensing capability to meet real-world healthcare needs. This integration enables tailored performance for practical applications like continuous blood pressure monitoring, prosthetic limb control, and minimally invasive surgical instruments that rely on precise pressure feedback. The comprehensive discussion in this research spans the methodology used in ink optimization, detailed results from experimental work, and the broad implications of this innovative technology for the domain of flexible pressure sensing. With a focus on precise control over sensor properties, this research aims to contribute to the ongoing advancement of sensor technology and its applications across various fields.

8:30 AM MF01.16.03
Adaptive 3D Printing of Resonant-Enhanced Microsensors Jared Anklam[1], Samuel H. Hales[1], LeiBin Li[1], Sanghoek Kim[2], John S. Ho[3] and Yong Lin Kong[1]; [1]University of Utah, United States; [2]Kyung Hee University, Korea (the Republic of); [3]National University of Singapore, Singapore

The ability to integrate wireless microelectronics on the surfaces of existing biomedical devices can functionalize an otherwise passive construct with advanced sensing capability. The digital freeform fabrication approach directly integrates sensors on a clinically proven device without requiring significant structural modification, lowering the clinical barrier for electronic integration. However, achieving microelectronics integration on biomedical devices (e.g., joint replacement implants) with microextrusion-based 3D printing remains challenging. Biomedical devices are typically geometrically complex three-dimensional constructs requiring extensive surface topological scanning, electronic design and calibration. Here, we develop a microscale closed-loop printing system aided with a laser displacement sensor capable of printing 3D resonant-enhanced microsensors with trace widths as small as 30 μm on a broad range of 3D constructs. The system adapts to the 3D surfaces, achieving conformal printing without requiring extensive alignment of the target substrate with the generated print path. As a proof of concept, we will demonstrate the ability to integrate sensors on biomedical devices such as joint-replacement implants and biological constructs such as bone. Finally, the sensors can be robustly and wirelessly interrogated with high sensitivity using readout techniques that leverage the enhanced sensitivity of systems at special degeneracies, enabling a fundamentally new approach to integrating electronics on existing biomedical devices.

8:45 AM MF01.16.04
Rapid Additive Manufacturing of Thermosetting Resins enabled via Radio Frequency Curing Ethan Harkin[1], Anubhav Sarmah[2], Thang Quyet Tran[1], Matthew Cupich[1] and Micah Green[1]; [1]Texas A&M University, United States; [2]University of Minnesota, United States

Direct Ink Writing (DIW) is an extrusion-based additive manufacturing method where the print medium is a liquid-phase ‘ink’ dispensed out of small nozzles and deposited along digitally defined paths. Conventional DIW methods for thermosetting resins rely on the use of viscosity modifying agents, novel crosslinking chemistries, and/or long curing schedules in an oven. Here we demonstrate the use of a co-planar radio frequency applicator to generate an electric field, which can be used to rapidly heat and cure nano-filled composite resins as they are printed. This method avoids the need for an oven or post- curing step. This process consists of a sequential print-and-cure cycle which allows for printing of high-resolution, multi-layered structures. Every extruded layer is partially cured using RF before depositing the next layer; this allows the printed part to maintain structural integrity without buckling under its own weight. The process enables both increased throughput and decreased touch time relative to traditional part manufacturing. Commercial epoxy resin with various carbon-nanotube loadings was examined as the primary DIW candidates. Rheological characterization was used to assess curing kinetics, extrusion behavior, and printability. After printing, the thermo-mechanical properties, surface finish, and shape retention of RF-cured samples were evaluated and found to be comparable against samples conventionally cured in an oven. This method of manufacturing establishes RF heating as a suitable alternative to conventional methods, facilitating rapid, free-form processing of thermosetting resins without a mold.

3D-Printing Liquid Crystal Polymers to Replicate The Anisotropic Complexity of Wood Kunal Masania; TU Delft, Netherlands

Anisotropic materials formed by living organisms such as cellulose fibres in wood grain and fibre bundles in osteons of bone can readily be found in Nature. Their microstructures can be shaped into any direction, with spatially tuneable gradients and sharp orientation changes. In contrast, engineered materials such as composite materials cannot be shaped with similar levels of anisotropy and directionality freedom. While the latter can be achieved with 3D printing, compatible anisotropic materials are typically fiber-filled. Paradoxically, these fibers restrict directionality freedom due to their intrinsic stiffness. Problems such as fiber breakage have been reported and often result in setting curvature constraints in the design space. Here, we present a new approach to replicate complex microstructures such as wood using 3D printing of self-assembling thermotropic liquid crystal polymers (LCPs). The LCPs can be reliably extruded to produce lines whose widths vary from half to three times the nozzle diameter, with stiffness ranging from 5 GPa to 35 GPa. This method allows shaping of anisotropic microstructures with tuneable stiffness and failure modes within a single material. By using a distance-aware toolpath generation algorithm, we can generate print lines of varying widths and curvatures that cover the shape domain homogeneously. We successfully 3D-print infills with no curvature constraint. By increasing allowed curvature, our method offers new design possibilities for composites, such as preventing crack propagation, or spatially distributing stress. Furthermore, this method creates the opportunity to study mechanical responses of natural anisotropic materials of intricate microstructures such as wood or bone.

Bridging the Gap to Higher Performance Silicone Elastomers for Direct Ink Write Spencer Schmidt[1], Jake Grondz[1,2], Michael Ford[1] and Jeremy Lenhardt[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Case Western Reserve University, United States

Additive manufacturing via direct ink write (DIW) offers several advantages over traditional manufacturing processes, such as the ability to fabricate polymeric components of complex geometry with spatially dependent properties and reduced waste production. Formulation science is critical to new DIW feedstock development as typical inks must exhibit low yield stress thixotropy while avoiding nozzle swell and post-extrusion flow. These ink properties result from the intertwined effects of reinforcing filler, thixotropic additives, polymer molecular weight, catalyst type, and target mechanical response. For DIW silicones, some standard systems that retain ultimate tensile strength (UTS) of ca. 5MPa and 150 - 350% elongation with varying hardness (ca. 20 - 60 ShoreA) set a baseline from which higher performance feedstocks can be developed.

One approach to enhance silicone mechanical response is to chemically graft functional groups to the fumed silica surface, such as vinyl groups that enable covalent silica bonding to the polymer crosslink network. Systematic variations of polymeric components and in-house surface functionalized silica enable both control over cured mechanical properties in a new set of silicones (achieving ca. 8MPa UTS, 400 - 1200% elongation, and 20 - 50 ShoreA hardness) and direct comparisons across treatment type systems. When aggregated, these comparisons begin a detailed, empirical detangling of the reinforcing filler's

roll in silicone performance from other formulation components that will aid more streamlined development of future generations of printable silicones.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Matrix assisted Pulsed Laser Evaporation for Layer-By-Layer processing of Thin Films containing Biological Materials Andrew Sachan[1] and Roger Narayan[2]; [1]University of North Carolina at Chapel Hill, United States; [2]North Carolina State University, United States

Matrix assisted pulsed laser evaporation has several advantages over dip coating, spin coating, and Langmuir-Blodgett coating for processing thin films that contain pharmaceutical agents and other biological materials. For example, matrix assisted pulsed laser evaporation allows for tight control of thin film thickness. Matrix assisted pulsed laser evaporation also allows for good control of thin film roughness. In addition, matrix assisted pulsed laser evaporation is a “cold” process that does not heat biological material. Matrix assisted pulsed laser evaporation has been used to deposit coatings of many types of biological materials; for example, it has been used to deposit thin films of the antiproliferative drug rapamycin on glass surfaces. Alamar Blue and Pico Green assays were used to evaluate the viability and proliferation rates of L929 fibroblast-like cells on the rapamycin coatings, respectively. The cells on the rapamycin thin films exhibited 70.6% viability ($p = 0.0097$) and 53.7% proliferation ($p=0.0120$) compared to cells on the control material (borosilicate glass), respectively [1]. This result indicates that the rapamycin thin films deposited by matrix assisted pulsed laser evaporation successfully reduced cell viability and proliferation. Matrix assisted pulsed laser evaporation offers many potential opportunities to impart biological functionality to the surfaces of medical devices and other medically-relevant structures.

2:00 PM MF01/MF02/MF03/MT03.02
Comparing The Effect of Single and Dual Sintering Methods Using Silver and Copper Nanoparticle Patterns for Flexible Electronics Applications Rajib Chowdhury and Seonhee Jang; University of Louisiana at Lafayette, United States

The utilization of metallic nanoparticle (NP) ink has gained significant attention in the fabrication of cost-effective and mechanically flexible printed electronic devices, including wearables, displays, sensors, and solar cells. The choice of metallic NPs is a crucial determinant of the electrical, material, and mechanical properties of the printed patterns. Commonly used NPs for ink formulation include silver (Ag), gold (Au), and copper (Cu). Ag NP ink is highly favored for its exceptional oxidation stability and electrical conductivity. Although Au NPs also offer good electrical conductivity and oxidation resistance, their high cost makes them less desirable. Cu NPs have good electrical conductivity and cost-effectiveness, but they have lower oxidation stability. The metallic NP ink is not electrically conductive after the printing process due to steric repulsion forces acting between the particles. These repulsion forces are caused by the introduction of organic additives and stabilizing agents to the ink, preventing the NPs from agglomerating due to Van Der Waals interactions between them. To achieve electrical conductivity, a post-processing step, known as the sintering process, is necessary to decompose the additives and stabilizing agents.

In this study, Ag NP ink (PSI-211, NovaCentrix) and Cu NP ink (CP-008, NovaCentrix) were chosen for printing and characterizing the conductive patterns. Flexible Kapton polyimide (PI) sheets with a thickness of 0.102 mm served as the substrate. The study explored the single and dual sintering methods on the printed Ag and Cu NP patterns. In the single sintering methods, the printed NP patterns were exposed to either laser irradiation (LO) or thermal treatment (TO). For the LO sintering condition, the Ag and Cu NPs underwent Nd: YAG laser irradiation at 600 mJ for 15 s and 800 mJ for 30 s,

respectively. For the TO sintering condition, the Ag and Cu NPs were placed in a formic acid (FA) environment at 140 °C for 1.5 min and 260 °C for 15 min, respectively. In the case of the dual sintering methods, one approach is to subject the printed metal patterns to thermal treatment followed by laser irradiation (TL), while the other method involves exposing the patterns to laser irradiation followed by thermal treatment (LT). The sintering parameters for TL and LT followed the same sintering conditions as LO and TO.

After analyzing the microstructure using the scanning electron microscope, the Ag NP patterns sintered using LT showed enhanced agglomeration and increased networking of particles through necking compared to the Ag NP patterns sintered using the other conditions. This pattern also displayed the highest roughness of 48 nm from atomic force microscopy (AFM) analysis, indicative of superior grain growth. Due to this fact, the Ag NP pattern sintered using LT demonstrated the lowest electrical sheet resistance with a value of 0.0031 Ω/Sq and the lowest resistance ratio (R/R_0) of 1.75 after the folding test. The highest hardness was found for the Ag NP pattern sintered using LT with a value of 4.28 N/mm^2, which contributed to a better result in the adhesion test. On the other hand, the Cu NP pattern sintered using TO showed the most uniform grain growth through agglomeration and coalescence. Additionally, due to increased connectivity between NPs, the patterns sintered under TO showed the highest mechanical hardness of 55.36 N/mm^2 and the lowest R/R_0 value of 10.58 after the folding test. The lowest electrical sheet resistance was observed for the Cu NP pattern sintered using LT with a value of 0.0117 Ω/Sq, which thermogravimetric analysis (TGA) showed to be due to the complete removal of organic residue from the pattern. Additionally, the Cu NP pattern sintered under LT showed the highest roughness value of 51.36 nm.

2:15 PM MF01/MF02/MF03/MT03.03
Improvement of Laser-Induced Graphene-Based Electrochemical Biosensors through Graphene-Conductive Polymer Ink Coating for Sensitive Detection of Alpha-Fetoprotein Ridma Tabassum, Ali Ashraf, Nazmul Islam, Pritu Parna Sarkar, Ahmed Jalal and Robert Freeman; University of Texas Rio Grande Valley, United States

Hepatocellular carcinoma (HCC) is the most common type of primary liver cancer and is the sixth most commonly occurring cancer worldwide with the second-highest mortality rate [1] [2]. Since the 1970s, alpha-fetoprotein (AFP) has been used as a prominent biomarker for the diagnosis of HCC. But AFP is electrochemically inactive, thus, detecting AFP is unreliable for early detection of HCC [3]. In this study, we demonstrated the highly sensitive detection of alpha-fetoprotein (AFP) by developing an electrochemical biosensor using Kapton film. The electrochemical sensor was fabricated by laser scribing technique which is a one-step method that does not require any oxidative acid synthesis route or chemical vapor deposition (CVD) to obtain graphene structure which reduced the cost tremendously [4]. The laser-induced graphene (LIG) electrodes were modified with developed graphene polyaniline (G-PANI) ink to effectively enhance the detection of electrical signals. The peak potential voltage difference was 600µV for the bare electrode, while after modifying with the ink the difference was reduced to 260 µV which indicates a 56% change. Therefore, the electrocatalytic effect of the electrode surface and electrochemical sensor signal was improved after modifying the electrode with ink. To evaluate the performance of the sensor, differential pulse voltammetry (DPV), and electrochemical impedance spectroscopy (EIS) techniques were performed in phosphate buffer saline (PBS) buffer with ferro-ferricyanide as the redox probe. For the DPV method, a significant surge in peak current was observed, increasing from 9.2 microamperes at a concentration of 20 pg/mL to 13.6 microamperes at 400 pg/mL which satisfied the fact that increasing the concentration of AFP, led to a higher number of analytes available for electron transfer, thus resulting in the observed current enhancement. The nearly identical current outputs in the DPV measurements were obtained consecutive 15 times which represents the sensor's stability with an RSD of 3.69% and exhibits high reproducibility (RSD=12.15%, N=5). The obtained EIS result showed good linearity in charge transfer resistance change (coefficient of determination, R2= 0.87) with the AFP concentration increment in the range of 20 pg/mL - 400 pg/mL, and the limit of detection (LOD) was 146 pg/mL at a signal-to-noise ratio of 3, indicating the sensor's sensitivity. The range was selected due to demonstrate high sensitivity in the picogram range and has the potential to cover the entire physiological range for a healthy adult. The specific selectivity of the sensor was evidenced by obtaining a random current peak when both AFP and estrogen were introduced simultaneously on the surface of the sensor. For both electrochemical techniques, a similar coefficient of determination was found from the calibration curves, suggesting that the fabricated biosensor offers high selectivity to the determination of AFP biomarker.

Laser-Induced Graphene (LIG) from Different Polymer Precursors Predicted Using Machine Learning Pranav Gupta[1], Dazhong Wu[2] and Gerd Grau[1]; [1]York University, Canada; [2]University of Central Florida, United States

The conversion of polymers to laser-induced graphene (LIG) is a facile and low-cost process to create a patterned conductive nanomaterial for applications such as sensing and energy storage. However, the complexity of the laser conversion process means that it is difficult to predict the effect of different laser parameters, especially for different polymer precursors. This research leverages advanced machine learning models to optimize and predict the laser parameters necessary for polymer conversion into LIG. Data to train the models was collected experimentally and extracted from the academic literature, after which preprocessing techniques were applied. A major input parameter studied in this work is the type of polymer precursor. To this end, we transformed the molecular structures of different polymers from their Simplified Molecular-Input Line-Entry System (SMILES) representation into molecular fingerprints, descriptors, and tokenized representations using RDKit and a pre-trained BERT model. A variety of predictive models including fully connected neural networks, random forest, gradient boosting, and XGBoost were trained, evaluated, and optimized. The cornerstone of the analysis was a specialized testing of feature importance across three distinct SMILES representations, illuminating the complex interplay between molecular structures and polymer properties. The superior performance of the random forest model highlights the vital importance of feature selection and optimization. This creates a comprehensive understanding of influential features in predictions including both laser parameters and different molecular representations. By integrating traditional molecular descriptors and advanced machine learning techniques, this research offers a robust framework for predicting LIG properties, potentially reducing extensive experimental needs. The results have broad implications in material science and flexible electronics.

2:25 PM MF01/MF02/MF03/MT03.05
Flexible Carbon Dioxide Sensors Based on Polyethyleneimine – A Study on Their Aging and Potential Solutions Tianyi Liu, Daniel Padilla, Kening Lang, Nickolas Boeser, Rishi Patel, Qihua Wu, Marriana Nelson, Christopher Landorf and Jiadeng Zhu; Brewer Science, United States

CO_2 sensors, being widely utilized in indoor air quality monitoring, ventilation systems, automotive emission control, and healthcare, can be constructed using various materials and technologies. In recent years, polymers have been considered a popular sensing candidate due to their low cost, outstanding processability, and excellent compatibility with other materials. Polyethyleneimine (PEI) is a polymer that can interact with CO_2 molecules and generate measurable responses; thus, it's been extensively explored in the development of CO_2 sensors. Even though many researchers have studied the stability of pure PEI, there are few studies for their real applications (i.e., CO_2 sensors) since it determines the sensor lifetime. Therefore, in this work, a systematic analysis of the screen-printed, PEI-based chemiresistive CO_2 sensors was conducted with emphasis on the sensors' aging behavior along with the mechanism. More importantly, we have demonstrated solutions to address the sensor aging by selecting the proper molecular weight PEI and doing the chemical modification on PEI. The produced sensors exhibit much better cycling stability compared to the control sample.

2:40 PM MF01/MF02/MF03/MT03.06
Laser 3D-Printing of Organic Semiconductor-Carbon Nanotube Microstructures for Flexible Microelectronics and Circuitry Omid Dadras-Toussi and Mohammad Reza Abidian; University of Houston, United States

3D printing is taking the stage in the forefront of technological and industrial advancements, particularly in the emerging field of organic micro/nano electronics. Amongst various 3D printing techniques, Direct Laser Writing based on Two-Photon Polymerization (DLW-TPP) reigns supreme, owing to its unique capability to construct arbitrary-shaped 3D architectures in sub-micron resolution. Herein, we have directly incorporated 2 organic semiconductor fillers, i.e. poly(3,4-ethylenedioxythiophene)-poly(styrene sulfonate) (PEDOT:PSS) and multi-walled carbon nano tubes (MWCNTs), in a photosensitive ink which can be fabricated into highly conductive microstructures via DLW-TPP.

The photosensitive ink contained polymer crosslinker poly(ethylene glycol) diacrylate (PEGDA), two organic semiconductors (PEDOT:PSS and MWCNTs), photo-initiator (ethyl (2,4,6-trimethylbenzoyl) phenylphosphinate), and two miscible agents (dimethyl sulfoxide and pentaerythritol tetrakis (3-mercaptopropionate)). Formulation-wise, maximum content of PEDOT:PPS and MWCNTs in the conductive, homogeneous, and stable ink was found out to be 0.4 wt% and 0.15 wt%, respectively. Microstructures were constructed on flexible poly(dimethylsiloxane) substrates through 3D movement of XYZ stages and irradiation of 130 femtosecond pulses from two-photon laser, which solidified the resin at it's focal point.

Current-voltage measurements revealed that conductivity of microstructures fabricated by the conductive ink was 140050 ± 29414 S m-1, almost ten orders of magnitude higher than their counterparts fabricated with inks without added conductive agent, i.e. 0.0002 ± 0.0003 S m-1 (n=5). Optical transparency of the conductive ink showed ink transmittance of 82% at 550 nm. Moreover, microstructures fabricated with the conductive ink presented average surface roughness of 258 ± 2 nm (n=4).

Fabrication and electrical/electrochemical characterization of various conductive microstructures were successfully demonstrated. In the space of flexible microelectronics and circuitry, printed circuit boards were fabricated via DLW-TPP based on the conductive ink. Functionality of sub-components such as resistors and capacitors were measured and confirmed. In another notable development, multi-site microelectrodes were constructed via DLW-TPP. Electrochemical impedance spectroscopy and cyclic voltammetry revealed that recording sites exhibited low impedance (18.28 ± 5.58 kΩ at 1 kHz) and high charge storage capacity (48.13 ± 4.67 mC cm-2), which promises their application in potential neural recording/stimulation. Development of these 3D-printed microstructures via DLW-TPP forges the path forward for development of advanced printed circuitry and wearable / implanted microelectronics.

2:45 PM MF01/MF02/MF03/MT03.07
3D-Printed Gyroid Architecture for Pressure Sensor Applications Danielle Agron, Chao Bao and Woo Soo Kim; Simon Fraser University, Canada

The gyroid structure represents a design renowned for its high strength and exceptional energy-absorbing qualities, rendering it a suitable choice for deployment as an energy damping device. Within the family of related gyroid structures, we have opted for the Slab single gyroid (Slab SG) model. This model has been meticulously crafted using the 3D printing method, with the intention of utilizing it as the basis for a capacitance-based pressure sensor. In this work, we introduce a simulation model to homogenize the variations introduced by the FDM manufacturing process. Our results indicate that the profile of the fused layer model, with a Young's modulus of 48.7%, exhibits performance closest to the isotropic model. To delve into the energy buffering capabilities of the Slab SG structure, we have developed a suite of closely related gyroid structures. Based on the model that demonstrates the highest linearity, we have fabricated a gyroid-based sensor. This sensor features an electrode network crafted with conductive ink via robot-assisted 3D printing. These electrodes are thoughtfully integrated into the parallel curved surface of the Slab SG structure to maximize the capacitance formed and, subsequently, the sensitivity of the sensor. We have devised a reinforced gyroid-based liner to ensure a uniform force distribution, thereby facilitating the assembly of components for an application in smart helmets.

2:50 PM *MF01/MF02/MF03/MT03.08
Sustainable Production of High-Energy Density Flexible Supercapacitors through Direct Laser Writing on Environmentally Friendly Substrates João Coelho[1,2,3], Rodrigo Abreu[3], Maykel d. Klem[3,4], Sara Silvestre[3], Tomás Pinheiro[3], Neri Alves[4], Elvira Fortunato[3] and Rodrigo Martins[3]; [1]Universidad de Sevilla, Spain; [2]Instituto de Ciencia de Materiales de Sevilla (Universidad de Sevilla-CSIC), Spain; [3]Universidade Nova de Lisboa and CEMOP/UNINOVA, Portugal; [4]School of Technology and Sciences, São Paulo State University (UNESP), Brazil

Supercapacitors (SC) and graphene are two cutting-edge technologies at the forefront of energy storage and materials science. Supercapacitors, often referred to as ultracapacitors or electrochemical capacitors, are energy storage devices that bridge the gap between traditional capacitors and batteries. They are known for their exceptional energy storage and rapid charge-discharge capabilities, making them essential components in a wide range of applications, from consumer electronics to electric vehicles and renewable energy systems[1]. Graphene, on the other hand, promises to revolutionize the field of supercapacitors, offering significant improvements in terms of energy storage, charge-discharge rates, and overall performance. This effect is mainly due to graphene's high surface area, high electrical conductivity, exceptional capacitance and flexibility, and lightweight. Among a plethora of graphene synthesis and deposition methods, laser-induced graphene (LIG) is one of the most studied[2]. This innovative technique has attracted considerable attention for its potential to improve energy storage devices and scalability. However, in terms of energy storage, LIG has mostly been fabricated in polyimide, which compromises the sustainability of the fabricated devices. In addition, as an electrical double layer (EDL) material, LIG-based supercapacitors will always have a relatively low energy density[3].

In this work, we have developed a simple yet elegant sustainable strategy to fabricate LIG SC on paper and cork with improved electrochemical performance. Based on a fire-retardant treatment, the fabricated EDLC exhibited areal-specific capacitances as high as 4.6 mF cm^{-2} (0.015 mA cm^{-2}) for paper and 1.43 mF cm^{-2} (0.1 mA cm^{-2}) for cork. In addition, the devices have excellent cycling stability (> 10,000 cycles at 0.5 mA cm^{-2}) and good mechanical properties[4,5]. In order to increase the energy density of the device, two different strategies were explored. In one approach, the substrate was impregnated with a precursor that is converted to manganese oxide, a pseudocapacitor material, upon laser irradiation. The other strategy involved electrodepositing the manganese oxide onto LIG electrodes. Both methods resulted in supercapacitors with relatively high energy densities. The advantages

and disadvantages of both techniques will be discussed in detail in this talk.

Despite these promising advantages, it's important to note that graphene-based supercapacitors are still undergoing extensive research and development to optimize their performance and cost-effectiveness. Challenges related to scalability and production costs need to be addressed for widespread commercial adoption. Nevertheless, laser-induced graphene supercapacitors hold great promise for improving energy storage solutions and contributing to a more sustainable and energy-efficient future.

10:30 AM *MF02.01.01
Selective Laser Based Postprocessing to Convert Flexible Printed Circuits into Stretchable Circuits and Their Use in Biomedical Applications Simon N. Dunham, Bobak Mosadegh, Varun Kashyap, Abdellitif A. Lahcen, Zixu Huang, Alex Caprio and Chris Liu; Weill Cornell Medical College, United States

Flexible printer circuit boards (Flex-PCBs) have become ubiquitous in commercial electronics and are pervasive across multiple industries. These components can bend and flex, allowing them to be used in a wide variety of interconnects and durable circuits, but they cannot accomodate significant in plane strain. More recently, a wide variety of applications have been demonstrated based on the use of fully stretchable sensors, that can undergo this type of deformation. In particular, because tissues are intrinscially soft and stretchable, and anatomies tend to be complex and unique, there are a wide variety of biomedical application where the ability of sensor to stretch and deform themselves to make intimate contact with tissue presents unique benefits.
A wide variety of wearable and soft robotics systems have been developed demonstrating the importance of these novel classes of devices. These are based on a wide variety of fabrication methods ranging from sophisticated approaches to use advanced fabrication of traditional brittle electronic materials, rendering them stretchable, to the use of novel materials that are intrinsically stretchable. We have demonstrated a low cost method to employ these design strategies, coupled with a self-aligned laser based postprocessing method to convert traditional Flex-PCBs into stretchable sensing arrays. We have demonstrated these approaches for both single and multilayer Flex-PCBs.
Here, we will describe this methodology. Fursthermore, we will describe thermal simulations to understand the underlying mechanisms for this process. We use these simulations to understand the basic design trade-offs associated with this method, such as limits to resolution, number of layers, and other process parameters.
Seperately, we describe the utility of these approaches by describing several practical demonstrations of biomedical devices that utilize these types of stetchable electronics, based on laser-based postprocessed Flex-PCBs. Here we describe the ability of these arrays to be easily integrated with stetchable biomedical grade polyurethanes for applications in cardiac mapping and patient intubation.

11:00 AM MF02.01.02
Enhancing The Conductivity of Laser-Induced Graphene with Functionalized Liquid Metal Particles Halil Tetik and Mohammad H. Malakooti; University of Washington, United States

The rapid and straightforward fabrication process of laser-induced graphene (LIG) has unlocked new possibilities in creating flexible sensors for emerging applications, such as wearable electronics and intelligent systems. While LIG exhibits remarkable sensitivity as a strain sensor, its application as a printed conductor on flexible substrates faces limitations.
In this talk, I will present our recent work on a versatile technique to significantly enhance the electrical conductivity and resistive heating capabilities of LIG, making it an ideal choice for flexible conductors in printed electronics. We achieve highly conductive traces by directly writing LIG onto a polyimide film using a CO_2 laser. Subsequently, we introduce functionalized liquid metal (LM), specifically eutectic gallium indium (EGaIn) particles, onto the LIG, leading to a remarkable ~400-fold increase in the electrical conductivity of LIG traces. This improvement is achieved while preserving mechanical flexibility and manufacturing scalability, all without the need for soldering. Electromechanical characterization of the LIG-LM traces reveals minimal resistance changes even under substantial bending deformations. Simultaneously, the enhanced electrical conductivity plays a pivotal role in improving the resistive heating performance, significantly reducing the input voltage requirement (by ~15 times) to achieve similar surface temperatures compared to pure LIG traces. By combining EGaIn with laser-synthesized graphene, we successfully fabricate flexible hybrid electronics, demonstrating the practicality of this technique through the creation of highly customizable patterns for flexible conductors and heating devices.

11:15 AM *MF02.01.03
Inkless Printing Multimaterial Electronics – A Multi-Laser-Based Additive Nanomanufacturing Approach Masoud Mahjouri-Samani, Zabihollah Ahmadi, Aarsh Patel and Adib Taba; Auburn University, United States

Printed flexible hybrid electronics (FHEs) have emerged as a remarkable technology in recent years due to the simple, cost-effective fabrication, reduced e-waste, and development of multifunctional devices. The rising demand for consumer and industrial electronic products that are uniquely fabricated/designed and increasing usage is boosting the demand for this technology. Current techniques rely on ink-based printing technologies such as inkjet and aerosol jet printers, which suffer from contamination, expensive formulation procedures, and limited materials sources, making it challenging to print pure and multimaterial devices. In this contribution, I will demonstrate a multi-laser-based additive nanomanufacturing (ANM) technique that allows dry, pure, solvent-free printing of electronics and functional devices on various substrates. The Key technology advantages include 1) on-demand and in-

situ laser generation of various pure nanoparticles without contaminations, 2) in-situ and real-time laser sintering of nanoparticles on various substrates with no further post-processing, 3) multimaterial printing of hybrid and tunable nanocomposite materials and structures. Several different mechanical and electrical performance tests like bending, cycling, and surface adhesion are performed on the printed devices, which demonstrate their exceptional performance and the considerable impact this technique has on the future of printed sensors and devices.

11:45 AM MF02.01.04
Establishing a Virtual Look into Laser-Driven Shockwave Synthesis of Nanocarbon Materials Rebecca K. Lindsey[1,1], Yanjun Lyu[1], Sorin Bastea[2] and Sebastien Hamel[2]; [1]University of Michigan–Ann Arbor, United States; [2]Lawrence Livermore National Laboratory, United States

Carbon nanomaterials are of tremendous interest due to the manifold of properties they can exhibit. For example, nanodiamond is renowned its hardness and biological inertness and is found in applications spanning industrial lubricants to biological implants and drug delivery vehicles; graphitic nanoparticles including quantum dots, nanotubes, and graphitic nanoonions exhibit tunable electronic and optoelectronic properties that are being explored for quantum computing, energy harvesting, and electronic devices. However, exploration in this materials space remains nascent due to challenges associated with (1) establishing efficient, scalable synthesis strategies, and (2) navigating the massive design space.
Nanocarbon design and discovery efforts have primarily focused on low pressure synthesis methods including chemical vapor deposition and flame pyrolysis, for which synthesis output is measured in mg/hr rates, and accessible states of carbon are limited. High pressure methods hold significant promise for overcoming these limitations. Decades of explosive materials (EM) research have established that detonation can be used to produce *kg to ton quantities of nanodiamond in under a single microsecond*, and that a variety of unique, technologically promising nanomaterials can be produced in this fashion simply by changing the explosive material composition. However, when appropriating detonation for *intentional* materials synthesis, a key limitation is the inherent coupling between the driver and the precursor – that is, the temperatures (T), pressures (P), and the kinetics with which those conditions are realized during detonation is characteristic to the specific EM itself, precluding independent control over precursor composition necessary to tune properties of the emergent nanocarbon materials.
Recently we demonstrated that this limitation can be overcome by through use of an external shockwave source (e.g., via projectile or laser rather than detonation) to drive arbitrary precursors to high T/P in a finely controllable manner through a combined experimental and computational study. This presentation will overview the computational portion of the work including ChIMES, the unique physics-informed machine learning capability that enabled this work. Recent advances toward elucidating mechanisms and kinetics for the governing reactive phase transformation and phase separation processes will be discussed.

SESSION MF02.02: Laser-Induced 3D Structures and Their Applications
Session Chairs: Antje Baeumner and Jonathan Claussen
Tuesday Afternoon, April 23, 2024
Room 324, Level 3, Summit

1:30 PM *MF02.02.01
Laser Material Interactions for Soft Electronics Keon Jae Lee; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

This seminar introduces recent progresses of laser material interactions that can extend the application of self-powered soft electronics in both materials and processes. Laser technology is extremely important for the future of flexible electronics, allowing high-temperature processing on plastics vital for high-performance electronics, due to its ultra-short pulse duration; for example, low temperature poly-silicone (LTPS) process enables over 1000 °C process on plastics, without damaging the flexible substrates. Specifically, this seminar presents current laser usages in soft electronics, which are classified into four main categories: i) ultrashort heat treatment for annealing or sintering inorganic materials on flexible substrates, ii) laser-induced reaction that leads to a new type of material different from its initial state, iii) exfoliation that separates thin films and devices from their parent substrate for high performance flexible inorganic electronics, and iv) laser-induced etching (LIE), which consists of laser material modification and subsequent wet etching for flexible micro LED. These technologies can produce complex three-dimensional and stretchable structures for human oriented soft electronics. Additionally, various applications of laser–material interaction for inorganic-based flexible devices, including self-powered acoustic sensors, blood pressure monitor, massive transfer of optoelectronics and nanomaterial synthesis will be demonstrated.

2:00 PM MF02.02.02
3D Nanofabrication and Integration of Various Metal Oxides Hu Huace[1], Wei Xiong[1,2], Chunsan Deng[1], Tao Han[1] and Hui Gao[1]; [1]Huazhong University of Science and Technology, China; [2]Optics Valley Laboratory, China

Microsystems can achieve higher performance, smaller sizes, and lower power consumption through integrating three-dimensional (3D) functional structures of various metal oxides. However, the nanomanufacturing and heterogeneous integration of 3D functional metal oxides still face long-standing challenges. Currently, the mainstream 3D manufacturing techniques of metal oxide structures can be classified into two methods including particle-loaded bonding and femtosecond laser direct writing (FLDW). Particle-loaded bonding technology utilizes material's jetting or extrusion to achieve the 3D printing and heterogeneous integration of various kinds of metal oxides. However, its manufacturing resolution (>10 μm) and quality (high roughness, low stiffness) are difficult to meet the application requirements of integrated microsystems. On the other hand, although the FLDW technology has nearly unrestricted 3D design freedom at the nanometer resolution, the 3D metal oxide structures manufactured by this technology commonly suffer from serious shape distortions, limited material applicability, and difficulties in heterogeneous integration.
To address the above issues, we propose a method for 3D nano-printing and heterogeneous integration of various kinds of metal oxides by FLDW the water-soluble resin of metal ion-coupled coordination. This method has the following three main advantages: 1) The mechanism of mutual promotion between acrylic acid and 1-vinylimidazole in coupled coordination with metal ions has been proposed, which breaks through the concentration limit of metal ions in the 3D structure manufactured by traditional methods, increasing the metal ion content to 30.5% in the 3D structure, thereby significantly reducing the degree of morphological distortion. 2) The resin for FLDW is designed to be water-soluble, which may potentially extend this method to the processing of oxide of all water-soluble metal elements. 3) Sequential 3D printing according to the priority of metal activity enables the 3D heterogeneous integration of various functional metal oxides. The successful design of this printing method enables us to manufacture 3D nanostructures and heterogeneous integrated structures of various types of metal oxides, including MnO_2, Cr_2O_3, ZnO, NiO, and Co_3O_4. Furthermore, we demonstrate a high-sensitivity 3D ZnO micro-integrated sensor with a sensitivity of up to 1.113 million in a 200 ppm NO_2 environment, which is much larger than the sensitivity of the 2D device. Therefore, this printing method expands our capability to achieve the 3D manufacturing and integration of metal oxides at the nanoscale and demonstrate its significant application potential in the field of integrated sensing devices, integrated medical endoscopes, nanogenerators, and other 3D microsystem applications.

2:15 PM MF02.02.03
Selective Laser Sintering of Functional Polymer Powders for Precise Fabrication of 3D Hierarchical Composites Weinan Xu; University of Akron, United States

Selective laser sintering (SLS) (also named powder bed fusion) has been regarded as the most promising polymer 3D printing technology for many industrial applications. Its unique advantages compared with extrusion- or photopolymerization-based technologies include the ability to fabricate complex geometries without support structures, highly isotropic properties of the printed parts, and batch production of multiple parts in one printing. However, the major limitation of SLS is the limited polymer powder selection (95% is based on polyamide) and difficulty in multi-material printing. Here, I will present our recent progress in the development of new types of polymer/composite microparticles for SLS, and more importantly, the simultaneous laser-induced graphitization of polyimide microparticles into 3D hierarchical graphene structures with precisely controlled geometry and internal structure. 3D graphene-metal oxide structures can also be fabricated by this strategy, which have superior electrochemical properties for energy storage and catalysis applications.

2:30 PM BREAK

3:00 PM *MF02.02.04
Direct Freeform Laser Fabrication of Multimaterials for 3D Electronics Jian Lin; University of Missouri-Columbia, United States

In the past decade, direct laser fabrication (DLF) has been witnessed an exponential growth in various applications. Among them, one prominent field is sensor and electronics. Despite much progress, the mainstream application of DLF is restricted to planar fabrication capability. In this talk, we will discuss our recent progress in bringing such a capability in the conventional 2D plane to 3D free space. The first technological advance is to develop a 5-axis laser processing platform. With the two additional two degrees of freedom, the laser beam can be focused on any arbitrary surfaces for freeform laser induction (FLI) of representative laser induced graphene (LIG), metals, and metal oxides as high-performance sensing or/and electrode materials in 3D conformable electronics. To make a new stride based on this success, recently, we developed a freeform multimaterial assembly platform (FMAP) by integrating 3D printing (fused deposition modeling (FDM), direct ink writing (DIW)) with the FLI technique. 3D printing performs the 3D structural material assembly, while the FLI can fabricate and pattern the functional materials in predesigned positions of the 3D structures by synergistical, programmed system actuation. By this platform, crossbar LED circuit, touchpad for human-machine interaction, multiple sensors, sensor-enveloped springs, electromagnets, force feedback manipulators, and microfluidic reactors with embedded heating elements were fabricated to demonstrate the versatility and effectiveness of the technique.

3:30 PM MF02.02.05
High Temperature Reactions in Laser-Assisted Ceramic Additive Manufacturing Leonard Siebert, Philipp Schadte and Rainer Adelung; Kiel University, Germany

Ceramics are the most temperature- and oxidation-stable materials known. Usually only strong acids or bases are capable of inducing ceramics to react. When dealing with extreme temperatures over 3000 °C, however, oxide ceramics can be induced to lose an oxygen and become reactive. This can be used in laser-assisted additive manufacturing (AM) of ceramics. Lasers are used here to sinter or melt the ceramics layer-by-layer. Additionally, each layer and even each spot can be irradiated with almost arbitrary high power and thus extreme heating, which lead to extraordinary reaction kinetics.
As an example, irradiating SiO_2 with a CO_2-laser (λ= 10.6 µm), it can be evaporated with ease, while more stable ceramics like ZrO_2 can be reduced to ZrO, losing one oxygen in the process. This state can be stabilized in inert gas atmosphere and quenched to room temperature, while in oxygen-rich atmosphere the recapture of oxygen takes place upon cooling. When in its reduced state (, i.e., ZrO) can react with other substances to form intermediaries that are usually hard to produce. For instance, by varying the gas atmosphere to forming gas (5% hydrogen, 95% nitrogen), the dark colored ZrO can be converted to the golden ZrN. The reaction zone is clearly molten, so that it can be concluded that the temperature for the reaction is above the melting point of both ZrO_2 (2680 °C) and ZrN (2980 °C). Thus, the gas phase can be employed as a reaction medium.
Additionally, the solid phase can trigger certain reactions as well. The addition of Ti powder and a forming gas lead to the formation of an interpenetrating phase composite made from TiN and ZrO. The commonly weak interface between these two very different ceramics is stabilized through mechanical interlocking of the two phases, observed by cross-section elemental mapping in TEM. These TiN films are only a few 100 nm thick, yet present the excellent electrical conductivity that is common for this material. Since ZrO_2 is itself the solid electrolyte in solid oxide electrolyte fuel cells, such a conversion can be used to produce stable contacts for current collection.
In additive manufacturing, the conversion technique can be employed to produce and partially convert ceramics to equip them with special functionalities. For example, Zn can be directly oxidized to the semiconductor ZnO in situ and thus produce functional nanostructures in the manufacturing process.
In this contribution, I will show how high-power CO_2-laser treatments and additive manufacturing can be employed together to create in situ high temperature reaction and ultimately convert and stabilize these products.

3:45 PM *MF02.02.06
Rapid, Continuous Projection Multi-Photon 3D Nanoprinting enabled by Spatiotemporal Focusing of Femtosecond Pulses Xianfan Xu; Purdue University, United States

Two-photon lithography has become the dominant fabrication process for 3D nanoprinting for most applications today due to its capability to produce submicron features and true 3D printing of arbitrary structures. Still, the printing rate is often considered slow. Multiple methods have been proposed for improving two-photon 3D nanoprinting rates. Here, a rapid, continuous, layer-by-layer projection two-photon lithography process is described. To achieve 3D printing with submicron feature sizes, a spatiotemporal focusing effect due to a digital micromirror device (DMD) projection system applied to the femtosecond printing laser pulses confines the polymerization region of the photoresist to a thin 2D plane. By continuously changing the projected DMD pattern without pauses in printing layers while varying the height of the print plane in the photoresin, smooth 3D prints are achieved rapidly. Millimeter scale printing is demonstrated by printing various complex 3D geometries. This presentation will also discuss recent progresses toward grayscale printing, real time imaging and feedback, multiple beam printing, and machine learning to improve the speed and accuracy of 3D nanoprinting.

4:15 PM MF02.02.07
Direct Laser Writing of Complex 3D Metal Nanoparticle Patterns within Polymer Microstructures for Photothermal Micro-Actuators Luisa Lavelle[1], Srikanth Kolagatla[1], Paola Parlanti[2], Mauro Gemmi[2], Colm B. Delaney[1] and Larisa Florea[1]; [1]Trinity College Dublin, Ireland; [2]Istituto Italiano di Tecnologia, Italy

This work describes the fabrication of complex 3D structures comprising of metallic Ag nanoparticles (NPs) which were manufactured inside prefabricated polymer structures by direct laser writing (DLW). In recent years, DLW has been established as a powerful tool for the fabrication of 3D micro-objects with features below 300 nm. This additive manufacturing technology is an adaptable, high-resolution process, where structure fabrication can be achieved

via multi-photon polymerisation or metal photo-reduction.[1,2] More recently, this technique has been applied to the fabrication of stimuli-responsive hydrogel microstructures. Due to their size, these structures offer dramatically improved response times, where the inherently slow diffusion-controlled hydrogel expansion is countervailed. In this context, stimuli-controlled hydrogel micro-actuators show improved performance compared to their macro-scale counterparts and find applications across many fields including micro-robotics, microfluidics and biomedical devices.[3]
The micro-structures described herein were realised using a two-step approach. The first step comprised the fabrication of polymer structures via DLW by free-radical polymerisation. Following their fabrication, the polymer structures were immersed in a solution of Ag^+ and a second DLW process was conducted to induce photoreduction of the Ag^+ ions, thereby creating complex patterns of Ag particles inside the 3D polymer microstructures. TEM characterisation of microstructure cross-section was used to characterise the metal particle size and the distribution of particles. The size of the obtained particles was also compared to the voxel size obtained under the range of laser powers and scan speeds, in order to establish a protocol for the realisation of controlled metal particle size via DLW.
The same two-step approach was used to create microstrucures showing photo-induced actuation. In this case, the microstructures were fabricated in the thermo-responsive polymer poly(*N*-isopropylacrylamide) (PNIPAAM). PNIPAAM is vastly employed for the realisation of thermo-actuators, owed to its thermo-responsive properties associated with a phase transition at the lower critical solution temperature (32 °C).[4] Ag NP patterns were then written *in situ* inside the PNIPAAM structure, to act as photothermal converters. Laser irradiation of the Ag NPs patterns caused localised heating, inducing fast, controllable and reversible actuation of the microstructures. We further demonstrate how the actuation direction and speed can be tuned by controlling the Ag pattern and by the laser writing/scanning speed.

SESSION MF02.03: Laser-Induced Functional Surfaces for Energy Storage Devices
Session Chairs: Antje Baeumner and Jonathan Claussen
Wednesday Morning, April 24, 2024
Room 324, Level 3, Summit

9:15 AM *MF02.03.01
Skin-Interfaced Wearable Biosensors based on Laser-Engraved Graphene Wei Gao; California Institute of Technology, United States

Laser-engraved graphene (LEG) has been applied increasingly in wearable and flexible electronics over the past decade owing to its unique physical and chemical properties. It has shown great promise in energy controls, chemical and physical sensing, and telemedicine. In this talk, I will introduce our efforts in developing LEG-based wearable biosensors for non-invasive molecular analysis. Such wearables can autonomously access body fluids (e.g., human sweat) across the activities and continuously measure a broad spectrum of analytes including metabolites, nutrients, hormones, proteins, and drugs. Laser engraving enables the manufacturing of high-performance nanomaterials-based biosensors at large scale and low cost. The clinical value of our LEG-based wearable systems is evaluated through various human trials toward precision nutrition, stress/mental health assessment, and chronic disease management (e.g., systemic inflammation monitoring). These wearable technologies could open the door to a wide range of personalized monitoring, diagnostic, and therapeutic applications.

9:45 AM MF02.03.02
E-Textile Enabled by Femtosecond-Laser-Induced Graphene Formation on Kevlar Dongwook Yang[1], Han Ku Nam[1], Truong-Son Dinh Le[1], Seung-Woo Kim[1], Soongeun Kwon[2] and Young-Jin Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Machinery & Materials, Korea (the Republic of)

Personal wearable devices are anticipated to have a pivotal role in advanced healthcare, sports, firefighting, and military contexts in the near future. E-textiles are a promising solution, as they can combine electrical and informative functions, incorporating various sensors, actuators, and energy storage components while maintaining a high degree of flexibility and adaptability. However, existing methods for e-textile production involve weaving conductive fibers and installing functional elements onto conventional textiles, which can be time-consuming, cause gradual wear and tear of conductive yarns, and create challenges in integrating different functional units seamlessly. To meet the growing demand for flexible and timely manufacturing of personalized e-textiles, a simpler design and patterning strategy is essential.
Graphene, with its remarkable electrical conductivity and mechanical and chemical stability, is a promising material for e-textiles. Laser-induced graphene (LIG) synthesis, which uses laser scanning to transform carbon precursors into graphene, has gained attention. Textiles, particularly Kevlar, have emerged as valuable LIG precursor materials. Previous attempts using CO2 lasers to convert Kevlar to LIG resulted in textile damage and limitations in resolution and conductivity. To achieve advanced e-textiles, it's essential to explore direct LIG patterning with improved resolution and minimal ablation, eliminating the need for fiber weaving and preserving high LIG conductivity without degradation concerns.
Textiles can be categorized into nonwoven, knit, and woven types, each with distinct physical properties due to their unique structures. Understanding these structures is crucial for creating high-performance e-textiles. Nonwoven textiles consist of randomly aligned yarns mechanically bonded or adhered together. They have high strength but low stretchability. Knit textiles, made from intersecting yarn loops, are inherently stretchable, resembling a mechanical spring. Woven textiles involve interlacing weft and warp yarns, creating special bending sensing networks when subjected to strain.
In this study, we introduce a straightforward method for creating multi-modal e-textiles. We achieve this by one-step, maskless patterning of LIG using near-infrared ultra-short femtosecond laser pulses on various Kevlar textiles, including nonwoven, knit, and woven varieties. Our approach directly transforms common textiles into e-textiles in a cost-effective and simple manner, without the need for fiber weaving, while preserving their flexibility, adaptability, and air-permeability with minimal ablation. This direct laser writing method is faster, more accessible, and allows for better carbon ratio control compared to conventional techniques like chemical vapor deposition (CVD) and thermal reduction. Nonwoven textiles, with their high mechanical strength and resistance to external strains, are suitable for applications unrelated to mechanical strain, such as energy storage devices and temperature sensors. The supercapacitor demonstrates a specific areal capacitance of 36.17 mF/cm^2, and the temperature sensor exhibits a thermal coefficient of

resistance (TCR) of -0.097% per degree Celsius within the temperature range of 5 to 100 degrees Celsius. The knit structure, known for its wide stretchability, is ideal for creating strain sensors to detect human motion, with a gauge factor (GF) reaching 117.9 within a 0-3% strain range. The woven structure, characterized by a lattice-like network, is suitable for fabricating a bending sensor for voice recognition, with a GF of 230 within a 0-0.5% strain range. These demonstrations underscore the capability of femtosecond pulse lasers for one-step, maskless patterning of high-performance LIG sensors and energy storage devices, paving the way for future wearable multi-modal e-textiles.

10:30 AM *MF02.03.03
Graphene Synthesis, Laser Scribing and Applications in Supercapacitors Richard B. Kaner; University of California, Los Angeles, United States

Graphene is the ultimate two-dimensional material consisting of a single layer of sp^2 hybridized carbon. A facile, inexpensive, solid-state method for generating, patterning and electronic tuning of laser converted graphene will be discussed. Briefly, graphite can be converted into graphene oxide (GO) sheets, which readily disperse in water, and can then be reduced by various methods. Due to its unique ability to be solution processed and patterned, GO can be laser reduced to graphene directly onto various substrates without masks, templates, post processing, or transfer techniques. This work paves the way for the fabrication of inexpensive electrochemical energy storage devices that combine the energy density of batteries and the power density of capacitors. This technique can create more than 100 micro-devices in a single run on virtually any substrate.

11:00 AM MF02.03.04
Pulsed Laser-Induced Dewetting for The Formation of Monometallic and Bimetallic Nanoparticle Arrays on Patterned Dimpled Tantalum Substrates and Their Electrochemical Properties Yujun Shi, Stephanie N. Bonvicini, Annie Hoang and Vilola Birss; University of Calgary, Canada

Highly ordered metal nanoparticle (NP) arrays have attracted great research interest due to their unique electronic, optical and magnetic properties, leading to their diverse applications as model electrodes for electrocatalysis in fuel cells, sensors, in magnetic memory arrays and catalyst arrays for the growth of semiconductor nanowires. Here in this work, we report the use of pulsed laser-induced dewetting (PLiD) for the fabrication of metallic NP arrays, including monometallic (Au, Pt) and bimetallic Au-Pt, on a pre-patterned dimpled Ta substrate. In PLiD, the metal is quickly heated to above its melting point within a short duration of the incident laser irradiation and the molten film breaks up to form metal NPs to reduce the free energy of the film-substrate-ambient system. The highly ordered dimpled Ta substrate, formed by anodization of polycrystalline Ta in a H_2SO_4 + HF solution, consists of a self-assembled array of inverted hemispherical caps, or nanodimples. It has been shown that highly ordered Au, Pt, and Au-Pt NP arrays can be produced on the dimpled Ta substrate with excellent monodispersity, long-range order and good dimple coverage. Compared with thermal dewetting, which is a solid-state dewetting method driven mainly by surface diffusion, PLiD is more efficient and better suited for metals of high melting point. The size of monometallic Au and Pt NPs can be controlled by the initial film thickness as the dewetting process is shown to follow the spinodal dewetting mechanism. For the bimetallic Au-Pt NPs, the total bilayer metallic film thickness plays a determining role. We have also shown that the metallic NPs formed by PLiD are more spherical in shape than those by thermal dewetting. The produced bimetallic Au-Pt NPs have a configuration of a Pt-rich core and Au-rich shell. Finally, characterization of the electrochemical properties of the Pt-rich core/Au-rich shell NPs reveals strong Pt-O bonding on the bimetallic NP surfaces. In addition, while Au is enriched on the bimetallic NP surfaces, a significant Pt content, ranging from 10% to close to 40%, is still present on the NP surfaces, which makes the produced Au-Pt NPs useful for bifunctional electrocatalytic reactions.

11:15 AM MF02.03.06
Laser-Induced Oxidation and Defect Formation of Thin-Film Materials for High-Throughput Materials Discovery Drake R. Austin[1,2], Brian Everhart[2], Michael Altvater[1,2], Mario Hofmann[3], Rahul Rao[2] and Nicholas Glavin[2]; [1]UES Inc., United States; [2]Air Force Research Laboratory, United States; [3]National Taiwan University, Taiwan

The discovery of nanomaterials is an exceptionally slow process requiring many years of development in order to translate fundamental research to real capabilities. Consequently, a rapid materials discovery approach is needed to understand and tailor the properties of materials for specific applications. In this work, we present a high-throughput laser-processing methodology for producing and characterizing hundreds of modified regions on a single precursor sample. In particular, laser-induced oxidation and defect formation in transition metal dichalocogenides is presented, where the thermodynamics of the process is controlled by scanning a continuous-wave laser across the sample surface at varying scans speeds and intensities. Coupled with in-situ Raman and photoluminescence spectroscopy, this allows for the generation of laser-processing diagrams indicating the conditions necessary to produce varying stoichiometries, crystal structures, and defect densities. With additional ex-situ optical and electrical characterization, this method can be used to identify novel materials with properties of interest for a variety of applications including sensing, photocatalysis, and neuromorphic computing.

11:30 AM *MF02.03.07
Laser-Matter Coupling Mechanisms Governing Nanoscale Damage on Particulate-Contaminated Optical Surfaces Manyalibo Matthews; Lawrence Livermore National Laboratory, United States

The recent fusion ignition breakthrough at Lawrence Livermore National Laboratory's National Ignition Facility has generated a renewed interest in improving high damage threshold optical materials.While decades of improvements in optical material processing for high power laser systems has led to unprecedented levels of laser damage tolerance, surface contamination on surfaces generated during laser operation, optic assembly or handling can still lead to damage initiation and local failure of the optic. Laser micromachining of optics for damage repair and laser-induced damage cross-contamination can also introduce nanoparticulate debris, compounding the issue further.In addition to local damage initiated at the site of the debris and leading to failure, *non-local* mechanisms associated with contamination have been recognized wherein nano- to microscale particles on the entrance surface of optics can lead to Fresnel diffraction of incident light and damage on the exit surface.The dynamics of the laser-particulate interaction involve high gradients of pressure,

temperature and corresponding changes to thermodynamic material properties, plasma formation and aerodynamic effects that drive nanoscale morphological changes to the optical surface. In addition, the formed plasma can interact with the laser pulse while the melted material layer on the particle is ejected and thus be the source of secondary nanoscale contamination/surface pitting.
In this talk, I will present a study of the interaction of microscale, metallic and glass particles bound to optical surfaces with nanosecond and picosecond laser pulses at 1064- and 355-nm that results in nanoparticle ejection and nanoscale modification of the optical surfaces. Our in situ experimental platform allows direct measurements of the particle velocity, plasma formation, and the kinetics of the ejected nanoscale material. Large aperture damage tests were also performed to assess damage probabilities and probe the stochastic nature of particle-induced damage events. We use FDTD, Fourier beam propagation and ray tracing to understand the effect of particle shape and particle-induced nano-pitting on beam propagation. By varying the combination of particle and substrate materials, we are able to gain important insights to the governing mechanisms of laser-particle interactions which could lead to improvements in inertial confinement fusion laser system designs. This work was performed under contract DE-AC52-07NA27344.

SESSION MF02.04: Laser-Induced Graphene Processing Methods and Applications

Wednesday Afternoon, April 24, 2024
Room 324, Level 3, Summit

1:30 PM *MF02.04.01
The Discovery of Laser-Induced Graphene James M. Tour; Rice University, United States

Described will be the initial discovery of laser-induced graphene in 2013 and early rapid developments over the next few years. This will be a historical outlook, noting the initial post docs, graduate, and undergraduate students, that laid the foundation for this remarkably simple method to patterned graphene surface and devices. The science of materials conversion to graphene will be discussed. The surfaces will be outlined, starting with polyimide, and then branching into nearly any carbon surface through simple adjustments to the laser. Early devices will be presented, including energy devices and sensors that set the groundwork for enormous advances in engineering designs around the world.

2:00 PM MF02.04.02
ReaxFF Simulations of Laser-Induced Graphene Formation Aniruddh Vashisth; University of Washington, United States

Polymer films subjected to CO2 infrared laser irradiation in ambient conditions undergo a transformation, resulting in the formation of porous graphene known as laser-induced graphene (LIG). In this presentation, we will discuss finding from reactive molecular dynamics simulations (ReaxFF) to investigate LIG formation from five different polymers structures. Our research revealed that the initial molecular structure of the parent polymer significantly influences the resulting graphitic structure. During the early stages of LIG formation, the polymer transforms into an amorphous structure, releasing CO, and subsequently evolves into an ordered graphitic structure, liberating H2 steadily. The resulting LIG exhibits out-of-plane undulations and bends due to the presence of numerous 5- and 7-member carbon rings throughout the structure. Our simulated molecular structure aligns well with recent experimental observations in the literature. Moreover, we observed that LIG yield is higher in inert conditions compared to oxygen-rich environments. Specifically, LIG derived from polybenzimidazole demonstrated the highest surface area and yield among the five polymers studied. These findings enhance our understanding of LIG formation mechanisms, offering valuable insights for various bulk LIG applications such as sensors, electrocatalysts, microfluidics, and precise polymer welding through targeted heating.

2:15 PM MF02.04.03
Exploring The Potential of Laser-Induced Graphene (LIG) from Polyfurfuryl Alcohol (PFA) for High-Performance Electrodes in Batteries and Supercapacitors Michael A. Pope; University of Waterloo, Canada

Infrared (IR) lasers, such as the carbon dioxide laser popularly used by hobbyists and various industries for precision cutting and marking/engraving, are increasingly employed in the conversion of carbonaceous precursors into a mesoporous graphene-like carbon material, known as laser-induced graphene (LIG). In this presentation, I will delve into my research group's recent explorations into the potentials and limitations of utilizing this technique to create electrodes for batteries and supercapacitors. Our focus centers on the carbon precursor polyfurfuryl alcohol (PFA), a common component for crafting glassy carbon electrodes, derived from waste biomass. By amalgamating PFA with IR transparent salts, we aim to extend the laser's penetration depth, thus producing electrodes with an enhanced surface area or greater areal mass loading. Our findings reveal that typical salts, such as sodium chloride or sodium sulfate, not only achieve these objectives but also serve a dual role as a templating and doping agent, markedly improving the areal capacitance of symmetric supercapacitors. Furthermore, by incorporating this system with metal salts or catalyst precursors, we engineer unique compositions and nanostructures exhibiting significant electrochemical activity towards the oxygen reduction reaction. Our studies show that the process of direct laser writing on air-cathodes is a superior method to develop high-performance zinc-air batteries.

High-Performing Electrochemical Sensors enabled by Electropsun Laser-Induced Carbon Nanofibers Nongnoot Wongkaew; University of Regensburg, Germany

Since its emergence, laser-induced carbon nanomaterial technology has revolutionized the fabrication of flexible electrodes applicable in several areas, which includes the development of high-performing electrochemical sensors at low cost. A wide array of substrates and composites have been successfully converted into carbon nanomaterials as well as their associated functional hybrids. Electrospun nanofibers as a substrate have caught our attention owing to their 3D-fibrous structure featuring high porosity and huge surface area-to-volume ratio, foreseeing the enhanced detection sensitivity when they are employed as electrochemical transducers. Moreover, doping the polymer solution prior to spinning allows tuning of properties and convenient modifications of fiber precursor, enabling facile fabrication of electrochemical transducers with favorable functionalities. In addition, their manufacturing process can be effectively controlled via spinning parameters, and easily scaled up at relatively low cost. However, when electrospun nanofibers are subjected to laser-processing their fluffiness and delicate structure pose significant challenges, which required thorough investigations to enable laser-induced carbon nanofibers (LCNFs) with desired properties. This talk will first highlight the parameters of the electrospinning and lasing processes, which critically govern the morphological and electroanalytical properties of the LCNF electrode. Afterwards, the talk will focus on how to implement the strategy to realize high performing enzyme-less electrochemical sensors. Here, the incorporation of metal salt precursor into the electrospun nanofibers

allows for further *in situ* formation of electronanocatalysts embedded with the LCNFs. Through electrospinning, the metal precursor can be uniformly distributed within the nanofibers, subsequently promoting homogeneous dispersion of the nanocatalysts within the LCNFs. As shown in an exemplary case, the immense electroactive surface area of LCNFs with highly dispersed Ni nanoparticles permitted the detection of glucose in sub μM range, which considerably outstands other reports where sophisticated procedure and costly instruments were required. Furthermore, the strategy for integration of LCNFs into miniaturized devices will be illustrated. Herein, the devices contained 3D-porous electrochemical transducers with pore sizes of ca. 5-10 μm (an order of magnitude smaller than the pores in comparable graphene foam) and unsurprisingly offered an impressive limit of detection for dopamine sensing (down to pM range). Finally, the talk will demonstrate LCNFs as part of a lateral flow assay (LFA). Here, 25-fold enhancement in detection sensitivity of a common redox marker could be obtained when compared to the LFA integrated with a flat screen-printed electrode. Overall, the investigations have proven that LCNFs are highly promising for the development of point-of-care testing where high analytical performance can be achieved together with high affordability.

Selective and Biocompatible Neural Probes with a Fluorous Sensing Phase Farbod Amirghasemi, Abdulrahman Al-Shami and Maral Mousavi; University of Southern California, United States

Laser engraving is becoming a widely popular method for producing porous graphitic carbon structures, known as Laser-Induced Graphene (LIG), for sensing applications. LIGs are produced by ablating carbon-rich polymers(mostly polyimide) using a laser beam, which creates local photothermal reactions converting SP_3 carbon atom hybridization into 3D porous graphitic structure. This method is a maskless, scalable, reproducible, cost-effective, and fast approach to producing graphene layers with high electrical conductivity and electrocatalytic nature, which makes LIGs superior over graphene created using conventional methods such as chemical vapor deposition (CVD) and wet chemistry.

Here, we developed the first use of a fluorous-phase potentiometric sensor for the measurement of acetylcholine (ACh), a vital neurotransmitter in brain activity. Fluorous compounds (molecules with high content of fluorine atoms) are extremely non-polar and non-polarizable to the extent that they are not miscible with both aliphatic compounds such as hexanes, and with water and other hydrophilic compounds. Therefore, fluorinated compounds are both hydrophobic and lipophobic. Since, the living systems are made of water and lipophilic compounds, makes fluorocarbons bio-orthogonal and nontoxic, meaning that they do not interfere with biology. Biocompatibility of fluorocarbons has resulted in many biomedical applications such as artificial blood, bio-orthogonal imaging contrast agents, and delivery and imaging vehicles. Fluorocarbons are used as coatings in biomedical devices to lower sensor biofouling and cell adhesion to the device. Exceptional selectivities that far outperform a conventional lipophilic sensing membrane were also reported for ionophore-doped fluorous sensing membranes. Such gain in selectivity is attributed to non-coordinating and poorly solvating properties of the fluorous-phase. The high selectivity, biocompatibility, and potentially exceptional resilience to biofouling make fluorous-phase sensors ideal for neural applications. Neurotransmitters present in nanomolar concentrations are a complex matrix (requiring high selectivity). Moreover, studying the dynamics of change and the correlation of such changes to behavior and stimulation is desired (requiring long-term in-vivo studies through implantable sensors).

We showed that selectivity gain in the fluorous phase resulted in more than an order of magnitude improvement in the limit of detection (LOD). Moreover, to move towards in-vivo application of the fluorous-phase ACh sensor (where probe size and flexibility are critical), we have developed the first compact and flexible solid-contact fluorous-phase potentiometric sensor. We fabricated the electrodes using laser-induced carbonization of flexible polyimide films.

Utilizing the laser engraving to fabricate neuroprostheses could enbale more efficient fabrication approach toward neural probe by eliminating the intricate and expensive microfabrication approach. We are utilizing polyimide due to providing a pinhole-free, high flexibility, high mechanical strength, and biocompatible platform to construct implantable ACh-detecting sensors consisting of a working electrode (containing an acetylcholine organic sensing membrane) and a reference electrode (containing a reference membrane). The electrical potential (emf or electromotive force) between the ACh sensor and reference electrode correlates to the activity of ACh in the biofluid, according to the Nernst Equation ($E=E°+(RT/nF)\ \mathrm{Log}\ (a_{ACh})$), where E° shows the standard potential, R the universal gas constant, T temperature, F the Faraday constant, n the charge of the ion, and a_{ACh} the activity of ACh. A theoretical slope of 59.2 mV/decade is expected at room temperature and is defined as the Nernstian slope. The fluorous-phase solid-contact LIG ion exchanger electrode showed a near Nernstian slope of 54.9 ± 0.8 and a 42 nM limit of detection.

Laser-Induced Graphene for Electrochemical Sensing: From Process Development to Real-World Applications Cicero C. Pola, Raquel Soares, Zachary T. Johnson, Gustavo Miliao, Nathan Jared, Robert Hjort, Jonathan Claussen and Carmen L. Gomes; Iowa State University, United States

Graphene-based electrodes offers a promising solution for developing effective electrochemical sensors due to their high surface area (2630 $m^2\ g^{-1}$), mechanical strength (Young's Modulus ~1100 GPa), electrical conductivity (~64 mS cm^{-1}), chemical stability, biocompatibility, and tunable properties. Among graphene-based electrodes, laser-induced graphene (LIG) has emerged as a cost-effective, scalable alternative by directly converting sp^3 carbon found in carbon-rich substrates, such as polyimide into conductive sp^2-hybridized carbon found in graphene through a laser scribing technique. We have demonstrated that the surface area and wettability of the LIG can be tuned to greatly improve the sensitivity of electrochemical enzymatic biosensors (detection limits down to the picomolar range) and reduce the water layer buildup between the ion-selective membrane and the electrode, which improves the accuracy of the sensor readings and its longevity. We have systematically characterized LIG formation and how the quality of graphene can be improved by varying the laser power, focus, DPI (dots per inch), and the number of repeat runs. We demonstrated that initial defocused lasing followed by focused lasing improves the quality of graphene produced, the surface wettability, and the resulting electrochemical sensors. The LIG electrodes have been used in a wide variety of electrochemical sensing applications including in food safety, environmental (soil and water) monitoring, wearable health sensors, and even for urinary potassium and ammonium, and salivary lactate and potassium sensing. All these electrochemical sensors have been validated in real-world samples and demonstrated to have limits of detection and linear sensing ranges that are relevant to their sensing applications. Additionally, we have demonstrated the ability to fabricate LIG electrodes using biodegradable substrates (i.e.; paper and cork) as a more sustainable approach to electrochemical sensing. The responses of the LIG-based ion-selective electrodes from cork and paper exhibited similarities to those made from the standard material, polyimide. In these studies, we show how high-quality, sensitive LIG electrodes can be systematically fabricated and integrated into electrochemical analytical devices for point-of-service and in-field applications.

Laser Reactive Sintering of Complex Oxides Jeldrik Schulte, Martin A. Schroer and Markus Winterer; Universität Duisburg-Essen, Germany

UV laser sintering allows densification and microstructural transformation of granular systems. The high photon energy of an UV laser leads to resonant heating if the energy is higher than the band gap of the irradiated material. Due to this effect, the heat load is strongly localized, and for nanostructured materials temperatures up to 2000°C and extremely high heating rates are reached at low laser powers [1]. Therefore, UV laser sintering is a versatile tool for materials engineering, as it enables reactive sintering of binary metal oxides to generate complex oxides with short process times. It is also feasible for processing (printed) electronic components with structures in the micrometer range.

The complex oxide $CuAlO_2$ is a transparent conductive oxide (TCO) with p-type conductivity [2]. TCOs are widely used in photovoltaics and optoelectronic devices like flat panel displays or solid-state lighting. However, the performance of p-type TCOs is still significantly lower compared to n-type TCOs. This impedes the production of high-performance p-n junctions, needed as key components for active electronic devices. Complex oxides with delafossite structure, like $CuAlO_2$, have shown great potential to overcome this problem [3].

The production of the $CuAlO_2$ delafossite is a challenge, because of the complexity of the binary phase diagram. In this contribution, we will present the generation of $CuAlO_2$ by reactive UV laser sintering of copper and aluminum nanoparticles and their characterization, including µXRD diffraction.

Pyrolytic Jetting of Free-Standing Laser-Induced Graphene Fiber for Cost-Effective Supercapacitor Hyunkoo Lee[1,2], Dongwoo Kim[3], Koungjun Min[1,2], Ji Hwan Lim[1,2], Sukjoon Hong[1,2] and Habeom Lee[3]; [1]Hanyang University, Korea (the Republic of); [2]BK21 Four Erica-Ace Center, Korea (the Republic of); [3]Pusan National University, Korea (the Republic of)

In recent times, the significance of energy storage has surged due to the expanding use of renewable energy for achieving carbon neutrality. Efficient energy storage is crucial for stabilizing power grids amid the intermittent energy production from sources like solar and wind, as well as for meeting the escalating demand for reliable energy storage. Simultaneously, the rapid and widespread adoption of electric vehicles has highlighted the significance of energy storage solutions. As conventional combustion engines give way to electric-powered vehicles, an escalating demand emerges for energy storage systems that embody safety, reliability, and cost-efficiency while delivering requisite power. These advancements underscore the growing significance of energy storage in shaping our energy landscape and ensuring future energy security. As our society steadily progresses towards a sustainable, low-carbon trajectory, the need for versatile energy storage solutions is accentuated.

Supercapacitors offer distinct advantages, including higher power density, extended cycle life, and simpler material composition compared to batteries, making them a prominent energy storage solution. Graphene, particularly in the form of Laser-Induced Graphene (LIG), has emerged as a standout material for supercapacitors due to its rapid charging/discharging capabilities and extensive specific surface area. LIG's unique porous morphology holds great promise for various applications and has the potential to enhance energy storage performance by maximizing surface-area-to-volume ratios. Considering an environmentally conscious perspective, it becomes imperative to minimize energy consumption and material utilization during the fabrication process, while simultaneously maximizing storage capacity. A recent study in laser technology, known as pyrolytic jetting, has come to light under precise laser conditions (125 J/m). This innovation yields an incredibly porous, freestanding fiber-shaped LIG, demonstrating potential advantages for energy storage applications. In contrast to electrodes affixed to specific substrates, these fiber-shaped electrodes present significant merits as energy devices for diverse applications, notably through their remarkable characteristic. Despite its vast potential, research on its practical application in energy devices has been relatively limited.

Our study on laser pyrolytic jetting presents an efficient method to produce highly porous, free-standing graphene fibers from polyimide film. This process involves precise scanning of a continuous-wave laser, resulting in significant advantages over conventional LIG techniques. In this follow-up investigation, we demonstrate the superior potential of the laser pyrolytic jetting process for energy device applications, offering remarkable energy and material savings. Notably, the pyrolytic jetting process significantly increases the volume of the pyrolyzed product compared to conventional LIG, leading to an expanded surface area capable of storing a greater amount of electric charges. Raman measurement verifies the comparable attributes of the exfoliated material obtained through pyrolytic jetting and traditional LIG, making it exceptionally suitable for supercapacitor applications. Consequently, supercapacitors produced via pyrolytic jetting demonstrate a notable increase in capacitance, indicating an improvement of over 4.7 times compared to conventional LIG. This underscores the potential of pyrolytic jetting as a cost-effective fabrication technique for carbon-based energy devices.

5:00 PM MF02.05.03
Direct-Laser Scribing of Electrodes Using Metal-Organic Frameworks for Electrochemical Detection Beatrice De Chiara, Fulvia Del Duca, Mian Zahid Hussain and Bernhard Wolfrum; Technical University of Munich, Germany

Electrochemical sensors have gained widespread recognition and utilization across diverse domains, encompassing applications such as clinical diagnosis, biochemical detection, and environmental monitoring. In the pursuit of enhancing these sensors, metal-organic frameworks (MOFs) have emerged as highly promising material candidates. MOFs are known for their porous structures, which exhibit substantial surface areas, remarkable stability, and a unique capacity for functionalization.
Here, we aim to integrate MOF structures into laser-induced graphitic (LIG) electrodes to improve the performance of electrochemical sensing devices. LIG electrodes present certain advantages over classical noble metal electrodes, such as reduced cost and ease of fabrication. We investigate the disparities between LIG sensors and LIG-MOF sensors, both of which are fabricated using direct laser scribing, a fabrication technique with the remarkable capability to convert non-conductive materials into active electrode materials, all the while generating desired patterns directly onto polymer substrates. Central to this investigation is the conversion of MOFs into patterned derived carbon utilizing an ultraviolet (UV) laser system. The process entails several steps. Initially, a solution containing MOFs is drop-cast onto a polyimide (PI) foil substrate. Once the MOFs composite is deposited onto the substrate, the

electrode is directly patterned with the UV laser. Importantly, the MOFs composites are confined to the electrode area, while the feedline and contact pad exclusively consist of LIG. For the passivation of the structures, Parylene C (poly(p-xylylene)), a flexible dielectric polymer, is chosen due to its good insulation properties and conformability. A thin film of Parylene C, approximately 5 micrometers thick, is deposited via chemical vapor deposition. Subsequently, the electrode area and contact pad are precisely opened using the laser.
The characterization of the resultant sensors was conducted using scanning electron microscopy, Raman spectroscopy, impedance spectroscopy, cyclic voltammetry, and differential pulse voltammetry. These characterizations revealed the emergence of a highly porous carbonaceous material, with low-impedance observed in the case of the LIG-MOF sensors. This approach not only expands our understanding of MOF integration into electrochemical sensing but also underscores the potential for applications where high charge injection capabilities and low impedance at an electrode/electrolyte interface are required.

5:00 PM MF02.05.04
Electrochemical CO_2 Reduction to HCOOH Catalyzed by $Ag_n(NO_3)_{n+1}$ Clusters prepared by Laser Ablation at The Air-Liquid Interface Teppei Nishi, Shunsuke Sato and Takeshi Morikawa; Toyota Central R&D Labs., Inc., Japan

Nanomaterials generated via laser ablation in liquid have been developed because of the capability to generate nanoparticles without chemical reagents. However, it is difficult to obtain monodispersed and small (< 2 nm) nanoparticles. We have reported laser ablation at the air-liquid interface to obtain monodispersed and small (ca. 5 nm) nanoparticles [1]. Here, we report laser ablation at the air-liquid interface using colloidal nanoparticles as a target to obtain smaller clusters [2]. Colloidal target was prepared by laser ablation of Ag powder precipitated on the bottom of the flask. Pulsed laser was irradiated through the bottom of the flask. After laser irradiation for 60 min, Ag nanoparticles stably dispersed in pure water was obtained. This colloid exhibited a large absorption peak at 400 nm. This colloidal solution was agitated in a measuring flask during laser ablation at the air-liquid interface. After laser ablation at the air-liquid interface, we obtained colorless and transparent solution, indicating the drastic size reduction. UV-Vis absorption spectra exhibited peaks in UV region. It indicated small cluster formation. The size was assessed by electro-spray ionization-mass spectrometry. It revealed $Ag_n(NO_3)_{n+1}$ cluster generation. To investigate the electrocatalytic activity, $Ag_n(NO_3)_{n+1}$ clusters were deposited on carbon paper substrate. Electrocatalytic activity for CO_2 reduction was assessed in CO_2 saturated aqueous 0.1 M $KHCO_3$ solution at an applied potential of -1.2 V vs RHE with Ag/AgCl reference electrode and Pt wire counter electrode. As well-known, micro and nano-sized Ag catalyst as comparisons generated CO via electrochemical CO_2 reduction. In contrast, $Ag_n(NO_3)_{n+1}$ clusters generated HCOOH with a Faraday efficiency of 33%. The results indicated a drastic change in the selectivity induced by laser ablation at the air-liquid interface. Because the unique selectivity, carbon source of HCOOH was determined by isotope tracer analyses using $^{13}CO_2$ and $KH^{13}CO_3$ together with ion chromatography-mass spectrometry. Because only $H^{13}COO^-$ peak was confirmed, it can be concluded that HCOOH was generated from CO_2. Both the catalyst size and modification by NO_3 potentially explain the results.

Quick and Reversible Superwettability Switching of 3D Graphene Foams via Solvent-Exclusive Microwave Arcs Soomin Cheon, Won-Jang Cho, Gi-Ra Yi, Byoungwoo Kang and Seung Soo Oh; Pohang University of Science and Technology, Korea (the Republic of)

For highly active electron transfer and ion diffusion, electrically and thermally conductive 3D graphene foams (3D GFs) heavily rely on precise control of their surface wettability with respect to different polarities of fluids. For their practical applications, either hydrophilic or hydrophobic 3D GFs are prepared in advance; even though there have been many different ways of controlling their surface wettability, such as solvent treatment, heteroatom doping, ultraviolet or laser irradiation, and plasma treatment, they are time-consuming and even high-cost processes, limiting them to be only applicable for 2D graphene or powders. Here, we present ultra-simple and rapid superwettability switching of 3D GFs in a reversible and reproducible manner, as mediated by solvent-exclusive microwave arcs. As the 3D GFs are pre-coated with vaporized solvents exclusively, short microwave radiation (≤10 s) leads to plasma hotspot-mediated production of polar or nonpolar radicals. Upon immediate radical chemisorption, the 3D surfaces become either superhydrophobic (water contact angle = ~170°) or superhydrophilic (~0°), and interestingly, the dramatic wettability transition can be repeated many times due to the facile exchange between previously chemisorbed and newly introduced radicals. Our microwave-mediated, quick and reversible wettability switching would be applicable for many different applications (e.g., energy storage, sensing, microfluidic transportation, and water-oil separation). Importantly, our superwettability switching is applicable for all kinds of carbon-based nanomaterials, including 2D graphene and carbon nanotubes.

5:00 PM MF02.05.06
Ultra-Thin Ultra-Light Planar Diffractive Lens with Laser-Induced Graphene (LIG) Younggeun Lee[1], Dongwook Yang[1], Hyeokin Kang[1,2], Han Ku Nam[1], Hyogeun Han[1], Seunghwan Kim[1], Joohyung Lee[2], Seung-Woo Kim[1] and Young-Jin Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University of Science and Technology, Korea (the Republic of)

By subjecting carbon-containing materials to a straightforward laser irradiation process, we can selectively transform them into laser-induced graphene(LIG), a material renowned for its outstanding electrical properties. This laser-induced graphene can be easily generated from carbon polymers like polyimide or even natural substances such as wood and leaves.

Polyimide, a leading precursor compound for Laser-Induced Graphene (LIG), is widely used in electronic devices for its remarkable chemical resistance and durability, particularly in circuits and displays. However, its application as an optical material, capable of effectively transmitting light, has been constrained by its selective performance in the visible light spectrum. To overcome this limitation, researchers have developed colorless polyimide(CPI), providing a solid foundation for polyimide to function as an optical material with exceptional performance in the visible light range.

We had converted this colorless polyimide(CPI) into laser-induced graphene(LIG) through femtosecond laser irradiation and embarked on research to create diffractive optical devices using it. The porous structure formed by the release of carbon dioxide and various gases during the laser-induced graphene(LIG) generation process leads to diffuse light reflection, resulting in significantly reduced transmittance. This unique property has enabled us to develop binary diffraction elements capable of blocking light beams through laser-induced graphene(LIG) structures. These elements are remarkably thin and lightweight compared to conventional refractive components, making them suitable for various optical applications crucial in modern society. With these innovative devices, we aim to introduce applications spanning a wide range of fields, from aerospace, which demands ultra-light lenses, to the bio-industry, where ultra-compact lenses are essential.

5:00 PM MF02.05.07
Arbitrary Three-Dimensional Alignment of Liquid Crystal Molecules via Laser Direct Writing Zexu Zhang[1], Wei Xiong[1,2], Chunsan Deng[1], Xuhao Fan[1], Mingduo Zhang[1], Xinger Wang[1], Fayu Chen[1], Yining Zhou[1] and Hui Gao[1,2]; [1]Huazhong University of Science and Technology, China; [2]Optics

Valley Laboratory, China

The precise construction of hierarchical ordered structures using nanomaterials as fundamental building blocks leads to enhanced optical, electromagnetic, and mechanical properties in functional devices. As one of the most promising functional nanomaterials, the three-dimensional (3D) assembly of liquid crystal (LC) molecules is crucial for the development of next-generation optical field modulation and stimulus response devices due to its distinct anisotropy and tunability. Spatial alignment of LC materials can be achieved through either contact or non-contact alignment methods. The contact alignment method can achieve orientation alignment of LC molecules through surface induced effects, shear forces, etc., but it is usually constrained by a low spatial resolution, material contamination and the lack of design freedom for processing. The non-contact alignment method can offer superior resolution and eliminate the contamination issue by aligning the LC molecules using electromagnetic fields. Nevertheless, it generally requires complex field-assisted (e.g. electric field, magnetic field) equipment and lacks the capacity for achieving arbitrary 3D alignment. Despite significant progress in LC alignment in recent years, a persistent challenge remains: the absence of a high-precision, non-contact, and straightforward method for achieving arbitrary 3D alignment of LC molecules.
To address the above issue, we propose a novel approach that enables us to align the 3D director of LC via two photon polymerization-direct laser writing (TPP-DLW). TPP-DLW is a non-contact method that utilizes femtosecond laser pulses to precisely align LC without any field-assisted devices. TPP-DLW's true 3D manufacturing capability facilitates the realization of arbitrary 3D spatial alignment. Its subwavelength resolution allows for the precise 3D assembly of LC with an accuracy of up to 140 nm. This method combines the advantages of both contact and non-contact alignment methods, achieving straightforward, high-precision, and high degree of design freedom 3D alignment of LC molecules. Finally, we have demonstrated the potential of this method by fabricating Fresnel zone plate devices for object imaging with polarization selection and spectral separation functions. We expect that this TPP-DLW alignment strategy will significantly contribute to the advancement of LC based optical processing, communication, and holographic displays and micro-robots, enabling extensive freedom and multifunctional capabilities.

5:00 PM MF02.05.08
Direct Patterning of Tungsten Oxide Nanoparticles via Laser Ablation Process for a Digital Informative Display Jinhyeong Kwon[1] and Junyeob Yeo[2]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of)

This study focuses on the fabrication and characterization of a tungsten trioxide (WO_3) electrochromic device (ECD) *via* laser ablation. The fabrication process involves the deposition of a WO_3 thin film on a fluorine-doped tin oxide (FTO) substrate using spin coating and selectively removing the WO_3 and FTO layers through laser ablation. The resulting patterned WO_3 is assembled on the substrate with a gel-type electrolyte and a cover FTO substrate to construct the ECD. The fabricated ECD exhibits considerable color change and effectively blocks infrared wavelengths. X-ray diffraction analysis confirms the complete removal of the WO_3 and FTO layers during laser ablation. UV/VIS spectrometry and X-ray photoelectron spectroscopy analysis demonstrate the difference in transmittance and the changes in the tungsten ion oxidation state for the WO_3 ECD. The fabricated WO_3 ECD can be utilized for informative display applications, generating binary barcodes. In summary, this study presents the fabrication of a tunable WO_3 ECD with potential applications in display devices.

5:00 PM MF02.05.09
Laser-Induced Graphitic Electrodes as Rapid Fabrication of Thin-Film Implantable Multielectrode Arrays Fulvia Del Duca, Lukas Hiendlmeier, George Al Boustani, Beatrice De Chiara, Mian Zahid Hussain and Bernhard Wolfrum; Technical University of Munich, Germany

In the field of implantable electronics, thin-film electrodes – usually made of polymeric substrates – have attracted attention for their flexibility and versatility. Common insulating polymer layers include parylene-C and polyimide. While thin-film technology offers many attractive advantages – such as increased compliance and minimal footprint – it also brings new challenges. Firstly, their patterning or selective removal requires a series of additional lithographic steps. Secondly, a major hindering factor is the stability of the polymer-metal adhesion under mechanically-challenging conditions within electrolyte environments.
Direct laser scribing of organic substrates has recently emerged as a rapid and straightforward method for patterning conductive tracks directly from insulating layers. Laser-induced graphite (LIG) electrodes are fabricated in a one-step process. A laser beam irradiation of suitable organic precursors thermally converts the insulating material into a multilayered graphite 3D structure with various degrees of porosity. Typically, CO_2 infrared lasers are employed for LIG fabrication over organic substrates with thickness down to 25 µm, but more commonly in the range of hundreds of µm. While LIG structures offer advantages such as direct fabrication, large charge storage for supercapacitor applications, and high effective surface area for biosensing, their higher feedline resistance compared to metals hinders their usability and advancement. Vomero et al. *[Sci. Rep. (2018) 8:14749]* fabricated parylene-based LIG electrodes over a 25 µm-thick metal foil, showing the possibility of employing LIG sensors in combination with metal feedlines.
Typically, the conductive layers used in microelectrode arrays (MEAs) and flexible electronics are hundreds of µm thin. Here, we present a method to fabricate graphitic carbon electrodes by direct laser scribing of insulating polymers over such thin metal layers, effectively opening the electrode sites with graphitic carbon without damaging the underlying metal tracks. The MEAs are fabricated by depositing an insulating layer of 5 µm parylene-C over a detachable substrate, then sputtering and patterning a conductive layer of 100 nm gold, and insulating again with 5 µm parylene-C. Then, a UV (355 nm) nanosecond pulsed laser is used to carbonize the parylene-C locally over the gold to open the electrode sites and contact pads. The 10-µm-thin electrodes are then released from the substrate. Therefore, no dry etching and hard mask patterning are required to open the electrode insulation, and the conductive material is directly generated from the insulating layer.
First, we test the fabricated electrodes by measuring the sheet resistance of the generated graphitic carbon material over gold, where we select the optimal laser parameters for best performance. Then, we test the electrodes in phosphate-buffered saline to measure the electrochemical impedance and the charge storage capacity, as well as the charge injection capabilities for neural stimulation applications. The mechanical stability of the adhesion between graphitic carbon and gold is also tested both in dry and aqueous environments, relevant to the contact pads and electrode sites, respectively. We also investigated the miniaturization limits of the fabricated electrode sites by laser scribing in different writing modes and with different line writing densities. In summary, we propose a new and rapid method for electrode fabrication applicable to thin-film and polymer-based electronics.

In-Field Monitoring of Plant Stress with a Low-Cost Electrochemical Sensor Sina Khazaee Nejad and Maral Mousavi; University of Southern California, United States

Environmental challenges, like drought, severe temperatures, pests, and diseases, have adverse effects on the growth, development, and yield of plants. Salicylic Acid (SA) serves as a plant hormone responsible for signaling in response to stress, and it plays a crucial role in plants' defense mechanisms against certain types of pathogens. Elevated levels of salicylic acid in plants serve as an indicator of stress. It is essential to monitor and assess plant stress to ensure the well-being and productivity of crops, as well as a steady food supply. The on-site measurement of salicylic acid aids in the early detection and diagnosis of plant stress, enabling prompt actions to reduce harm and sustain crop productivity.

Point-of-care diagnostic technologies have emerged as an advancement in medical analysis and monitoring. These technologies offer a decentralized and

cost-effective approach, making accessibility to crucial diagnostic services easier. As a rapid first line of diagnosis, they serve as a frontline defense.

In this work, we introduce an affordable electrochemical tool designed for the purpose of tracking plant stress by detecting Salicylic Acid (SA). The device is equipped with wireless connectivity, allowing it to transmit data to a smartphone via the Bluetooth Low Energy (BLE) protocol.

Methods
Electrochemical techniques have been used to monitor SA levels. We've utilized laser-induced graphene (LiG) electrodes, a low-cost and scalable 3D porous carbon material created through laser-based polymer-to-graphene conversion, which shows promise for electrochemical sensors.

We've developed an affordable, portable potentiostat to continuously monitor salicylic acid (SA) levels in plants, with the collected data being transmitted to a nearby smartphone via Bluetooth Low Energy technology.

Results
The ability to efficiently scale the production of LiG electrodes offers a cost-effective method for creating these systems. Examination of these electrodes reveals the formation of a graphene layer on the PI film. Moreover, by optimizing laser machine parameters, we have achieved electrodes that not only consistently reproduce but also exhibit impressive electrochemical capabilities.

Square-wave voltammetry measurements were conducted using the LiG sensors, with varying concentrations of SA in buffer. The peak current value demonstrates a linear relationship with the SA concentration, with a sensitivity of 130.54 µA/mM, and linearity range between 5 µM and 150 µM. The limit of detection is 1.75 µM.

Conclusion
An affordable device based on laser-induced graphene (LiG) for monitoring plant stress is created, and it is seamlessly integrated with a portable potentiostat. This device enables the detection of salicylic acid, a phytohormone vital for plant stress signaling. The detection is achieved using a 3-electrode LiG design, and our system has successfully demonstrated this capability.

5:00 PM MF02.05.11
A Nafion-Modified Laser-Induced Graphene Sensor for Spontaneous Monitoring of Caffeine and Vanillin Haozheng Ma, Stephanie Bartholomew, Jay Yoo, Caden Pak, Abdulrahman Al-Shami, Mona A. Mohamed and Maral Mousavi; University of Southern California, United States

Introduction: Coffee is a globally consumed beverage, widely known for its main active ingredient, caffeine. Although a daily caffeine limit of 400 mg is considered safe, exceeding this limit can lead to adverse effects such as depression, anxiety, irritability, and other health issues. Another frequently used compound in the food and beverage industry is vanillin, which provides a characteristic sweet and creamy aroma. Like caffeine, excessive consumption of vanillin can also lead to adverse effects like headaches and gastrointestinal disturbances. Despite the widespread consumption of caffeine and vanillin, accurately determining their content in different foods and beverages is challenging. This complicates the monitoring of daily intake, making it difficult to manage potential health risks effectively. Laser-Induced Graphene (LIG) is a specialized form of 3D porous carbon nanomaterial with unique properties. It is created through a process called direct laser writing, which is performed on certain polymer materials in ambient conditions. The technique is both simple and quick, making LIG an attractive material for a variety of applications. Due to its excellent physical and chemical attributes, including a large surface area and superior electrochemical performance, LIG has become particularly valuable in the development of medical sensing devices.
Methods: We fabricated Laser-Induced Graphene (LIG) with 30 W 9.3 µm CO_2 laser engraver (VLS 2.30, Universal Laser System), and used it as working electrode by applying a Nafion monolayer to its surface. The electrode was then dried at room temperature for 30 minutes. A LIG reference electrode was prepared using screen printing to cover silver ink on LIG, leaving the counter electrode blank. The sensor's performance was tested using varying concentrations of caffeine and vanillin in PBS (pH=7.26). Testing methodologies included cycle voltammetry and square wave voltammetry with an electrochemical working station (CHI760E, CH Instruments, Inc.).
Results: To facilitate the monitoring of daily caffeine and vanillin intake, we have utilized Nafion-modified LIG sensor to develop an electrochemical point-of-care sensor. Based on the extensive surface area and superior electrochemical performance of LIG and the protective Nafion layer that imparts high stability for long-term storage and multi reproducibility, this novel sensor can detect caffeine, that shows a peak around 1.4 V, and vanillin which has a peak around 0.6 V, both within a linear range of 10 µM to 200 µM.
Conclusions: The developed Nafion-modified LIG sensor offers a promising approach for effectively monitoring caffeine and vanillin consumption. This technological advance aids in better dietary management, thereby contributing to overall health.

Laser-Induced Pyrolytic Jetting of Porosity Variable Silica Thin Film for Fog Harvesting Koungjun Min[1,2], Hyunkoo Lee[1,2] and Ji Hwan Lim[1,2]; [1]Hanyang University, Korea (the Republic of); [2]BK21 Four Erica-Ace Center, Korea (the Republic of)

Laser direct writing (LDW) is a renowned maskless manufacturing technology that employs laser beams for the direct creation of micro and nanostructured devices. It overcomes the limitations of conventional multi-step manufacturing processes such as lithography and molding. LDW has a significant impact in a multitude of sectors, spanning from microelectronics and optics to medical devices and beyond, thanks to its merits, including rapid prototyping, customization flexibility, precise control, and adaptability to various materials.
For PDMS, its exceptional optical transparency across a broad spectrum of wavelengths fundamentally constrains the potential applications of laser patterning technology. However, recently, successive laser pyrolysis (SLP) has been proposed as an on-demand laser-based transparent polymer patterning process, relying on the controlled sequence of photothermal pyrolysis phenomena guided by a continuous-wave (CW) laser. After effectively removing the pyrolysis by-product, SLP offers the rapid digital patterning of high quality 2D and even 3D PDMS microstructures, which can be directly utilized without the need for supplementary post-processing steps.
Moreover, the by-products generated in the SLP process, including SiC and the silica layer on the surface, present versatile opportunity for utilization as microstructure in various applications including surface treatment such as wettability modification. In our study, to harness the extensive utility of the surface silica layer, we employed the SLP process on a PDMS-glass hybrid substrate, facilitating the creation of a tunable silica film with controlled porosity through the pyrolytic jetting phenomenon.
The PDMS-glass hybrid substrate is prepared through the deposition of a thin PDMS layer onto a soda-lime glass substrate via a spin-coating method. During the SLP process, the gas generated as a result of PDMS pyrolysis is effectively contained by the glass substrate, directing gas concentration towards the PDMS surface, thereby facilitating the requisite pressure for the ejection of the silica film. Furthermore, the glass substrate plays a dual role by not only acting as a gas barrier but also composing the PDMS layer, thereby optimizing the efficiency of the silica film pyrolytic jetting process by providing a stabilizing counterforce.
In a more detailed approach, we have developed a microporous silica film with dimensions of approximately 10 µm through the optimization of laser

power, laser scanning speed, and scanning interval, in the pyrolytic jetting process. Furthermore, by adjusting these variables, we achieved the capability to tune porosity under 50%. Through water contact angle measurements, it was determined that silica films with approximately 45% porosity exhibited hydrophilic characteristics, while those with around 10% porosity demonstrated hydrophobic properties.
The microporous silica film was employed in a fog harvesting application, wherein it was affixed to a 2 cm x 2 cm surface area of a PTFE rod. Real-time measurements of the harvesting rate resulted in an average yield of approximately 55 mg/min. This level of performance aligns with that of several mesh-style fog harvesting applications sharing analogous structures, underscoring the potential viability of this approach in the field.

Laser-Induced Graphene Potentiometric Platform for At-Home Quantification of Choline in Infant Formula and Milk Powders Abdulrahman Al-Shami[1], Farbod Amirghasemi[1], Ali Soleimani[1], Sina Khazaee Nejad[1], Victor Ong[1], Alar Ainla[2] and Maral Mousavi[1]; [1]University of Southern California, United States; [2]International Iberian Nanotechnology Laboratory, Portugal

Introduction:
Choline (Ch+) is a water-soluble vitamin-like micronutrient used by the human body to regulate brain and nervous system functions such as mood, memory, and muscle control. Ch+ also has a structural function since it is involved in synthesizing phospholipids within cell membranes. Deficiency of Ch+ in infants' diet has been correlated with long-term visual and neurocognitive deficits and impaired learning capabilities and memory function. The U.S. Food and Drug Administration (FDA) and similar agencies have set guidelines and requirements for choline levels in commercialized infant formula. Not all families have access to well-standardized infant formula, and some families practice formula stretching due to economic limitations or difficulties obtaining infant formula, similar to the COVID-19 pandemic. In the U.S., 31% of families relying on infant formula for infant feeding encountered difficulties accessing these products during the COVID-19 pandemic. Moreover, 33% of infant formula users adopted adverse formula-feeding practices, encompassing the dilution of formula, the preparation of smaller feeding bottles, and the retention of partially used formula mixtures for subsequent utilization. These practices affect infants' choline intake and, therefore, their health. Precise quantifying of choline in infant formula is essential to ensure that infants receive the required nutritional intake, and yet there are no accessible tools for this purpose. Here, we report an innovative integrated sensor for the periodic observation of choline designed for at-home quantification of choline in infants' formulas and milk powders. This system comprises a choline potentiometric sensor and ionic-liquid reference electrode developed on laser-induced graphitic structure (LIG). The platform also includes a micro-potentiometer that conducts the potentiometric measurements and transmits results wirelessly to the parent's mobile devices.

Materials:
We fabricated the electrochemical electrodes through CO2 laser ablation of a polyimide film using a laser cutter machine emitting at a 1060 nm wavelength. The choline-selective electrode was created by depositing a 40 µL choline-selective membrane composed of a mixture containing 330 mg of poly(vinyl chloride) (PVC), 660 mg of o-nitrophenyl-octyl-ether (NPOE), 13.8 mg of sodium tetraki [3,5 bis(trifluoromethyl)phenyl] borate, and 13.22 mg of calix 4 arene (ionophore) dissolved in 3 mL of THF, onto the electrode surface. The reference membrane solution was formulated by blending 50 mg of MeOctIm TFSI with 316 mg of PVC and 634 mg of o-NPOE in 3.0 mL of THF.

Results and Discussion:
The LIG structure electrochemical electrodes were characterized using Raman, EDX, XPS, and SEM. Characterization results confirmed the successful carbonization of P.I. film and the formation of a 3D multilayered porous graphitic structure with a thickness of 20 µm. The obtained LIG-based choline-detecting platform showed a sensitivity of 55.3 ± 0.17 mV/decade, close to the Nernstian theoretical value of 59.2 mV/decade. The achieved limit of detection by our platform is about 95.4 µM. The choline platform also showed an outstanding selective performance toward choline compared to other milk components such as vitamins, minerals, proteins, and sugars. Moreover, the reference electrode demonstrated a highly stable and sample-independent response, which is desired to obtain accurate and precise analysis results. The developed device was used to quantify choline in different commercially available infant formulas and milk powders, showing an accuracy between 100.4 and 108.6 %.

Conclusion:
The LIG-based choline sensing platform showed outstanding sensitivity, selectivity, stability, and accuracy in choline analysis. Leveraging the unique properties of LIG, the platform is flexible, portable, cost-effective, and efficient, making it a promising tool for choline periodic quantification in at-home settings.

Laser Induced Formation of Functional Metal Oxides for Enhanced Electrochemical Sensing Devendra Sarnaik, Sotoudeh Sedaghat and Rahim Rahimi; Purdue University, United States

The use of electrochemical sensors in different sectors has highlighted the need for sensors with high sensitivity, low cost and high stability over time. However, the high cost, and low long-term stability of biomolecule electrochemical sensors have yielded the need for other approaches. Alternatively, metal oxides have shown promise to be used for sensing applications without the need of receptors but have yet to be widely adopted due to the complicated and expensive multistep manufacturing process associated with producing them. To develop the functional metal oxide surfaces, laser processing has been seen as an alternative, owing to the low costs, high degree of control and rapid processing time which can be adapted to more scalable manufacturing processes. The use of laser induced oxidation has shown great promise by creating highly localized modifications of the surface morphology without affecting the bulk properties of the metal, while providing a more stable and robust electrical connection between the oxide and bulk metal layer. Laser induced oxidation was used to develop of low cost, rapid detection electrochemical sensors, taking advantage of the create three-dimensional micro/nano oxide structures which exhibit enhanced electrocatalytic properties compared to that of bulk metal. Copper and nickel were laser processed to obtain the rapid, low cost and scalable manufacturing of electrochemical sensors for the detection of nonenzymatic glucose. The obtained laser-induced oxidized copper (LIO-Cu) and laser-induced oxidized nickel (LIO-Ni) contained highly nano/micro porous oxide structures which greatly increased the electrocatalytic activity enabling the detection of glucose. A systematic study of the composition, crystallinity, microstructure and wettability was conducted through the use characterization techniques including scanning electron microscopy (SEM), X-ray diffraction (XRD), Raman spectroscopy, and water contact angle measurement. The electrochemical sensing performance of the devised sensors were tested against a range of glucose concentrations to test sensitivity and detection limit. The LIO-Ni sensor demonstrated a high linear sensitivity of 5222µA $mM^{-1}cm^{-2}$ over glucose concentration range of 5µM to 1.1mM, and the LIO-CU sensor demonstrated exceptional sensitivity of 6950µA $mM^{-1}cm^{-2}$ over a wide range of 0.01 to 5 mM glucose concentration. The obtained results demonstrate the capability for laser processing to be adapted for a scalable manufacturing environment to produce rapid, low-cost and highly sensitive electrochemical sensors, which have application in various field of study including medicine and agriculture.

Laser-Induced Carbon Composite Electrode from Photoresist for High Performance On-Chip Energy Storage Devices Soongeun Kwon, Yunji Eom, Hak-Jong Choi, Junhyoung Ahn, Hyungjun Lim, Geehong Kim, Kee-Bong Choi and Jaejong Lee; Korea Institute of Machinery and Materials, Korea (the Republic of)

We report a laser-induced carbon composite (LICC) electrode prepared from a photoresist for a miniaturized electrochemical energy storage device. A photoresist material comprising of a conventional photoresist matrix and carbon black nanoparticles was photo-thermally converted to LICC by high-power carbon dioxide (CO_2) laser carbonization. Due to the high absorption of carbon blacks in the composite materials, the laser-irradiated composite material was directly exfoliated and carbonized, providing a hierarchically macro-porous, graphitic carbon composite with fewer defects. Depending on the precursor materials mixed with photoresist matrix, the LICCs with functional metal or metal oxide nanoparticles were successfully fabricated by one-step laser carbonization.
The experimental conditions of CO_2 direct laser writing were optimized to fabricate high-quality LICCs for on-chip micro-supercapacitor (MSC) electrodes with low sheet resistance and good porosity. In addition, the results revealed that the high-resolution electrode pattern in the same footprint as that of the LICC-MSCs significantly affected the rate performance of the MSCs.
Consequently, the proposed laser-induced carbonization technique using a photoresist provides simple and facile fabrication of porous, graphitic and high-resolution carbon composite electrodes for high-performance on-chip energy storage devices without high-temperature thermal pyrolysis.

5:00 PM MF02.05.16
Fabrication Defect-Insensitive Minimal Surface-Based 3D Metamaterial at Nanoscale Dahye Shin[1,2], Kisun KIM[2], Sanghyun Nam[2], Seokwoo Jeon[2] and Dongchan Jang[2]; [1]Agency for Defense Development, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Material scientists have been striving to break the conventional relationships between mutually exclusive materials' properties such as density-strength and to fill the white area in the materials' property space. One effective way to explore the empty space is harnessing nanoarchitectures to develop lightweight and strong artificial materials not only by the architectural designs but also by embedding the benefits of nanoscale effects of materials into hierarchical nanostructures. Generally, in fabrication aspects of those nanoarchitectures, multi-step procedures are required including fabrication of architecture frames and material conversions. During these complicated procedures, fabrication defects are almost inevitable, especially when we considering mass production too. Therefore, at some point, the design of architecture itself is demanded to be defect insensitive with high tolerance of fabrication defects.
For that purpose, we make the best use of 3D minimal surface structure to the design of nanoarchitectures. Since the minimal surface is a local minima of surface area under given constraints by its definition, it is energetically beneficial and efficient in the use of limited resources. Moreover, 3D minimal surface, so called Triply Periodic Minimal Surface (TPMS), exhibits smooth continuous surface without any self-intersections or singularities in all three dimensions avoiding the stress concentrations. And one important characteristic of them is that Gaussian curvature is negative everywhere on the surface by definition. This negative Gaussian curvature plays a key role to superior load carrying capacity and defect insensitivity which will be discussed in this study. Because of these fascinating features of TPMS structures, many engineers have been trying to use them for architected materials in macro- and microscale to achieve the best mechanical performance. However, many of the experimental works barely reach to the level of their initially designed performance due to the fabrication defects. Especially, for brittle ceramic materials, not many experimental works have been investigated and the performance of them has been severely affected by the imperfections resulting to the steep slope on the density-strength Ashby plots.
Therefore, in this study, we are suggesting nanoscale diamond-like 3D minimal surface shell made of brittle amorphous alumina by intertwining the advantages of TPMS structure and the nanoscale effect of the base material to overcome these limitations. Nanopatterning using near-diffraction patterns of laser with multi-phase masks enables us to fabricate the nanoscale TPMS structures with rapid large area production. In addition, it has been reported that the elastic body at nanoscale withstands high stress fields without catastrophic fracture so that to bring additional opportunities for the inelastic deformation even in intrinsically brittle materials. This unexpected inelastic deformation of the ceramic body makes the TPMS structure defect-insensitive.
Experimental data from monotonic and cyclic micropillar compressive tests reveals that our nanoarchitecture exhibits damping behavior, high strength and low scaling exponent of 1.07 in density-strength chart even with severe geometric defects. This new minimal surface nanoarchitecture will contribute to creating superior engineering ceramics with capability of mass production through its high defect tolerance.

5:00 PM MF02.05.17
Simultaneous Electrochemical and Fluorescence Sensing of Myocardial Infarction Biomarkers Using a Femtosecond Laser-Fabricated Fiber-Optic Platform Homayoon Soleimani Dinani[1], Bohong Zhang[1], Rex Gerald[1], Zheng Yan[2] and Jie Huang[1]; [1]Missouri University of Science and Technology, United States; [2]University of Missouri-Columbia, United States

The need for rapid and precise detection of biomarkers indicative of myocardial infarction has been emphasized in medical diagnostics and patient care. Conventional sensing approaches primarily utilize electrochemical or optical detecting mechanisms, each characterized by unique advantages and limits. This study aimed to design an advanced fiber-optic platform that integrates simultaneous electrochemical and fluorescence sensing. The integration of these two techniques enhances the reliability and comprehensiveness of biomarker identification. Microsized Laser-Induced Graphene (LIG) electrodes were fabricated on the outer surface of polyimide-coated optical fibers using femtosecond laser technology. The proposed innovation is presented as a scalable, reproducible, and economically viable approach to sensor manufacturing. The electrochemical sensing module was tailored explicitly to target myoglobin, an imperative biomarker for myocardial infarction. Enhanced sensitivity and specificity were achieved through a suite of electrochemical analyses encompassing Cyclic Voltammetry (CV), Square Wave Voltammetry (SWV), Differential Pulse Voltammetry (DPV), and Electrochemical Impedance Spectroscopy (EIS). The electrochemical sensing process was controlled by redox reactions and principles of charge transfer, facilitating high-accuracy measurements. Concurrently, fluorescence sensing was integrated into the platform, adding an auxiliary layer of biomarker validation. The fluorescence sensor was engineered to quantify the fluorescence quantum yield and absorption coefficients of specific fluorophores extant in the blood. This auxiliary mechanism offers supportive evidence and exhibits the potential for identifying other associated biomarkers or substances. The amalgamation of these bifurcated sensing modalities into a unified fiber-optic platform enriched the data acquisition process and accelerated the diagnostic timeline. The provision of multi-faceted, real-time data by the platform paves the way for sophisticated, point-of-care health monitoring systems. The research represents significant progress in sensor technology, particularly integrating electrochemical and optical sensing methodologies. The robust and versatile nature of the platform earmarks it as an optimum choice for diverse applications in medical diagnostics and real-time health monitoring applications.

Diagnosis and Monitoring of Milk Fever with a Laser-Engraved Calcium Sensor Ali Soleimani, Farbod Amirghasemi, Abdulrahman Al-Shami, Sina Khazaee Nejad, Alicia Tsung, Delaram Parvin and Maral Mousavi; University of Southern California, United States

Milk fever is a metabolic disorder that occurs in dairy animals and its occurrence is more prevalent a few months before and after calving and can lead to a range of clinical symptoms, including loss of appetite, muscle spasms, lateral recumbency, and eventually coma or death if left untreated. The primary cause of these symptoms is a decrease in blood calcium levels, hypocalcemia. Previous studies have categorized cows into three groups based on their serum calcium levels: normocalcemia ($\geq$ 2.0 mmol/L), subclinical hypocalcemia ($<$ 2.0 mmol/L but without any observable clinical signs), and clinical hypocalcemia (with clinical signs). Based on previous studies, the prevalence of subclinical hypocalcemia in the pasture-based system was around %50. Moreover, the productive life of dairy cows with hypocalcemia decreases by 3.4 years, which can have economic impacts on animal husbandry businesses.

Since subclinical milk fever does not have symptoms and frequent testing of calcium levels is expensive, subclinical milk fever is rarely diagnosed. Thus, having a Point-of-Use inexpensive sensor for frequent and on-demand calcium measurement is beneficial. For this purpose, we fabricated an inexpensive Laser-induced Graphene based potentiometric electrode to detect calcium levels in the clinically relevant range.
Materials and Methods:
We prepared the calcium selective membrane by mixing poly(vinyl chloride) (PVC) (33%), 2-nitrophenyl octyl ether (66%), calcium Ionophore (IV) and potassium tetrakis(4-chlorophenyl)borate (KTPClB) (1%), with tetrahydrofuran. We fabricated the LIG sensors by directly operating a CO2 laser on a Kapton film. Then, we drop-casted the membranes on the electrodes. We performed all the measurements at room temperature using a 16-channel potentiometer relative to a commercial reference electrode.
Results and Discussion:
We used laser engraving to pattern graphene on a low-cost polyimide film. SEM results indicated a 3D porous structure of LIGs with a thickness of 20 µM. Furthermore, EDX and RAMAN spectroscopy were performed on the sensors to confirm the presence of graphene on the PI films. The results indicate that the sensitivity of our LIG-based sensors is 26.58± 0.28 mV/dec, which is close to the theoretically expected value (29.6 mV/dec). Moreover, the limit of detection (LOD) of the sensor is 1.87 µM, which is ~ 3 orders of magnitude lower than the clinically relevant range of calcium in the body. Another important characteristic of the sensor that ensures its reliability is the selectivity toward the ion of interest. The Selectivity results of the sensor indicates superior selectivity of the sensor over physiologically relevant ions and biologicals. Finally the sensor's performance in the bovine sample was evaluated. To this purpose, first the sensor where calibrated in two different solutions of artificial serum and then the sensors were exposed to the bovine serum. The results were compared with a commercial Calcium sensor indicating %104.54 recovery of LIG sensors.
Conclusion:
We fabricated a LIG-based potentiometric sensor that shows outstanding sensitivity and selectivity toward the ion of interest. Moreover, the sensor shows %4.54 error compared with a commercial electrode that is suitable and acceptable for in field detection of subclinical milk fever. Moreover, using a laser as an inexpensive, fast, and mass-producible method for fabricating the sensors makes them a suitable choice for in-field frequent use.

SESSION MF02.06: Laser Surface Modification for Enhanced Biocompatibility and Antibacterial Properties

Designing Ti-Alloys Using 3D Printing for Load-Bearing Applications: Enhanced Biocompatibility, Minimized Tribo-Corrosion and Inherent Infection Resistance Amit Bandyopadhyay; Washington State University, United States

Metal 3D Printing was utilized to design novel Ti-alloys for load-bearing implant applications focusing on improving biocompatibility, minimizing bio-tribo-corrosion and related metal ion release, and adding inherent infection resistance. Successful alloy design can minimize adverse local tissue response (ALTR) from total hip implants (THAs) taper corrosion and septic loosening due to polymicrobial infections, eventually reducing implant failure in vivo. In one case, we designed a Ti-Ta-Cu alloy where Cu offers intrinsic microbial resistance and Ta-enhanced biocompatibility to mitigate potential Cu toxicity. Instead of using Ti6Al4V alloy, vanadium and aluminum contents were reduced to design a Ti3Al2V alloy for metallic implant applications. The biological and mechanical properties of Ti3Al2V alloy were measured. A 10% Ta and 3% Cu were added to the Ti3Al2V alloy to enhance biocompatibility and impart inherent bacterial resistance. Additively manufactured implants were investigated for resistance against *pseudomonas aeruginosa* and *staphylococcus aureus* strains of bacteria up to 48 h. A 3% Cu addition to Ti3Al2V showed an improved antibacterial efficacy, between 76 and 81% higher than CpTi and Ti6Al4V. Mechanical properties for Ti3Al2V-10Ta-3Cu alloy were measured, demonstrating excellent fatigue resistance, good shear strengths, and better tribological characteristics than Ti6Al4V. *In vivo* studies using a rat distal femur model showed improved early-stage osseointegration for alloys with 10%Ta addition than CpTi and Ti6Al4V. Ti6Al4V-ZTA-HA metal matrix composites were designed and investigated for load-bearing femoral heads in another alloy design. The composites were fabricated via 3D Printing. A rabbit distal femur 16-week *in vivo* study for implantation and histological characterization was conducted. An induced *in vitro* 16-week applied potential polarization study of the Ti6Al4V and Ti6Al4V-zirconia toughened alumina (ZTA)-hydroxyapatite (HA)-based composites was conducted to investigate the coupled taper-corrosion behavior. The Ti6Al4V-ZTA-HA composites displayed increased hardness, decreased wear volume, increased surface passivation during tribological testing, and faster re-passivation post-tribological testing, validated by increased contact resistance and more cathodic open circuit potential. Finally, a first-of-a-kind table-top joint simulator was designed and manufactured to simulate volumetric tribo-corrosion of femoral heads. The simulator mimics the gait-like motion of the hip joint. Ti6Al4V+ZTA+HA metal matrix composite femoral heads were produced via 3D Printing. The ability to move into volumetric articulating-based testing has shown promising results for improving these innovative materials to address the shortcomings of currently used metallic biomaterials in load-bearing orthopedic devices where corrosion and wear are of concern. The presentation will discuss 3D Printing-based alloy design and related characterization of next-generation Ti-alloys for load-bearing implants.

9:15 AM MF02.06.02
Laser Assisted Selective Texturing and Alloying of Titanium Implant surfaces for Enhanced Bactericidal and Osteointegration Properties Akshay Krishnakumar, Sotoudeh Sedaghat, Vidhya Selvamani, Sina Nejati and Rahim Rahimi; Purdue University, United States

Orthopedic device-related infections (ODRIs) in implants represent a critical and multifaceted healthcare challenge, necessitating a comprehensive understanding of their impact on patient well-being, management, and prevention. While titanium-based (Ti) implants are commonly used due to their favorable corrosion resistance, excellent biocompatibility, and mechanical properties similar to that of bone, the development of bacterial infections owing to ORDI remains a daunting concern. Functionalizing the implant surface with antimicrobial agents, without altering the bulk properties of the Ti alloy, presents an effective approach to improving the efficacy of orthopedic implants and elevating patient outcomes. In this context, we have developed a two-step process involving laser texturing and alloying of silver (Ag) nanocomposites into the widely used titanium alloy (Ti6Al4V) implant surfaces, thereby conferring antibacterial properties. The process involved spray coating silver nanoparticles onto the implant surface, followed by heat sintering and laser-induced alloying of Ag into the Ti alloy. The local heat generated by the laser process enables simultaneous intermetallic alloying and texturing of the implant surface, enhancing its surface roughness without affecting its bulk mechanical properties. A systematic study was conducted by varying the laser beam power to analyze the structural, morphological, and elemental composition of the surface, utilizing X-ray diffraction (XRD), scanning electron microscopy (SEM), and energy-dispersive X-ray spectroscopy (EDX) analysis. The results demonstrated that the developed laser-textured surface exhibited enhanced wettability, increased surface roughness, and effective alloying of silver on the implant surface without compromising bulk mechanical properties. The optimized laser-textured surface was subjected to a seven-day antibacterial test against a model population of gram-positive (*Staphylococcus aureus*) and gram-negative bacteria (*Escherichia coli*). Furthermore, the osteointegrative properties of the developed surface were

assessed through in-vitro bone mineralization assays using Mesenchymal Stem Cells (MSC), and the calcified extracellular matrix levels were measured. The results indicated a two-fold increase in bone cell mineralization and long term antibacterial properties for the optimized laser-textured surface compared to the control Ti alloy surfaces. By modifying the implant surface, the antibacterial properties can help prevent bacterial colonization, while the enhanced osteointegration properties can promote bone cell adhesion and colonization. Ultimately, this scalable laser-assisted alloying approach holds the potential to enhance the long-term success of orthopedic implants and improve patient outcomes.

9:30 AM *MF02.06.03
Laser-Induced Graphene Composites for Electrically-Mediated Antimicrobial and Environmental Applications Christopher J. Arnusch; Ben Gurion University of the Negev, Israel

Laser-induced graphene (LIG) is a three-dimensional, porous, electrically conductive graphene material generated predominantly by irradiation of polymer substrates with a 10.6 μm CO_2 laser. Since 2014, this material has been shown to be useful in myriads of applications. In this presentation, I will discuss the synthesis and exceptional properties of LIG composites in antibacterial or antiviral environmental applications including air and water treatment technology. Electrical effects and electro- and photo-thermal heating for bacterial killing will be shown and insights into the mechanism of action will be discussed. Notably, LIG surfaces can deactivate bacteria when low currents are passed through the surface, when the surfaces are used as electrodes, or as heaters. Also, LIG on dense and porous substrates exhibited an electrically mediated antifouling effect. Other metal-doped LIG composites showed antibacterial effects due to the release of metal ions into the solution as well as contact with metal-embedded nanoparticles. This method to generate electrically conductive graphene on water treatment technology such as porous polymer membranes and dense substrates will enable many new applications in water treatment and separations.

Laser-Induced Graphene (LIG) Membranes with Different Subsurface Morphologies for Electrically Dependent Microbial Decontamination
Maurício N. Kleinberg[1,2], Chidambaram Thamaraiselvan[3,1], Camilah D. Powell[2,1] and Christopher J. Arnusch[1]; [1]Ben-Gurion University of the Negev Sde Boquer Campus, Israel; [2]The University of Texas at San Antonio, United States; [3]Indian Institute of Science, India

Laser-induced graphene (LIG) is a graphitic material that can be easily formed by CO_2-laser irradiation on various carbon-based substrates, including porous polymeric membranes. LIG-membrane formation involves lasing the top surface of a polymeric membrane, and converts essential polymer separation structures to porous LIG foam. However, in previous studies, separation properties could be partly recovered by forming LIG polymer composite layers[(1,2)] or by coating the polymeric membrane substrate with trimethylaluminum (TMA)[(3)] or graphene oxide (GO)[(4)] to avoid melting or damaging the subsurface polymeric structures during the lasing process. Herein, by optimizing the laser settings and fabrication conditions, we made LIG directly on uncoated porous polyethersulfone (PES) membranes while preserving the subsurface polymer.[(5)] The effects of lasing on membrane properties were studied by comparing porous polymeric PES membranes fabricated using the non-solvent induced phase separation (NIPS) method with membranes obtained using the vapor-induced phase separation (VIPS) method. Membrane fabrication conditions, such as the polymer concentration of the casting solution and the exposure time to the non-solvent, were varied, and the NIPS method resulted in membranes with a finger-like polymer substructure morphology, while the VIPS method resulted in membranes with an asymmetric cellular morphology. LIG-membranes prepared on NIPS membranes resulted in large permeability changes, while LIG on VIPS membranes gave only very minor changes. The antimicrobial activity of these LIG-membranes as porous electrodes was dependent on applied voltage and solution contact time, and 4-6 log removal of bacteria at 10 V was achieved. Understanding LIG formation on porous polymeric membranes will minimize processing steps and might lead to electrically conductive membranes with controlled separation properties.

Laser-Scribed Soft Bioelectronics and Robotics Zheng Yan; University of Missouri-Columbia, United States

Laser-assisted fabrication offers a simple, mask-free, cost-effective approach to pattern conductive materials on various substrates under ambient conditions. This process allows for high-precision customization and miniaturization, essential for emerging soft bioelectronics and robotics applications. With the ability to finely tune the porosity, morphology, composition, and electrical conductivity of the resultant patterns, a broad spectrum of applications can be realized, including biophysical and biochemical sensing technologies, as well as innovations in soft actuators for robotics. In this presentation, I will discuss our latest explorations into laser-scribed graphene and molybdenum dioxide on flexible substrates. I will highlight their significant contributions to the realms of soft bioelectronics and robotics. A showcase of various soft devices we have developed based on these materials will be provided, including sensors for hydration, temperature, electrophysiology, sweat biochemistry, UV, and gas. These demonstrate the material's aptitude in sensory technology. Furthermore, we will display our work in crafting reconfigurable three-dimensional architectures and light-driven smart worms using laser-scribed materials. These instances underscore the immense potential of laser-scribed materials in orchestrating devices with intricate behaviors and responses, paving the way for novel applications in a connected world.

Crystallization in Er/Yb:$BaTiO_3$ Perovskite Induced by fs-Laser Pulses Cleber Mendonca, Jose Clabel, Kelly Tasso, Marcelo Pereira-da-Silva, Jose Vollet-Filho, Filipe Couto and Euclydes Marega; University of Sao Paulo, Brazil

Perovskite films have been attracting tremendous attention as promising candidates for applications in photonics and optoelectronics, including light-emitting diodes, photo-detectors, energy-harvesting devices, etc. Such applications are sensitive to changes in crystallization, size, and distribution of grains in the perovskite films. Hence, studies have been carried out to improve the quality of thin films and investigate the effect of sintering on the crystalline phase of the sample. Even though several sintering methods have been developed, fs-laser sintering has appeared as a versatile and rapid option, offering precise and localized energy distribution to the sample. The fs-laser sintering can produce highly crystalline devices with complex structures, although it depends on the processing parameters.
This study demonstrates the crystallization of amorphous Er^{3+}/Yb^{3+}:$BaTiO_3$ (BTEY) thin film upon fs-laser processing at 1030 nm. The threshold fluence to achieve laser processing was determined as 1.1 J/cm^2 at 1 kHz, as well as the irradiation conditions for crystallization. Raman spectroscopy confirmed

crystallization when irradiation was carried out at a 1 kHz repetition rate. Also, an increase in the sample emission was observed in the crystallized regions and on the surface potential. Such results provide insights into using fs-laser pulses for the crystallization of BTEY, which is relevant for device applications.

11:30 AM MF02.06.07
Laser-Induced Carbonization of Polyimide Films for Physically Unclonable Anticounterfeiting Applications Srinivas Gandla, Changgyun Moon and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

Laser-induced carbonization (LIC) on polymers with aromatic and imide repetitive units, particularly Kapton polyimide (PI), has revolutionized the production of carbon-based devices and sensors. This includes supercapacitors, triboelectric nanogenerators, actuators, heater devices, as well as gas, humidity, strain, and biological sensors. Furthermore, PI demonstrates remarkable mechanical and thermal stability, positioning it as a compelling choice for a myriad of flexible electronic devices.
In contrast to traditional pyrolysis, where polymer materials undergo thermal decomposition in an inert atmosphere, the LIC technique offers a notable advantage in swiftly achieving patterned carbon. This is crucial for electrode fabrication and the creation of individual, isolated devices. Pulsed lasers emit high-intensity pulses with short durations, affecting only a small portion of the sample with limited penetration depth, thereby avoiding damage to the surrounding material. Various lasers, such as carbon dioxide (CO_2, 10.6 µm), infrared (IR, 1064 nm), ultraviolet (UV, 248 nm), and blue (456 nm), are commonly employed for carbonizing PI materials in diverse applications. Significantly, the carbonization mechanism varies with different wavelengths and other parameters such as laser power, speed, frequency, hatch distance, and pyrolysis environment. This is attributed to distinct absorptions by both PI and carbon. Although the exact mechanisms are not universally agreed upon, both photochemical and photothermal processes have been proposed to elucidate this phenomenon.
On the other hand, as the global population grows rapidly, there is an increasing demand for a larger quantity of goods to meet the needs and comforts of individuals. However, this heightened demand has inadvertently given rise to counterfeit markets. To combat this issue, the implementation of anti-counterfeiting tags on products has emerged as a practical solution. Various traditional anti-counterfeiting tags like quick-response codes, radio-frequency identifications, graphical elements, holograms, and watermarks have been utilized for consumer goods. Unfortunately, these tags are susceptible to cloning attacks and are primarily employed as "identifiers" rather than security tags for authentication. In response to the cloning issue, physically unclonable (PU) tags have been introduced. These tags, generated through stochastic processes, possess unique patterns of randomly distributed physical features that are extremely challenging to duplicate. Additionally, it is crucial for the tags to be low-cost and manufactured using easy, reconfigurable, and ultrafast processes. One effective technique for creating a unique and visually appealing PU tag is the LIC method. Notably, the creation of carbon content without the need for external matter eliminates the material cost drawback associated with tag production.
In this study, we demonstrate the fabrication of a unique and visually appealing PU tag based on a facile, low-cost, rapid, and scalable LIC approach. The LIC dot shapes, sizes, and density can be adjusted based on the input design and laser processing parameters, allowing the tags to be reconfigured according to the manufacturer's requirements. A PI sample with LIC spots of varying sizes distributed randomly in an array format is considered a tag. The LIC spot patterns, formed under the same laser beam energy incidence, are attributed to the heterogeneity of aromatic compounds in the PI film. The spot images are classified into three-level bits based on their sizes and brightness, serving as representations of an identity. The digitalized information encoded by these bits can be stored and utilized for authentication purposes. With this innovative approach, unique spot patterns can be directly engraved onto a flexible printed circuit board, providing a highly secure and customizable solution.

11:45 AM MF02.06.08
Development of Robust Superhydrophobic Surfaces Through Laser-Induced Micro/Nanoscale Armor Textured Structures Muhammad Bilal Asif; Hong Kong University of Science and Technology, Hong Kong

Superhydrophobic surfaces have attracted the attention of researchers across the globe due to their utility in a range of applications such as biotechnology, anti-corrosion, anti-fouling, and heat transfer. Super hydrophobicity is typically achieved through low surface energy and high micro to nano-scale surface roughness, allowing reduced contact between the liquid and the surface of solid material. However, during mechanical loading, this increase in surface roughness leads to high localized pressures due to reduced contact area between the interacting surfaces. This increase in local pressures makes such surfaces fragile and susceptible to damage during mechanical abrasion wear. As a result, the material underneath gets exposed which may cause a change in the hydrophobic property of the surface under abrasion. Therefore, most superhydrophobic surfaces are fragile and prone to damage when exposed to harsh environments.
In this study, we have proposed a methodology to achieve robustness in superhydrophobic surfaces on metals making them resistant to mechanical abrasion wear and can withstand harsh operating conditions, such as acidic and alkaline environments, sea water exposure, ultraviolet radiation (UV) exposure, exposure to water jet, and elevated temperatures. This was achieved by splitting the problem statement into two sections. The mechanical robustness is achieved through a single-step laser-induced micro-to-nanoscale surface texturing, obtaining interconnected armor grids of various shapes and sizes, whereas the low surface energy was achieved using the silica-based nanoscale superhydrophobic coating.
The microstructure armor shapes investigated in this study include interconnected hexagonal, triangular, and square-shaped holes. Optimization was carried out by testing eight different sizes of each microstructure shape. The interconnectivity in microstructure shapes was inspired by nature as observed in honeycomb structures and fish-scale skin structures.
The grid microstructure offers pockets to hold nano-coating and acts as protective armor for the superhydrophobic coating against abrasion wear. The water-repellent coating housed inside microstructure pockets offered superhydrophobic behavior to the surface. The influence of various geometric factors such as microstructure wall thickness, hole depth, and microstructure size on the superhydrophobic behavior was also investigated. The initial water contact angle (WCA) was measured to be around 168 degrees and after 1000 sandpaper abrasion cycles under loading, the surface retained its superhydrophobic property with WCA measuring above 150 degrees for most sizes of all microstructure shapes. The prepared surface retained its superhydrophobic property when exposed to; 30 days of UV radiation, 600 minutes of water jet impact test, 30 days in sea water, acidic and alkaline environments, and 30 cycles of thermal cycling testing as per ASTM D6644-15. The proposed methodology is a scalable process for achieving durable robust superhydrophobic surfaces and can be utilized for a range of materials in a variety of applications.

SESSION MF02.07: Laser Assisted Manufacturing of Functional Materials for Sensors and Actuators
Session Chairs: Jonathan Claussen and Varun Kashyap
Thursday Afternoon, April 25, 2024
Room 324, Level 3, Summit

1:30 PM *MF02.07.01

Laser-Assisted Sythesis and Texturing of Graphene Electrodes for Biosensing Devices Amit Barui and Lia Stanciu; Purdue University, United States

The pressing global demand for rapid, point-of-care detection of enveloped RNA viruses necessitates innovative sensor manufacturing approaches. We present a biosensor manufacturing method, focusing on flexible electronics employing graphene inks printed on flexible polymeric substrates. These are subsequently cured and laser-textured under conditions specific to our experiments, incorporating optimized electrode geometries. A crucial component of our advancement is the novel 2D layered structure and electrode coating geometry. In conjunction, the precise laser texturing and curing protocols allow for functionalization using single-stranded (ss) DNA primers. These primers, interacting with graphene layers, play a significant role in constructing DNA sensors adept at detecting enveloped RNA viruses directly, without the need for PCR amplification.
Laser texturing significantly influences the hydrophobicity of these graphene sensors, enhancing their hydrophilic nature. Notably, differences were observed in hydrophilicity between different generations of sensors. Further, the methodology for DNA primer application is considered. While dip coating results in false negatives due to inadequate DNA ligand loading, drop casting amplifies the electrode resistance, denoting a superior yield in functionalization. Our evaluations further emphasize the superiority of unidirectional printing for sensor construction, evidenced by consistent, minimal resistance measurements.
The DNA sensor construction strategies reported in our research offer compelling insights into the manufacturing and deployment of highly specific, portable devices for enveloped RNA virus detection at point-of-care facilities, all within minutes. These findings underscore the role of laser-assisted processes, optimal electrode design, and DNA functionalization methods in advancing the field of RNA pathogen detection.

2:00 PM MF02.07.02
Potential Application of Laser Reduced Graphene Oxide Electrode for Pressure Sensing Yijing Stehle; Union College, United States

Reduced graphene oxide (rGO) has attracted attention as an active electrode material for flexible electrochemical devices due to the high electric conductivity and large surface area. Compared to the other reduction strategy, laser reduction is a single-step, precise, low-cost, and chemical-free processing that can be directly applied on the graphene oxide (GO) membrane under ambient conditions. In general, the quality of the rGO is limited to that of pristine graphene due to incomplete reduction, and oxygenated defects involved in the reduction process. The partially removed oxygenated functional groups not only influence the impedance of the electrode, but also make it sensitive to the humidity of the working environment. Most of the studies are focused on the laser irradiation parameter optimization to achieve the lowest O/C ratio. This study aims to explore the potential of applying the Laser reduced graphene oxide (LrGO) for pressure sensing. Beyond the laser irradiation parameters including intensity, frequency, and scan speed, the impact of partially reduced GO on the bottom and the interlayer distance increase during the reduction is studied to improve the sensing performance of LrGO. Our results demonstrate the potential of applying LrGO in the pressure sensing field through facile post treatment.

2:15 PM MF02.07.03
Laser-Induced Graphene (LIG) based Green Gas Sensor Cheolmin Kim, Hanku Nam, Mingu Kang, Kichul Lee, Youngjin Kim and Inkyu Park; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

In recent years, the global electronics industry has experienced rapid growth, driven by advances in technology and increasing demand for electronic devices. However, this growth has come at a significant cost to the environment, as electronic products consume vast amounts of energy and resources during their production, use, and disposal. As a result, there is a growing need for more sustainable and environmentally friendly electronics, also known as "green electronics". Green electronics refers to the design, production, and use of electronic products and systems that minimize environmental impact, reduce energy consumption, and promote sustainability throughout their lifecycle. The global green technology and sustainability market was valued at $13.28 billion in 2021 and is expected to expand at a compound annual growth rate (CAGR) of 22.4% from 2022 to 2030. In the field of gas sensors, the development of green gas sensors that are easy to dispose of after use by using sustainable materials such as cellulose and gelatin has been actively developed in line with the changing times.

Recently, femtosecond lasers and their use to create laser-induced graphene (LIG) have received a lot of attention. The femtosecond laser used in this study to fabricate the gas sensor is a pulsed laser that can have a very high peak power of terawatts by focusing the photon energy of the laser beam in a very short time of femtoseconds. Femtosecond lasers are useful in many applications because they have a very high frequency, resulting in high energy and minimal heat transfer to surrounding materials. These characteristics make a process using femtosecond lasers suitable for fabricating the laser-induced graphene (LIG)-based gas sensors in this study. When certain materials containing carbon are irradiated with a laser beam, they carbonize and produce a three-dimensional porous material, which is known as LIG. LIGs have excellent electrical and mechanical properties, and their three-dimensional porous structure makes them ideal for use in gas sensors. In addition, LIGs created in wood do not require any special chemical treatments during fabrication, making them eco-friendly, easy and quick to manufacture, and inexpensive to make in any desired design.

In this work, we present a novel approach for the fabrication of a LIG-based eco-friendly gas sensor coated with a sensing material and patterned on wood substrates using a one-step process. The combination of LIG and the sensing material coating allows for the creation of a highly sensitive and selective gas sensor. This sensor is not only eco-friendly but also has the potential to be cost-effective due to the use of a renewable and sustainable wood substrate and a one-step fabrication process. The one-step patterning process allowed for precise and efficient production of the sensor, while the use of wood substrates made it environmentally sustainable and biodegradable. The gas sensors are reactive to CO, NH_3, and CH_4 gases, and are fabricated in an array by doping different materials to effectively detect different types of gases. The gas sensor also demonstrated its potential as a forest fire monitoring system by using deep learning algorithms to detect different types of gases in a fast time.

3:00 PM MF02.07.04
Scalable Laser-Assisted Manufacturing of Chipless RFID Sensors on Metallized Films Muhammad Masud Rana, Sarath Gopalakrishnan, Akshay Krishnakumar, Sotoudeh Sedaghat, Sina Nejati, Ulisses Heredia and Rahim Rahimi; Purdue University, United States

The global food packaging industry, valued at 311.4 billion dollars in 2020 and projected to reach 456.6 billion dollars by 2027, is witnessing growing demands for improved food quality and safety. Monitoring the quality of packaged food plays a vital role in reducing spoilage and enhancing food safety. Key indicators like humidity levels, pH, and chemical changes in meat products necessitate sensors for effective monitoring. Current solutions, such as colorimetric sensors and active sensors, have limitations. While colorimetric sensors are cost-effective and suitable for transparent packaging, they cannot be used in non-see-through packages, requiring labor-intensive manual inspection. Active sensors, though automated, are expensive and may not always be biocompatible due to batteries and electronic chips.

Battery-less chipless wireless sensors, due to their low cost and wireless capabilities, are becoming increasingly popular in food packaging. However, challenges in the commercialization of chipless sensors are associated with their manufacturing processes. Scalable manufacturing techniques like printing

have been employed for chipless sensors in applications like moisture sensing, soil analysis, and identification. These techniques reduce the complexity and resources needed for sensor production but introduce challenges related to ink formulation, custom screens, and drying and sintering times.

Our Scalable Laser-Assisted Manufacturing (SLAM) process offers a solution for large-scale, roll-to-roll production. It enables one-step patterning of a conductive aluminum layer on paper or PET sheets while concurrently creating high-surface-area Al2O3 nanoparticles within the laser-ablated regions, enhancing the sensitivity of the wireless sensor.

This work presents a systematic investigation of different laser processing conditions on metalized paper films to optimize structures. These structures provide high-performance antennas while minimizing structural damage to the underlying paper substrate. Results demonstrate that optimized processing conditions yield concurrent patterning of the metalized film into desired antenna structures and high-surface-area metal oxide nanoparticles within the ablated region. This results in exceptional sensitivity (linear sensitivity of -87 kHz/RH in a relative humidity range of 0% to 85%), surpassing standard RFID sensors produced using conventional photolithography methods.

The second part of this work demonstrates the post-functionalization of laser-patterned resonators and antennas to achieve responsive sensitivity to pH and hypoxanthine (HX), biomarkers relevant to food spoilage and fresh meat and fish produce. This technology opens new possibilities for scalable and cost-effective sensor production, paving the way for their implementation in smart packaging to address the challenges associated with food waste.

Bandgap Engineering of Laser-Patterned Diamond-Like Carbon Structures Naveen Narasimhachar Joshi, Ben Sekely, Pranay Kalakonda, Sachin Kadian, John Muth, Roger Narayan and Jagdish Narayan; North Carolina State University, United States

We report the formation of Si-DLC thin films on Si (100) and sapphire (0001) substrates via plasma-enhanced chemical vapor deposition (PECVD) technique. Subsequently, these thin films were irradiated with nanosecond ArF excimer laser pulses (λ = 193 nm; pulse duration = 20 ns) of varied energy density (0.6 Jcm^{-2}. 0.7 Jcm^{-2}, and 0.8 Jcm^{-2}). The pulsed laser annealing (PLA) technique melts the Si-DLC films in a super-undercooled state that can be quenched rapidly. As such, the sp^2 content in the films can be modified by controlling the energy density of the laser pulse. We show that the optical bandgap of Si-DLC structures can be controlled by suitably tuning the sp^2 content in Si-DLC thin films through the PLA technique. Raman spectroscopy and XPS studies were employed to determine the sp^2/sp^3 ratio in the as-deposited and PLA-treated Si-DLC thin films. Absorption spectra were obtained by UV-Vis spectroscopy and used to determine the optical bandgap (Tauc's method) and Urbach energy and correlated with the sp^2 content in the films. This study shows that PLA is a powerful technique for controlling the functional properties of DLC thin films for state-of-the-art optoelectronic applications.

10:30 AM *MF03.01.01
Processing Fun with Nanocellulose Jeffrey P. Youngblood; Purdue University, United States

Cellulose Nanomaterials (CNMs) are an attractive material class for possible applications in nanocomposites reinforcement, nanomaterials and biomedicine as they have high strength and stiffness, yet are renewable, biodegradable, non-toxic, and cheap. They are also of particular interest for rheology control. However, as nanoobjects they can prove challenging to process due to water binding ability and lack of dispersion. Here we detail our journey towards processing various materials with CNM. Of particular note will be our recent efforts at additive manufacturing with CNM and CNM as an additive in cement.

11:00 AM *MF03.01.02
Highly Effective Nanocellulose-Based Flocculants for Use in Freshwater and Saltwater Conditions Wim Thielemans; KU Leuven, Belgium

The rigidity of cellulose nanocrystals and the ability to modify tthem at differnet surface planes makes them interesting candidates as flocculants for larger particles or organisms becasue they can flocculate using a patch mechanism and coiling under high salt conditions is avoided. Therefore, we investigate cationically modified CNCs for the flocculation of microalgae. Cellulose nanocrystals (CNCs), extracted from cotton via a standard H_2SO_4 acid hydrolysis, were chemically modified with methyl-imidazolium (MIM) and pyridinium (PYR) grafts at various degrees of substitutions (DS). The extent of grafting was determined by elemental analysis and FTIR and EXPS spectroscopy, while retention of crystallinity and morphology were confirmed by WAXS and AFM respectively.
When testing *Chlorella Vulgaris* (freshwater microalgae) flocculation, it was found that the flocculation efficiency did not vary significantly with surface graft or with DS. However, the required dose varied virtually linearly with DS and remained independent of graft type (Fig 1(a)). Applying these flocculants to marine microalgae *Nannochloropsis oculata*, flocculation remained effective and flocs could readily be removed using a large pore filter (Fig 1 (b)).
Adhesion force histograms and rupture distance measurements by securing (1) a microalgal cell on the AFM tip and probing a film of modified CNCs or (2) modified CNCs on the AFM tip and probing microalgal cells in solution, both showed that the interaction is governed by electrostatic interactions. This explains the linear relation between DS and required dose for flocculation. The interaction force for PYR-CNCs with *Chlorella vulgaris* was only a third of that for MIM-CNCs but that did not seem to affect its flocculation efficacy. Therefore, the strength of interaction does not seem to be a very important parameter so that our results show that increasing DS is more important than optimizing the type of cationic charge. This work was then extended to prepare fully biobased materials, using glycine betaine as the surface grafts on CNCs, giving similar results to pyridinium and methylimidazolium modified CNCs. We also investigate CO_2-sensitive grafts allowing us to add the CNCs to the microlagal growing medium, after which CO2 could be bubbled through the medium redering the CNCs positively charged thereby flocculating the microalgae. Finally, we are currently investigating in more detail the interaction strength between cationically modified CNCs with microalgal cell walls to be able to devise models capable of predicting flocculation performance.
Our work thus shows that CNCs offer great potential as biobased flocculants, even in high-ionic strength conditions. Extending this work to the removal of particulate matter in waste water is currently in progress and shows similar excellent flocculation performance, showing the wide applicability of cationic CNCs as flocculants.

11:30 AM *MF03.01.03
The Importance of Crystallite Bundles in The Chiral Self-Assembly of Cellulose Nanocrystals: Origin, Morphology and Function Thomas G. Parton[1,2], Kevin Ballu[2], Bruno Frka-Petesic[2], Richard M. Parker[2] and Silvia Vignolini[1,2]; [1]Max Planck Institute of Colloids and Interfaces, Germany; [2]University of Cambridge, United Kingdom

Cellulose nanocrystals (CNCs) are elongated negatively-charged nanoparticles produced by acid hydrolysis of cellulosic biomass (e.g. cotton, wood pulp). CNC suspensions spontaneously form a left-handed cholesteric mesophase, which has a periodicity (pitch) determined by the characteristics of the individual CNCs (e.g. morphology, surface chemistry) and the suspension formulation (e.g. solvent, additives). This helicoidal arrangement of CNCs can be preserved as the suspension is dried, resulting in films with vibrant structural color. The chiral self-assembly of CNCs is thus a promising route to create materials with a tunable optical response from a sustainable biopolymer feedstock, but understanding how the properties of the large-scale structure emerge from the behavior of individual nanoparticles has been a persistent challenge.

First, by gradually tuning the size and shape of cotton CNCs using ultrasonication, and correlating the morphology of individual particles with their cholesteric mesophase behavior in suspension, we found that CNC “bundles” (i.e. clusters of laterally-bound elementary crystallites) are essential for the formation of a cholesteric phase. These bundles appear to act as chiral dopants, analogous to those used for molecular liquid crystals, whereby an increase in dopant concentration leads to a decrease in cholesteric pitch (and blueshifted film color). We then compared common ways to induce aggregation in CNC suspensions (e.g., post-hydrolysis centrifugation or excess ionic strength). This investigation revealed that the formation pathway significantly affects the morphology of the bundles and thus their effectiveness as chiral dopants. These findings demonstrate that the "making" and "breaking" of crystallite bundles offers a facile way to tailor the self-assembly behavior of CNC suspensions.

SESSION MF03.02: Nanocellulose Fundamentals II

1:30 PM *MF03.02.01
Making Active and Responsive Materials Using Rod Shaped Fillers: Structuring Nanocomposites Johan Foster; The University of British Columbia, Canada

Cellulose nanocrystals (CNCs) are high-aspect ratio, mechanically stiff fibers which can serve as both a bio-renewable reinforcing agent in nanocomposites, as well as a handle for adding stimuli responsiveness. CNCs can be extracted from a wide range of natural cellulosic materials, with characteristics such as crystal structure, crystallinity and aspect ratio fluctuate widely between sources.

Here, we report functionalized cellulose prepared for reinforcing materials in a variety of environments, ranging from cement to implantable materials in the human body. Moieties attached to the surface of cellulose show that both irreversible and reversible changes can be induced by application of an external stimuli. These specifically designed materials are mechanically tunable, matching use conditions, while creating surprising mechanical properties.

2:00 PM *MF03.02.02
Agarose Facilitating Functional Hydrogels Olli Ikkala and Hang Zhang; Aalto University, Finland

Agarose is polysaccharide that is extracted from seaweed and has amply been applied, e.g., in biological characterizations. It forms hydrogels by physical crosslinks, showing thermoreversible sol-gel transitions, wherein nanoscopic bundles of semiflexible fibrils are formed in the gel state in comparison to polymer coils in the sol state. In hydrogels it allows strain stiffening (1). Here we show that agarose facilitates new hydrogelation functionalizations. We combine agarose physical gel networks with poly(N-isopropylacrylamide), PNIPAm, chemical gel networks. PNIPAm classically shows Lower Critical Solution Temperature (LCST) thermoresponsive behavior. Upon removing the agarose network, emptied channels remain facilitating rapid water flow (2). Such channelled PNIPAm gels are transparent at room temperature, but show intense white colour upon heating. Chemically modified agarose can also be

used as a chemical macro-crosslinker therein to allow even promoted whiteness upon heating (3). Similarly, upon removing the agarose network to allow channeled PNIPAm hydrogels allows rapidly thermally switchable underwater adhesion taken that PNIPAm has been functionalized with catechol (4). Finally, thermally trainable mechanical and volumetric properties are shown using networks consisting of PNIPAm and agarose or acrylated agarose (5). The approaches suggest that agarose is a versatile polysaccharide to functionalize composite hydrogels, relevant in foreseen applications.

Latex-Based Pressure Sensitive Adhesives with Unmodified vs. Polymer-Grafted Cellulose Nanocrystals Julia Antoniw[1], Michael Kiriakou[2], Vida Gabriel[3], Michael F. Cunningham[4], Marc A. Dubé[3] and Emily D. Cranston[1]; [1]University of British Columbia, Canada; [2]Anomera Inc., Canada; [3]University of Ottawa, Canada; [4]Queen's University, Canada

Meeting the requirements for "green" materials, cellulose nanocrystals (CNCs) have been demonstrated as good additives and stabilizers in emulsions, however their exact role is not always clear. Our work on miniemulsion, microsuspension, and seeded semi-batch emulsion polymerization has demonstrated that polymer latex properties (e.g. size, surface charge, surface roughness, polymer degree of polymerization) can be highly tuned through the incorporation of CNCs. Most notably, the addition of CNCs always improves all performance metrics in latex-based pressure sensitive adhesives (PSAs). This is uncommon given that additives that increase adhesive properties normally decrease cohesive properties and vice versa. We have investigated nano-scale adhesive properties and their link to macroscopic tack, peel and shear strength to elucidate how CNCs act as "anchor points" for polymer entanglement, improve wettability and latex film coalescence, and form percolated networks throughout PSA films. Most recently, we have studied the effect of CNC surface chemistry (sulfated vs. carboxylated) as well as polymer-modified CNCs on PSA properties – the trends are not straightforward as changing the CNC surface affects aggregation/dispersibility, colloidal stability, the location of CNCs in the latex, and the tendency for coagulation to occur during polymerization. This talk will explain the main conclusions across a series of papers on CNCs in latex-based PSAs and recommendations for when/if to modify CNC surface chemistry. While the focus is on latex-based PSAs we believe the work is translatable to a range of latex products including paints, coatings, inks, toners and rubbers.

3:15 PM *MF03.03.01

From Synthesis of Functional Lignin Nanoparticles to Their Catalyst-Free Ozonolysis: Closing The Loop Alexandros E. Alexakis and Mika H. Sipponen; Stockholm University, Sweden

Recent years have seen a growing interest in lignin nanoparticles (LNPs) based on technical lignins extracted from plant biomass. A common method to produce LNPs involves diluting a lignin solution in an aqueous organic solvent by adding water or evaporating the organic phase. Our group has contributed to overcoming obstacles of LNPs such as their instability in aqueous and organic solvents. These approaches aim to preserve the spherical shape and allow for chemical modification before or after particle preparation. Hydroxymethylation of lignin with subsequent production of colloidal particles and their hydrothermal processing gave rise to particles that remain stable at acidic media as well as alkaline pH 13 and anhydrous polar organic solvents.[1] Another means to produce LNPs with tailored functionality involves first fractionating lignin into solvent-soluble and insoluble fractions, epoxidation of one of these fractions, and their combination in original mass ratio.[2] When epoxidized high-molecular weight lignin fraction was combined with the low Mw fraction the particles could be internally cross-linked via simple heating at 100 °C in colloidal state.
Moreno et al. (2023) established a method to stabilize LNPs using only natural components.[3] By co-aggregating urushi, a black oriental lacquer, with softwood kraft lignin, hybrid particles were formed. Owing to its catechol-type structure with unsaturated hydrocarbon chains linked to the aromatic ring urushi served as a renewable stabilizer through hydration barrier effects and thermally triggered internal cross-linking. The weight ratios of the components allowed adjustable stabilization levels. Hybrid particles with Urushi content >25 wt% underwent interparticle cross-linking, creating multifunctional hydrophobic coatings that enhanced water resistance of wood.
Covalently stabilized lignin structures present in the aforementioned LNPs also pose questions regarding their resistance to oxidative degradation that occurs in natural environment due to oxidoreductive enzymatic activities. Likewise, if these particles were found to be persistent to advanced water purification processes there would be a risk of environmental pollution in the form of nanoplastics. Ozone is a well-known decomposition agent targeting the aromatic rings present in lignin. Because of the chemical robustness of the LNPs, their degradation should be investigated in order to close the loop. For this reason, the acidic aqueous LNP dispersion (non-covalently crosslinked) was treated with ozone and their degradation was monitored by means of DLS, SEM, FTIR, UV-Vis and ^{31}P-NMR within three hours and it was compared with that of the most stable LNPs, i.e., the crosslinked hydroxymethylated ones.[4] Upon ozonolysis, the phenols were linearly converted to muconic acid structures and at longer times the degradation of LNPs was accompanied with the formation of small acidic compounds as identified by LC-MS. Although the chemical composition of the materials was significantly affected even after 15 min of ozonolysis, the size and spherical morphology of the LNPs was retained for one hour followed by their aggregation or complete degradation. Interestingly, mechanically homogenized softwood kraft lignin displayed considerable slower degradation rates compared to LNPs or HLNPs under similar conditions. The results of this study demonstrate that even chemically stabilized LNPs can be degraded with industrially relevant approaches. Further work should be directed to study biodegradation of LNPs that possess a high surface area under environmentally relevant conditions.

Greener Protocol for Chloromethylation of Lignin and its Diverse Applications Yevgen Karpichev and Mahendra Kothottil Mohan; Tallinn University of Technology, Estonia

Lignin, a highly abundant biopolymer characterized by its elevated carbon content and substantial aromaticity, holds immense potential as a valuable resource for fuel production and the synthesis of platform chemicals. However, despite its promising attributes, lignin remains underutilized within the spectrum of lignocellulosic biopolymers. Lignin's innate versatility can be harnessed through various chemical modifications at both "upstream" and "downstream" stages following its extraction. The chemically modified lignin exhibits the potential to serve as a precursor for the development of nanomaterials tailored for drug delivery, contingent upon its source, chemical alterations, and physicochemical properties.
Efforts to improve lignin's utility have predominantly involved "upstream" chemical modifications, which either target the hydroxyl groups for alteration or introduce new chemically active sites, thereby expanding its applications3. Yet, the quest for a versatile and environmentally friendly method for these modifications persists. In this context, the concept of a greener chloromethylation process, currently experiencing renewed interest and offering extensive prospects for "greener" applications, remains unexplored within the realm of lignin.
In this study, we present a novel method for the chloromethylation of lignin, which has paved the way for the creation of a diverse range of lignin-based products utilizing chloromethylated lignin (CLM) as the starting material.
The resulting lignin-based materials encompass catalytic agents, antibacterial formulations, and thermoplastic additives. Our lignin-based catalyst exhibits several advantages over other catalysts, including straightforward synthesis, heterogeneity, recoverability, and recyclability. Furthermore, we have substantiated the efficacy of the lignin-based catalyst in a range of carbon-carbon bond formation reactions, such as Suzuki-Miyaura, Sonogashira, Heck reactions, click reaction, and hydrogenation. The introduction of various quaternary amines with variable chain lengths to chloromethylated lignin has resulted in a series of innovative surface-active materials with enhanced antibacterial activity against Gram-negative and Gram-positive clinical isolate bacteria. The products of CML estrification are shown to alter thermoplastic properties of biopolymer (PLA). This research, along with the greener chloromethylation approach for lignin, holds the promise of shedding new light on lignin valorization, rendering it economically attractive and environmentally benign.

Semicrystalline Polymers from Lignin-Derivable Monomers Ty Christoff-Tempesta, Garrett F. Bass and Thomas Epps; University of Delaware, United States

Semicrystalline chain-growth polymers from lignin-derivable compounds are desirable for their potential to combine material sourcing from renewable feedstocks with performance-advantaged material properties (*e.g.*, higher tensile strengths and improved barrier properties in comparison to their amorphous polymer counterparts). Despite significant effort in the synthesis of vinyl monomers from lignin-derivable molecules, the resulting chain-growth polymers to date have been dominantly amorphous. Here, we describe the chemical transformation of lignin-derivable molecules into monomers that enable the generation of semicrystalline macromolecules. We harness living polymerization strategies to synthesize these polymers with stereoregularity under mild conditions, and we further probe the impacts of synthesis conditions on molecular weights, crystallinities, and thermal properties. This work introduces a strategy for utilizing lignin-derivable molecules to generate semicrystalline polymers with tunable properties, providing a pathway to valorize lignin for a new range of polymer applications.

Sonochemical Synthesis of Lignin Nanoparticles and Their Applications in Poly(vinyl) Alcohol Composites Dylan D. Edmundson, Anthony Dichiara and Rick Gustafson; University of Washington, United States

Lignin is a common and abundant byproduct of the pulp and paper industry and is generally burned to produce steam. Opportunities exist to acquire greater value from lignin by leveraging the properties of this highly conjugated biomacromolecule for applications in UV absorption and polymer reinforcement. These applications can be commercialized by producing value-added lignin nanoparticles (LNPs) using a scalable sonochemical process. In the present research, monodisperse LNPs have been synthesized by subjecting aqueous dispersions of alkali lignin to acoustic irradiation. The resulting particle size distribution and colloidal stability, as determined by dynamic light scattering, transmission electron microscopy and zeta potential analysis, of LNPs can be adjusted by varying the solution pH and ultrasonication energy. As-synthesized LNPs with a mean diameter of 204 nm were incorporated into poly(vinyl) alcohol (PVA) to prepare thin and flexible nanocomposite films using a simple solvent casting method. The addition of 2.5 wt.% LNP increased the material’s Sun Protection Factor up to 26 compared to 0 for neat PVA, while maintaining light transmission above 75% in the visible spectra. In addition, the tensile strength and elastic modulus of the PVA nanocomposites improved by 47% and 36%, respectively. The presence of LNP also enhanced the thermal stability of the materials. Significantly, the proposed sonochemical process may be generally applicable to the synthesis of a range of naturally-derived LNPs for a variety of value-added applications.

SESSION MF03.04: Poster Session I

Synthesis and Antibacterial Properties of Lignin-Based Quaternary Ammonium and Phosphonium Salts Mahendra Kothottil Mohan[1], Harleen Kaur[2], Angela Ivask[2], Jean-Manuel Raimundo[3], Tiit Lukk[1] and Yevgen Karpichev[1]; [1]Tallinn University of Technology, Estonia; [2]Institute of Molecular and Cell Biology, University of Tartu, Estonia; [3]SINaM - Aix-Marseille University, France

Lignin, a naturally occurring aromatic polymer, possesses diverse biological functions, particularly in the defense mechanisms of plants against pathogenic microbes. The prospect of utilizing isolated lignin as an eco-friendly antimicrobial agent presents a promising avenue for enhancing the value of lignin. Furthermore, as lignin derives from plant photosynthesis, its integration into the antimicrobial industry carries the potential to reduce carbon emissions. While numerous studies have explored lignin's utilization for the development of antimicrobial agents across various applications, the highly heterogeneous nature of lignin, encompassing variations in monomer composition, linkages, molecular weight, and functional groups, has obscured the relationship between lignin's structure and its antimicrobial properties.

To bridge these knowledge gaps, we conducted a comprehensive study in which we synthesized forty-two quaternary ammonium/phosphonium organosolv lignin samples from Aspen, Pine, and Barley straw, representing hardwood, softwood, and grass sources, respectively, employing a recently developed versatile intermediate known as chloromethylated lignin. These lignin samples were systematically evaluated for their antibacterial potential against *E.coli* and clinical isolates of Gram-positive (MRSA) and Gram-negative (*K. pneumonia*) bacterial strains.
Our findings indicate that the antibacterial activity of these lignin samples exhibits a notable increase with the length of the hydrophobic chain, up to C14, beyond which it begins to decline. Ongoing research is also exploring the antimicrobial activity of ammonium and phosphonium surfactant materials, both individually and in combination. This research underscores the significant enhancement in lignin's antimicrobial efficacy through chemical modification and highlights the potential for further improvements by incorporating additional chemical structures, such as cationic functional groups through chemical modification. This study opens new avenues for maximizing the antimicrobial potential of lignin, contributing to sustainable and eco-friendly solutions for pathogen control.

5:00 PM MF03.04.02
Tough 3D Printable Hydrogels Based on Force Responsive Protein Unfolding Ana Paula Kitos Vasconcelos, Naroa Sadaba, Antonio Vazquez and Alshakim Nelson; University of Washington, United States

The field of mechanochemistry has primarily focused on small molecules as the mechanophores that undergo mechanically-induced chemical transformations. Nature, however, uses macromolecules, such as proteins, as mechanically responsive elements in biological signaling and response. 3D printed thermosets based on the globular protein bovine serum albumin (BSA) as a biologically-derived mechanophore crosslinker have demonstrated high strength, ductility and shape memory, attributed to mechanically-responsive protein unfolding and refolding; however, these properties were not observed for the associated hydrogel. Herein, we develop a photopolymerizable hydrogel with a highly defined network topology based on norbornene functionalized BSA and poly(ethylene glycol) dithiol and a loosely-crosslinked interpenetrating network to observe mechanically-induced BSA unfolding. Harnessing BSA as a force-responsive crosslinker imparts high strength, toughness, ductility and tear resistance in 3D printable hydrogels, due to the disruption of the protein native structure and subsequent release of stored length as an energy dissipation mechanism to resist material failure. The development of this network enables the incorporation of a vast array of proteins as stimuli-responsive crosslinkers in vat photopolymerizable hydrogels.

5:00 PM MF03.04.03
Extrusion-Based 3D Printing of Gelatin-Carboxymethyl Cellulose Scaffolds for Tissue Engineering Applications Sule Yetis and Duygu Ege; Bogazici University, Turkey

3D printing in tissue engineering with natural polymers has significantly grown in the past decade. Gelatin (Gel) is a biocompatible polymer with high cell affinity due to it’s RGD groups; however it is not possible to 3D print it solely due to its low viscosity. Carboxymethyl cellulose (CMC) is another natural polymer used in tissue engineering and by blending CMC with Gel, the viscosity of the prepared ink can be increased and scaffolds can be efficiently 3D printed. In this study, Gel-CMC-based tissue scaffolds were prepared by using extrusion-based 3D printing. Tissue scaffolds were prepared for 3D printing using varying concentrations of Gel-CMC. The Gel concentration was adjusted within the range of 7.5% to 15% (w/v), while the CMC concentration remained constant at 7.5% (w/v), resulting in four formulations named as Gel7.5CMC7.5, Gel10CMC7.5, Gel12.5CMC7.5, and Gel15CMC7.5. Then, the samples were crosslinked with NHS:EDC to enhance their stability. The prepared inks were characterized with rheological study and the printed scaffolds were analyzed in terms of their Fourier Transformed Infrared Spectroscopy (FTIR), mechanical study, swelling, degradation and contact angle measurements. The rheological results showed that the dominance of the storage modulus (G') over the loss modulus (G") highlights a prevalent elastic behavior, a solid-like response exhibited by all groups. The increase in Gel concentration resulted in higher viscosity values, printing temperature and pressure, primarily due to the enhanced electrostatic interactions between Gel and CMC. According to the mechanical test results, the elastic modulus ranged from 921±23.50 kPa to 543.12±42.42 kPa indicating a suitable platform for soft tissue engineering applications. Furthermore, as the amount of Gel increased, the tissue scaffolds swelled less, and G15-C7.5 had the lowest swelling ratio. This is because G15-C7.5 had the most covalent crosslinking, which made it swell relatively less than other groups. The contact angle measurements for the 3D printed scaffolds ranged from 45.69° to 71.68°, indicating that these scaffolds possess hydrophilic characteristics. Overall, Gel-CMC inks with different concentrations were printable, which are promising ink candidates for 3D printing for tissue engineering applications, and 3D printed Gel-CMC-based tissue scaffolds presented proper hydrophilic and mechanical properties.

5:00 PM MF03.04.04
Scalable Advance Manufacturing of Complex Multilayer Structures Film with Simultaneous Slot Dies Deposition Method Minwoo Jung; Georgia Institute of Technology, United States

The application of slot die coating manufacturing techniques has been widely studied due to their scalability, continuous process, and relatively cost-effectiveness. Slot die coating is applied to manufacturing organic thin film transistors (OTFT), organic capacitors, organic solar cells (OSC), and membranes. However, OTFT, organic capacitor, OSC have multilayer complex structures for their functionality, and advanced membrane often requires multilayer and patterned structure. Fabricating such products that have multiple-layer complex structures requires multiple manufacturing steps since the most widely used slot dies are limited to a single layer. With additional layers, a separate single-layer slot die and drying oven are needed, which often results in energy consumption and requires space for extra manufacturing tools. Therefore, reducing manufacturing steps to a minimum can be beneficial in terms of cost and environment. To overcome limitations of single-layer slot die, current technology allows depositing two layers at single steps using a bilayer slot die but limited to two layers and patterning deposition using a co-deposition slot die but limited to a single layer. However, these techniques still require more than two steps to fabricate the abovementioned products. To further reduce the extra steps for a multilayer complex structure, the co-deposition slot die, and Bilayer slot die can be deposited simultaneously on top of each other. Simultaneous deposition of co-deposition slot die and Bilayer slot dies can reduce the drying step, which consumes a large portion of the energy in the slot die process. Furthermore, negating drying ovens can reduce the footprint of the manufacturing line as mentioned above.

Using advanced manufacturing methods by simultaneous deposition of co-deposition and bilayer slot die, unique structure of simple capacitor can be achieved. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) was used as conductive polymer, Polyvinyl alcohol (PVA) as insulating polymer, and Sodium carboxymethyl cellulose (CMC) as viscosity modifier. The surface tension and viscosity of the PEDOT:PSS was modified to stabilize the co-deposition film while the bilayer was deposited on top. Co-deposition slot die deposit alternating strip pattern that consists of PEDOT:PSS for conducting layer and PVA for insulation between PEDOT:PSS stripes. The bilayer deposits two layered films on top of the Co-deposition, without any drying step, that consist of PVA as the bottom layer and PEDOT:PSS as the top layer. The resulting film structure is a conductive polymer layer on the bottom of the film, an insulating layer for the middle layer, and another conducting layer on top resembling the capacitor's structure. Even though the resulting capacitor performance is subpar due to low-grade PEDOT:PSS, the advanced manufacturing method using simultaneous co-deposition and bilayer slot die can be applicable to a variety of products that consist of complex structure in reduced steps.

Nanocellulose Networks: Utilizing Colloidal Processing Principles to Tune The Mechanical Properties of Solid Foams Aban Mandal, Hareesh Iyer and Eleftheria Roumeli; University of Washington, United States

In recent years, nanocellulose has emerged as a sustainable and environmentally friendly alternative to traditional petroleum-derived structural polymers. However, the widespread implementation of nanocellulose is hindered by high energy-intensive extraction and processing methods, limited quality reliability, and cost-effectiveness **[1]**. In addition, the required fundamental understanding of process parameters that govern the morphology and structure-property relationships of nanocellulose systems, from colloidal suspensions to bulk materials, has not been developed and generalized for all forms of cellulose. This further hinders the more widespread adoption of this biopolymer in applications.
In this study, we explore the tunability of mechanical properties of cellulose bulk structures, by investigating the intricate connections between thermodynamic, electrokinetic, and hydrodynamic interactions in nanocellulose networks, within the context of stability, phase transformations, and their profound impact on enhancing the properties of bulk materials. To delve into thermodynamic interactions, we examine different concentrations of various nanocellulose-solvent pairs with varying Flory-Huggins interaction parameters. Electrokinetic interactions are explored by manipulating surface charge densities, while hydrodynamic interactions are studied through concentration-based transitions. The interplay between thermodynamic and electrokinetic stability is elucidated through time-series polarized light and cross-polarized light imaging of the nanocellulose colloids. We employ Dynamic Light Scattering (DLS) to assess the Fuchs Stability Ratio and correlate the Diffusion Limited Cluster Aggregation (DLCA) and Reaction Limited Cluster Aggregation (RLCA) regimes**[2]** with the rheological properties of the colloids. This sheds light on the underlying mechanisms and the specific interactions responsible for the concentration-based Onsager's Isotropic to Nematic phase transition, and in addition, enables a co-relation of the properties at the colloidal state **[3]** and the final solid structures. Small-angle X-ray scattering (SAXS) is employed to comprehensively understand the influence of various processing parameters on the ordering of the final bulk structure and, subsequently, the structure-property relationships. Our study enriches the understanding of nanocellulose processing from a polymer physics and colloidal chemistry perspective. These findings hold the potential for extending to multicomponent biomass-based systems in the future, contributing to sustainable and high-performance materials development.

Effect of Wet-Stretching and Confinement on Fiber Alignment in Bacterial Cellulose Films Kuotian Liao, Julia Blair, Kwon-Teen M. Chen, Esther Nicolaou and Eleftheria Roumeli; University of Washington, United States

Recent progress in sustainable materials has provided viable solutions to address the escalating challenges posed by non-renewable sourcing, environmentally harmful manufacturing processes, and the ultimate fate of synthetic plastics. Within this context, biopolymers have garnered increasing interest for their potential as eco-friendly substitutes to petroleum-derived counterparts, offering the distinct advantage of reduced environmental impact across their entire lifecycle. Bacterial cellulose (BC) stands out as a particularly compelling candidate, combining a high molecular weight, high degree of crystallinity, and a scalable, adaptable biosynthetic manufacturing process. Unlike plant-derived cellulose, BC circumvents the need for extensive extraction procedures, rendering it more accessible and environmentally benign. Following drying, the naturally grown BC hydrogels, called pellicles, can be transformed into self-supporting, lightweight yet mechanically robust films with prospective applications in structural panels or protective garments. This study delves into the effect of mechanical stretching/confinement as means of aligning the fibers in BC pellicles and their impact on the overall mechanics of the resulting dried films, aiming to offer fundamental insights into the structure-property interplay of this networked polymer. The results will not only enrich our fundamental understanding of polymer physics pertaining to BC-based networks, but also pave the way for future tailoring of the properties of the resulting films to cater to a diverse array of applications.

5:00 PM MF03.04.07
Effects of Chemical Treatments and Additives on Bacterial Cellulose Foams Hareesh Iyer, Michael Holden and Aban Mandal; University of Washington, United States

Renewable and biodegradable materials, including algae and cellulose, have emerged as promising alternatives to non-biodegradable petrochemical plastics. Bacterial cellulose (BC), a form of pure cellulose that is synthesized by bacteria, is an interesting alternative to plant cellulose due to the reduced processing required to harvest it. Here, we explore the utilization of BC as a biodegradable and renewable substitute for petroleum-derived plastic foams, both in its pure form and as a composite. The study investigates the chemical modification of cellulose, specifically using deep eutectic solvents (DES), to change its mechanical and morphological properties. Compression testing, Fourier transform infrared spectroscopy (FTIR), and X-ray photoelectron spectroscopy (XPS) are used to analyze the mechanical, morphological, and chemical bonding changes made to the cellulose. Subsequently, natural additives such as xanthan gum, glucomannan, pectin, and agar are evaluated as potential additives for BC composite foams. These additives are added with the aim to replicate the recoverability of commercial polymer foams made of materials such as polystyrene and polyurethane. By modifying the types of biopolymers, as well as their amounts and processing, we show significant changes in the mechanical and micromorphological properties of the cellulosic foams. We show that, especially with the addition of pectin, we are able to significantly improve the compressive strength and recoverability of BC foams while maintaining stiffness. Lastly, aiming to address the viscoelastic responses of the produced composite foams, we subject them to cyclic compression and stress-relaxation tests.

5:00 PM MF03.04.08
Understanding 3D Networks Structure during Biosynthesis of Cellulose from Bacteria Julia Didier Amorim[1,2], Kuotian Liao[2], Hareesh Iyer[2] and Eleftheria Roumeli[2]; [1]Universidade Rural de Pernambuco, Brazil; [2]University of Washington, United States

Materials sourced from renewable sources and synthesized under mild conditions offer coupled benefits in terms of sustainability, in contrast to petroleum-derived polymers, which are known contributors to pollution and adverse health consequences. Bacterial cellulose (BC) consists of high aspect ratio fibrils that bundle into fibers, forming 3D networks which can be influenced by growth conditions. BC pellicles, which are produced in static conditions and are often used in research and applications, exhibit a layered structure at the mesoscale. These layers form as successive entangled fiber networks are deposited extracellularly during BC growth. The layered structure is a distinctive feature of BC pellicles and contributes to their unique mechanical properties. The growth conditions during BC fiber synthesis significantly influence the alignment, crystallinity, and 3D morphology of the formed network. However, there is a lack of understanding of the fundamentals of cellulose fiber aggregation into network assemblies. Understanding how nanoscale fibrils bundle, entangle, and form larger structures at the mesoscale is crucial for tailoring BC's properties for various applications, from biotechnology to materials

science. We investigate the intricate structural evolution of BC, spanning from the nanoscale to the mesoscale, with a specific focus on understanding entanglement phenomena. Furthermore, our investigation explores the significance of fibril entanglement in BC networks, providing insights into the intricate process by which individual nanofibrils interweave to construct the broader mesoscale framework. This research aims to provide a comprehensive understanding of BC's structural development.

Bio-Based Pickering Foams, From Fundamentals to Applications Roozbeh Abidnejad[1], Bruno Mattos[1], Eero Kontturi[1] and Orlando Rojas[2,1]; [1]Aalto University, Finland; [2]The University of British Columbia, Canada

Colloids are suitable options to replace surfactants in the formation of multiphase systems, while simultaneously achieving performance benefits. We introduce a synergistic combination of colloids for the interfacial stabilization of complex fluids that can be converted into lightweight materials. The strong interactions between high aspect ratio and hydrophilic fibrillated cellulose (CNF) with low aspect ratio hydrophobic particles afford Pickering foams. Compared to foams stabilized by the hydrophobic particles alone, the introduction of CNF significantly increased the foamability (by up to 350%) and foam lifetime. These effects are ascribed to the fibrillar network formed by CNF. The CNF solid fraction regulated the interparticle interactions in the wet foam, delaying or preventing drainage, coarsening, and bubble coalescence. Upon drying, such a complex fluid was transformed into lightweight and strong architectures, which displayed properties that depended on the surface energy of the CNF precursor [1].
Such systems can be further utilized for various purposes, including fire retardancy and thermal insulation. Many applications, including buildings and chemical and thermal processes, call for thermal insulation. Environmental awareness, however, is driving the industry toward more ecologically friendly and sustainable technologies. In this light, switching to renewable raw materials from petroleum-based foams is of importance [2,3]

Hydrogel-Ceramic Composite for Efficient Oil Water Separation in Emulsified System Harsh Rohit, Shobha Shukla and Sumit Saxena; Indian Institute of Technology Bombay, India

Water pollution due to oil remains a prominent environmental concern, primarily driven by escalating incidents of oil spills, intensive petroleum operations, rapid expansion of the food industry, and the growth of textile, metal, and leather sectors. Oily wastewater discharged from these industries aggravates the problem, posing a significant threat to soil quality, water bodies, aquatic ecosystems, and human health. Ships discharge bilge oily water which is governed by MARPOL. Although numerous techniques and materials are available for oil-water separation, filtration material systems exhibit promise due to their expansive surface area, appropriate pore sizes, lightweight structure, and cost-effectiveness. Filtration systems being invested across the community are majorly made of polymers and ceramics. Polysulfone (PSf), Polyacrylonitrile (PAN), Cellulose Acetate (CA), Sodium Alginate (NaAlg), Polyvinylidene fluoride (PVDF) are some of the polymers which, post morphological and chemical modification using functional groups are used for oil water separation. Across ceramic membranes, Titania (TiO_2), Silicon Carbide (SiC), Alumina (Al_2O_3), Silicon Nitride (Si_3N_4) etc. have been explored. A novel composite of Hydrogel with ceramic membrane made of Alumina, Zirconia and SiC has been tailored for efficient oil-water separation. The composite shows very high separation efficiency (beyond 99%) with very good antifouling properties. Furthermore, it is non-toxic and has very high pH and salinity resistance. The composite has potential to be used for pressure driven operations in industries for a high flux and better separation efficiency for continuous oil-water separation where water is in continuous phase.

Mycelium Bridge Behavior for Sustainable, Architected Biocomposites Branden Spitzer, Sabrina Shen and Markus Buehler; Massachusetts Institute of Technology, United States

There is growing interest in the design of sustainable materials based on mycelium, the root network of fungi, due to its robust, interconnected growth and its degradable end of life. Our work aims to understand the fundamental interactions between mycelium, substrate materials, and void spaces, which can inform the design of complex and functional mycelium composites. In particular, here we investigate the ability of mycelium to bridge gaps of empty space within a waste-derived bio-composite material and observe the effects of varying nutritional content. The bio-composite substrate is suitable for 3D printing, which enables the creation of an array of complex forms. Understanding the formation and strength of mycelial bridges supports the future design of mycelium composite materials for self-healing, bio-welding, directed growth, and sustainable structure applications.

5:00 PM MF03.04.12
Sequence Control of Bioinspired Calcium-Responsive Protein-Based Polymers Marina P. Chang, Gatha M. Shambharkar, Winnie Huang, Kenny M. Hernandez and Danielle J. Mai; Stanford University, United States

Protein-based polymers offer improved sustainability over fossil-based synthetic polymers because of their biodegradability and their composition from abundant, renewable materials. Natural proteins exhibit a wide range of functions, providing bioinspiration for engineering responsive protein-based polymers. Responsiveness to biological signals, such as calcium ions, allows protein-based polymers to mimic biological functions like muscle contraction. The amino acid sequence of protein-based polymers is often modified to tune the function of the polymers without requiring additional steps of chemical synthesis and purification. Tunability is advantageous for applications such as scaffolds for tissue regeneration, where the mechanical properties of the scaffold can be matched to specific tissues.

To create tunable, calcium-responsive, protein-based polymers, we take inspiration from a class of “Repeats-in-Toxin” (RTX) protein domains found in bacterial proteins. These RTX domains undergo a reversible conformation change from random coils to β-roll structures upon binding to calcium. RTX domains are characterized by the repetitive sequence GGXGXDXUX, in which glycine (G) and aspartic acid (D) are highly conserved in the calcium-binding region. For positions that are less conserved, U represents an aliphatic amino acid and X represents any amino acid. We explored the impact of amino acid substitutions at a non-conserved X site in the calcium-binding region. These amino acid substitutions probe the impact of monomer size, electrostatic interactions, and hydrophobicity on the calcium-responsive behavior of RTX domains. Additionally, we explored the impact of sequence variability by creating consensus RTX domains, which comprise tandem repeats of the simplified consensus sequence GGAGXDTLY. Circular dichroism reveals that some variants exhibit more ordered structures in the absence of calcium compared to wild-type RTX, particularly variants with smaller amino acid substitutions. By varying the amino acid sequence, we can tune the calcium sensitivity of RTX between 1 – 100 mM $CaCl_2$. Finally, RTX domains are incorporated into fusion protein polymers to create calcium-responsive materials with tunable stiffness for biomedical applications such as tissue scaffolds.

5:00 PM MF03.04.13
Rapid Photo-Triggered Release Kinetics of PPA Microcapsules Youngsu Shin[1], Jared Schwartz[1], Anthony Engler[1], Brad H. Jones[2] and Paul Kohl[1]; [1]Georgia Institute of Technology, United States; [2]Sandia National Laboratories, United States

Stimuli-responsive microcapsules have been investigated as a means to release special-purpose payloads such as catalysts inside solid polymer materials. These catalyst payloads have garnered recent interest in the recycling and upcycling of plastics. A microcapsule can be loaded into common commodity plastics and triggered to release a catalyst for depolymerization. Specific chemical conditions or structural changes have commonly been used to trigger microcapsules for controlled release, but these mechanisms tend to not be amplified or take substantially long times to induce release. Long times for release impact the cost of processing, especially for recycling that would otherwise require an outside-in mechanism. Unlike other stimuli, light has advantages in that it is readily available and convenient to use with low cost. This study utilized poly(phthalaldehyde) (PPA) microcapsules formulated with various UV-sensitive photo-acid generators (PAGs). Upon exposure to UV irradiation followed by heat treatment, PAGs generate and release strong acids that attack the PPA, which initiates rapid depolymerization back to the monomer. In the case of a microcapsule made with a PPA shell, the rapid depolymerization results in the immediate release of the capsule payload to its surroundings. PPA capsules were made using an oil-aqueous emulsification process in the presence of surfactants and their morphologies are a fraction of blueberry shapes (high loading of core) and a fraction of concave shapes (low loading of core). As UV dose increased, more capsules were depolymerized and more dodecane core was obtained, indicating core release. The percentage of dodecane release and depolymerized PPA were analyzed using ^{1}H NMR. The photo-triggered response was further tuned by varying PAG concentration, PAG type, and post-exposure heating time. The efficiencies of the PAGs were compared for their release kinetics and the energy required to fully decompose the shell. PPA microcapsules with UV-sensitive PAGs successfully released their core within a short time and with low UV doses.

5:00 PM MF03.04.14
Investigating The Pozzolanic Reactivity of Natural Zeolite as a Supplementary Cementitious Material: Correlations to Mechanical Performance Brandon T. Lou, Dwayne Arola and Eleftheria Roumeli; Univeristy of Washington, United States

Cement, the binding material in concrete, produces a significant amount of atmospheric CO_2 during its production. Therefore, methods to reduce the amount of cement used in concrete production, while maintaining adequate strength and durability, has substantial environmental implications. Natural zeolites are being considered to replace a portion of cement content as a supplementary cementitious material (SCM) due to its high pozzolanic activity, which is attributed to their porous aluminosilicate framework. However, the detailed reactions between the zeolite and cement, namely the effect of the hydration reactions, as well as zeolite's contribution from physical characteristics, are not fully understood. Previous studies have characterized pozzolanic activity, assessed particle size and preprocessing contributions, mechanical properties, and performed chemical component analyses separately. However, there are inconsistencies among reported results and the materials science of the structure/processing/performance was not elucidated. Here, the pozzolanic activity of natural zeolite is characterized with respect to the degree of hydration of mortar mixes and correlated to the mechanical performance of concrete composites. The natural zeolite is first analyzed to understand its microstructure, elemental, and mineralogical composition using scanning electron microscopy (SEM), energy dispersive x-ray spectroscopy (EDS), and x-ray diffraction (XRD). Bound water measurements are utilized to quantitatively assess the pozzolanic reactivity of the zeolite, and over a range of particle sizes (achieved via milling). We then varied the percentage of natural zeolite in mortar composites at different particle sizes and concentration with respect to cement content. The effects of particle size on the micromorphology, degree of hydration, and development of bonding environments of the composites is observed via SEM, thermogravimetric analysis (TGA), and Fourier transform infrared spectroscopy (FTIR). The experimental results confirm that zeolite replacement of cement content in mortar composites enhances the mechanical performance at a discrete particle size and concentration. There are optimum parametric conditions to maximize strength that appear based on the increased degree of hydration stemming from increased pozzolanic activity of zeolite. Overall, this experiment demonstrates that natural zeolites are a viable SCM to reduce cement content in concrete composites and that further work could support the development of a truly superior sustainable concrete.

Energy-Efficient Manufacturing and Lightweight Applications of Expanded Ethylene-Propylene-Butene-1 Copolymer Bead Peng Guo; SINOPEC Beijing Research Institute of Chemical Industry, China

Ethylene-propylene-butene-1 ternary copolymer (TPP) and ethylene-propylene copolymer (EPC) were fabricated to produce expanded polypropylene (EPP) beads through batch-foaming followed by steam-chest molding. The microstructure and thermal behaviors of both TPP and EPC were investigated by nuclear magnetic resonance, gel permeation chromatography, wide-angle X-ray diffraction, analytical temperature rising elution fractionation, and differential scanning calorimetry. EPP beads made of TPP and EPC were prepared by an autoclave batch-foaming process using compressed CO_2 as the blowing agent. Polypropylene micropellets (average diameter is approximately 1 mm) were obtained using an underwater micro-pelletizer system, which shorten the CO_2 diffusion distance. The effects of CO_2 content on the melting temperature of two types of polypropylene were studied. Magnetic suspension balance was used to measure the solubility of CO_2 in semi-molten PP. The effects of introducing comonomers on the foaming processing and cell structure of EPP beads were preliminarily investigated. The addition of 1-butene played a significant role in enhancing the mechanical properties and decreasing the energy cost during both batch-foaming and steam-chest molding with reduced carbon dioxide emissions.

5:00 PM MF03.04.16
Engineered Wood Materials Utilizing Seaweed Biomass as an Adhesive Mallory Parker[1], Paul Grandgeorge[1], Ian R. Campbell[1], Hannah Nguyen[1], Rebekah I. Brain[1], Scott Edmundson[2], Deborah Rose[2], Chinmayee Subban[2] and Eleftheria Roumeli[1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

The increasing concerns associated with petroleum-derived resources call for sustainable renewably sourced alternatives. Engineered wood materials are widely used in the form of panels and particleboards in structural applications, construction and packaging. Wood-products provide multiple advantages such as sustainable feedstocks and lightweight final products that can meet load-bearing requirements for a plethora of applications. However, engineered wood products, such as medium density fiberboards (MDF), most predominately rely on formaldehyde-based adhesives to achieve wood particle/fiber bonding. Such adhesives are not only petroleum-derived but also have detrimental health effects during use (formaldehyde emissions) and at their end-of-life. To further mitigate the environmental impact of construction materials, more sustainable bonding agents need to be investigated. In this work, we hypothesize that the biopolymers within seaweed biomass can form a strong hydrogen bonding network with wood particles, that can be sufficient to create a set of fully biobased engineered wood composites. The use of seaweed as an adhesive would offer the benefits of carbon sequestering and renewable sourcing, as well as non detrimental end-of-life effects. We test our hypothesis using Ulva expansa (Ulva) as a proof-of-concept seaweed species and report the manufacturing of engineered wood composites with varying concentration of waste wood particles and Ulva, as well as a detailed study of their structure, bonding and mechanical properties. We demonstrate that upon hot-pressing, powderized Ulva flows in between the wood particles and provides a strong binding effect. We show that the flexural strength of produced engineered wood composites increases with increasing Ulva concentrations. We further report that the presence of Ulva attractively improves other properties such as water resistance and flammability. To highlight the bonding mechanisms at the biopolymeric level, we perform Fourier-transform infrared spectroscopy (FTIR) studies. We also show that the resulting wood panels can be machined using traditional drilling or laser-cutting methods. Finally, we perform an analysis of the environmental impact of ulva-bonded engineered

wood composites.

5:00 PM MF03.04.17
Recyclable Cellulose-Polymer Composites Using Silica Nanoparticle incorporated Nano- and Micron-Sized Cellulose Fibers Jung-woo Park and Young-soo Seo; Sejong University, Korea (the Republic of)

Interest in sustainable and biodegradable plastic fillers has increased due to environmental concerns and legislative regulations. Therefore, cellulose fiber (CF) with excellent mechanical properties has attracted attention recently. However, there are issues when it is mixed with plastics, which are lack of dispersion and limited thermal stability of CF. CF that aggregates immediately when dried due to capillary forces does not disperse well in plastic and oxidizes easily to render a brownish color during the melt mixing process reducing circularity. Here, to address these issues, the CF surface was modified with silica nanoparticles via a sol-gel reaction to provide some distance between fibers in the powder form of CF resulting in dispersion enhancement by reducing van der Waals interactions. At the same time, its thermal stability is improved due to the silica cladding that protects the CF surface from heat. We applied the silica-covered nano- and micron-sized CF to plastics such as polyamide (PA6) and polylactic acid (PLA) using melt-mixing processes including extrusion. Mechanical properties such as tensile and flexural strength of the composites and rheological and thermal properties such as glass transition and melting temperatures and heat distortion temperature will be presented.

5:00 PM MF03.04.19
Developing Sandwich Structure with Novel Biobased Composite Using Additive Manufacturing Mahyar Fazeli; Aalto University, Finland

Sandwich structures are considered as promising designs for structural applications showing high stiffness, low weight, and high energy absorption properties. In this study, the sandwich panel is designed and fabricated using different plywood as the face sheet and thermoset-based composite as the core. The additive manufacturing (AM) method is employed to print the composite structure onto the plywood surface, enabling precise control over the material distribution and enhancing the bonding between the face sheets and the core. The optimized design and manufacturing process allowed for the integration of a thermoset-based composite core, which contributed to the overall weight reduction of the panel while maintaining its structural integrity. The flexural testing showed significant improvement in the sandwich panel compared to the plywood with the same thickness. The flexural strength and modulus increased up to 3.4 and 3.6 times, respectively. The resulting sandwich panel demonstrated exceptional load-carrying capacity and resistance to bending, making it a viable candidate for various structural applications where weight reduction and high performance are critical.

The Transfer to Sustainable Fashion: How The Textile and Clothing Industry Promote Waste Joud AlKhawashki[1] and Mohammad Hayal Alotaibi[2,1]; [1]Alfaisal University, Saudi Arabia; [2]King Abdulaziz City for S&T, Saudi Arabia

the textile industry is the second largest industry in manufacturing. The textile industry pays a huge contribution to the fashion and clothing industry by acting as its base, however with the high and on-going demand in clothing and garments “Fast Fashion”, and overconsumption are increasing as well moreover leading to a substantial and sequential rise in environmental issues and concerns such as pollution. The textile and fashion industry are the highest polluting industries, playing a critical role in water consumption and pollution, solid waste pollution as well as resource depletion. Due to its greatly negative impacts on our environment in addition to our environment’s current deteriorating state, global organizations such as the European Union (EU) as well as individual designers and the fashion and textile industry as a whole’s implementing techniques for sustainable fashion in order to sustain a green environment and lifestyle as well as promote a circular economy. Clothing has a significant influence on Saudi Arabia’s tradition and culture. Saudi Arabia’s vision 2030 is following a green initiative and in order to succor a sustainable approach Saudi designers and entrepreneurs are following sustainable fashion and clothing as an eco-friendly alternative. The essence of green chemistry as well as up-cycling redesigning are used in the sustainable clothing industry, in addition to implementing regulations and laws.

5:00 PM MF03.04.22
Non-Isocyanate Polyurethanes from Mixed Cyclic Carbonates: Carbonated Soybean Oil and Cyclic Carbonate Terminated CO_2-Based Poly(ether carbonate) Ga Ram Lee, Eun Jong Lee, You Jin Jeon and Sung Chul Hong; Sejong University, Korea (the Republic of)

Non-isocyanate polyurethane (NIPU) has received significant attention in sustainability research due to its potential to be synthesized without the inclusion of toxic isocyanate raw material and catalysts. In this study, CO_2 is further employed as an eco-friendly resource to afford poly(ether carbonate) polyols, which is then chemically transformed to introduce cyclic carbonate terminal groups (PECC). Separately, soybean oil with cyclic carbonate functional groups (CSBO) is prepared as an example of sustainable raw material from bio-renewable resources. NIPU is then prepared through the ring-opening reaction of multi-amines and the cyclic carbonate functional groups of PECC/CSBO mixtures. Characteristics of the resulting NIPUs including physical and thermal properties are investigated, demonstrating reasonable and tunable tensile properties. This study demonstrates the preparation of industrially important polyurethane materials from eco-friendly renewable resources, well exemplifying our current and increasing endeavors to realize sustainable polymers. This work was supported by Korea Institute of Energy Technology Evaluation and Planning (KETEP) grant funded by the Korea government (MOTIE) (20208401010080, Development of Demonstration for Synthesis of High Value Chemical using Captured CO_2).

5:00 PM MF03.04.23
Towards The Recycling of Plastic Mixed Wastes: Noncatalytic C-H Insertion of Azidoformate-End Functionalized Polystyrene to modify Polypropylene for Compatibilized Polypropylene/polystyrene Blend Ga Ram Lee, Rama Moorthy Appa and Sung Chul Hong; Sejong University, Korea (the Republic of)

Recycling of heterogeneous mixed plastic waste poses a formidable challenge due to the strong incompatibility arising from the different chemical and molecular structures of the constituent polymers. This challenge inspires us to study industrially viable method to enhance compatibility of polymer blends, leading to more homogeneous morphologies and improved mechanical performances. In this study, an azo-type radical initiator with azidoformate (AF) at both ends is firstly prepared, which is then employed for the radical polymerization of styrene to afford AF end-functionalized polystyrene (AFPS). The noncatalytic C-H insertion capability of AF group of AFPS allows the grafting reaction of AFPS onto polypropylene (PP) through industrially acceptable conventional melt process, affording PP-*graft*-PS. The characterization on the resulting PP-*graft*-PS demonstrates enhanced Young’s modulus and more elastic rheological behaviors, along with homogeneous fractured surface morphology and slightly decreased crystallinity. Given the substantial contributions of PP and PS in plastic consumption, the PP-*graft*-PS prepared in this study is expected to work as an *in-situ* compatibilizer in PP/PS, which may alleviate separation issue of mixed plastic wastes.

5:00 PM MF03.04.25
Production of Biodegradable Plastic Composites Using Agricultural Residual Biomass Alexandrea Maerz, Anthony Dichiara, Renata Bura and Rick Gustafson; University of Washington, United States

Global plastic pollution is a major environmental problem, with millions of tons of plastic waste accumulating in the oceans and landfills every year [2]. It becomes crucial to develop biodegradable alternative materials that generate less greenhouse gas emissions, can be broken down by microorganisms in the environment, and improve soil health and fertility when composted. Many currently available bioplastics, such as polylactic acid (PLA), fail to biodegrade effectively unless treated under conditions found in commercial composting facilities – high temperatures and forced air [4]. Other more biodegradable polymers are typically challenged by either high manufacturing costs or poor strength and barrier properties [3]. An innovative approach to imparting biodegradability to a polymer while achieving excellent mechanical characteristics consists of introducing fibrous structures into polymer matrices. This method not only endows the composite with good mechanical properties but also provides a vehicle for water and biodegrading enzymes to slowly penetrate the composite structure leading to complete biodegradation [7]. Recent research revealed that the incorporation of nanocellulose into polymer matrices can improve the composite performance both in terms of strength and biodegradability [1, 5, 7]. The present work reports the production of lignocellulosic nanomaterials from inexpensive wheat straw feedstock and alkaline peroxide pulping followed by mild peracetic acid treatment at pilot scale [6, 7]. The resulting cellulose nanofibrils have been extensively characterized and applied to prepare thin, flexible, and translucent composite films with low poly(vinyl) alcohol contents (i.e. below 40 wt.%) using a simple solvent casting method. The mechanical, optical, and barrier properties of as-prepared composites have been thoroughly examined. This novel bioplastic has the potential to replace petroleum-derived plastics across a broad range of industries such as aquaculture, agriculture, food packaging, and more; promising applications include ground covers, drip lines, gooey duck tubes, aqua nets, and paperboard lining or film covering for food packaging [2, 3, 8]. Furthermore, this work provides an analysis of the techno-economic performance of the system accounting for optimization of operational efficiency, cost-effectiveness, and sustainability factors. The findings contribute valuable insights into resource allocation and investment strategies in sustainable bioproduct systems.

SESSION MF03.05: Computational
Session Chairs: Gustav Nystrom and Eleftheria Roumeli
Wednesday Morning, April 24, 2024
Room 323, Level 3, Summit

9:00 AM MF03.05.01
A Computational Study of Cellulose Regeneration: All-Atom and Coarse-Grained Molecular Dynamics Simulations Igor Zozoulenko[1], Jiu Pang[1], Patrick Heasman[1], Sarbani Ghosh[2] and Aleksandar Mehandzhiyski[1]; [1]Linkoping University, Sweden; [2]Birla Institute of Technology & Science, India

Processing natural cellulose requires its dissolution and regeneration. It is known that the crystallinity of regenerated cellulose does not match that of native cellulose, and the physical and mechanical properties of regenerated cellulose can vary dependent on the technique applied. In this paper, we performed all-atom molecular dynamics (MD) simulations attempting to simulate the regeneration of order in cellulose.[1] Cellulose chains display an affinity to align with one another on the nanosecond scale; single chains quickly form clusters, and clusters then interact to form a larger unit, but the end results still lack that abundance of order. Where aggregation of cellulose chains occurs, there is some resemblance of the 1–10 surfaces found in Cellulose II, with certain indication of 110 surface formation. Concentration and simulation temperature show an increase of aggregation, yet it appears that time is the major factor in reclaiming the order of "crystalline" cellulose.

Available experimental data indicates that regeneration of cellulose is a sluggish process. While we tried to push all-atom MD simulations to their limits in terms of the system size and simulation time, our findings demonstrate that to capture the order of the regenerated crystalline cellulose, evolution of much larger systems should be traced for much longer times. For this purpose, coarse-grained (CG) MD simulations based on Martini 3 force-field were developed and applied to study cellulose regeneration at a scale comparable to the experiments.[2] The X-ray diffraction (XRD) curves were monitored to follow the structural changes of regenerated cellulose and trace formation of cellulose sheets and crystallites. The calculated coarse-grained morphologies of regenerated cellulose were backmapped to atomistic ones. After the backmapping we find that the regenerated coarse-grained cellulose structures calculated for both topology parameters of cellulose I_β and cellulose II/III, are transformed to cellulose II, where the calculated XRD curves exhibit the main peak at approximately 20–21 degrees, corresponding to the (110)/(020) planes of cellulose II. This result is in good quantitative agreement with the available experimental observations.

Our results demonstrate that coarse-grained molecular dynamics simulations represent a powerful tool to provide a microscopic insight into the process of cellulose regeneration, which is not available by conventional experimental means.

9:15 AM MF03.05.02

Machine Learning-Aided Design of Biodegradable Polymers Jessica N. Lalonde[1], Ghanshyam Pilania[2], Babetta L. Marrone[3], Chiho Kim[4,5], Huan Tran[4,5], Rishi Gurnani[4] and Rampi Ramprasad[4,5]; [1]Duke University, United States; [2]GE Global Research, United States; [3]Los Alamos National Laboratory, United States; [4]Matmerize, Inc, United States; [5]Georgia Institute of Technology, United States

In the pursuit of sustainable materials, biodegradable polymers have emerged as promising alternatives to traditional plastics, finding applications across diverse industries. Particularly, the degradation products of traditional plastic are of specific concern, and fully biodegradable and non-toxic plastic alternatives offer promising solutions to this ongoing challenge. However, a rational design approach to engineer biopolymers for degradation after their intended use still remains elusive. This is largely due to our inability to understand and model performance metrics (such as weight loss over time) capturing degradation behavior of these materials as a function of chemical, geometric and environmental factors.
As an exciting development in this direction, we have established predictive machine learning models which utilize physics-informed deep neural networks (NN) on previously established, manually curated experimental data that characterizes the weight loss behavior of fully biodegradable polyester copolymer samples in both water and soil natural environments. The models were applied in a series of experiments to predict the mass loss of approximately 10,000 structural and compositional variations of the 230 homo- and copolymers originally included in the original training set. The predicted mass loss for these candidate biodegradable polymers over a period of 365 days allowed us to identify novel copolymers with the potential to replace existing chemistries while matching property values to the desired performance metric ranges. This talk will discuss our findings and future directions, including the integration of critical properties, such as, thermal and mechanical characteristics, into the screening and design workflow and thereby bringing us one step closer to realizing the grand vision of a sustainable circular plastic economy.

9:30 AM *MF03.05.03
Experimental-Computational Design of Protein-Based Materials Diego López Barreiro; University College London, United Kingdom

Nature leverages the self-assembly propensity of structural proteins like elastin, resilin, collagen, or silk to generate sustainable functional materials with remarkable performance and that span a wide range of mechanical and structural properties: from soft to stiff, from porous to densely packed, from static to dynamic... This is inspiring scientists and engineers to use structural proteins as a sustainable replacement for fossil-based polymers in the manufacture of synthetic functional materials with applications in food, healthcare, adhesives, energy, textiles, or membrane technology, to name a few.
Structural proteins are normally harvested from animal sources (e.g., silkworm cocoons, animal tissue), but these suffer from batch-to-batch variability, presence of contaminants, and cultural or religious concerns that limit their commercial use. Fortunately, developments in engineering biology allow us to overcome these issues and biofabricate non-animal-derived recombinant structural proteins. Furthermore, by carefully engineering their amino acid sequence, we can design entirely new structural proteins with properties inspired by natural structural proteins, but that do not exist in Nature, and use them to develop materials with e.g., adjustable mechanical properties, programmed functionalities, or the ability to adapt or respond to the environment.
However, a complete framework that connects amino acid sequence to material properties is unavailable. Thus, *de novo* recombinant structural proteins are normally developed through low-throughput trial-and-error experimentation, which impedes rapid prototyping. In this talk, we will showcase our work on the combination of computational and experimental tools to accelerate the exploration of the design space of structural proteins. Specifically, we will present examples of how this approach has aided us in the design of new protein-based materials including flexible conductive films, biomineralizing films, or injectable stimuli-responsive hydrogels.

Room 323, Level 3, Summit

10:30 AM MF03.06.01
Pathways to Biorenewable Circularity in Plastics Brett A. Helms; Lawrence Berkeley National Lab, United States

Here, I will discuss how synthetic biology provides an inexhaustible toolbox for the creation of monomers useful for the creation of next-generation circular plastics collectively known as polydiketoenamines. I will highlight how materials properties are dictated not only by the diverse functionlization afforded such strategies, but also the importance of chirality, which is inherent to biology, but lacking or otherwise challenging to scale using conventional chemical approaches. From a materials perspective, not only is it interesting to understand factors governing materials properties stemming from biofunctionalization, but these choices also deeply impact how the materials undergo deconstruction to monomers. I will discuss a variety of phenomena unique to polymers compared to small molecules that guide our understanding of polymer reactivity, particularly as they manifest at different length scales and time scales. I will showcase operando X-ray and NMR capabilities that permit mechanistic studies unperpinning deconstruction, which feedback into the materials design and biomolecular target selection.

10:45 AM *MF03.06.02
Engineering Microbes to Produce High-Strength Protein-Based Materials Fuzhong Zhang; Washington University in St. Louis, United States

Microbially-synthesized protein-based materials (PBMs) present an appealing alternative to petroleum-derived synthetic polymers. However, their widespread adoption has been hindered by challenges such as the repetitive sequences, high molecular weight of proteins, and skewed amino acid compositions, particularly for high-strength PBMs. In this presentation, I will introduce our recent advances in synthetic biology aimed at overcoming these hurdles. We have developed a range of synthetic biology tools that enable the stable expression of high molecular weight and highly repetitive proteins within engineered microbes. These tools have been instrumental in the microbial production of recombinant spider silk of similar mechanical properties. We further engineered amyloid-silk proteins which have a remarkable propensity to form nano β-crystals, resulting in fibers that possess exceptional mechanical properties. Additionally, we have devised a universal strategy to augment material strength and toughness by incorporating intrinsically disordered mussel foot protein fragments at the termini of these proteins. This approach promotes end-to-end protein-protein interactions, leading to the creation of protein fibers that surpass natural spider silk and petroleum-derived nylon fibers in both strength and toughness. Moreover, these fibers can be produced at a yield of 8 g/L.

11:15 AM MF03.06.03
Macromolecular Composites as Physical Analogues for Biomatter Plastics Ian R. Campbell[1], Ziyue Dong[2], Paul Grandgeorge[1] and Ella Lee[1]; [1]The

University of Washington, United States; [2]University of Colorado Boulder, United States

Innovative and sustainable technologies intended to prevent the harmful effects of sourcing, manufacturing, and disposing of synthetic plastics are rarely both biobased and biodegradable. Even many biodegradable plastics will not fully decompose in natural settings and despite the best recycling efforts, a significant portion of the plastic produced annually escapes into the biosphere. In an effort to create a fully biobased and backyard-compostable plastic alternative, we recently reported a bioplastic produced directly from spirulina biomass, without the need for chemical extraction or other preprocessing. The application of heated compression molding was found to transform the spirulina biomass into a rigid, compostable biomatter plastic with mechanical performance comparable to polylactic acid and polystyrene. In this work, we investigate the mechanism governing the self-bonding of spirulina during thermomechanical processing by creating a representative analogue for biomatter plastics. Varying ratios of pure carbohydrates, lipids, and proteins are physically combined and subjected to heated compression molding to form materials similar to algal bioplastics. The effect of the varying macromolecular composition, and the contribution of each class of macromolecule to the morphology of the produced bioplastics and their mechanical properties are evaluated through scanning electron microscopy (SEM) and flexural testing. Specifically, the varying ratio of protein to carbohydrates is utilized to compare the mechanical performance of biomatter analogues to several species of algae. The bonding mechanism of the biomatter analogues is first assessed qualitatively during sequential reprocessing to isolate contributions of dynamic bonding. Fourier transform infrared spectroscopy (FTIR) and x-ray photoelectron spectroscopy (XPS) are then utilized to quantitatively measure both secondary and primary bonding interactions between different macromolecular components of the analogue composites. Experimental measurements of bonding and cohesion are complemented by molecular dynamic (MD) simulations of multi-component macromolecular systems and a mechanism is proposed for self-bonding in biomatter plastics.

11:30 AM MF03.06.04
Protein-Based Shape Memory Polymer Metamaterials with Strain-Induced Remodeling Lucas Meza[1], Naroa Sadaba[1], Eva Sanchez-Rexach[2], Curt Waltmann[3], Shayna Hilburg[1], Lilo D. Pozzo[1], Monica Olvera de la Cruz[3], Haritz Sardon[4] and Alshakim Nelson[1]; [1]University of Washington, United States; [2]General Atomics, United States; [3]Northwestern University, United States; [4]POLYMAT, Spain

Mechanical deformation of a polymer network is transferred from the macroscale to nanoscale to cause molecular-level motions and bond scission that ultimately lead to material failure. Understanding how to mitigate polymer disentanglement and bond scission is a significant challenge, especially in the development of active and shape-morphing materials. We report the additive manufacturing of hierarchically designed mechanical metamaterial lattices made with a protein-based polymer network that undergoes a unique strain learning behavior that combines mechanical remodeling with shape memory. At the molecular level, protein mechanophores unfold in the presence of a mechanical force to release its “stored length”, thereby stiffening in the direction of applied load after undergoing a healing cycle. Incomplete refolding of proteins during shape recovery affords a network with enhanced stiffness. At the macroscale, architected lattices distribute stress across a 3D printed structure to mitigate damage and enable complete shape recovery, and the efficiency of this process varies with the lattice architecture. The combined hierarchical responses cause a mechano-activated remodeling of folded proteins in the network to afford up to a 2 to 3-fold improvement in the mechanical properties. These bio-inspired materials offer a unique opportunity to develop novel materials that can autonomously remodel under an arbitrary applied load.

11:45 AM MF03.06.05
Cannabinoid-Based Polymers Materials Ecosystem Michael Sotzing[1], John M. Toribio[2], Gregory Sotzing[2] and Alex Chortos[1]; [1]Purdue University, United States; [2]University of Connecticut, United States

To mitigate the negative health and environmental impacts of synthetic petroleum-based plastics, new methods to use natural resources must be developed. Materials such as poly(lactic acid) have established that cost-competitive polymers with favorable properties can be leveraged to replace plastics in some applications, notably additive manufacturing. Bio-derived polymers with a greater range of properties may help to increase the market penetration of products based on natural resources. This work explores printed electronics created with a new class of biopolymers created from polymerized hemp oil. Some benefits of cultivating hemp include an increased capacity as a carbon sink, improved water consumption, and scrubbing of heavy metals from soil (phytoremediation). The resurgence of hemp with the passing of the Farm Bill in 2018 has led to larger supplies of hemp oils (cannabinoids) such as cannabidiol (CBD).
Poly(cannabinoid)s are prepared through step growth polymerization of bifunctional carboxylic acids with hemp-derived cannabinoids containing two hydroxyl groups. With over 120 naturally occurring cannabinoids and hundreds of dicarboxylic acids, a large range of properties can be achieved. This is demonstrated notably with 3 plastics that possess different desirable properties, such as high glass transition temperature >100 °C, hydrophobicity with water contact angles >120°, and a block-copolymer with high adhesion to a variety of surfaces including skin.
Practical applications of these materials are demonstrated through the fabrication of additively manufactured biomedical devices. Electrocardiogram electrodes illustrate the advantages of these materials when applied in aqueous environments, not possible for long periods with conventional silver/silver chloride electrodes. Conformal on-skin heating elements that show self-limiting at 35 °C reducing the potential for thermal runaway present with conventional heaters. Devices were fabricated with multi-material additive manufacturing whereby conductive metal/polymer composites and adhesives were printed.
PolyCBD materials have been demonstrated to be susceptible to base-catalyzed hydrolysis leading to depolymerization of polyCBD into component monomers and varying molecular weight oligomers. Different base solutions such as sodium hydroxide, ammonium hydroxide and phosphene buffered saline impact the duration of the depolymerization and the number of oligomers left in solution. Identifying the right media that does not denature CBD or result in incomplete depolymerization will enable repolymerization of monomers.

SESSION MF03.07: Nanocellulose Fundamentals III

Room 323, Level 3, Summit

1:30 PM *MF03.07.01
Structuring Nanocellulose into Heat-Insulating Mesoporous Structures with Light Permeability Tsuguyuki Saito; The University of Tokyo, Japan

Decreasing the heat loss in buildings and vehicles is important for the realization of the low-carbon society. A transparent insulator applicable to windows is effective in reducing such a heat loss. Conventional candidates for transparent insulators are silica aerogels, with optical transparency and high thermal insulation. However, silica aerogels prepared through an unscalable supercritical-drying process are mechanically brittle. Herein, we report a structurally aerogel-like “cryogel” comprising sustainable wood-derived, mechanically strong cellulose nanofibers (CNFs) through a scalable freeze-drying process.

Cryogels refer to freeze-dried porous structures. The optical transparency of the cryogels was achieved by suppressing the agglomeration of CNF during freezing. The CNF cryogels exhibited good insulating properties and circularity. Such a heat-insulating yet light-permeable cryogel of wood resource with scalability and circularity is expected to reduce CO2 emissions in buildings and vehicles when used as the interspace material in double-glazed windows compared to normal heat energy-losing windows..

2:00 PM *MF03.07.02
Green Products for The Red Planet: Sustainable Materials for Human Exploration Lynn J. Rothschild; NASA, United States

Synthetic biology – creating new capabilities with life – promises to create a greener future for planet Earth, from fields as diverse as pharmaceuticals to manufacturing, agriculture and nanotechnology. Progress can be stymied by such considerations as economics, politics, legal and philosophical issues surrounding GMOs. Often solutions to these problems already exist, so it is difficult for a new, superior method to displace the old. As we move humans beyond Earth, to long duration stays in the International Space Station, and then onward to the Moon and Mars, the challenges of supporting human life will need radical new solutions. For example, while life on Earth uses an enzymatic machinery which evolved over 3.5 billion years ago, synthetic biology promises to be able to engineer the systems to adapt to current natural or industrial environments. A focus on solutions off planet require a focus on a circular economy. While there are new constraints, such as worrying about the mass of a solution, constraints offer opportunities for game-changing solutions that will then allow revolutions back on our home planet. Example projects include biomining and fungal-based habitats off planet.

2:30 PM BREAK

3:30 PM *MF03.08.01
3D Printing Cell-Laden Living Materials Gilberto Siqueira, Rani Boons, Tanja Zimmermann, Gustav Nystrom and André Studart; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Microbes are extensively used in industry to convert carbon sources into valuable end-product chemicals and have found applications in the food industry, waste treatment, water quality assessment and bioremediation. Among them, species of two microalgal groups, diatoms and dinoflagellates, that exhibit appealing features for sensing devices were selected and encapsulated in hydrogels with different degrees of complexity to create 3D printed biohybrid materials with sensing behavior. We explore the encapsulation of such microorganisms within multifunctional hydrogels that supports the growth and proliferation of those non-mammalian cells by designing a set of ink and methods (direct ink writing-DIW or digital light processing-DLP) that allow to shape them in complex functional 3D structures. To accomplish our goals, we have first investigated the effect of the ink composition on the rheological behavior, printability, mechanical properties and cell growth in the hydrogels. The hydrogel inks were mainly composed of a suspension of microalgae (diatoms or dinoflagellates), polymers, water and nutrients. Next, we explored different printing methods to develop sensors to access water quality- and mechano-sensing hydrogels. The cell survival and activity upon encapsulation was confirmed and correlated to the mechanical properties of the hydrogels. We concluded that the proposed methods are promising for the design and fabrication of living materials with sensing properties such as water quality and force impact sensors.

4:00 PM *MF03.08.02
You Are What You Eat: How Conditions of Growth Influence The Properties of Myco-Materials Alicia Vivas Hernando, Wenjing Sun and Tiffany Abitbol; EPFL, Switzerland

Fungi are remarkably adaptive organisms, modifying their behaviors and characteristics in response to their environment, including nutrient availability. Over the past 15 years, fungi have emerged as a promising source of sustainable materials, finding applications in areas such as packaging and building materials. However, there are still knowledge gaps in the field, compromising our ability to consistently produce reliable materials. In this presentation, we delve into the potential of manipulating growth environment to tune material properties, drawing both from the wider literature and our own research. Our aim is to contextualize the current state of the art and to ask the question: How can materials science leverage biological adaptation to develop functional mycelium-based materials?

4:30 PM MF03.08.03
Advanced Manufacturing with Engineered Living Materials for Sustainable Polymer Composites Weinan Xu; University of Akron, United States

Engineered living materials (ELMs) are an emerging class of materials that combine living biological entities especially bacteria with functional soft materials. The incorporation of living bacteria provides the materials with biosensing, self-regenerative, and molecular computing capabilities. Recently, ELMs have also been used for direct ink writing-based 3D printing, which enables the fabrication of dynamic and active 3D structures for various applications. In this talk, I will discuss our recent progress on 3D printing with functional bacteria embedded in a supporting matrix or 3D printed bioreactors for advanced biofabrication. The bacteria can be genetically engineered to have specific functions, such as generating bacterial cellulose or reacting to external stimuli. We have demonstrated that 3D cellulose structures can be generated by in situ biosynthesis in the 3D printed templates followed by controlled shape transformation, which provides an efficient and versatile approach for fabricating 3D customizable bio-scaffolds for tissue engineering. More importantly, programmable microbial biosynthesis with two or multiple types of bacteria can be integrated with 3D printing, so that programmable biosynthesis of organic-inorganic biocomposites can be achieved in 3D printed bioreactors. We have shown that 3D hierarchical biocomposites with bionanofiber matrix and inorganic mineral nanoparticles with well-defined shape and internal structure can be produced, which provides a new platform for bone mimetic materials and tissue engineering.

Enhancing Food Security with 3D Printing Technology Woo Soo Kim; Simon Fraser University, Canada

The global challenge of food security is intensifying due to various factors such as population growth, insufficient agricultural investment, and inefficient distribution systems. As a result, food insecurity is often a complex interplay of elements including diseases, processing methods, and distribution challenges. These issues are particularly acute in vulnerable regions where traditional food safety testing methods are often impractical for detecting foodborne diseases. In response to these challenges, 3D printing technologies and 3D printed sensors emerge as a transformative solution. They provide a means to develop portable, precise, and cost-effective sensors that bridge the existing gaps in food security. This presentation explores the pivotal role of 3D printed sensors, specially such as disposable 3D printed sensors in addressing food security concerns, encompassing detection, processing, and quality monitoring in the food supply chain, ultimately ensuring reliable access to nutritious and affordable food. Furthermore, we discuss the applications of 3D printing technology in the agriculture sector, with a focus on the promising future of plant wearables and plant health detection. This innovative approach not only advances food security but also holds the potential to revolutionize agricultural practices, contributing to a more sustainable and secure global food supply.

Developing a Technology Platform based on The Spinning of Bio-Based Nanostructured Fiber-Based Materials Daniel Soderberg[1,2]; [1]KTH Royal Institute of Technology, Sweden; [2]Wallenberg Wood Science Center, Sweden

Transitioning from promising scientific findings to practical engineering technologies often presents significant challenges. One such advancement lies in spinning high-performance reinforcement fibers from nanocellulose. We have been working broadly, spanning several projects, around a spinning technology built on the concept of flow-focusing spinning, which has shown some potential.[1-3] These previously published scientific results represent a substantial leap beyond current state-of-the-art techniques, particularly in achieving continuous and controllable conditions for nano assembly. This includes several routes for functionalization beyond the stress-strain curve.
The challenge has been pursued by addressing some key challenges related to conventional filament (fiber) spinning, such as e.g., winding, online drying, and multi-filament spinning. In addition, the need for consistent processing and material properties has been addressed, a specific challenge when working with nanocomponents.
An overview of recent results will be presented, considering the performance of continuously spun fibers and attempts to fabricate composite materials based on fabrics constructed from these fibers. One example is that the results show how the parameter space for processing and, specifically, drying strongly impacts the final material's properties. Another indicates that fibers spun using hydrodynamic flow-focusing show a surprisingly high thermal conductivity.[4] Following this, the piezoelectric properties have been studied, as well as functionalization using other nanoparticles and polymers, Finally, the possibility to fabricate significant amounts has also made it possible to evaluate the compatibility with various polymer resins and the performance as a composite, where the apparent result is that the composites become more or less transparent.
Apart from the investigated property space, the vision is to develop further a technology platform that can provide society with innovative material solutions that are biobased, lightweight, functional, sustainable, and resilient.

9:00 AM MF03.09.02
Unravelling The Governing Factors for Polysaccharide and Biopolyester Processing Cecile Chazot[1], Simona G. Fine[1], Eleanor C. Grosvenor[1], Sara Branovsky[1] and Gabrielle Wood[1,2]; [1]Northwestern University, United States; [2]Howard University, United States

The production, consumption, and disposal of polymers for textile and packaging applications pose several problems for the environment, including carbon emissions and the persistence of microscale and nanoscale debris in the ocean. In recent years, biopolyesters (e.g. Polybutylene adipate terephthalate or polybutylene succinate) have emerged as environmentally friendly alternatives to petroleum-derived polymers, due to their biodegradability, easy thermal processing and tailorable mechanical and barrier properties. Other biopolymer alternatives, such as polysaccharides (e.g. chitosan and cellulose ethers), are naturally abundant and have the potential to self-assemble in cholesteric liquid crystals with a tailored photonic bandgap, opening new opportunities for the development of functional optical materials. However, the widespread adoption of all these biopolymeric alternatives remains limited due to challenges in their large-scale synthesis and manufacturing. In this talk, we will discuss scalable processing of these polymers through fast and open-air reaction schemes, and their integration in the development of packaging and textiles with advanced functionality. We will discuss how chemical factors such as molecular weight and repeat-unit chemistry affect chain mobility and solution-based and thermal processing of biopolyesters and polysaccharides. We will also discuss how interchain interaction can be leveraged to result in long-range order such as liquid crystal self-assembly, therefore enabling new advanced functionality such as colorimetric sensing and circular dichroism. These relationships are expected to assist in the large-scale deployment of biopolymer-based functional materials with tailored structure and properties.

9:15 AM *MF03.09.03
Fundamental Issues Governing The Properties and Functions of Nanocellulose Networks Eero Kontturi; Aalto University, Finland

Nanocellulose networks have been extensively surveyed as so-called nanopapers for packaging applications on one hand and membranes for purification purposes on the other. Despite the two distinct ways of end use, the fundamentals of the network structure and its function remain the same. This presentation aims to introduce a fundamental discussion from both sides by consolidating both aspects. For example, hemicellulose is seen as a binder molecule when assessing the tensile properties of dry nanopapers but its water-accumulating capability in wet state is rarely discussed in membrane technology or even with hydrogels. Similarly, porosity is among the central properties of membranes but it is not usually considered with nanopapers, notwithstanding its pivotal role in strength development of any cellular material. The aim here is to address similar parameters from different application

perspectives.

10:15 AM *MF03.09.04
Materials and Methods for Sustainable Soft Devices Martin Kaltenbrunner; Johannes Kepler University, Austria

Soft devices provide unique opportunities in our quest for a more sustainable future. Among the key issues to overcome are the search for high performance green materials, end-of-lifetime considerations in complex (soft) systems, and their energy efficiency. This talk aims at suggesting solutions for some of these grand challenges. We introduce bioderived materials and fabrication methods for soft systems that biodegrade, yet are of high resilience. Based on highly stretchable biogels and degradable elastomers, our forms of soft electronics and robots are designed for prolonged operation in ambient conditions without fatigue, but fully degrade after use through biological triggers. Electronic skins provide sensory feedback, while stretchable and biodegradable batteries enable autonomous operation. 3D printing of biodegradable hydrogels enables omnidirectional soft robots with multifaceted optical sensing abilities. Going beyond, we introduce a systematically-determined compatible materials systems for the creation of fully biodegradable, high-performance electrohydraulic soft actuators. These embodiments reliably operate up to high electric fields, show performance comparable to non-biodegradable counterparts, and survive over 100,000 actuation cycles. Pushing the boundaries of sustainable electronics, we demonstrate a concept for growth and processing of fungal mycelium skins as biodegradable substrate material. Mycelium-based batteries with capacities as high as ~3.8 mAh cm^{-2} allow to power autonomous sensing devices including a Bluetooth module and humidity and proximity sensors, all integrated onto mycelium flexible circuit boards.

10:45 AM *MF03.09.05
Ever Ancient Ever New - Cellulose as The Material Platform for Sustainable Flexible Devices Tian Li; Purdue University, United States

Cellulose, the main component in cotton, features a naturally occurred hierarchical structure down to the ångström scale, providing a scaffold with multiscale interspace and abundant functional groups. In this talk, I will talk about our work using cellulose as the material platform for flexible ionic and electronic devices. We will focus on the design principles as well as the application scenarios in energy generation, conversion and sensing.

11:15 AM MF03.09.06
Quasi-Two-Dimensional Marangoni Convection and Specific Polymer Deposition in Meniscus Splitting Phenomenon Leijie Wu and Kosuke Okeyoshi; Japan Advanced Institute of Science and Technology, Japan

Spontaneous pattern formation in polymer dissipative systems such as Turing patterns is highly valued in material design. However, the process of fixing patterns to the substrate through evaporation strategy involves a complex pathway from equilibrium to disequilibrium and back to equilibrium as the dispersed particles undergo deposition from saturation to supersaturation. Understanding the non-equilibrium process is essential for the advancement of materials innovation and applications. However, because of high viscosity, polymer dispersions have often received limited attention, presenting processing challenges. Inspired by the viscous fingering phenomenon, we use aqueous polysaccharide dispersions to induce stable spatial patterns within Hele-Shaw cells through controlled water evaporation. These spatial patterns effectively formed deposition patterns in the fluids, dividing the space from one into multiple with anisotropic polysaccharides membrane, splitting the meniscus. [1,2] In this study, we meticulously tracked the evolving behavior of internal fluids of aqueous polysaccharide dispersion during the evaporation process using the Particle Image Velocimetry method. As the concentration of the dispersion increased, we observed that periodic convection gradually emerged within the cell. At higher concentrations of the dispersions, Brownian motion gradually loses its dominance, and evaporation-induced Marangoni flow under the influence of viscous forces triggers spatial periodic Marangoni convection, taking over as the dominant behavior. This quasi-two-dimensional convection encourages particles to aggregate at specific areas in the dispersion, which supplements the fluctuating flocculation caused by interfacial evaporation. Differing from the Rayleigh–Bénard convection, by the effect of capillary force, this spatial quasi-two-dimensional convection can be immobilized into polymer membranes with self-assembled polysaccharide structure through evaporating. This aggregation effect of convection is not limited to this kind of biopolymer but also can be extended to various functional polymer particles, complementing what has been achieved in assembling particles from fluids using convection fields.

Cellulose and Nanocomposite 3D Printing in Optimized Dispersions for High-Performance Properties Rigoberto C. Advincula; The University of Tennessee/Oak Ridge National Laboratory, United States

The interest in renewable, natural, and bio-based polymers has a high potential, especially for commodity plastic replacement. From miscanthus grass, abaca fibers, chitin, and coconut coir, the key is determining their ability to form synergistic blends and composites. This means investigating their miscibility and dispersion properties, including a fundamental understanding of their secondary and tertiary structures(alpha-crystallinity and beta-sheets). The nanostructuring involves utilizing their sometimes high-aspect ratio or non-covalent interactions to determine the need for compatibilizations. Then, they must determine their minimum percolation threshold for the desired property at a minimum cost. These "optimization" protocols often unlock their true techno-economic value rather than simply using them to "replace the plastic". In this talk, we will describe strategies and projects where we have focused on preparing nanocomposites for high value in applications with coastings and 3D printing. Utilizing nanocellulose or cellulose nanocrystals, it is possible to unlock those advantages by emphasizing nanostructuring and derivatization. This is evident in their use with various dispersions in photopolymerizable resins, hydrogel metal precursors, and polyelectrolyte complexes. AI/ML strategies are emphasized as a method of improving optimization for additive manufacturing.

11:45 AM MF03.09.08
Quantifying The Softness of Wool via Structure-Property Relationships Serafina R. France Tribe and Cecile Chazot; Northwestern University, United States

State-of-the-art evaluation of textile touch sensation (e..g., scratchiness) follows broadly-adopted qualitative and time-intensive procedures that rely on consumer-based studies. This is due to the lack of understanding of how material properties and fiber morphology affect the surface interaction of the fabric with human skin. Wool, in particular, is an animal-derived fiber that can range from extremely soft to uncomfortably scratchy, due to the broad range of fiber properties depending on the source. Here, the morphological, compositional, and mechanical properties of a variety of natural wool fibers of reported consumer-based haptic feel are investigated. Using scanning electron microscopy (SEM) and a custom image analysis framework, we assessed the evolution of fiber morphology (e.g., diameter and surface roughness) across a large variety of animal sources. We also analyzed how fiber composition

varies between sheep breeds through Fourier transform infrared (FTIR) spectroscopy, thermogravimetric analysis (TGA), and x-ray diffraction (XRD). Last, we characterized the mechanical properties of the fibers such as tensile strength and viscoelastic moduli through dynamic mechanical analysis (DMA) and uniaxial tensile testing. This comprehensive study of wool fibers is essential in establishing structure-property relationships and quantifying how composition, microstructure, and mechanical properties impact fiber interaction with human skin and haptic feel. This will in turn enable the development of standardized human-subject-free test methods for fiber scratchiness and will guide the design of new fibers and textiles for the apparel and medical industries.

SESSION MF03.10: Upcycling, Recycling, Depolymerization I
Session Chairs: Megan Robertson and Eleftheria Roumeli

Room 323, Level 3, Summit

1:30 PM *MF03.10.01
Leveraging Stereochemistry to Advance The Design and Degradation of Sustainable Polymeric Materials Andrew P. Dove; University of Birmingham, United Kingdom

Nature has evolved the ability to create large and complex molecules in which the precise control over both the sequence and spatial arrangement of the atoms is critical to their performance. The 3-dimensional control over the arrangement of bonds is as important to the function and behaviour of molecules as any other factor and is critical to the structure-function relationships that occur within biological systems. Specifically, the advantageous mechanical properties of most commodity plastics are intimately connected to their low glass transition temperature and crystallinity, the latter of which can be modulated by stereochemistry of the polymer. For polypropylene (PP), stereochemical control of the pendant methyl group on the polymer backbone (isotactic, or alternating bond orientation) contributes to its useful properties. While this concept has similarly been leveraged to improve the thermomechanical properties (i.e. increase the melting temperature or tensile modulus) of bioplastic polyesters (e.g. polylactic acid (PLA)) these materials are incessantly plagued by brittleness, lacking the flexibility and toughness of petrol plastics. By controlling the stereochemistry of polymer backbones, much more significant changes to polymer mechanics can be achieved. The most well known example is stereochemical differences between natural rubber (poly(cis-isoprene)) and Gutta percha (poly(trans-isoprene)), which lead to a complete change in physical properties from an elastomeric to plastic material. Despite this being well known, the state of the are in synthesis has not made it possible to readily exploit this effect more widely. To this end, our work has focused on developing polymerization methods that can result in materials in which the stereochemistry can be used to leverage a wide range of materials properties from thermomechanical to degradation, in both linear polymers and networks, with a high level of tuneability.

2:00 PM *MF03.10.02
Degradable and Thermally Stable Spiro Polycycloacetals from Renewable Resources Megan Robertson, Elvis Enebeli, Justin Smith and Minjie Shen; University of Houston, United States

A series of partially bio-based spiro polycycloacetals were synthesized using bio-renewable feedstocks, such as vanillin and its derivative syringaldehyde, along with pentaerythritol and commercially available co-monomers including 4,4′-difluorobenzophenone and bis(4-fluorophenyl) sulfone. These spiro polycycloacetals displayed high thermal stabilities (degradation temperatures in the range of 343 – 370 °C, as quantified by 5% mass loss) and glass transition temperatures (in the range of 179 – 243 °C). Importantly, these polymers were effectively degraded to small molecules under acid-catalyzed hydrolytic conditions in less than 7 h. The kinetics of hydrolytic degradation was quantified through *in situ* NMR analyses.

2:30 PM MF03.10.03
Catalyst Development for Polymerization and CO_2 Capture, Storage and Upcycling to High Value Materials James Hedrick[1,2], Nathan Park[1], Luis Campos[2] and Dino Wu[2]; [1]IBM Research, United States; [2]Columbia University, United States

Current strategies to reduce CO2 emissions are insufficient—both point-source and direct-air-capture (DAC) must be considered to mitigate excessive atmospheric CO2 concentrations. Given the urgency of climate change issues and the immense challenges of developing viable methodologies for CO2 conversion, we posit that understanding structure–property relationships of organic/inorganic molecular reactivity across multiple length scales will lead to the evolution of remarkably efficient transformations of CO2 and revolutionize chemistries to control the fate of this greenhouse gas. Thus, we sought to investigate families of superbases (SBs) that serve as CO_2 mitigating agents. This talk will focus on describing the wide-scope reactivity of a family of modular SBs that can be exploited in a variety of chemical transformations of CO_2 from dilute and pure gaseous sources as well as polymerizations. We found that the SBs can form zwitterionic complexes to activate CO_2, which can be readily mineralized into metal carbonates. Importantly, the highly reactive nature of SBs renders them widely useful to upcycle CO_2 into high value products.

2:45 PM MF03.10.04
Sustainable Polymer Networks that can be derived from Biobased or Waste Materials and Offer Reprocessabilty with Full Crosslink Density and Property Recovery John M. Torkelson; Northwestern University, United States

Covalent adaptable networks (CANs), sometimes called vitrimers, offer promise for overcoming long-standing recycling and polymer circularity issues associated with conventional, permanently crosslinked thermosets that cannot be recycled for high-value use. It is also vital to demonstrate that properties of reprocessable networks can be optimized to meet the demands for high-performance materials. For example, it is important that the dynamic covalent bonds in CANS are robust at use conditions, including elevated temperatures where creep needs to be minimal, while ensuring reprocessabiltiy at yet higher temperatures that are well below conditions where degradation occurs. We have designed several classes of CANs that show that such performance demands can be met while contributing to polymer circularity and sustainability. Additionally, in many cases, such CANs can be derived from biobased or waste starting materials. We wiill provide examples ranging from non-isocyanate polyurethane networks, including both polyhydroxyurethane networks and non-isocyanate polythiourethane networks, that exhibit non-catalyzed dynamic chemistry of a dual associative and dissociative nature and can be made from a variety of biobased sources. We will also provide examples in which some polyolefins, including thermoplastic polyethylene, can be upcycled into CANs via simple one-step reactive processing with a radical initiator and an appropriate covalent crosslinker with dynamic chemistry that is strictly dissociative in nature, e.g, a dialkylamino disulfide or other disulfide-based crosslinker. For example, waste thermoplastic polyethylene can be can be transformed into crosslinked polyethylene exhibiting robust properties and reprocessabiltiy. Additionally, because of the dissociative nature of the dynamic chemistry, these CANs offer the possibility of being processed by conventional, continous melt-processing methods such as melt extrusion.

3:00 PM BREAK

3:30 PM MF03.10.05
Depolymerizable and Recyclable Luminescent Polymers Wei Liu[1,2], Yukun Wu[1,3], Jianguo Mei[3], Sihong Wang[2,1] and Jie Xu[1,2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States; [3]Purdue University, United States

Solution processable luminescent polymers are of great interest in a number of photonic technologies, including electroluminescence, bioimaging, medical diagnosis, bio-stimulation, and security signage. Ensuring the integration of depolymerizability and recyclability factors into the initial stages of the material design is of pivotal for promoting sustainability and mitigating environmental impacts throughout the entire product lifecycle. In this work, we unprecedently propose a general design concept utilizing cleavable moiety, herein tert-butyl ester, to create programmable depolymerizable and potentially recyclable thermally activated delayed fluorescence (TADF) polymers, without compromising their highly efficient luminescent properties. The programmable depolymerizability and remarkable luminescent properties of these polymers exemplify an innovative benchmark for endowing end-life environmental friendliness and circular economy to current photonic technologies.

3:45 PM MF03.10.06
Valorising Waste Plastics into Functional Materials and Industrially-Relevant Chemicals Jason Y. Lim and Derrick Fam; Institute of Materials Research and Engineering (IMRE), Singapore

Petroleum-based plastics are amongst the most versatile synthetic materials available today. They are produced in excess of 300 million tons a year and are ubiquitous in modern society due to their favourable combination of light weight, low cost and usefulness for a diverse range of applications. However, their existing life cycles are extremely linear, with most post-use plastics disposed unsustainably in landfills, incinerated or irresponsibly discarded in the environment, representing a huge loss of inherent material value. In recent years, these existing petroleum-based plastics are receiving increased attention as promising feedstock materials for production of functional polymers and chemicals essential for society. Herein, several examples of how plastics can be post-synthetically transformed into functional polymers will be described. These include upcycling waste poly(ethylene terephthalate) (PET) bottles into polymer electrolytes for energy storage, and synthesis of water-soluble antifungal polymers from polyethylene (PE). In addition, our recent methods for valorisation of waste polystyrene into benzoic acid, a commodity chemical with annual demand exceeding 500,000 tonnes, will be discussed. These proof-of-concept applications highlight the vast untapped potential for using waste plastics as a future source of raw material for producing high-value products for societal needs, ultimately reducing our collective reliance on petroleum sources for a more sustainable materials future.

4:00 PM MF03.10.07
A General Strategy for Upcycling Plastic Commodity Waste to Self-Healable and Fully-Recyclable Materials Haixu Du; University of Southern California, United States

The rapid expansion of the plastic industry has led to significant environmental and ecological harm due to plastic waste. Considering the drawbacks of traditional recycling methods, as most of the plastic wastes are down-cycled into low-value products such as garden furniture or pots, upcycling has garnered increased attention for transforming plastic waste into high-value products. This study presents a general strategy to upcycle commodity plastic waste to a class of fully recyclable and self-healable polymers. Coumarin and its derivatives are light-sensitive and can self-react when triggered by ultraviolet (UV) light at varying wavelengths. Upon exposure to 365 nm UV light, coumarin undergoes dimerization and forms a cyclobutene ring. Conversely, exposure to 254 nm UV light results in the cleavage of the ring and a reversion to its original state. We demonstrate that after embedding the coumarin groups into our polymer matrix, thanks to the photodimerization and photocleavage occurring on the coumarin group C=C bonds under 254 nm and 365 nm UV light, our materials exhibit four distinct properties: light-tunable mechanics, reprocessing ability, light-activated self-healing, and recyclability. We show our strategy is universal to various commodity plastic wastes, such as PS, PP, PET, and PE. This transition from plastic waste to multifunctional materials offers a new strategy for upcycling various plastic wastes into a category of high-value products.

4:15 PM MF03.10.08
Effects of Nickel on The Acceleration of Radiation-Induced Decomposition of Polytetrafluoroethylene (PTFE) Hao Yu, Akira Idesaki, Kimio Yoshimura, Akihiro Hiroki and Yasunari Maekawa; National Institutes for Quantum Science and Technology (QST), Japan

Introduction
High-performance plastics, such as PTFE (Polytetrafluoroethylene) and PEEK (Polyether ether ketone), have extensive applications in various industries. However, recycling and reusing these plastics pose challenges due to their exceptional heat resistance. This study presents our findings on a new method to reduce the decomposition temperature of PTFE. The method involves utilizing the catalytic effects of Nickel (Ni) for the radiation-induced decomposition of PTFE.

Materials and Methods
PTFE (Mw=5,000~20,000) and Ni/NiO/Al_2O_3/SiO_2 powders were purchased and used. The PTFE or the mixture of PTFE with Ni was irradiated with an electron beam under air or argon gas. The maximum dose of the electron beam was 15 MGy, and the dose rate was measured using a cellulose triacetate (CTA) film dosimeter. Mixtures containing different mixing ratios of PTFE and Ni catalyst were prepared to investigate the impact of proportion of catalyst. The mixing time was varied before and after irradiation to observe the sequential effects of irradiation and catalyst.
To perform quantitative analysis, the weight change of samples resulting from radiation was measured, and the solid residue remaining after irradiation was collected. The thermal decomposition of the samples with and without irradiation was measured using thermogravimetric differential thermal analysis (TG-DTA) from room temperature to 1000°C under argon gas. The gaseous products via thermal treatment were collected and introduced into a gas chromatograph-mass spectrometer (GC-MS) for their identification. Furthermore, the chemical groups were measured using Fourier transform infrared spectroscopy (FT-IR), the crystal structure changes were measured using X-ray Powder Diffraction (XRD), and the binding energy changes were measured using X-ray Photoelectron Spectroscopy (XPS), as a function of irradiation and temperature.

Results and Discussions
Both the use of Ni catalyst and irradiation accelerated the reduction of the decomposition temperature of PTFE. Increasing the proportion of Ni catalyst and irradiation dose had a positive effect on decomposition. In addition, the synergistic effect of Ni catalyst and irradiation had the greatest impact on the decomposition. In the presence of oxygen, when mixing was followed by irradiation, the 5% weight loss temperature of the solid residue was 103°C, which is 419°C lower than the pyrolysis temperature of pure PTFE (522°C). Under 15 MGy irradiation, approximately 40% of the PTFE equivalent experienced weight loss below 200°C.
During the irradiation, several changes were observed in the PTFE. In PTFE alone, the presence of carbonyl groups (-CO-) was confirmed, and GC-MS analysis indicated the occurrence of oxidation (C_nF_{2n} to $C_xF_yO_z$). These oxidative substances are responsible for the decomposition of irradiated PTFE at lower temperatures. There were no changes in crystal structure or binding energy (C 1s, F 1s). In the presence of Ni, the presence of -CO- was also

confirmed, but the gaseous products detected in GC-MS decomposed into smaller fragments ($C_xF_yO_z$ to CO_2/COF_3). Additionally, new crystalline structures were confirmed in the irradiation process involving oxygen. The binding energy of C 1s, Ni 2p3/2 remained unchanged, but a new peak of F 1s (F^-, 685 eV) was confirmed, indicating the production of F^- from the original PTFE ($p(CF_2$-$CF_2)$, 689 eV) during irradiation. In summary, the presence of oxygen played a crucial role in the degradation of PTFE, and we propose that Ni acts as a catalyst to accelerate the decomposition of PTFE.

4:30 PM MF03.10.09
Selective Deconstruction and Upcycling of Step-Growth Polymers Nick Galan[1], Jackie Zheng[2,1], Md Arifuzzaman[1], Md Anisur Rahman[1], Jeff Foster[1], Bobby G. Sumpter[1] and Tomonori Saito[1,2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

Engineering plastics based on step-growth polymerization such as poly(ethylene terephthalate) (PET), polyamides (PA), polyurethanes (PU), and polycarbonate (PC) comprise ~30% of the global plastic production. The catalytic deconstruction is one of the major paths for chemical recycling of step-growth polymers. Although there has been progress on their chemical recycling especially PET, most step-growth polymers are not recycled because of the difficulty in depolymerization to pure building blocks especially from mixed state in an energy efficient manner. Here, we have developed a tailored organocatalyst to enable low energy depolymerization pathways for step-growth polymers. Our catalyst allows glycolysis of PET, PA, PU, PC and their multiple mixture at moderate temperature with high yield. A wide range of post-consumer plastics waste, such as bottles, packaging, foam, carpet, etc. is readily deconstructed into monomers with high efficiency. The Life Cycle Assessment indicates that the reproduction of various engineering plastics from the deconstructed monomers will result in a significant reduction in greenhouse gas emissions (82-95% reduction) and energy input (68-94% reduction). Furthermore, we have developed a path to deconstruct those step-growth polymers to selective length of oligomers. We have utilized those deconstructed building blocks to synthesize upcycled polymers, and the upcycled polymers can be further deconstructed to reusable building blocks. Such circular design contributes to establishing new closed-loop circularity of polymers by energy efficient selective deconstruction and upcycling of various engineering plastics.

4:45 PM MF03.10.10
Itaconic-Based Copolyesters as Potential Replacement of Epoxy-Based Coatings in Metallic Food Contact Materials Jose Hector Ramirez Suarez and Julie Goddard; Cornell University, United States

Replacement of Bisphenol A (BPA) based coatings in food contact materials has been of industrial interest for decades due to health concerns and consumer perception. Although polyester- and acrylic-based resins have been introduced into the market as potential replacements, matching the chemical, mechanical, and thermal properties of BPA-based resins remain a challenge. Specifically, their remarkable performance into delaying the onset of corrosion in metal packaging, which protects the safety and quality of foods and beverages during their shelf-life.
Unsaturated polyesters (UP) are versatile, low molecular-weight thermoplastics that can undergo cross-linking reactions to yield thermosets or be functionalized to tailor their properties for potential use as additives in coating formulations. In an effort to improve the sustainability of petroleum-based UP thermosets, the incorporation of biomass-derived molecules in UPs, such as itaconic acid derivatives or short-length chain diols, has been explored. However, the thermal and mechanical properties of the resulting UPs is often negatively affected, limiting their potential use as coatings.
In this research, we present the synthesis of novel itaconic-based unsaturated copolyesters with improved mechanical and thermal properties by copolymerization with monomers of high structural rigidity (i.e. cyclic, substituted, or aromatic). We found that the nature of the catalyst played a role in favoring side reactions during the polycondensation affecting the structure and size of synthesized UPs. Zinc acetate as the melt-polymerization catalyst, yielded UPs with molar mass in the range of 3,000 to 4,000 g/mol and controlled and narrower molar-mass distributions (PDI < 2) in comparison to dibutyltin oxide (PDI > 10). Additionally, the backbone-integrated unsaturated moieties and the hydroxy chain-end groups were better preserved for post-functionalization.
Cross-linking of UPs was performed with branched thiol-functionalized or biomass-derived cyclic vinyl monomers by UV-initiated radical polymerization. Thiol-functionalized monomers yielded thermosets with a glass transition temperature of up to 60 °C, due to the high degree of cross-linking promoted by the introduction of branching to the linear UPs and high efficiency of thiol-ene reactions. Further, only UPs containing branched or cyclic diols were able to form flexible, thin, free-standing films (15 – 20 µm) while formulations containing aliphatic diols yielded brittle films.
Ongoing work involves the characterization of tensile properties and protective performance against corrosion over time in saline and alcoholic standard solutions by electrochemical characterization to assess their potential use as coatings.
Upon completion of this work, an industrially attractive and scalable UP-based thermoset capable of enhanced corrosion protection is developed as alternative to epoxy based resins. This research addresses the need for high-performance and environmentally sustainable materials for the food packaging industry in their quest to maintain the quality and safety of foods and beverages.

SESSION MF03.11: Poster Session II
Session Chairs: Kunal Masania and Eleftheria Roumeli
Thursday Afternoon, April 25, 2024
Flex Hall C, Level 2, Summit

5:00 PM MF03.11.01
Advancements in Biopolymer-Based Materials for Sustainable Packaging Applications Sezen Buell; Estee Lauder Companies, United States

This presentation aims to explore the diverse landscape of biopolymer-based materials and their promising applications in sustainable packaging. Focusing on innovative solutions derived from mycelium, yeast, plant and algae cells, the talk will delve into the unique properties and environmental benefits of each biopolymer.
Mycelium, as a rapidly renewable and biodegradable resource, offers a compelling alternative for packaging applications. Yeast-derived materials showcase versatility and potential for customization, while plant based materials highlight the rich biodiversity that can be harnessed for sustainable packaging. Additionally, protein-based materials present exciting possibilities for creating biocompatible and high-performance packaging solutions.
The presentation will address key aspects of material synthesis, characterization techniques, and the inherent advantages of these biopolymers, including their biodegradability, low environmental impact, and potential for circular economy integration. Moreover, the discussion will extend to the scalability and commercial viability of these materials, exploring their potential to revolutionize the packaging industry and contribute to a more sustainable future.
This comprehensive overview of biopolymer-based materials aims to inspire collaborative efforts and stimulate discussions within the material research

community and industry to further propel the development and implementation of these environmentally friendly alternatives in packaging applications.

5:00 PM MF03.11.02
Scalable Interfacial Polymerization of Thermally Processable Biodegradable Polyesters Sara Branovsky and Cecile Chazot; Northwestern University, United States

Aliphatic-aromatic polyesters (AAPE) have gained traction as sustainable alternatives to polyethylene-based packaging due to their superior biodegradability and comparable mechanical properties. Unfortunately, the large-scale deployment of these polyesters remains limited due to manufacturing challenges such as time- and energy-consuming syntheses and difficulty with thermal processing due to depolymerization. In this work we describe the implementation of a stirred interfacial polymerization (IP) framework to enable the rapid, open-air, high-yield synthesis of AAPE with tailored chemical structures and properties. We explore the effect of reaction conditions – such as aromatic vs aliphatic character and additive concentrations – on polymer yield and thermal properties. We characterize the mechanical properties of AAPE films made via hot pressing and compare the results with state-of-the-art synthetic packaging. This IP synthesis has potential as a scalable manufacturing pathway for biodegradable polyester-based packaging with enhanced thermal processability and mechanical properties.

5:00 PM MF03.11.03
Water-Based Sustainable Ink Composed of Regenerated Silk Fibroin and Upconversion Nanoparticles for Printing/Painting on Arbitrary Surfaces Heeeun Choi[1], Junyong Ahn[1], Taehoon Kim[2], Fiorenzo Omenetto[2] and Junyong Park[1]; [1]Kumoh National Institute of Technology, Korea (the Republic of); [2]Tufts University, United States

Regenerated silk fibroin derived from silkworm cocoons is considered as one of the promising sustainable materials for various fields such as biomedicine, photonics, and electronics. To date, a variety of unconventional material platforms have been demonstrated by engineering regenerated silk fibroin in various ways. In this study, we fabricate a nanocomposite composed of regenerated silk fibroin and upconversion nanoparticles (UCNPs) and demonstrate its printing/painting capabilities as an eco-friendly and biocompatible functional ink. The research is largely divided into three parts:
1) securing robust RGB emission spectra under 980 nm NIR excitation through systematic dopant control of citrate-capped hydrophilic UCNPs, which can be easily dispersed in aqueous silk fibroin solution;
2) selecting an appropriate auxiliary solvent that prevents the aggregation of silk fibroin and UCNPs to improve the room temperature storage and printability of ink;
3) expanding the color palette through mixing RGB inks and demonstrating printing/painting capabilities of the inks on arbitrary surfaces, including 3D curved substrates.
In conclusion, we developed a functional ink that can be designed with a total of six emission colors (RGBCMY), and succeeded in creating colorful patterns and tags that can be selectively revealed under NIR excitation on biological surfaces such as silkworm cocoons, pig skin, fruits, and leaves through stencil printing and brush painting. The natural product-based upconversion ink developed in this study may provide new opportunities for biocompatible and transient tattoos for medical purposes, anti-counterfeiting platforms, and sustainable nanophotonic devices.

5:00 PM MF03.11.04
Rapid Manufacturing of Smart Nanofibers: Solution Blow Spinning Polycaprolactone with Anthocyanins from Agri-Food Waste Sources Josemar G. Oliveira Filho[1], Henriette M. Azeredo[2], Luiz Henrique C. Mattoso[2] and Alexander L. Yarin[1]; [1]University of Illinois Chicago, United States Minor Outlying Islands; [2]Brazilian Agricultural Research Corporation, Embrapa Instrumentation, Brazil

The continuous advancement in rapid manufacturing techniques has played a crucial role in the fabrication of nanofibers intended to produce smart food packaging. This study aimed to employ the solution blow spinning (SBS) technique for the rapid production of intelligent nanofiber mats based on polycaprolactone (PCL) and red cabbage extract (CE) obtained from retail waste for application in monitoring food quality. The addition of CE to the PCL matrix increased the nanofiber diameter from 156 nm to values between 261.05 and 278.14 nm for PCL/CE10 and PCL/CE15, respectively. The addition of CE also improved the mechanical and water-related properties of the nanofibers, although it reduced thermal stability. CE-incorporated nanofiber mats exhibited visible color changes ($\Delta E \geq 3$) in response to buffer solutions with a pH range between 3 and 10, as well as when exposed to ammonia vapor. The smart nanofibers demonstrated the ability to monitor fish fillets through visible color changes during storage. Initially, at 0 hours, the PCL/CE10 and PCL/CE15 mats exhibited a lilac hue, but after 24 hours, this color became less saturated. After 48 hours, bluish-gray tones were observed, and after 72 hours, the blue color indicated deterioration of the fish fillets with a pH of 8.01. Thus, smart nanofibers produced by the SBS technique reveal potential as intelligent food packaging materials. The authors are grateful to FAPESP (processes 2021/13260–7 and 2023/02038-7) for financial support.

5:00 PM MF03.11.05
Facile Preparation of Anti-Mold Wood Fibers for Integration into Biocomposites Yuqi Feng and Denvid Lau; City University of Hong Kong, Hong Kong

Public awareness of energy and climate change drives the development of energy-efficient buildings, leading to increased indoor airtightness and bio-based building materials. Wood-based materials, known for their low embodied energy and sustainable life cycle, are highly valued in green building practices. Despite the energy-saving benefits of wood fibers, their susceptibility to mold contamination due to high moisture absorption is often overlooked. This challenges indoor air quality and human health, particularly in warm and humid climates and poorly ventilated buildings. While various coating strategies have been developed to make wood surfaces hydrophobic and mold-resistant, coating durability issues remain. Therefore, this study aims to modify wood fibers for creating wood fiber composites with inherent anti-mold properties. Wood fibers with mold-resistant behavior are prepared by in-situ growth of Zn-containing layered double hydroxides combined with a hydrophobic modification process by stearic acid. The mechanisms of antifungal action of the treatments on fibers and mold cells are understood through molecular dynamics simulations. Mold growth on the composites of untreated and treated wood fibers is then investigated by laboratory tests. The effects of anti-mold coating on the water resistance, dimensional stability, and mechanical properties of the composites are also evaluated. The mold-resistant biocomposites developed here provide a viable candidate for indoor and outdoor construction materials, with great potential for application in green buildings that advocate the healthy and harmonious coexistence of humans and the environment.

5:00 PM MF03.11.06
Designing Cellulose Nanomaterials to Craft Environmentally Conscious Polyurethane Nanocomposites Teahoon Park; Korea Institute of Materials Science, Korea (the Republic of)

This research endeavors to manipulate the mechanical and thermal characteristics by optimizing the polymerization conditions of urethane foam while integrating cellulose nanomaterials (CNMs), known for their eco-friendly properties, through chemical reaction induction. Within the domain of urethane materials, foam variants, notably rigid urethane foam as an insulator and flexible urethane foam employed in memory foam and interior applications, are of particular interest.

Rigid urethane foam, primarily employed in construction and cooling sectors as insulation, is now gaining prominence in advanced insulation techniques for the transport and storage of liquefied natural gas (LNG). Its lighter weight and superior mechanical strength potential offer economic advantages by potentially reducing the material quantities required. Enhancing mechanical robustness while simultaneously reducing thermal conductivity holds promise for space optimization in LNG storage or transport contexts where superior thermal insulation and mechanical properties are paramount.
The surge in demand for environmentally sustainable construction materials aligns with the integration of cellulose, a sustainable alternative, to modulate properties. In addition, we need lighter materials. Glass fiber-reinforced insulation, prevalent in LNG transport, possesses a density of 2.5 g/cm^3, significantly higher than the urethane foam material under consideration.
Flexible urethane foam, notably used in automotive seat interiors, demands heightened durability and toughness to withstand long-term usage and repeated stress conditions.
This study's focal objectives involve the development of eco-friendly cellulose nanomaterials and the refinement of urethane compositions to generate nanocomposite foams. The most important goal is to manipulate the physical properties of these nanocomposites through an intricate understanding and advancement of urethane reaction mechanisms. The study's scope encompasses thorough investigations into nanomaterials, polymerization processes, and optimized mixing methodologies to achieve desired material enhancements.

5:00 PM MF03.11.07
Understanding the Influence of Morphology and Chemical Compositions of Algae on the Hydration Reactions of Portland Cement Meng-Yen Lin, Brandon T. Lou, Paul Grandgeorge, Li-Yuan Lin and Eleftheria Roumeli; University of Washington, United States

Cement accounts for up to 10% of global carbon dioxide emissions and has become one of the targets of recent decarbonization efforts. Algae is an abundant and easy-to-cultivate biomass, which can sequester carbon during growth and can be used to replace cement. Recently, we showed that certain microalgae hinder the primary hydration reaction of ordinary Portland cement at high concentrations, significantly hampering mechanical performance. To optimize the structural performance of algae-cement composites, here we focus on the effects of morphology and chemical compositions of algal biomatters on cement hydration. Applying a bottom-up approach, we first study the effects of algae-related biopolymer building blocks, including proteins, carbohydrates, and lipids, on the resulting hydration products through thermal gravimetric analysis (TGA) and scanning electron microscopy (SEM), and their relationships with the composites' compressive strength. To further characterize the influence of particle size, bonding structure, and chemical compositions of the algae on the composites, we then pretreat the microalgae and macroalgae through grinding, hot-pressing, and biopolymer extraction. SEM is used to investigate the effects of particle morphology on the binding interfaces and distribution in the cement matrix. Fourier transform infrared spectroscopy (FTIR) and X-ray photoelectron spectroscopy (XPS) are used to characterize the bonding environment and chemical compositions of the biomass, which are correlated with the hydration products in the algae-cement composites and their contribution to mechanical properties. We show that using specific pretreatment for both algal biomatters, the strength of composites can be improved by up to twofold compared to the unprocessed algal biomatter. The proposed processing methods allow for higher algae replacement content, effectively reducing the environmental impact of the cementitious binder.

5:00 PM MF03.11.08
X-Ray Tomography for Visualizing the Internal Structure of Paper Products and its Correlations with Mechanical Properties Anderson Thiago Vasconcelos Veiga, James Drummond, Mark Martinez and Emily D. Cranston; The University of British Columbia, Canada

Mechanical pulp has traditionally been utilized in newsprint and low-value paper products. With emerging opportunities in bio-based products, mechanical pulp is now standing out as a greener alternative to plastics and fossil-based materials. The development of new sustainable products based on mechanical pulp involves exploring and combining different size fractions, creating composites with chemical and semichemical pulps, and forming layered or dispersed fiber structures.
The challenge in advancing the production of high-quality and specialty paper products based on high-volume mechanical pulp lies in elucidating the internal distribution and interaction of fibers within composites made from different kinds of pulp fibers. X-ray micro-computed tomography has proven to be a powerful tool for visualizing the 3D internal structure of materials, and its potential for elucidating paper structures at the fiber level has already been demonstrated. However, visualizing reinforcing pulp fibers or different phases of pulp fiber composites remains a challenge due to the similar chemical composition of fibers and the surrounding matrix.
In this work, we present a labeling protocol employing iron oxide nanoparticles to enhance the X-ray attenuation of added fibers or pulp phases, resulting in higher contrast fibers in X-ray tomographs. Through *in-situ* synthesis and deposition, iron oxide nanoparticles were deposited on the external and lumen surfaces of long fraction pulp fibers to prepare iron-labeled fibers. These iron-labeled fibers were then incorporated into paper handsheets at various loadings and examined via X-ray tomography. An in-house algorithm for the segmentation of iron-labeled and unlabeled fibers was developed based on tomograph histograms. To optimize the segmentation process, we embedded the handsheets in oil to eliminate the signals associated with air (background signal). After image processing, we successfully visualized the spatially and randomly oriented fibers within the handsheet plane at diverse loadings of iron-labeled fibers. Furthermore, we investigated the impact on mechanical properties of randomly oriented iron-labeled fibers in handsheets in comparison to unlabeled fibers to delineate the limitations of labeling fibers with iron nanoparticles as contrast agent for X-ray tomography.
This study not only provides valuable insights into the role of the large fraction of pulp fibers in reinforcing papers but also sheds light on how different kinds of pulp fibers are distributed in paper products and how the formation of a network impacts mechanical properties. A better understanding of the 3D distribution and network formation of fibers can be leveraged to support the development of high-value products based on high-yield mechanical pulp, aligning with opportunities toward sustainable and bio-based materials for the papermaking industry.

5:00 PM MF03.11.09
Oil-Paper-Umbrella-Inspired Passive Radiative Cooling Using Recycled Packaging Foam Yang Liu and Yi Zheng; Northeastern University, United States

Passive daytime radiative cooling (PDRC) is a promising energy-saving cooling method to cool objects without energy consumption. Although numerous PDRC materials and structures have been proposed to achieve sub-ambient temperatures, the technique faces unprecedented challenges brought on by complicated and expensive fabrication. Herein, inspired by traditional Chinese oil-paper umbrellas, we develop a self-cleaning and self-cooling oil-foam composite (OFC) made of recycled polystyrene foam and tung oil to simultaneously achieve efficient passive radiative cooling and enhanced thermal dissipation of objects. The OFCs show high solar reflectance (0.90) and high mid-infrared thermal emittance (0.89) during the atmospheric transparent window, contributing to a sub-ambient temperature drop of ~5.4 °C and cooling power of 86 W m^{-2} under direct solar irradiance. Additionally, the worldwide market of recycled packaging plastics can provide low-cost raw materials, further eliminating the release of plastics into the environment. The OFC offers an energy-efficient, cost-effective and environmentally friendly candidate for building cooling applications and provides a value-added path for plastic recycling.

5:00 PM MF03.11.10
A Concept of Haze Matching for Cloaking of Bulk Anticounterfeiting Patterns Made of Silk Fibroin-Based Upconversion Nanocomposites Seohan

Yun[1], Taehoon Kim[2], Fiorenzo Omenetto[2] and Junyong Park[1]; [1]Kumoh National Institute of Technology, Korea (the Republic of); [2]Tufts University, United States

Since 2010, anticounterfeiting technology utilizing $NaYF_4$-based upconversion nanoparticles (UCNPs), which can emit visible light under invisible near-infrared (NIR) excitation, has been extensively studied. Typically, upconversion patterns and codes are realized by printing viscous nanocomposites composed of a polymer matrix and UCNPs. There are two technical issues: the first is to select a sustainable and environmentally friendly polymer matrix, and the second is to increase the concentration of UCNPs doped in the polymer matrix, considering the extremely low quantum yield of UCNPs. However, when a large amount of UCNPs are concentrated in a unit volume, scattering by nanoparticles increases, creating an opaque pattern. Because bulk patterns are intuitively identifiable, codes can be generated based solely on differences in the colors emitted by NIR excitation. One could consider making the pattern transparent to a level similar to the background by extremely reducing the concentration of UCNPs, but this would exponentially increase the output of the 980 nm light required for decoding. As alternatives, invisible UCNP-doped microbarcodes or microparticles have been proposed, but their processing involves expensive lithography and still requires inconvenient microscopy systems for decoding. Therefore, the practicality of UCNP-based anticounterfeiting platforms in actual fields outside the laboratory is very limited.

In this study, we propose for the first time the concept of haze matching, a convenient way to conceal bulk anticounterfeiting patterns by making the background opaque to a similar level as the pattern. This approach has the advantage of being able to easily control the optical characteristics of the background regardless of the haze level of the pattern, allowing the use of high-concentration UCNP patterns with bright upconversion emission. Regenerated silk fibroin extracted from silkworm cocoons was used as a sustainable and eco-friendly medium to disperse UCNPs. Dopant-free $NaYF_4$ nanoparticles synthesized under the same hydrothermal conditions were prepared as a medium for haze matching. Based on optical analysis of the transmittance and haze at various nanoparticle concentrations, we established the optimal conditions for the background to completely conceal the bulk pattern with extremely high concentrations of UCNPs. A variety of bulk codes and tags that appear selectively only under NIR excitation have been successfully demonstrated through printing/painting techniques. In particular, opaque anticounterfeiting films containing haze-matched codes and tags were more difficult to identify on white surfaces such as paper or ceramics.

The strategy for upgrading the sustainable nanocomposite-based anticounterfeiting platform proposed in this study will provide new options for the practical use of UCNPs.

5:00 PM MF03.11.11
Vat Photopolymerization-Based Multi-Material 3D Printing of Overhangs with Highly Removable and Recyclable Thiol-ene Photopolymer Supports Tengteng Tang, Prem Nawab, Parimal Prabhudesai, Saleh Alfarhan, Ivan Pesqueira, Kailong Jin and Xiangjia Li; Arizona State University, United States

Vat photopolymerization (VPP) based 3D Printing technology boasts the capability to print 3D structure with remarkable precision and rapidity. In the fabrication of complex structures beyond traditional capabilities, extensive additional support structures are often essential for creating overhanging and free-hanging features. Yet, these internal supports pose challenges as they are not directly removable, necessitating time-consuming manual removal and potentially causing unintended damage and surface imperfections. While specific materials like NaOH-soluble substances and wax have been employed for creating removable supports, these solutions are limited to specific printable materials and often result in considerable waste during the removal process. The current predicament lies in the fact that traditional vat photopolymerization 3D printing of overhangs employs a photocurable liquid resin, which forms a permanently crosslinked polymer. This invariably leads to disposal of body and especially support structure after its usage due to the material's non-recyclable nature.

To counter these drawbacks, this study leverages the properties of crosslinked thiol-ene photopolymer, such as polybutadiene and polyisoprene, which are renowned for their robust structures and excellent thermomechanical characteristics. The innovation lies in utilizing liquid polydiene elastomer as a building block in VPP-based 3D printing, a technique yet to be thoroughly explored. The research focuses on creating a chemically recyclable crosslinked polydiene elastomeric liquid resin, capable of undergoing photoinitiated thiol-ene click reactions with commercially available materials, apt for VPP-based 3D printing. The approach involves using liquid polysulfides with photoreactive thiol end groups and dynamic disulfide bonds, which react with polydienes' carbon-carbon double bonds (ene groups) through photo-crosslinking. The internal disulfide bonds in the resulting crosslinked polydiene elastomers allow for base-catalyzed thiol-disulfide exchange reactions, leading to the decrosslinking or degradation into photoreactive thiol oligomers. Combining conventional permanently crosslinked resin with developed recyclable resin allows for the printing of complex multi-material structures. Subsequent processing to recycle thiol-ene photopolymers can yield intricate overhangs, such as microfluidic channels, spinning tops, and interlocked da Vinci drones. In addition, the impact of surface to volume ratio and crosslinking rate under grayscale projection on the recycling rate is extensively investigated. The optimized porous support structures exhibit properties that are highly removable and recyclable. By demonstrating this scalable method, the study opens up new avenues for fabricating overhangs with easily removable and highly recyclable elastomeric resins via VPP, maintaining material properties across multiple recycling. This development not only offers a superior alternative to current casting/molding manufacturing methods for elastomeric materials but also paves the way for more sustainable and environmentally friendly practices in 3D printing technologies.

5:00 PM MF03.11.12
Biobased Epoxy Resin via Algae Curing Agent Keshan Lighty; North Carolina A&T State University, United States

A growing number of manufacturers are looking for environmentally friendly substitutes for conventional methods in order to cut down on carbon emissions. This research presents a viable path toward environmentally friendly manufacturing methods by investigating the creative use of bio-curing chemicals produced from algae as a novel technique to curing epoxy resin.

Given its abundance and quick development, algae provides a sustainable and renewable supply for bio-curing agents. The purpose of the study is to determine whether chemicals produced from algae may successfully replace traditional curing agents in epoxy resin formulations. Algae-based curing agents have the potential to perform on par with or even better than synthetic counterparts when their mechanical attributes, thermal stability, and curing kinetics are examined.

The use of curing agents generated from algae in epoxy resin formulations not only adds biodegradability and reduces toxicity, but also lessens the environmental impact of traditional curing agents. This move to bio-curing agents is consistent with the global movement toward a circular economy and more environmentally friendly industrial practices.

This research has important economic ramifications in addition to environmental benefits. The cultivation and processing of algae has the potential to generate additional revenue streams for bio-based material enterprises, hence promoting job development and portfolio diversification. Furthermore, the manufacturing industry benefits from increased resource security and resilience because to the decreased reliance on curing agents sourced from fossil

fuels.

By highlighting the crucial role that algae play in changing material science and advancing a more robust and sustainable future, this research provides the foundation for a paradigm change in the manufacturing sector.

5:00 PM MF03.11.13
Automotive Plastics Recycling in a Circular Economy through Molecular Recycling Technologies: Technology Status, Material Advances and Challenges Mahshid Mokhtarnejad[1,2], Gary Hawkins[3] and Hendrik Mainka[2]; [1]The University of Tennessee, United States; [2]Volkswagen Group of America, United States; [3]Eastman Chemical Company, United States

The urgent need to address the global plastic waste crisis and its impact on climate change has created a demand for a materials revolution. Volkswagen Group of America Inc. (VWGoA) in collaboration with Eastman Chemical Company, is taking the lead in driving circular economy solutions for plastics through groundbreaking molecular recycling technologies. This innovative approach enables the conversion of difficult-to-recycle plastics from the automotive industry into raw materials for producing new specialty plastics and fibers, all while maintaining their quality and performance. Our primary focus lies in dealing with a wide range of plastic waste streams, including mixed plastics, colored plastic materials, post-consumer car carpets, and textiles. The collaboration between VWGoA and Eastman Chemical Company not only brings innovation but also addresses recycling challenges associated with these difficult materials, while providing environmental and sustainability metrics for the recycling process. The knowledge gained from this project contributes to global waste management efforts and fosters a cleaner and more sustainable future. With the molecular recycling process enabling the synthesis of various polymer types, it presents a direct alternative to virgin fossil-based plastics. This is particularly relevant as the automotive industry strives to reduce carbon footprints and divert plastic scrap and automotive shredder residue (ASR) from landfills, benefiting original equipment manufacturers (OEMs) and their suppliers. This molecular recycling process, developed by Eastman Chemical Company and successfully implemented by Volkswagen (VW), has proven to reduce greenhouse gas emissions by 25-50 percent compared to the conventional use of virgin-fossil-based raw materials in the automotive sector. Leveraging their expertise in automotive manufacturing, VW has successfully implemented initiatives to reduce CO_2 emissions through the use of lightweight body panels. This collaboration builds upon their past achievements of the VW's innovation hub in North America. Proof of concept is demonstrated through the Atlas Cross Sport Spoiler Assembly, Passat R-Line Diffuser, and Atlas Cup Holder Substrate, showcasing the successful recycling of mixed plastics. These components serve as examples of the effectiveness and viability of the mixed plastic recycling process to manage plastics from end-of-life vehicles in a sustainable way. In this study, by employing innovative molecular recycling technologies, these proof of concepts highlight the ability to transform challenging waste plastics into high-quality materials suitable for automotive applications. The successful recycling of mixed plastics not only demonstrates technical feasibility but also emphasizes the commitment to sustainability and circular economy principles within the automotive industry.

5:00 PM MF03.11.14
Dye Emission Solvatochromism to Monitor Local Environment in Polyhydroxybutyrate Nanoparticles Gareth Redmond; University College Dublin, Ireland

In this work, the use of Nile red as a solvatochromic probe of biopolymer nano-environments was investigated. Firstly, relationships between measured dye fluorescence spectral maxima and solvent dielectric constant ε and Reichardt solvent parameter $E_T(30)$ were developed. Then, aqueous dispersions of NR-doped nanoparticles (NPs) of poly-hydroxybutyrate (PHB) were prepared using a batch-type emulsion process facilitated by tip sonication and the effect of NP preparation conditions on NR nano-environment was spectroscopically probed.
Photoluminescence spectra of aqueous dispersions of PHB/NR NPs indicated that NR fluorescence spectralmaxima were redshifted for samples prepared with 2 min of tip sonication, blueshifting to similar values for samples prepared with 5 or 8 min of sonication. The data suggested that for NPs prepared with 2 min sonication, NR dye molecules were situated at locations ranging from highly dipolar aprotic to polar protic (H-bonding donor/HBD) in character. The dyes were comparatively poorly encapsulated in the PHB NPs being located near or at the interface in regions close to the PVA surfactant stabiliser and the surrounding aqueous medium. The data also indicated that for NPs prepared with 5 and 8 min sonication, the dye molecules were situated at locations that were mildly dipolar and non-HBD in character, i.e., the dyes were on average better encapsulated within the NPs, located away from the polymer-water interface and less exposed to H-bonding effects. Statistical analysis of emission maxima obtained for particles prepared with different sonication conditions showed a clear trend of shifting NR nano-environment character, from high polarity/HBD-type to lower polarity/non-HBD-type, on changing the NP batch preparation sonication time from 2 min to 5 or 8 min.The mean extracted value for the local dielectric constant ε in the 5/8 minPHB/NR NPs is estimated as 8.5 ± 1.5, slightly larger than reported bulk values, suggesting that the dielectric response of these nanoparticles reflects contributions due to interfacial effects.
Photoluminescence decay data for aqueous dispersions of PHB/NR NPs were also acquired and fitted by a double exponential function, suggesting that the NR dye molecules were located in heterogeneous environments. The short emission decay component has previously been attributed to interaction between dye molecules and water molecules *via* H-bonding, leading to rapid non-radiative deactivation of the NR excited state. From the data, the relative amplitudes of the short and long decay components varied from 2 min through 5 min to 8 min sonication indicating a progressively decreasing contribution of the short decay process to the overall emission decay, consistent with reduced NR-H_2O H-bonding interactions due to improved dye encapsulation.
To gain further information about the possible locations of NR molecules within the 5/8 minPHB/NR NPs, emission anisotropy studies were undertaken. Steady-state emission anisotropy spectra gave mean anisotropy values consistent with dye molecules being typically located in restricted environments. Time-resolved emission anisotropy decays were acquired, fitted by a double exponential function, and analysed using a “wobbling-in-a-cone” model that suggested that the measured anisotropy decays arise from rotational relaxation of dye molecules in the NPs by a wobbling-in-cone motion and by lateral (2D) diffusion relative to the NP surface. Trends in the extracted rotational relaxation parameters were consistent with inclusion of NR molecules in progressively more restrictive environments due to improved dye encapsulation with increasing sonication time.
The ability to employ a solvatochromic probe of nano-environments in novel polymer nanoparticles offers promising opportunities for future studies aimed at understanding the guest- and host-dependent mechanisms of encapsulation and controlled release of active ingredients in biopolymer nanostructures.

5:00 PM MF03.11.15
Biodegradable and Renewable Polymer Obtained from the Reactive Extrusion of Corn Derivatives Paula D. Santiago[1], Tamires d. Nossa[2] and Vagner R. de Mendonça[2]; [1]Federal University of Sao Carlos, Brazil; [2]Federal Institute of Education, Science and Technology - IFSP, Brazil

The waste generation caused by human consumption of plastic has been growing exponentially in the last century, causing several environmental impacts. One of the alternatives to mitigate this effect is the development and application of biodegradable polymers. Starch is one of the most promising materials for this purpose, given its low cost, availability, and ability to be modified chemically, biologically, and physically. One of the sources of starch is corn, and its use is extremely attractive due to the high production of this food. However, starch has limited properties regarding its low mechanical strength and high hydrophilicity. Studies have been carried out to improve the properties of this material, making its processing and application more satisfactory. We can highlight the inclusion of glycerol, a residue from the biodiesel industry, as a plasticizing agent and coconut oil to increase mechanical resistance and water absorption. In this work, the effects of modifying products derived from corn, pre-gelatinized starch, were investigated for the processing of

polymers using glycerol and coconut oil through the reactive extrusion process to obtain a biodegradable product from a renewable source with potential application in the packaging industry. Thermogravimetric, Differential Exploratory Calorimetry and Fourier transform infrared spectroscopy analyses were carried out, and the mechanical properties, biodegradation, and moisture absorption were analyzed. It was possible to verify an improvement in the mechanical properties of the formulation with the addition of 20% by mass of coconut oil, with an increase of approximately 37.5% in the tensile strength limit and 32.1% in the elongation at break and a reduction in moisture absorption.

5:00 PM MF03.11.16
Thermoplastic Starch Reinforced with Bamboo Fibers: A Biodegradable Composite Alternative Nicolas A. Maricato, Vagner R. de Mendonça and Tamires d. Nossa; Federal Institute of Education, Science and Technology of Sao Paulo - IFSP, Brazil

Due to the large consumption of plastics and their frequent use in disposable applications, it is essential to direct studies toward the development of alternative materials that are biodegradable or come from renewable sources in order to reduce the impact generated by the disposal of these materials on the environment. This study focused on the production of a sustainable biocomposite, produced from a renewable and biodegradable source, using corn starch as a thermoplastic matrix, in which glycerol, a residue from the biodiesel industry, was used as a plasticizing agent. Different production parameters were studied through reactive extrusion in order to produce homogeneous filaments with a thermoplastic starch matrix (TPS), in the proportion 70:30 (% starch: % glycerol), reinforced with bamboo fibers with different filler addition proportions between 5%, 10%, 15%, 20% and 30% by mass. To incorporate the fibers, an alkaline treatment was carried out with sodium hydroxide (5% NaOH) in order to make the composite interface compatible. It was possible to observe that the presence of bamboo filler increased the mechanical tensile strength and modulus of the TPS while the elongation decreased. The presence of fibers also modified the TPS biodegradation profile, acting to preserve the proliferation of fungi, preserve the material, and increase the biodegradation time.

5:00 PM MF03.11.17
Curdlan Hydrogels as Sustainable Scaffolds for Cell-Based Meat Production Reyhaneh Sarkarat and Reza Ovissipour; Texas AM, United States

Cellular agriculture has drawn significant attention as a potential solution to challenges associated with traditional farming, such as environmental pollution, animal welfare, and sustainability. To support the cells to grow into desired tissues, a physical structure as a scaffold is needed. Scaffold development is a well-studied field in the tissue engineering discipline, more specifically for biomedical purposes. However, the biomaterial used in fabricating scaffolds for food products should meet different criteria. In addition to being biodegradable and biocompatible, cultured meat scaffolding biomaterial should be edible and be able to mimic meat texture and structure. This work aims to investigate microbial, plant, and insect-based biomaterials that have not been exploited for cultured meat scaffolding and introduce a new combination as a potential scaffolding biomaterial for food purposes. In this study, novel protein-enriched hydrogels have been developed, characterized, and applied to develop bio-based films supporting bovine muscle satellite cell growth. Curdlan, a microbial polysaccharide, was used as the gelling agent, combined with three different types of proteins, including hemp, alfalfa, and black soldier fly. To characterize the scaffold and assess the mechanical and chemical properties of the scaffold, FTIR, differential scanning calorimetry (DSC), and rheology tests were selected to be performed before and after seeding cells on biofilms. Additionally, patterned biofilms were developed to investigate the possibility of enhancing cell adhesion and differentiation.

Bacterial Cellulose Nanoparticles for Sustainable Drug Delivery Gabrielle Balistreri, Ian R. Campbell, Xinqi Li, Julia Didier Amorim, Shuai Zhang, Elizabeth Nance and Eleftheria Roumeli; University of Washington, United States

Sustainable nanomedicine is an emerging concept to address the challenges of scalability, reproducibility, thermostability, and waste free processing for nanotherapeutic manufacturing. This significant problem has created access barriers for patients in need of disease treatments in low-resource settings and under-developed countries. Bacterial cellulose (BC) is a nanomaterial with the potential to overcome these challenges and be a versatile drug delivery platform for disease treatments. The development of BC nanoparticles (BCNPs) for drug delivery is motivated by the material's biodegradability and biocompatibility properties, important for nanomedicine applications. BCNPs are nanoscale in all dimensions and are grown in a kombucha media in agitated and aerated conditions for 24 h and size separated utilizing polysorbate 80 surfactant solution. BCNPs are approximately 200 nm in particle size, and have a near neutral zeta-potential, and amorphous structure. Here, we study the morphology and structure of BC fibers within BCNPs over the course of 5-days. We find an increase in BC crystallinity and demonstrate significant differences in the hierarchical fiber organization with time of growth. Furthermore, we characterize the BCNPs thermal stability which is important for biomedical applications. Lastly, we demonstrate drug loading and unloading performance of BCNPs using bovine serum albumin (BSA) as a model. These results highlight the potential of BCNPs to be used in biological settings and in particular, their application as a sustainable drug delivery nanotherapeutic platform to treat critical diseases.

5:00 PM MF03.11.19
Texture and Pitch Evolution in Cholesteric Chitosan Mesophases Eleanor C. Grosvenor and Cecile Chazot; Northwestern University, United States

Chitosan has demonstrated value as a biodegradable packaging material due to its antibacterial and hydrophobic properties, but it has untapped potential in optical applications. This abundant, waste product-derived polysaccharide is known to develop chiral nematic liquid crystalline order upon suspension in various solvents. However, the thermodynamics of its self-assembly are not well understood. Through the measurement of cholesteric pitch using polarized light microscopy, we can pinpoint the critical concentration at which cholesteric mesophases begin to form. In concert with a phase diagram model to inform thermodynamic mesophase behavior, we have developed a framework to optimize the optical activity of chitosan suspensions for a variety of applications. We propose a quantitative relationship between cholesteric pitch and concentration, as well as other formulation and processing parameters like molecular weight, solvent choice, degree of deacetylation, and aging time. This relationship helps to elucidate the complex interactions occurring between chitosan and solvent. With a better understanding of this system, we open the door to new applications of structurally colored films, such as colorimetric sensing for food packaging.

5:00 PM MF03.11.20
Versatile Method to Produce Wood Particle Foams for Building Insulation Elizabeth Dobrzanski[1,1], Elisa Ferreira[2,1,1], Praphulla Tiwary[3], Prashant Agrawal[3], Richard Chen[3] and Emily D. Cranston[1,1,1]; [1]The University of British Columbia, Canada; [2]Brazilian Nanotechnology National Laboratory, Brazil; [3]Plantee Bioplastics Inc., Canada

Lightweight foams are excellent thermal insulators due to their structure, which traps layers of air pockets and results in low thermal conductivity. Modern buildings overwhelmingly use insulative foams derived from petrochemical sources, which not only contribute greenhouse gases during manufacturing but also end up in a landfill at the end of their life. Alternatives to petrochemical-based foams, such as mineral wool, have been linked to health concerns. As a result of these environmental and health concerns, the appetite for bio-based and environmentally-friendly materials is growing and may be awarded through building sustainability certifications like LEED or BREEAM [1].

Materials that are truly sustainable must be considered holistically, from their feedstock source to their manufacturing process to their end-of-life stage. Some examples of bio-based insulative foams are cellulose- and pulp-based foams, which are moving towards being fully sustainable but still require relatively high amounts of processing energy to transform them from their raw feedstock form. One feedstock source that is often overlooked is forest residues, materials generated by the forestry industry that have little to no economic value and includes bark, dead trees, off-cuts, and small-diameter trees. Due to their poor mechanical qualities, they are often used for low-value products [2].

We previously showed that we can circumvent the poor macro-scale mechanical properties of forest residue wood by milling the feedstock to < 1 mm and recombining the wood particles as a lightweight, high bio-based content foam [3]. This previous work focused on pine beetle-killed wood, which refers to trees that have been killed by mountain pine beetles and may contribute to high-intensity fires if left in the forest [4]. To produce these foams, waste wood particles are foamed in water with surfactant and a water-soluble polymer binder and then oven dried [5], a relatively facile and low-energy method of solid foam production. The resulting foams have mechanical (density ca. 0.12 g cm^{-3}) and thermal (thermal conductivity ca. 0.042 W m^{-1} K^{-1}) properties that are competitive with conventional petrochemical-based foams. The promising performance of our foams is attributed to their low density and hierarchical pore structure consisting of polyhedral cells templated by air bubbles and natural honeycomb pores from the wood cell walls [3]. The end-of-life stage is also considered, as the foams are able to be re-wetted, re-foamed, and re-dried while maintaining their original properties.

Our current research pushes this method further by exploring different waste wood feedstocks, different particle sizes, and the replacement of our surfactant and polymer binder with bio-based materials alternatives. Verifying the potential of alternative waste wood feedstocks and particle sizes is important for scalability and adaptability, while alternative surfactants and binders are important to create a fully bio-based product with no negative environmental impact. In most cases the thermal and mechanical properties of these alternative foams are competitive and have the potential to replace petrochemical-based foams. The alternative foams that do not meet ASTM or building standards may still be able to pass if the milling procedure is tweaked to allow for higher aspect ratio particles, which may result in more comingling of the wood particles and binder and produce a more cohesive solid foam structure.

5:00 PM MF03.11.21
Physico-Mechanical Evaluation of Electrospun Nanofibrous Mats of Poly(3-hydroxybutyrate) / Poly(butylene succinate) Blends with Enhanced Swelling-Dynamics and Hydrolytic Degradation-Kinetics Stability for Pliable Scaffold Substrates Harshal Peshne and Bhabani Satapathy; Indian Institute of Technology Delhi, India

Biodegradable blends of PHB/Bio-PBS were successfully electrospun with solvent system 2,2,2-trifluoroethanol as the solvent to obtain electrospun mats (EMs) of fiber diameters ranging from 534 ± 135 nm to 181 ± 84 nm. The addition of $CaCl_2$ led to defect/bead free morphology of PHB and PHB/Bio-PBS blends with the exception for Bio-PBS at ~ 20 wt. % concentration. Bio-PBS based electrospun mats with $CaCl_2$ led to the lowest fiber diameter (due to high conductivity and low viscosity of solution). Further, our study indicates that PHB/Bio-PBS blends displayed shear-thinning behavior with reduction in solution viscosity which in turn remained in tune with increasing Bio-PBS concentration. DSC studies indicated a more significant drop in crystallinity for PHB/Bio-PBS blends and as well corroborated by WAXD. Mechanical properties were affected by immiscibility, resulting in lower tensile strength from ~ 4.0 MPa to ~ 2.0 MPa and tensile modulus from ~186 MPa to ~ 64 MPa, while strain-at-break increased from ~ 1.5 % to ~ 46.5 % with Bio-PBS content in PHB matrix. Electrospun mats with up to 50 % Bio-PBS loading demonstrated optimal ductility and strength and also exhibited a tensile modulus comparable to that of cancellous bone. Additionally, the blend with ~ 50 wt. % of Bio-PBS showed increased hydrophobicity (116°) and decreased swelling characteristics (84 %) compared to neat PHB (95° and 124 %). Hydrolytic degradation studies showed improved structural robustness and consistent morphology in Bio-PBS based electrospun mats even after 30 days in phosphate buffer solution compared to PHB based mats. Thus, up to 50 % Bio-PBS incorporation into Polyhydroxyalkanoates matrices, i.e. in the blends with 50:50 compositional the mats obtained showed enhanced pliability in combination with the desired extent of physico-mechanical properties and stiffness for soft bone tissue engineering.

5:00 PM MF03.11.22
Structure-Property Relationships of Lignin-Based Structural Building Materials Malavika Bagepalli[1], Priscilla Pieters[2], Jian Zhang[1], Kevin Miller[3], Hemant Choudhary[1,4] and Sumanjeet Kaur[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Murray State University, United States; [4]Sandia National Laboratories, United States

Buildings enable long-term storage of carbon due to their long lifespans (> 50 years). Engineered wood, including wood biopolymer composites, is a potential replacement for concrete and steel in construction to limit CO_2 emissions. However, current formaldehyde-based binders used in engineered wood are toxic and have environmental concerns, so there is a need to explore bio-based, formaldehyde-free binders. Lignin is one of the most abundant biopolymers on earth and is a natural glue which holds up a plant's structural framework. Currently, lignin (Kraft) is treated as a low-value waste product by the paper and pulp industry, with a significant amount burned for fuel. The use of lignin from waste streams and agricultural waste in building materials emerges as a cost-effective solution. However, the chemical composition of lignin is sensitive to lignocellulose source and method of extraction, leading to inhomogeneity. Extracting lignin through ionic liquids (IL) or deep eutectic solvents (DES), are environmentally friendly and energy efficient. However, the effects of lignin variability on adhesive performance have not been well explored. Specifically, ideal characteristics for the development of structural wood composites have not been systematically studied. To address this gap, this study aims to develop structure-property relationships of lignin-based adhesives from different sources and extraction methods. The study includes a comprehensive baseline characterization of the different lignin and repeated mechanical strength measurements of lignin-based adhesives.

SESSION MF03.12: Sustainable Structural Materials
Session Chairs: Kunal Masania and Eleftheria Roumeli
Friday Morning, April 26, 2024
Room 323, Level 3, Summit

8:45 AM *MF03.12.01

Bio-Inspired Biomineralized Bacterial Cellulose Composite Material Marie-Eve Aubin-Tam; TU Delft, Netherlands

There is an important need for sustainable structural materials that combine high mechanical strength, possibility of control over 3D shape, and ease in upscaling material production. I will present how we use microorganisms to fabricate inorganic-biopolymer composite materials that show a layered structure reminiscent of tough biominerals in nature (nacre, bone, dentin). The inorganic component consists of calcium carbonate ($CaCO_3$) crystals formed by *Sporosarcina pasteurii* bacteria, and the organic components include bacterial cellulose and polyglutamic acid, produced by the bacteria *Gluconacetobacter hansenii* and *Bacillus paralicheniformis*, respectively. This 'bacterial nacre' reaches and exceeds the toughness of natural nacre, while being fabricated in an ecological, economical, and simple manner using bacteria. The 3D shape can be controlled via molding or direct ink writing. The resulting composite materials show promising applications as light weight structural materials.

9:15 AM MF03.12.02
MICP Biomineralization and Biotic Additive Manufacturing Toward The Design of Strong Biocomposites Sabrina Shen[1,1,2], Ethan Viles[2,2], Chelsea Heveran[2,2] and Markus Buehler[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Montana State University, United States

Microbial-induced calcium carbonate precipitation (MICP) has been explored as a more sustainable alternative for producing concrete-like load-bearing materials. Concurrently, additive manufacturing of biotic composites enables the production of complex hierarchical materials with minimally refined organic feedstocks. Such materials can be designed to be functional and highly biodegradable, however organic materials without a mineral phase are limited in mechanical strength, and material longevity is necessary for some applications. Here we explore MICP biomineralization of additively manufactured biotic composites, and investigate the interaction between mineral formation and biocomposite structure at multiple scales. We characterize the resulting materials and consider how MICP biomineralization and additive manufacturing can be used to design for strong and durable biocomposite materials.

9:30 AM MF03.12.03
Innovative Circular Building Technologies: Recycled Brick Sand, Geopolymer Mortars, Robotic Arm, Computer Vision and Low Carbon Emission Solutions Mohammad Rizwan Bhina and Liu Kuang-Yen; National Cheng Kung University, Taiwan

The construction industry is undergoing a transformative shift towards sustainability due to environmental concerns and resource scarcity. The cement industry, responsible for 8% of industrial CO_2 emissions, exacerbates this issue. Haphazard and overbuilding construction practices also lead to a 3% annual increase in concrete demand, further contributing to global warming. This research explored innovative technologies, focusing on recycled brick sand, geopolymer materials, robotics, computer vision, and low-carbon solutions. Recycled brick sand reduces resource demand and minimizes waste, while geopolymer materials, derived from industrial by-products, cut carbon emissions and promote circularity. Automation, robotics, and computer vision enhance efficiency and safety. Moreover, AI-driven algorithms and drones improve site management, defect detection, and progress tracking. Addressing carbon emissions through carbon-capture technologies and renewable energy integration aligns with circular principles. This integration represents a significant step toward sustainability in construction.
Thus, as a result, the use of blend of low calcium fly ash and S4000 GGBS as a binder, 10 M NaOH as an activator, and recycled brick sand as a fine aggregate from recycled bricks used as a source material for evaluating the flowability and mechanical strength of geopolymer bricks in this study has been explored. For further study of the compressive strength of recycled brick, 0.363 was selected as the optimum binder-to-recycled brick sand ratio. In this study, it was found that brick sand is the most significant factor contributing to reduced flowability of geopolymer mixtures. Binder-to-recycled brick sand ratio of 0.363 with 10 M NaOH activator provided the highest 1-day compressive strength of 24.2 MPa. An inhomogeneous microstructure was observed with a binder replacement ratio of less than 0.35 in FESEM-EDS analysis of the specimens. Geopolymer materials bricks were more durable and mechanically strong when NaOH concentrations and curing temperatures were higher.
In conclusion, the integration of these innovative circular building technologies into construction practices was paving the way for a more sustainable and environmentally responsible industry. By reimagining materials, embracing automation, harnessing AI, and prioritizing low-carbon solutions, the construction sector is moving towards a circular economy model that aims to minimize waste, reduce resource consumption, and mitigate the environmental impact of building projects. These advancements hold the potential to reshape the future of construction and create a more sustainable built environment.

9:45 AM MF03.12.04
Deconvoluting The Effects of Chemical Composition and Structural Confinement of Algal Biomatter on The Hydration Reactions of Portland Cement Meng-Yen Lin, Brandon T. Lou, Paul Grandgeorge, Li-Yuan Lin and Eleftheria Roumeli; University of Washington, United States

Decarbonization of cementitious materials, which contributes to 10% global carbon emissions, is one of the primary targets to achieve carbon net zero by 2050. Utilizing the abundance, easy cultivation and carbon-sequestering ability of algal biomatters to reduce cement usage has received rising attention. We recently reported that certain algal strains in the unprocessed form hinder the hydration reactions of ordinary Portland cement, preventing the application of replacement at high algae content. Here, to understand the interactions between the algal biomatters and cement further, we aim to deconvolute the effects of chemical composition and structural confinement of algal biomatters on the performance of algae-cement composites. We first study the influence of algae-related biopolymers, including carbohydrates, lipids, and proteins, on the resulting hydration products using thermal gravimetric analysis (TGA) and scanning electron microscopy (SEM), and their contribution to composites' compressive strength. We then apply pretreatments, involving grinding, self-bonding induced by heat and pressure, and biopolymer extraction, to the macro- and microalgae respectively to investigate the impact of particle size, bonding structure, and chemical composition on the algae-cement interactions. The effects of varying particle size and morphology of biomass on the binding interfaces and distribution in cement matrix are evaluated by SEM. The modified bonding environment and chemical composition of biomass are measured with Fourier transform infrared spectroscopy (FTIR) and x-ray photoelectron spectroscopy (XPS), and then correlated with the hydration products and mechanical properties of the algae-cement composites. Compared to the unprocessed algal biomatter, we significantly improve the strength of composites by twofold using specific pretreatment for both algal biomatters. The proposed processing method and mechanisms enable higher algae replacement in cement with low energy trade-off, showing great potential for reducing cement usage and carbon footprint.

10:30 AM MF03.13.01
Selective Mechanical Deconstruction of Multilayer Film Interfaces Naomi Deneke, Natalie Stingelin and Blair K. Brettmann; Georgia Institute of Technology, United States

Studies have investigated the use of mechanically heterogeneous interfaces having compliant and rigid components for control of adhesion strength. From Kirigami-inspired tapes to composite micropillars. In a similar fashion, mechanically heterogeneous interfaces can be used to trigger delamination events due to localization of stress at the rigid-soft interface. This is especially useful for improving the circularity of multilayer films, which are difficult to recycle due to their multi-material chemistry and use of tie layer adhesives that prevent facile separation of the layers. I will present a material design that utilizes mechanically heterogeneous interfaces that when coupled with a mechanical trigger, selectively deconstructs a multilayer film. Rigid silica microparticles are placed at the tie layer (polyethylene acrylic acid (PEAA)) and aluminum foil interface of a tri-layer film comprised of polycarbonate, PEAA, and aluminum foil. A high intensity ultrasound pulse is sent through the sample, taking care to select a wavelength and voltage that will generate a pressure wave capable of generating significant mechanical stresses at the interfaces. Delamination of the foil layer was observed when 5 µm size particles were positioned at the interface and subjected to an ultrasound pulse, while no delamination was observed if no particles were used, suggesting that interfacial patterning with mechanically heterogenous particles assists in delamination of the layers. Additionally, particle size, density, and location of within the bulk of the material play a significant role in the delamination mechanism. In this work, we design our multilayer materials with end-of-life in mind in order to improve recovery and reuse of layers used in multilayer films.

10:45 AM MF03.13.02
Biowaste Enabled Porous Carbon towards Ultrahigh Capacitance for Energy Storage Yingchao Yang; University of Missouri, United States

Lignin is the second most abundant biopolymer and the most abundant aromatic-containing polymer in nature. Typically, lignin accounts for 15–30% of plants and serves as an adhesive by forming a lignin-carbohydrate complex to bind cellulose and hemicellulose together. Lignin is a waste product in the production of paper or chemicals (*e.g.* ethanol) from biomass. If not removed, the lignin could cause the paper-derived wood pulp to weaken and discolor rapidly.
Valorization of useless lignin to high value-added materials for advanced applications would help address the environmentally detrimental biowaste and satisfy the societal need. To date, lignin has been used as a functional component in polymer synthesis. For example, polyhydroxyalkanoate (PHA)/lignin shows better microbial resistance than PHA alone due to the formation of strong hydrogen bonds. Lignin blended polylactic acid (PLA) exhibits a great non-flammable capability. Furthermore, monomers in lignin have been used to synthesize polymers, such as polyester and polyurethanes. However, owing to the chemically recalcitrant nature, it is very challenging and costly to convert lignin into value added biopolymers.
Recently, the focus on using lignin and its derivatives has been shifted to fabricating energy storage devices, including lithium-ion batteries and supercapacitors. Regarding batteries, lignin has been used by either combining it with additives and binders as electrodes for lead-acid batteries or by fabricating it into three-dimensional (3D) hierarchical porous carbon as electrodes for lithium-ion batteries. Without a doubt, the lignin-based electrode is cheaper and greener, which is a great alternative to existing electrodes for energy storage.
In this presentation, a thick freestanding electrode coupled by lignin carbon and sodium without any binder and additives was fabricated demonstrating a specific area capacitance of 19.7 F cm^{-2} at a current density of 1 mA cm^{-2}, which is the highest among to date reported freestanding lignin carbon electrodes with similar thickness. This excellent electrochemical performance originates from high electro-positivity and oxygen content promoted by the sodium. Our brings a new strategy towards lignin utilization and energy storage through coupling lignin carbon and alkali metals.

11:00 AM MF03.13.03
Accessibility of Ring-Closing Depolymerization for Polycarbonates with Multiple Theory Validation Brandi Ransom, Dmitry Zubarev, Nathan Park, James Hedrick and Kristin Schmidt; IBM Research, United States

We present an accelerated protocol to qualitatively screen polycarbonate monomers for viability of depolymerization in solvents of varying polarities. The largest barrier in the exploration of reaction kinetics is the necessary conformational analysis to identify lowest energy paths in depolymerization, which can depend on the solvent. Tight-binding DFT allows for an accurate quantification of depolymerization barriers as compared to DFT, with an increase in speed by up to 3 orders of magnitude. By a detailed featurization of over 30 compounds we verified that depolymerization barriers are not linearly correlated to the dielectric constant of the solvent. Volume of the molecules is explicitly not correlated with the depolymerization barrier; the solvent-molecule interactions and chemistry of the molecules is extremely influential due to the over coordinated oxygens in the transition state. Though computation of the solvent-solute interaction parameter is necessary for future predictive work in kinetic barriers, even alongside the 1800 Mordred features, conformational analysis is still necessary to determine the lowest kinetic barrier across solvents. We present multiple examples of the of lowest-barrier polycarbonates in acetonitrile, tetrahydrofuran, and toluene to highlight the large opportunity in this field for development in this multi-dimensional optimization problem. For the current available simulation and predictive models, our high-throughput protocol can evaluate the ideal solvent for 6-member polycarbonate depolymerization. From this work, further investigation into solvent-molecule interactions for quick computing features will lead towards the goal of data-driven methods for polycarbonate discovery and optimization.

11:15 AM MF03.13.04
Using Piezoelectricity to Make Force-Responsive Polymeric Materials Sarah M. Zeitler and Matthew Golder; University of Washington, United States

Stimuli-induced polymerizations continue to gain interest as synthetic polymers become more desirable for materials, industrial, and medical applications. While traditional stimuli such as heat, light, and electrochemistry have been extensively studied, they still have shortcomings such as unwanted side reactions, lack of consistent penetrability, and irregular and irreproducible equipment setups. Additionally, high energy inputs and large amount of solvent are regularly used with such stimuli. Many of these shortcomings can be overcome by using force as a stimulus for polymerization. As has been shown in organic small molecule synthesis, the use of piezoelectric nanoparticles enables force to initiate redox reactions, thus making force an even more useful, accessible, and sustainable stimulus for polymerization chemistry.
Herein, we show iodonium salts can initiate free and controlled radical polymerizations of acrylates upon the introduction of various types of force in the presence of piezoelectric nanoparticles, consuming less energy and solvent than traditional polymerization methods. These salts have demonstrated to be reactive with piezoelectric nanoparticles and useful in synthesizing high molecular weight polymers with relatively low dispersities. Furthermore, these polymerizations have been effectively carried out in both solid and solution states with multiple force sources, including ultrasound, ball milling, and vortexing. Preliminary data also indicates that force might be a new useful tool for crosslinking materials and for force-curing in additive manufacturing taking advantage of the mentioned multiple force sources. This iodonium initiated mechanoredox chemistry unlocks the possibility to better utilize force in synthesizing polymers and creating useful adaptable materials.

Recycled Polymers for a Circular Economy Model: Case Study of 3D Printed Wind Energy Generator Vitaliano Dattilo, Kunal Bachim, Nikhil Alagandula, Louis Sponton, Sarvenaz Ghaffari, Andrew Makeev and Michael Bozlar; The University of Texas at Arlington, United States

Polymers are essential components of society as they are versatile, lightweight, and low-cost materials. On the other hand, the growing amount of plastic waste creates a global environmental concern. It is therefore necessary to investigate innovative methods and technologies to achieve a circular economy based on the recycling of plastic waste followed by a reprocessing. In this work, we focus on retrieving the original mechanical properties of polymers after recycling. We produce polymer composite fibers using recycled polyethylene terephthalate water bottles or polypropylene bottle caps, reinforced with various fillers, including graphene. We conduct tensile testing and analytical studies on these composites, and eventually demonstrate their 3D printing potential for application in vertical axis wind turbine rotors. The design process for the wind turbine, site selection, and wind climate analysis are briefly provided.

11:45 AM MF03.13.06
Trash to Treasure: 3D Printing of Waste-Based Polycotton Composite for The Production of Water Filters and Commodity Products Varvara Apostolopoulou Kalkavoura, Natalia Fijol, Salvatore Lombardo, Maria-Ximena Ruiz-Caldas and Aji Mathew; Stockholm Univ, Sweden

The textile industry has been proven to be one of the most polluting industries worldwide due to the extensive use of virgin resources, the vast amount of water and land used and the emergence of fast fashion which resulted to double production of garments the last 20 years. Most of these textiles end up in landfills or incineration facilities. However, the recycling of textiles is still in seminal stage due to lack of proper sorting but also due to the limitations of recycling blended fabrics and the lack of upscalable technology. Polyethylene terephthalate (PET) dominates more than 50% of the textiles market and even if there are routes to recycle it, its presence in blended fabrics mostly in combination with cotton burdens its recyclability. Most of the recycling studies investigate either the depolymerization of PET or the dissolution of cotton in order to efficiently separate them. However, in most of the cases those processes are very energy and materials intensive.

Here we present an upcycling route in one-pot valorization of blended cotton-PET fabrics without separating the two constituents. We performed a mild chemical treatment of cotton-PET (1:1) fragmented post-consumer fabrics during which PET was inert but the cotton was functionalized with carboxyl groups and partially fibrillated. The reaction resulted in high yields (>90%) and the treated textiles were further mechanically disintegrated using a facile and short process in order to enhance their fibrillation and reduce their size. The treated textile mixture was then used for film casting which were oven-dried and cut into 1x1 cm pellets suitable for extrusion taking into account the thermoplastic nature of PET. The obtained filament was used as a feedstock for the Fused Deposition Modelling (FDM) 3D printer and several composite materials for water purification and commodity applications were printed. The presence of carboxyl groups enhanced the adsorption capacity of the polycotton filters making it possible to manufacture advanced materials from discarded garments for water purification applications. Furthermore, several fashion products with various designs were also successfully printed extending the use of the same waste feedstock in the preparation of every day polymer-based accessories.

The facile fabrication of customised waste-based pellets followed by extrusion and the successful 3D printing of the developed filaments into water purification filters and commodity accessories highlight the potential for upscaling and widespread commercialization. Compared to traditional 3D printing feedstocks, the waste-based filaments offer a cost-effective on-demand solution which can be widely accessible.

8:15 AM *MT01.01.01
Structure Complements: A New Materials Taxonomy for ML-Guided Materials Discovery James M. Rondinelli; Northwestern University, United States

Functional inorganic electronic materials design has undergone a shift from chemical-intuition-based strategies to data-driven synthesis and simulation. Numerous machine learning models have been developed to successfully predict materials properties and generate new crystal structures. Many existing approaches, however, rely upon physical insights to construct handcrafted features (descriptors), which are not always readily available. For novel materials with sparse prior data and insufficient physical understanding, conventional machine learning models may display limited predictability and are often applied to known structure types. In this talk, I will address this challenge by introducing a new paradigm of materials taxonomy, dubbed "structure complements," by generalizing anti-structures (or inverse structures). Materials properties depend strongly on crystal geometry but also on the distribution of charge. Thus, our algorithm for classifying materials by geometry and cation/anion decoration proves not only useful as a novel categorization scheme but also as a framework for targeted materials discovery. As a use case, I will showcase our workflow which combines structure complement analysis, a transparent machine learning model, and high throughput density functional theory (DFT) calculations to discover novel ferroelectric materials. We then examine the microscopic origins of ferroelectricity in these new quasi-2D materials and compare them to state-of-the-art compounds. Finally, I propose how this workflow is designed to be integrated into an autonomous, closed-loop materials discovery platform which integrates a unified materials database, machine learning, simulation, and high-throughput synthesis and characterization.

8:45 AM *MT01.01.02
Combining Dataset Curation and Many-Body Calculations for describing Structurally Complex 2D and Quantum Materials Felipe H. da Jornada[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

There is considerable excitement about the family of van-der-Waals-bonded materials, such as transition metal dichalcogenides (TMDs). They not only display unique electronic and optical properties when thinned down to a monolayer, but also allow for a radical new approach to making materials by judiciously stacking individual layers. However, there is a large phase space of possible layered materials when one considers the various possible interfacial stacking angles and layer chemical compositions, making a brute-force exploration of the problem via density-functional theory (DFT) unfeasible. We will discuss how to address these challenges with machine-learning- (ML-) parametrized classical force fields that capture the atomistic reconstruction in chemically nontrivial materials. In particular, we show how careful dataset generation and augmentation techniques can reduce the computational effort to train accurate ML force fields and yield structural information for chemically and symmetrically dissimilar materials. In parallel, we will comment on how similar techniques can be utilized to study the structural and dynamical properties of photoexcited materials. By combining accurate excited-state calculations based on the first-principles GW plus Bethe-Salpeter equation with machine-learning force fields, we can describe the dynamics of atoms after a material is optically excited, paving the way for the description of processes ranging from exciton-polaron formation to photochemical processes in structurally complex heterogeneous systems.

Ultrafast Nonadiabatic Dynamics in 2D Perovskites assisted by Machine Learning David Graupner and Dmitri Kilin; North Dakota State University, United States

An exploration of the on-the-fly non-adiabatic couplings (NAC) for nonradiative relaxation and recombination of excited states in 2D Dion Jackobson Lead-halide perovskites is accelerated by a machime learning approach to ab initio molecular dynamics. Molecular dynamics of nanostructures composed of heavy elements is performed with use of machine learned force-fields (MLFF), as implemented in Vienna Ab initio Simulation Package (VASP). The force field parameterization is establised using on-the-fly learning, which continuously builds a force field using *ab initio* MD data. At each step of MD it is determined whether to perform an *ab initio* calculation or to use the force field and skip learning for that step using a Bayesian-learning algorithm. The total energy and forces are predicted based on the machine-learned force field at each time step of the MD simulation and if the Bayesian error estimate exceeds a threshold an *ab initio* calculation is performed. Model training and evaluation were performed for a range of for a 2D Dion-Jaconson lead halide perovskite models of different thickness and composition. The MLFF-MD trajectories were evaluated against AIMD trajectories to asses level of discrepancy and error accumulation. To examine the practical effectiveness of this approach we have used the MLFF-based MD trajectories to compute NAC and excited-state dynamics. At each stage, results based on machine learning are comapred to traditional ab initio-based electronic dissipative dynamics. We find that MLFF-MD provides comparable results to *ab initio* MDs when the MLFF is trained in a NpT ensemble.

Structure, Mechanical and Thermal Properties of Monolayer Amorphous Carbon and Boron Nitride Yuyang Zhang[1], Xi Zhang[1], Yupeng Wang[2], Shixuan Du[1] and Sokrates Pantelides[3]; [1]Chinese Academy of Sciences, China; [2]Central South University, China; [3]Vanderbilt University, United States

Amorphous materials exhibit various characteristics that are not featured by crystals and can sometimes be tuned by their degree of disorder (DOD). Here, we report results on the structures, mechanical and thermal properties of monolayer amorphous carbon (MAC) and monolayer amorphous boron nitride (maBN). The pertinent structures are obtained by kinetic-Monte-Carlo (kMC) simulations separately using empirical potential [1,2] and machine learning potentials (MLP) [3]. We find that despite conducting extensive validation on the reliability of empirical potentials for kMC simulations, and obtaining results consistent with DFT, kMC simulations using empirical potentials and more accurate MLP still yield significantly different results. Z-CRN containing crystallite instead of compositionally disordered "pseudocrystallite" is the favored structure of both elemental MAC and binary maBN. An intuitive order parameter, namely the areal fraction Fx occupied by crystallites within the Z-CRN, is proposed to describe the DOD. The mechanical and thermal properties of MAC and maBN were calculate via molecular dynamics simulation. The mechanical properties of MAC and maBN were found to be solely determined by Fx and are insensitive to the sizes and arrangements of crystallite. On the other hand, about two orders of magnitudes reduction in thermal conductivity was found in monolayer carbon after amorphization. The present results demonstrate the superiority of MLP over empirical potentials in the study of amorphous materials and reveal the relation between structures and properties in monolayer amorphous materials.

Sampling Complex Energy Landscapes in Material Science Using Data-Driven Force Fields Mihai-Cosmin Marinica; Université Paris-Saclay, France

Statistical methods, such as Machine Learning (ML) trained on physical data, can be invaluable when traditional approaches are limited or when their direct application is hampered by challenges like high computational costs. In materials science the interaction and transformation of crystal defects networks give rise to an extraordinarily diverse range of defect morphologies [1]. Additionally, accounting for chemical disorder presents another layer of complexity that is often overlooked in the emerging field of machine learning approaches. By utilizing the recently open-sourced MiLaDy (Machine Learning Dynamics) package [2] combined with accelerated Molecular Dynamics based on the Bayesian adaptive biasing force method [2], we aim to sample the intricate energy landscapes of defects by: (i) using methods that can identify complex networks of minima and saddle points at zero K; (ii) offering reliable force fields that handle intricate defects such as interstitials and dislocation loops; (iii) probing the atomistic free energy landscape of metals with ab initio accuracy up to the melting temperature [3]; (iv) examining chemical disorder in high entropy alloys (HEA); and, finally, (v) proposing surrogate models that sidestep traditional approaches to access challenging properties, like vibrational entropies [4].

10:45 AM *MT01.01.06
Physics-Based Molecular Modeling and Machine Learning for Accelerated Discovery of Metal-Organic Frameworks Diego A. Gomez Gualdron; Colorado School of Mines, United States

Metal-organic frameworks (MOFs) are a class of crystals, whose chemically and structurally tunable pores have made them exciting prospects for a myriad of applications across chemistry, engineering, and materials science. MOF tunability stems from a modular structure that can drastically (or subtly) vary by "mix and matching" potential constituent building blocks. This tunability, however, gives rise to an overwhelmingly large material design space that cannot be efficiently explored by experiments, or even by relying solely on traditional computational methods such as molecular simulation. In this presentation, I discuss some of the ways molecular simulation and machine learning have been combined to accelerate the navigation of databases of MOF computational "prototypes" for applications seeking to exploit selective sorption of molecules into MOF pores.

First, I discuss how the switch to a physics-based approach allowed us to address the issue of (sorption) data scarcity by allowing us to create "synthetic data" that led to the training of an effective multitasking machine learning model to predict sorption of a diversity of molecules in MOFs at a variety of thermodynamic conditions. The use of this model to find promising MOFs from a 50,000+ MOF database for removal of Xe and Kr in nuclear fuel reprocessing is demonstrated.

Second, I discuss the combination of physics-based MOF representations, traditional descriptor-based hierarchical screening, and iterative machine learning model training to efficiently explore a 10,000+ MOF database to find promising MOFs for product extraction in plasma reactors used for synthesis of NH3. The efficacy of the above combination of domain-knowledge and "off the shelf" machine learning tools is compared against more data-science involved approaches such as diversity-driven Bayesian optimization.

Large-Scale and Machine-Learning-Aided Investigations of Metal-Organic Frameworks for Water Harvesting Li-Chiang Lin[1,2], Yi-Ming Wang[1], Zhi-Xun Xu[1], Shiue-Min Shih[1], I-Ting Sung[1] and Archit Datar[2,3]; [1]National Taiwan University, Taiwan; [2]The Ohio State University, United States; [3]Celanese Corporation, United States

Water adsorption in metal-organic frameworks (MOFs) has recently drawn considerable attention for its tremendous potential in mitigating water scarcity. An important key to the development of such water harvesting technology to capture atmospheric water is the selection of optimal adsorbent materials. To date, tens of thousands of MOFs have been reported experimentally, while orders of magnitude more candidates have been theoretically predicted. Given the large materials space of available MOF adsorbents, computational studies, by employing state-of-the-art molecular simulations, play an important role in the selection of potential materials. In this study, a large-scale *in silico* screening, employing state-of-the-art Monte Carlo techniques, is conducted to explore more than 10,000 MOF candidates that are included in the CoRE (Computational-Ready Experimental) MOF database for their potential in water harvesting. While the widely used grand canonical Monte Carlo (GCMC) simulations to compute water adsorption can converge very slowly may therefore yield unreliable results, the large-scale computations performed herein employ a method, denoted as the flat-histogram-based C-map method reported by some of us [1,2], to determine the water adsorption capability and capacity of MOFs. Through extensively studying a diverse set of MOFs, our results identify promising candidates as well as shed light on the structure-property relationships. Moreover, to facilitate the future development of optimal water adsorbents, machine learning models are also developed. Specifically, tree-based methods such as random forest as well as convolution neural networks (CNNs) are employed. For the former, aside from including commonly used structural features such as largest cavity diameter and surface area, a newly developed metric – the so-called continuously adsorption channel (CAC) recently developed by some of us [3], is also used to help develop more accurate models. For the latter, computer vision techniques are exploited to "see" the structures directly for model training, followed by making quantitative predictions. These machine learning models are also investigated to better understand the structure-property relationship in a quantitative manner. Overall, this work represents a synergistic effort between large-scale molecular simulations and machine learning studies, and we anticipate the outcomes achieved herein can facilitate future computational and experimental efforts on the development of optimal water adsorbents.

Accelerating The Selection of High Uptake Covalent Organic Frameworks with Supervised Machine Learning for Methane Storage Niraj Bhatt, Sandip Thakur and Ashutosh Giri; University of Rhode Island, United States

Covalent organic frameworks (COFs) have been identified as ideal candidates for natural gas storage and catalysis applications primarily because of their tunable microstructure as well as the vast design space for their chemical makeup. COFs with high gas uptake values at workable pressures are highly desired for applications such as gas storage, carbon capture and catalysis. Methane (CH_4) storage is highly sought after because of the low carbon-hydrogen ratio, high calorific value and natural abundancy. However, the vast design space for COFs makes the screening of high CH_4 uptake COFs very difficult as it requires time-intensive grand-canonical Monte Carlo (GCMC) simulations to calculate the uptake values. To overcome this challenge, we employ machine learning to develop a model that captures the structure-property relationship in COFs using a large in-silico database of hypothetical COFs. A machine learned regression model based on powerful random forest algorithm is developed that maps the structural and chemical features of the 5000 COFs used in training to their uptake values. The validated model is then used to find the uptakes of COFs in the experimental database eliminating the need of resource intensive GCMC. Thousands of diverse COFs are selected from the database and featurized using MATMINER, a powerful inbuilt python library used in material's informatics. The features are used to uniquely represent each COF which is mapped to their respective CH_4 uptake values during training of the ML model. The feature space includes the chemical features like elemental property features and structural features like radial distribution functions and density-based structural features. Various dimensionality reduction techniques like feature selection using co-relation analysis and feature extraction using principal component analysis are employed to make an accurate and efficient ML model. We employed this model to predict the CH_4 uptake values for an experimental database of ~ 600 COFs and screened top performers with CH_4 uptake values as high as 1260 molecules/unitcell.

Investigating The Binding Interactions between Newly Synthesized Metal-Organic Frameworks (MOF) and Organic Pollutants Using Computational Chemistry Melissa Mapula, Shiru Lin and Manal Omary; Texas Woman's University, United States

Benzene and toluene are hazardous organic pollutants due to their potential health effects. Benzene is a known carcinogen and exposure to high levels of toluene can cause central nervous system depression. Applying porous materials for the removal of benzene and toluene can be an effective approach for mitigating the environmental and health impacts of these organic pollutants. Metal-organic frameworks (MOFs) are a type of porous material consisting of metal nodes connected by organic linkers. MOFs have unique properties such as high surface area, tunable pore size, and the ability to selectively adsorb small molecules, making MOFs promising candidates for various applications including removing pollutants. In our study, we apply computational chemistry methods to investigate interactions of organic pollutants and synthesized MOF structures, such as MOF-TW1, which was formed from the crystals of the reaction of Cu(I) and Ag(I) precursors with pyrazine (Pyz) and piperazine (Ppz) and boasting a significant surface area of (1278 m^2/g) and porosity of 23.7% void volume. We investigate the adsorption ability of MOF structures toward organic pollutants, which can guide the design and modification of MOFs for more organic pollutant absorptions and removals. Furthermore, we apply machine learning algorithms to predict organic pollutant absorption performances on synthesized MOF structures.

Invariant Graph Neural Network Models for Accelerated Prediction of Equilibrium Structure, Defect Energetics and Electronic Properties of Semiconductor Materials Brian L. DeCost, Kamal Choudhary and Francesca Tavazza; National Institute of Standards and Technology, United States

Accelerated material property predictions are an important component of large scale search and optimization of new semiconductor device materials. We present ongoing work developing and applying invariant graph neural network models for modeling the properties of multicomponent semiconductor materials. We use such models to predict defect energetics in semiconductor materials. Initial results on prediction of equilibrium interface structures and electronic properties in semiconductor heterointerface systems will be discussed as well. Robust and fast uncertainty quantification methods are of particular concern for predictive design of semiconductor heterointerface systems, for which currently-available reference data is limited. We will discuss how we use graph neural network uncertainty quantification for active learning of force fields, out-of-distribution detection for predictive models, and for targeted allocation of theory-based modeling.

2:00 PM *MT01.02.02
Uncertainty-Quantification-Driven Autonomous Workflows for Upscaling of Complex Materials Properties Danny Perez; Los Alamos National Laboratory, United States

Many engineering models for require parametric or functional inputs that can in principle be obtained from lower scale simulations. For example, transport coefficients for radiation-induced defects computed from molecular dynamics can be used to inform kinetic Monte Carlo models, that can themselves inform cluster-dynamics simulation of microstructural evolution. However, in many cases, the number of lower-scale calculations required to obtain these higher-scale properties can be very large, which can lead to extremely long times-to-solution, especially when human intervention is needed at any step of the process. We demonstrate how tailored uncertainty-quantification approaches can be used to autonomously drive the execution of upscaling workflows at large computational scales. I will show how information can be systematically upscaled into different representations in order to develop reliable reduced-order models from simulation data.

2:30 PM MT01.02.03
A Physics Informed Bayesian Optimization Approach for Material Design Raymundo Arroyave; Texas A&M University, United States

The design of materials and identification of optimal processing parameters constitute a complex and challenging task, necessitating efficient utilization of available data. Bayesian Optimization (BO) has gained popularity in materials design due to its ability to work with minimal data. However, many BO-based frameworks predominantly rely on statistical information, in the form of input-output data, and assume black-box objective functions. In practice, designers often possess knowledge of the underlying physical laws governing a material system, rendering the objective function not entirely black-box, as some information is partially observable. In this study, we propose a physics-informed BO approach that integrates physics-infused kernels to effectively leverage both statistical and physical information in the decision-making process. We demonstrate that this method significantly improves decision-making efficiency and enables more data-efficient BO. The applicability of this approach is showcased through the design of NiTi shape memory alloys, where the optimal processing parameters are identified to maximize the transformation temperature.

Materials Discovery for High-Temperature Clean-Energy Applications (and Beyond) via Defect Graph Neural Networks Matthew Witman[1], Anuj Goyal[2], Tadashi Ogitsu[3], Anthony McDaniel[1] and Stephan Lany[2]; [1]Sandia National Laboratories, United States; [2]National Renewable Energy Laboratory, United States; [3]Lawrence Livermore National Laboratory, United States

We present a graph neural network (GNN) approach that fully automates the prediction of defect formation enthalpies for any crystallographic site from the ideal crystal structure, without the need to create defected atomic structure models as input [1]. Using density functional theory (DFT) reference data for vacancy defects in oxides, we trained a defect GNN (dGNN) model that replaces the DFT supercell relaxations otherwise required for each symmetrically unique crystal site. Interfaced with thermodynamic calculations of reduction entropies and associated free energies, the dGNN model is applied to the screening of oxides in the Materials Project database, connecting the zero-Kelvin defect enthalpies to high-temperature process conditions relevant for solar thermochemical hydrogen production and other energy applications. The dGNN approach is applicable to arbitrary structures with an accuracy limited principally by the amount and diversity of the training data, and it is generalizable to other defect types and advanced graph convolution architectures. It will aid tackling future materials discovery problems in clean energy and beyond.

Machine Learning Based Electronic Structure Prediction: From Nanostructures to Complex Alloys Amartya S. Banerjee[1], Shashank Pathrudkar[2], Shivang Agarwal[1], Susanta Ghosh[2], Stephanie Taylor[1], Hsuan Ming Yu[1] and Ponkrshnan Thiagarajan[2]; [1]University of California, Los Angeles, United States; [2]Michigan Technological University, United States

I will describe our work on using specialized first principles calculations with machine learning tools to enable prediction of the electronic structure of various nanomaterials and bulk systems. I will focus on two related but independent directions. First, I will show how helical and cyclic symmetry adapted density functional theory calculations may be used to train interpretable machine learning models of the electronic fields of quasi-one-dimensional materials. The descriptors in this framework are global geometry and strain parameters. Through examples involving distorted carbon nanotubes, I will show how the framework can be particularly accurate in its prediction, even with limited training data. I will discuss the use of this framework for automated materials discovery, and in multiscale modeling.

Second, I will discuss the use of high-throughput first principles calculations to train machine learning models of bulk systems, possibly featuring some degree of disorder in atomic arrangements. The descriptors in this framework are local in nature and the prediction of electronic fields occurs in a pointwise manner spatially. I will describe how a combination of strategies, including transfer learning, thermalization, and the use of Bayesian Neural Networks can allow the development of machine learning models that are systematic, reliable, and very efficient (both in terms of training and prediction). I will discuss the use of this framework for calculation of the electronic structure of bulk solids with defects, and compositionally complex alloys, from which, other material properties of engineering interest may be inferred. I will end with a discussion of future research directions.

4:00 PM MT01.02.06
Learning Polarization Using Equivariant Neural Networks Stefano Falletta[1], Andrea Cepellotti[1], Albert Musaelian[1], Anders Johansson[1], Chuin Wei Tan[1] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch Research and Technology Center, United States

Polarization is an essential physical quantity for understanding the properties of dielectrics and ferroelectrics [1]. The modern theory of polarization [1] and further developments on electric enthalpy functionals [2] have enabled the study of polarization in periodic electronic structure calculations. Interestingly, predicting the polarization over a molecular dynamics allows for the determination of experimentally-relevant quantities such as infrared and Raman spectra from first principles. However, this remains a challenging problem in electronic structure calculations, because of their high computational cost.

Here, we introduce an equivariant neural network approach to efficiently learn and predict polarization for each atomic configuration, building on and extending state-of-the-art machine learning force field architectures. This allows one to determine the autocorrelation function of polarization over long-lasting molecular dynamics, thereby giving access to infrared spectrum, frequency-dependent dielectric constant, and Raman cross section from first principles. We implemented our scheme in the E(3)-equivariant NequIP/Allegro framework [3,4], and interfaced it with the LAMMPS code for performing molecular dynamics calculations.

4:15 PM MT01.02.07
***Ab Initio* Investigations of a Two Dimensional form of Silicon featuring Dispersionless Electronic States** Chenhaoyue Wang and Amartya Banerjee; UCLA, United States

Materials with dispersionless electronic states (or flat bands) have been intensely investigated in recent years, owing to their association with strongly correlated electrons. Due to the negligible kinetic energies of electrons in such states, the electron-electron interaction dominates, thus resulting in superconductivity, ferromagnetism, and other exotic phases of matter. While a number of bulk materials and heterostructures have been investigated for their connection with flat-band physics, the discovery of new, simple low-dimensional materials with such electronic features, continues to be an alluring possibility. Following this line of thought, and motivated by the consideration that silicon is a versatile material with many known low-dimensional allotropes that have already been experimentally synthesized, we investigate here a two-dimensional form of silicon in the decorated honeycomb (or star) lattice. The proposed material has a buckled structure similar to silicene, consists of dodecagonal rings, and features electronic flat bands near the Fermi-level. We describe extensive first principles investigations into the static and dynamic structural stability of the material and observe that in-plane strains stabilize it. Furthermore, the bandwidth of the flat band is found to be highly tunable with strains. Finally, we investigate the possibility of using substrates to apply such stabilizing strains, suggesting the fabricability of this novel two dimensional material under experimental conditions.

4:30 PM MT01.02.08
Atomistic Modeling of Advanced Transistor Gate Stack Using Graph Neural Networks Pratik Brahma[1], Krishnakumar Bhattaram[1], Jack Broad[2,2], Sinead M. Griffin[2,2] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Modern microelectronic devices such as silicon transistors are composed of multiple material interfaces whose electronic interactions significantly affect electron transport and, ultimately, device performance. These complex interfacial interactions between various materials of crystalline, polycrystalline, and amorphous phases, as well as boundary effects such as quantum confinement, present a significant challenge to the atomistic modeling of electronic devices. Traditional modeling approaches often use ab-initio methods such as density functional theory for molecular dynamics and electronic structure calculations. However, these methods scale poorly with increasing system size as they rely on diagonalization of the quantum Hamiltonian, posing a challenge for fast and accurate simulations of electronic devices that contain thousands of atoms and various structural phases.
In this work, we demonstrate the viability of graph neural networks (GNNs) [1, 2] to overcome this scaling challenge. Our architecture is designed to accelerate ab-initio molecular dynamics and electronic structure calculations by characterizing the relationships between local chemical environments and global electronic transport properties such as carrier injection velocity and gate capacitance. For given macroscopic transistor dimensions, we use our neural network predicted atomic forces to generate the heterogeneous crystalline silicon channel–dielectric gate stack (amorphous SiO_2-amorphous HfO_2), with bond lengths within 3% of experimental values. Furthermore, we predict global electronic (density of states) and transport properties (injection velocity) of crystalline nanoslab silicon channels, showing good agreement—within 0.18% for density of states and 5.4% for injection velocity—with the baseline material simulation model for channel thicknesses outside the training domain, while also accelerating the simulation speed by four orders of magnitude. The obtained accuracies demonstrate that our neural network captures the structural confinement effects of thin silicon channels in advanced transistors. Overall, the scalability and accuracy of our predictions over a wide range of material and transport properties demonstrate the efficacy of GNNs to accelerate advanced electronic device simulations, paving the way for rapid design and modeling of next-generation transistors.

Electronic Stopping Power Predictions from Machine Learning Andre Schleife[1], Logan Ward[2], Cheng-Wei Lee[3], Ben Blaiszik[2] and Ian T. Foster[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Argonne National Laboratory, United States; [3]Colorado School of Mines, United States

We aim to develop an affordable computational approach that provides the electronic stopping power for arbitrary trajectories of ions impacting a target material with an accuracy comparable to that of modern quantum mechanical first-principles simulations. Currently, real-time time-dependent density functional theory can accomplish this in reasonable agreement with experiment. However, the computational cost of this method is high which limits the number of trajectories and host material atomic geometries that can be studied. This prevents a routine integration of electronic-stopping power, e.g. in the molecular dynamics simulation of radiation damage cascades. We use cutting-edge descriptors of atomic geometries to train modern machine-learning models on data from real-time time-dependent density functional theory. We find very low error bars and very high accuracy at million-fold reduced computational cost of the trained model for proton irradiated aluminum. We also are able to predict velocity dependent electronic stopping and entire Bragg peak simulations with our models. In this presentation we discuss our framework in detail as well as its broad applicability in the particle-radiation community, including target materials with complex atomic geometry or low-dimensional materials.

SESSION MT01.03: Machine Learning and Simulations III
Session Chairs: Joshua Agar and Elif Ertekin
Tuesday Morning, April 23, 2024
Room 320, Level 3, Summit

10:30 AM *MT01.03.01
Ultra-Compact and Parsimonious Machine Learning Frameworks for High-Velocity Scientific Discovery in Materials Microscopy Joshua Agar; Drexel University, United States

Machine learning (ML) offers unparalleled opportunities for accelerating advancements in materials microscopy. Yet, practical implementation often stumbles due to the lack of models that are both machine-interpretable and conforming to underlying physical laws, as well as the absence of specialized computational infrastructure for automated data analytics. We address these bottlenecks by focusing on the codesign of microscopy technique, ultra-compact physics-aware ML models, connection to physics-inspired models, and bespoke hardware solutions.
Our contribution is three-fold. First, we present a robust infrastructure for the automated aggregation and management of high-velocity synthesis data, including real-time in-situ diagnostics. We introduce a federated, searchable scientific data management system optimized for high-throughput analysis. This infrastructure allows robust linkages between experiment and theory. Second, we go beyond traditional ML approaches by introducing highly parsimonious, physics-conforming neural networks specifically tailored for real-time analysis of band-excitation piezoresponse force microscopy data. These models are meticulously codesigned to be executable on field-programmable gate arrays (FPGAs) for edge-real-time analytics.
Lastly, we unveil a neural network architecture aimed at automating 4D–scanning transmission electron microscopy strain mapping. Leveraging a cycle-consistent spatial transforming autoencoder, we incorporate an affine transformation layer to parsimoniously capture the governing equations of geometric transformations. This is further optimized through advanced compression, regularization, and optimization strategies to facilitate the otherwise computationally intensive training process. Remarkably, our method outperforms traditional template-matching techniques, achieving a sub-pixel precision of 0.3, as benchmarked against py4DSTEM.
In sum, this work offers a comprehensive blueprint for seamlessly incorporating ultra-compact and parsimonious AI systems into the analysis of large-scale, high-velocity, and noise-prone experimental datasets. This facilitates closer connections between experiments and theory thereby revolutionizing the practical utility of AI in scientific discovery.

11:00 AM MT01.03.02
Learning Latent-Variable Representations of Microstructure Accounting for Materials Stochasticity Sajad Hashemi[1], Michael Guerzhoy[1,2] and Noah H. Paulson[3]; [1]University of Toronto, Canada; [2]Li Ka Shing Knowledge Institute, St. Michael's Hospital, Canada; [3]Argonne National Laboratory, United States

Over the past decade, generative machine learning has found application in the design of materials with tailored properties. Generative latent-variable models represent high-dimensional data in low-dimensional spaces. The original data is n-dimensional, for example, 2-D/3-D image-based representations of materials microstructure with k pixels/voxels. New plausible examples of image-based representations can be generated from points in the low-dimensional space. The variational autoencoder (VAE) is a popular latent-variable model. The VAE is learned by optimizing the L2 distance in data space (2-D/3-D) between real and generated examples (in addition to regularization). This is suboptimal, since materials microstructure is stochastic. Therefore, image-based representations should be considered similar if their statistical properties are similar rather than just if they are close in Euclidean data space. We develop a novel VAE architecture to prioritize statistical representations of materials microstructure and the generation of statistically similar microstructure examples from a single location in the latent space. A successful implementation of this architecture would greatly aid materials development and optimization through iterative materials simulations. This novel capability will be demonstrated on both synthetic and natural microstructure datasets.

11:15 AM MT01.03.03
Spatial Atomic Structure Reconstruction for Transmission Electron Microscopy Images Using a Deep Learning Algorithm Congjie Wei[1], Chenglin Wu[1] and Jiaxin Zhang[2]; [1]Texas A&M University, United States; [2]Intuit, United States

With the significant improvements and developments in transmission electron microscopes (TEM) techniques, accurate observation and identification is now more commonly adopted in angstrom-level precision, which reveals as sequential images about the real-space information. However, it still has difficulties to analyze the spatial defect distribution, phase transformation and dynamic phenomena since the TEM images can only record the appearances of the surface atoms while the out-of-plane information is severely missing. In this work, a first principle based deep learning algorithm is proposed and adopted to reconstruct the 3D transition states of a MXene healing process experimentally observed. Starting from the TEM image, all related Ti and C atoms around or within the laser-made hole could be categized into 3 groups based on the confidence of the information obtained from the TEM images. Around hole atoms are assumed to have crystalline structure and set as the input along with the in-plane information of atoms that can be observed directly within the hole. Out-of-plane information of the latter group of atoms are then treated as the output of the algorithm along with the spatial distribution of all underlying atoms. The input and output information are reformed into graphical representations and treated as a graph reference problem. The trunk of this algorithm is set as a deep convolutional neural network incorporated with attention-based and non-attention-based components. To conform to the distance prediction, smooth potentials are constructed for Ti-Ti, Ti-C and C-C interactions based on first principle calculation. Simplified potentials are constructed based on this calculation as well as possible bond length ranges from all type of structures. The minimum potential energy accumulation of all atoms within the hole is set as one of the convergence conditions of the algorithm along with the fitting of the training data sets. Our models are trained on defected MXene structures optimized with DFT, where different sizes and number of atoms are considered. The predictions of this algorithm fit well with the TEM images and help with the understanding of the healing processes observed in MXene materials.

A Flexible Formulation of Value for Experiment Interpretation and Design Matthew Carbone; Brookhaven National Laboratory, United States

Optimal design of experiments is an outstanding challenge in the materials science community. Standard techniques such as Bayesian optimization can address this challenge as long as the goal of an experimental campaign is maximizing some observable. While useful in a wide variety of cases, it is insufficient to address more epistemic goals, such as thoroughly exploring a sample space when an explicit objective is lacking. In this work, we showcase a formulation of "scientific value," a scalar representation of local uniqueness. Our method scalarizes arbitrarily high-dimensional data, allowing for the traditional optimization toolbox to be applied to any problem. Intuitively, our method, which we call the Scientific Value Agent, explores regions of space in which observables change rapidly, whilst exploring other areas sufficiently, wasting minimal experimental budget. It is also robust to the cold start problem, and can be utilized with no prior knowledge and next-to-no data. We demonstrate this technique by exploring a variety of simulated and real-world examples, including phase boundaries, autonomously changing the temperature measurement of a ferroelectric material, and analyzing nanoparticle synthesis data. Our method can be seamlessly extended to studies with multiple outputs, or fidelities, and can seamlessly integrate into existing autonomous experimentation frameworks with minimal added effort to the user.

Simultaneous Analysis of Wide Angle X-Ray Scattering Data (WAXS) and Extended X-Ray Absorption Fine Structure Spectroscopy (EXAFS) of Very Small Nanoparticles Markus Winterer and Jeremias Geiss; University of Duisburg-Essen, Germany

Although experiments investigating the atomistic structure of disordered materials are today facile through modern instruments for X-ray scattering and spectroscopy, it is still a challenge to extract the relevant information especially in case of very small nanoparticles with a diameter smaller than 10 nm. In our contribution we will present recent advances in data analysis of this inverse problem using Reverse Monte Carlo (RMC) analysis [1].

RMC simulations enable the analysis of WAXS data as well as EXAFS spectra via partial pair distribution functions (pPDF) obtained from a physical, structural model. In case of nanoparticles and scattering data this approach suffers from the termination of the pPDFs due to the finite size of the particles. This produces artifacts in the computed scattering intensity due to the long-range probing distance of scattering which are eliminated by using the Debye scattering equation (DSE) for computing the scattering intensity from a particle model. Computational efficiency is provided by binning the distance distribution of atom pairs in the DSE.

Data fusion, i. e. simultaneous refinement of WAXS data and EXAFS spectra of small nanoparticles, is thus enabled using a mutual structural model. Therefore, this method allows the self-consistent extraction of complementary information on the local structure contained in EXAFS and on the long-range order in WAXS data. We describe this novel method for the nanocrystalline complex oxide $LaFeO_3$ [1]. The results are highly relevant for example for heterogeneous catalysis [2].

The method described can be further developed to additionally include small angle scattering data and provides an interface either via the (atomistic) structural model or the pPDFs to other physics simulation and materials modeling methods such as molecular dynamic (MD) simulations or density functional theory (DFT) modeling.

Campaign Design for Autonomous Experimentation in Materials Research Benji Maruyama; AFRL/RXA, United States

The current materials research process is slow and expensive; taking decades from invention to commercialization. The Air Force Research Laboratory pioneered ARES™, the first autonomous experimentation system for materials development. A rapidly growing number of researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of making research progress orders of magnitude faster than today. We will discuss concepts and advances in autonomous experimentation in general, and associated hardware, software and autonomous methods.

Campaign design for autonomous experimentation or self-driving labs is complex and dependent on research objectives, experimental apparatus, analysis capabilities and decision strategies. Examples of autonomous experimentation campaigns to explore important aspects of campaign design will be given.

Beyond Fingerprinting: Process Exploration and Optimization via High-Throughput and Machine Learning Brad L. Boyce[1,2]; [1]Sandia National Laboratories, United States; [2]Center for Integrated Nanotechnologies, United States

Material properties are governed by composition and associated microstructure dictated by the thermodynamics and kinetics of manufacturing processes. Often, the connectivity between process conditions and the resulting structure and properties is complex, evading full predictivity via high-fidelity modeling. In this work, we are exploring three manufacturing processes where material properties are difficult to predict directly from process settings: electroplating, physical vapor deposition, and additive manufacturing (laser powder bed fusion). Each of the three processes offer unique challenges and opportunities. Across these three exemplars, we are augmenting traditional process-structure-property investigations with an accelerated workflow to detect material structure/composition, prognose associated properties, and adapt the associated process to achieve improved product outcomes. This accelerated detect-prognose-adapt cycle is aided by three key elements: (1) automated combinatorial synthesis to enable rapid parameter sweeps, (2) high-throughput evaluation of both conventional and surrogate indicators of material chemistry, structure, and properties, and (3) machine learning algorithms to unravel correlations in high-dimensional spaces beyond expert cognition. In each of these three domains, we take advantage of previously developed capabilities, or where such capabilities are insufficient, we develop novel techniques. For example, in the domain of electroplating synthesis, we have employed an existing robotic pipetting system for formulation of solution chemistries while developing a custom 12-cell parallel electroplating system that enables hundreds of unique conditions to be explored in about a day. While we consider purely data-driven ML algorithms for some correlation analysis, a more interpretable and robust solution includes physical models based on established governing equations. In this regard, we have developed a physics-informed multimodal autoencoder that fuses data from multiple modalities alongside physical models to provide a deeper fingerprint of material state, enabling unsupervised detection of high-dimensional clusters and cross-modal correlations. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

2:30 PM MT01.04.03
Leveraging Physics and Machine Learning to Predict Battery Aging Michael J. Kenney[1], Maxim Ziatdinov[2], Katerina Malollari[1] and Sergei Kalinin[3]; [1]Amazon Lab126, United States; [2]Oak Ridge National Laboratory, United States; [3]The University of Tennessee, Knoxville, United States

A primary concern with lithium-ion battery technology is the performance deterioration over time. Capacity retention, a vital performance measure, is frequently utilized to assess whether these batteries have approached their end-of-life. Machine learning offers a powerful tool for predicting capacity degradation, leveraging both past data and physical knowledge in the form of simulations or phenomenological models. In this study, we showcase the utility of probabilistic machine learning and transformer-based deep learning modeling in battery health prediction. For our probabilistic models, which operate without pre-training, we employ: i) a structured Gaussian process (GP) - an enhanced version of the standard GP that integrates a phenomenological model as a probabilistic prior mean function, and ii) a multi-fidelity GP, augmented by prior physics-based simulations to boost its predictive power. Concurrently, we deploy time-series transformers pre-trained on existing datasets for forecasting purposes. Our findings juxtapose these models, offering insights into their optimal application scenarios, and the associated codes are open for access.

Understanding Complex Crystal Structures and Phase Transitions through Self-Assembly Simulations Julia Dshemuchadse; Cornell University, United States

How do atoms come together to form crystal structures? Powerful theoretical and experimental tools exist to elucidate the structure of crystalline materials on multiple length scales. Directly observing the formation of their ordered structures, however, remains supremely challenging. How can we understand the path that a material takes to its crystalline state? We take a general approach toward understanding crystallization across multiple materials families by simulating their self-assembly using simple coarse-grained models, in order to investigate the emergence of long-range order from short-range interactions. In this way, we gain systematic insights into the phenomena that lead to the crystallization into even complex types of order, such as materials with large unit cells or aperiodic crystals. Our goal is to use these insights to find ways to tailor crystallization pathways and to create new materials. In this talk, I will discuss the broad spectrum of structural phenomena captured with particles that interact via simple isotropic pair potentials, which we apply to study crystal growth and solid–solid phase transformations. Our work promises to establish new pathways to materials design through simulations, which explicitly incorporate and explore phase transformation kinetics.

3:45 PM *MT01.04.05
Deep Learning Probability Flows and Entropy Production Rates in Active Matter Eric Vanden-Eijnden; New York University, United States

Active matter systems, from self-propelled colloids to motile bacteria, are characterized by the conversion of free energy into useful work at the microscopic scale. These systems generically involve physics beyond the reach of equilibrium statistical mechanics, and a persistent challenge has been to understand the nature of their nonequilibrium states. The entropy production rate and the magnitude of the steady-state probability current provide quantitative ways to do so by measuring the breakdown of time-reversal symmetry and the strength of nonequilibrium transport of measure. Yet, their

efficient computation has remained elusive, as they depend on the system's unknown and high-dimensional probability density. In this talk, building upon recent advances in generative modeling, I will present a deep learning framework that allows for the estimation of the gradient of the logarithm of this density, a quantity know as the score in the machine learning literature. This score, together with the microscopic equations of motion, gives direct access to the entropy production rate, the probability current, and their decomposition into local contributions from individual particles, spatial regions, and degrees of freedom. I will demonstrate the broad utility and scalability of the method by applying it to several high-dimensional systems of interacting active particles undergoing motility-induced phase separation (MIPS).

4:15 PM MT01.04.06
Programming Soft Materials with JAX-MD Chrisy Xiyu Du[1,2], Ella King[3,2], Qian-Ze Zhu[2], Samuel S. Schoenholz[4] and Michael Brenner[2]; [1]University of Hawai'i at Mānoa, United States; [2]Harvard University, United States; [3]Simons Foundation, United States; [4]OpenAI, United States

Soft Materials are ubiquitous in everyday life and are crucial in many different forms of revolutionary technologies. One property of Soft Materials is their ability to self-assemble into intricate structures from a finite set of building blocks with continuously tunable parameters. This giant design space of building blocks is a double-edged sword: on one side it provides researchers infinite possibilities to design building blocks for targeted functions, while on the other side it might take forever to search the design space. Here, we propose a new inverse design method that captures both interaction and geometry of building blocks. By enabling rigid body functionalities in JAX-MD, an end-to-end differentiable molecular dynamics engine, we can create soft materials model with components that are simple enough to design yet powerful enough to capture complex materials properties. In this talk, I will discuss the implementation of the methods alongside examples to showcase its potential applications.

4:30 PM MT01.04.07
Representation-Space Diffusion Models for Generating Periodic Materials Anshuman Sinha, Shuyi Jia and Victor Fung; Georgia Institute of Technology, United States

Generative models hold the promise of significantly expediting the materials design process when compared to traditional human-guided or rule-based methodologies. However, effectively generating high-quality periodic structures of materials on limited but diverse datasets remains an ongoing challenge. Here we propose a novel approach for periodic structure generation which fully respect the intrinsic symmetries, periodicity, and invariances of the structure space. Namely, we utilize differentiable, physics-based, structural descriptors which can describe periodic systems and satisfy the necessary invariances, in conjunction with a denoising diffusion model which generates new materials within this descriptor or representation space. Reconstruction is then performed on these representations using gradient-based optimization to recover the corresponding Cartesian positions of the crystal structure. This approach differs significantly from current methods by generating materials in the representation space, rather than in the Cartesian space, which is made possible using an efficient reconstruction algorithm. Consequently, known issues with respecting periodic boundaries and translational and rotational invariances during generation can be avoided, and the model training process can be greatly simplified. We show this approach can provide competitive performance on established benchmarks compared to current state-of-the-art methods.

Combining Data, Physics and Machine Learning for Accelerating Materials Computations Boris Kozinsky and Albert Musaelian; Harvard University, United States

Discovery and understanding of next-generation materials requires a challenging combination of the high accuracy of first-principles calculations with the ability to reach large size and time scales. We pursue a multi-tier method development strategy in which machine learning (ML) algorithms are combined with exact physical symmetries and constraints to significantly accelerate computations of electronic structure and atomistic dynamics. First, density functional theory (DFT) is the cornerstone of modern computational materials science, but its current approximations fall short of the required accuracy and efficiency for predictive calculations of defect properties, band gaps, stability and electrochemical potentials of materials for energy storage and conversion. To advance the capability of DFT we introduce non-local charge density descriptors that satisfy exact scaling constraints and learn exchange functionals called CIDER [1]. These models are orders of magnitude faster in self-consistent calculations for solids than hybrid functionals but similar in accuracy. On a different level, we accelerate molecular dynamics (MD) simulations by using machine learning to capture the potential energy surfaces obtained from quantum calculations. We developed NequIP [2] and Allegro [3], the first deep equivariant neural network interatomic potential models, whose Euclidean symmetry-preserving layer architecture achieves state-of-the-art data efficiency and accuracy for simulating dynamics of molecules and materials. In parallel, we implement autonomous active learning of interactions in reactive systems, with the FLARE algorithm that constructs accurate and uncertainty-aware Bayesian force fields on-the-fly from a molecular dynamics simulation, using Gaussian process regression [4]. These MD simulations are used to explore long-time dynamics of phase transformations and heterogeneous reactions.

Not as Simple as We Thought: A Rigorous Examination of Data Aggregation in Materials Informatics Taylor D. Sparks[1,2], Federico Ottomano[2], Giovanni De Felice[2] and Vladimir Gusev[2]; [1]University of Utah, United States; [2]University of Liverpool, United Kingdom

Recent Machine Learning (ML) developments have opened new possibilities for materials research. However, due to the underlying statistical nature, the performance of ML estimators is heavily affected by the quality of training datasets, which are severely limited and fragmented in the case of materials

informatics. Here, we investigate whether state-of-the-art ML models for property predictions can benefit from the aggregation of different datasets. We probe three different aggregation strategies in which we prioritize training size, element diversity, and composition diversity by using novelty scores from the DiSCoVeR algorithm. Surprisingly, our results consistently show that both simple and refined data aggregation strategies lead to a reduction in performance. This suggests caution when merging different experimental data sources. To guide the size increment, we compare the use of DiSCoVeR, which prioritizes chemical diversity, with a random selection. Our results show that targeting novel chemistries is not beneficial in building a training dataset.

9:30 AM MT01.05.03
Leveraging Fragment-Based Representations in Active Learning and Reinforcement Learning Frameworks for Materials Design Daniel Tabor; Texas A&M University, United States

This talk will focus on the development and application of two types of methods for accelerating materials design. First, we will focus on developing reinforcement learning methods that are used to accelerate the design of functional materials, including radical-based polymers and organic optoelectronic materials. In our first demonstration of the reinforcement learning scheme, we show that this framework can integrate with quantum chemistry calculations in real-time, and through a careful design of the learning curriculum, we are able to find a diverse set of molecules with desired singlet and triplet energy levels. Second, we will describe our work on developing representations for predicting the polymer physics of disordered polymers at a much lower computational cost than current coarse-grained methods. One advantage of the new representation is that it avoids specifying the longest length of the chain in advance. In addition, this representation works well with a set of highly charged sequences, uncovering new insights to the fundamental interactions and scaling behavior of these systems. We will then discuss the compatibility of this representation with reinforcement learning methods.

9:45 AM MT01.05.04
Physics Supervised Deep Learning-Based Optimization (PSDLO) with Accuracy and Efficiency Hanqing Jiang and Xiaowen Li; Westlake University, China

Identifying efficient and accurate optimization algorithms is a long-desired goal for the scientific community. At present, a combination of evolutionary and deep-learning methods is widely used for optimization. In this paper, we demonstrate three cases involving different physics and conclude that no matter how accurate a deep-learning model is for a single, specific problem, a simple combination of evolutionary and deep-learning methods cannot achieve the desired optimization because of the intrinsic nature of the evolutionary method. We begin by using a physics-supervised deep-learning optimization algorithm (PSDLO) to supervise the results from the deep-learning model. We then intervene in the evolutionary process to eventually achieve simultaneous accuracy and efficiency. PSDLO is successfully demonstrated using both sufficient and insufficient datasets. PSDLO offers a new perspective for solving optimization problems and can tackle complex science and engineering problems having many features. This new approach to optimization algorithms holds tremendous potential for application in real-world engineering domains.

10:30 AM *MT01.05.05
End-To-End Differentiability and Tensor Processing Unit Computing (TPU) to Accelerate Materials' Inverse Design Mathieu Bauchy; University of California, Los Angeles, United States

Numerical simulations have revolutionized material design. However, although simulations excel at mapping an input material to its output property, their direct application to inverse design has traditionally been limited by their high computing cost and lack of differentiability. Here, taking the example of the inverse design of a porous matrix featuring a target sorption isotherm, we introduce a computational inverse design framework that addresses these challenges. First, we adopt end-to-end differentiability to build a differentiable forward numerical simulation. Thanks to its differentiability, the forward simulation is used to directly train a backward deep generative model, which outputs an optimal porous matrix based on an arbitrary input sorption isotherm curve. Second, this inverse design pipeline leverages the power of tensor processing units (TPU)—an emerging family of dedicated chips, which, although they are specialized in deep learning, are flexible enough for intensive scientific simulations. This approach holds promise to accelerate the inverse design of novel materials with tailored properties.

11:00 AM *MT01.05.06
Accelerated Development of Materials Using High-Throughput Strategies and AI/ML Surya R. Kalidindi; Georgia Institute of Technology, United States

The dramatic acceleration of the materials innovation cycles is contingent on the development and implementation of high throughput strategies in both experimentation and physics-based simulations, and their seamless integration using the emergent AI/ML (artificial intelligence/machine learning) toolsets. This talk presents recent advances made in the presenter's research group, including: (i) a novel information gain-driven Bayesian ML framework that identifies the next best step in materials innovation (i.e., the next experiment and/or physics-based simulation to be performed) that maximizes the expected information gain towards a specified target (e.g., optimized combination of material properties, refinement of a material constitutive response), (ii) computationally efficient versatile material structure analyses and statistical quantification tools, (iii) formulation of reduced-order process-structure-property models that enable comprehensive inverse solutions needed in materials design (e.g., identifying specific compositions and/or process histories that will produce a desired combination of material properties), and (iv) high throughput experimental protocols for multi-resolution (spatial resolutions in the range of 50 nm to 500 microns) mechanical characterization of heterogeneous materials in small volumes (e.g., individual constituents in composite material samples, thin coatings or layers in a multilayered sample). These recent advances will be illustrated with case studies.

11:30 AM MT01.05.07
MACE-MP: A Foundation Model for Atomistic Materials Chemistry Janosh Riebesell; Lawrence Berkeley National Laboratory, United States

Machine-learned force fields have transformed the atomistic modelling of materials by enabling simulations of ab initio quality on unprecedented time and length scales. However, they are currently limited by: (i) the significant computational and human effort that must go into development and validation of potentials for each particular system of interest; and (ii) a general lack of transferability from one chemical system to the next. Here, using the state-of-the-art MACE architecture we introduce a single general-purpose ML model, trained on a public database of 150k inorganic crystals, that is capable of running stable molecular dynamics on molecules and materials. We demonstrate the power of the MACE-MP-0 model - and its qualitative and at times quantitative accuracy - on a diverse set problems in the physical sciences, including the properties of solids, liquids, gases, chemical reactions, interfaces and even the dynamics of a small protein. The model can be applied out of the box and as a starting or "foundation model" for any atomistic system of interest and is thus a step towards democratising the revolution of ML force fields by lowering the barriers to entry.

11:45 AM MT01.05.08
Machine-Learning Solar Cell Efficiency from a Dataset of Continuum Simulations Andrea Crovetto; Technical University of Denmark, Denmark

Power conversion efficiency limits of solar cells based on ideal semiconductors are well known as a function of the semiconductor's band gap energy (Shockley-Queisser limit and their derivatives). However, it is notoriously difficult to estimate the maximum photovoltaic (PV) efficiency potential of real-world materials featuring a number of unavoidable imperfections.

In this contribution, I will show that this problem can be addressed by integrating a dataset of 30,000 drift-diffusion (continuum) simulations with machine learning to estimate the PV efficiency of a generic, non-ideal PV material. With this data-driven approach, and unlike any previously reported method, a generalized effect of, e.g., finite carrier mobilities and doping densities on the maximum PV efficiency can be modeled.

Importantly, the simulation dataset is not static but instead new data can be collected in a closed-loop fashion, depending on how the machine learning model performs with the available data at a given time. Furthermore, the relevant solar cell physics is incorporated into the model at various stages of our workflow, resulting in a favorable trade-off between statistical generality and physical understanding.

The relevance of the machine-learned PV efficiency is demonstrated on a sample of 16 PV materials of current research interest. The method can immediately be applied to experimentally synthesized or computationally examined materials at any development level, as long as seven of their bulk material properties (the basic descriptors) have been determined by experiment of first-principles calculations.

1:30 PM *MT01.06.01
Harnessing Materials Imperfections: Case Studies of 'Defects' in Materials for Energy Sustainability Wennie Wang; University of Texas at Austin, United States

We present work in the Wang Materials Group (https://wangmaterialgroup.com) in understanding and harnessing defects in materials for energy sustainability applications that leverage and/or are inspired by aspects of machine learning. Our goal is to elucidate and predict the materials properties at the microscopic level using first-principles calculations, drive the exploration of novel materials platforms, and create strategies that directly couple to/guide experiments. Here, we present on two such case studies on next-generation memory and storage applications and electrocatalysts.
Memristors are an emerging memory technology that can help meet the capacity and energy efficiency demands. Non-volatile resistive switching (NVRS) between high- and low-resistive states has been broadly observed in various two-dimensional materials. As atomically thin systems, two-dimensional materials are promising as the active switching layer for two-terminal vertically stacked memristor devices. We examine one particular mechanism of NVRS based on the formation and dissolution of point defect complexes to describe the switching energetics and switching processes. In this talk, we will present our efforts in leveraging automated calculations to screen for defects capable of inducing NVRS in two-dimensional materials and extract materials-based scaling relationships for the switching energy.
In the second case study, we turn to the investigation of structure and catalytic activity relationships in electrocatalysts. Low-temperature electrocatalysis of water is at the forefront of strategies that could help realize a clean hydrogen economy. The (oxy)hydroxides are scientifically significant as electrocatalysts that electrochemically form on many pre-catalyst surfaces in the amorphous state. Interestingly, amorphous electrocatalysts have been reported to consistently outperform crystalline ones. Our goal is to connect the structural disorder in amorphous electrocatalysts to mechanism(s) in enhancing the electrocatalytic activity. We will discuss the considerations to appropriately describe the electronic and atomic structure and strategies in using point defects and genetic algorithms to understand local structural disorder.

2:00 PM MT01.06.02
Anion Charge Distribution Effects of Lithium Diffusion in Polymer Electrolytes Using End to End Force Field Parameterization through Machine Learning Pablo A. Leon and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Solid polymer electrolytes (SPEs) are seen as promising alternatives to conventional liquid electrolytes in lithium battery systems due to their low density, mechanical compliance, and low flammability but are challenged by lower ionic conductivity. Molecular dynamics (MD) simulations can be used to guide the design of novel SPEs by allowing quantitative determination of separable anion and cation diffusions as well as local solvation environments. Classical potential MD simulations update molecular conformations by the net force on each atom due to covalent and nonbonded interactions. However, these classical potentials require materials- and local environment-specific parameters such as nonpolarizable point charges on each atom that have historically been meticulously hand-tuned across decades.

In this work, we explore the effects of using distinct anion charge distributions based on minimum energy Lithium ion coordination on ionic solvation and conductivity in polymer electrolyte simulations. An in-house, machine learning-based workflow, named AuTopology, was used to autonomously learn the interatomic potential parameters of unique atomic environments for two different classical models from DFT forces as training data. In particular, the effect of machine learning regularization and chemistry-informed training data selection on resulting polymer-ion system behavior is highlighted. The learned harmonic OPLS model and anharmonic PCFF+ model parameters were then used to equilibrate condensed-phase simulations at a variety of experimentally-relevant concentrations. These simulations were allowed to run for hundreds of nanoseconds to determine the individual anion and cation diffusivities and resulting conductivities. Using this framework and an in-house database of molecular conformations, we have been able to reproduce wB97XD3-level DFT forces from trained OPLS force fields to within 5.5 kcal/mol-A. Lithium solvation environments and ion diffusivities were found to match legacy parameterizations to the same order of magnitude.

2:15 PM MT01.06.03
Breaking Boundaries: AI-Driven Design of High-Temperature Polymer Dielectrics Madhubanti Mukherjee, Shivank S. Shukla, Rishi Gurnani, Joseph D. Kern, Harikrishna Sahu and Rampi Ramprasad; Georgia Institute of Technology, United States

In the domain of electrical and electronic applications, the demand for flexible polymer dielectrics capable of withstanding extreme temperatures and

electric fields is pressing. The dielectric breakdown strength, signifying the maximum electric field a polymer can endure while retaining excellent insulating qualities (i.e., sufficiently high bandgap (E_g)) is a pivotal parameter. Together with the dielectric constant of the polymer, it dictates the upper limit of electrostatic energy storage in a capacitor. Another key parameter for high-temperature energy storage is the high glass transition temperature (T_g), which ensures thermal and electromechanical stability, thereby preserving capacitive performance. Simultaneously obtaining high T_g, a high dielectric constant, and a high E_g for achieving enhanced energy density proves to be a formidable challenge due to the observed negative correlation between T_g and E_g, further complicated by potentially increased dielectric loss at higher T_g. Identifying such suitable candidates in the vast chemical landscape of polymers, entangled with the complexities of dielectric breakdown mechanisms is daunting. Artificial intelligence-driven screening methods have emerged as proficient tools for sifting through expanding polymer libraries, streamlining the selection process for experimental exploration [1]. The application of screening criteria based on readily accessible proxy properties has expedited the search process in contrast to the laborious manual extraction of chemo-structural attributes. These criteria include a high bandgap to ensure an insulating phase, a high glass transition temperature to ensure thermal stability, and a substantial dielectric constant that enhances energy density [2, 3]. Employing these criteria in conjunction with machine learning models, we conducted an extensive screening initiative encompassing over 14,000 previously synthesized polymers and an additional 6 million hypothetical polymers crafted from diverse reaction templates. This systematic approach has unraveled a multitude of promising candidates, boasting attributes such as a glass transition temperature reaching 400°C, a bandgap of 4 eV, and a dielectric constant within the range of 3-5. These characteristics hold the promise of remarkably high energy density. Furthermore, our study leverages density functional theory and molecular dynamics simulations to further validate the bandgap and glass transition temperature for a significant portion of these polymers. This study also provides valuable insights into the structural elements essential for designing robust, high-temperature polymer dielectrics with exceptional energy storage capabilities.

3:30 PM *MT01.06.04
Uncertainty Quantification in Machine Learning Models of Materials Properties Dane Morgan[1], Ryan Jacobs[1], Lane Schultz[1], Vidit Agrawal[1], Shixin Zhang[1], Glenn Palmer[2], Ben Blaiszik[3], Aristana Courtas[3] and KJ Schmidt[3]; [1]University of Wisconsin--Madison, United States; [2]Duke University, United States; [3]The University of Chicago, United States

Machine learning models are being increasingly used to predict an enormous range of materials properties. Such models are typically trained on computed and/or experimental data that has strong biases in terms of the sampled systems, potentially leading to models with limited accuracy and very specific domains. It is therefore of increasing importance to establish effective practices for uncertainty quantification of machine learning models used for materials properties. In this talk we share an approach that divides uncertainty quantification into separate challenges of error and domain determination, which together provide a strong framework for practical uncertainty quantification. This approach leads to uncertainty quantification that can guide users whether prediction on any given test data point is likely to be appropriate, and if it is appropriate, what accuracy might be expected. For determining errors, we demonstrate that, when properly calibrated, ensembles of models fit to bootstrap sampling of training data can provide robust and easily accessible estimates of test data point residuals[1]. For determining domain, we demonstrate that a kernel density estimate of training data density in feature space can be used to identify regions of feature space with inadequate sampling and therefore likely to be out of domain. Assessing any domain determination strategy is difficult as there is no unique ground truth for a test data point being in or out of domain. To manage this problem we propose a set of criteria for ground truth based on matching chemical intuition and expected large residuals and residual estimation errors with being out of domain. We show that a kernel density approach can generally categorize new test data points as in/out of domain with good accuracy (e.g., max F1 scores of about 80% or better) when using any of these criteria. Finally, we discuss how these methods can be trivially integrated into model fits through the MAST-ML[2] package and how such uncertainty aware models can be easily hosted in the cloud through the Foundry[3] service.

Elucidating Structural Heterogeneity of Amorphous Materials with X-Ray Absorption Spectroscopy and Machine Learning Hyuna Kwon, Yu-Ting Hsu, Wonseok Jeong, Wenyu Sun, Liwen Wan, Michael Nielsen and Tuan Anh Pham; Lawrence Livermore National Laboratory, United States

The ability to precisely determine the atomic structure of functional materials would have a transformative and broad impact on a broad range of emerging technologies, from energy storage and conversion to ion-selective membranes. In this talk I will summary our rencent activities in integrating atomistic simulations, data science, and spectroscopic measurements to elucidate structural and chemical heterogeneities in disordered systems. I will show how machine learning potential is used to efficiently explore the vast configuration space of amorphous carbon nitrides and to identify the local structural motifs of the systems. Density functional theory simulations were used to establish a correlation between the local structure motifs and X-ray absorption spectroscopic signatures, which then serves as the basis for interpreting and extracting chemical content from experimental data. Beyond predicting the chemical content, I will also discuss a strategy to predict the three-dimensional atomic structure of amorphous sytems from X-ray absorption spectroscopy via a generative diffusion model. Using amorphous carbon as a case study, it is found that the generative model exhibits a remarkable scale-agnostic property, enabling the generation of large-scale atomic structures, while being able to accurately predict the atomic structure from targeted spectroscopy. The methods developed here are general and can be broadly applied for inverse design of functional materials.

Decoding Structure-Spectrum Relationships in X-Ray Absorption Spectra with Physically Organized Latent Spaces Deyu Lu, Zhu Liang, Matthew Carbone, Wei Chen, Fanchen Meng, Eli Stavitski, Mark Hybertsen and Xiaohui Qu; Brookhaven National Laboratory, United States

X-ray absorption spectroscopy (XAS) is a premier materials characterization technique, which is element specific and sensitive to the local chemical environment. However, the physical information in XAS, in particular, x-ray absorption near-edge structure (XANES), is encoded in the spectral function in an abstract form. First principles calculations are widely used to unravel the complex structure-spectrum relationship. However, this approach requires a great deal of domain expertise and is computational expensive. These drawbacks limit the scope of XAS modeling for complex systems and in real-time analysis. To address this challenge, data-driven XAS analysis methods emerge, which take advantage of the fast developing machine learning tools for

spectral interpretation. Successful examples show that machine learning models can be used to accelerate XAS simulations and identify the physical origin of spectral trends in a statistically salient way.

In this study, a semi-supervised machine learning method for the discovery of structure-spectrum relationships is developed and then demonstrated using the specific example of interpreting XANES spectra. This method constructs a one-to-one mapping between individual structure descriptors and spectral trends. Specifically, an adversarial autoencoder is augmented with a rank constraint (RankAAE). The RankAAE methodology produces a continuous and interpretable latent space, where each dimension can track an individual structure descriptor. As a part of this process, the model provides a robust and quantitative measure of the structure-spectrum relationship by decoupling intertwined spectral contributions from multiple structural characteristics. This makes it ideal for spectral interpretation and the discovery of descriptors. The capability of this procedure is showcased by considering five local structure descriptors and a database of more than 50000 simulated XANES spectra across eight first-row transition metal oxide families. The resulting structure-spectrum relationships not only reproduce known trends in the literature but also reveal unintuitive ones that are visually indiscernible in large datasets. The results suggest that the RankAAE methodology has great potential to assist researchers in interpreting complex scientific data, testing physical hypotheses, and revealing patterns that extend scientific insight.

4:30 PM MT01.06.07
Physics Informed Disentangled Latent Space of X-Ray Absorption Spectra Sophie D'Halleweyn[1,2], Anatoly Frenkel[1] and Prahlad Kumar Routh[1]; [1]Stony Brook University, United States; [2]The Bronx High School of Science, United States

X-ray absorption spectra provide insights into the atomic scale local structures of a wide range of materials with nanoscale dimensions. This information is often inaccessible to experimentalists through traditional structural analysis techniques. To analyze XAS spectra, theory-driven structural models are needed, particularly for fitting the extended part of the spectra (EXAFS). While the quantitative analysis of the near-edge part of XAS (XANES) remains an active research area, neural networks have proven their efficacy as universal approximators. They efficiently learn the mapping between theory generated spectra and structural descriptors in various cases of mono and bimetallic metallic nanocatalysts. However, challenges arise in uncertainty quantification and out-of-distribution performance when these networks are applied to experimental data. Recent studies have highlighted that low-dimensional embeddings of XANES, obtained via autoencoder frameworks, encapsulate these structural descriptors. To enhance the interpretability and utilize the generative capability of the autoencoder framework, a structured and continuous latent space is essential.

In our work, we introduce a physics-informed robust analysis of XANES spectra, striking a balance between reconstruction and descriptor-specific information. Our method, the Multitasking Algorithm for Variational Auto Encoder (MAVEN), achieves a disentangled, interpretable latent space through multi-objective optimization, focusing on reconstruction, denoising, autocompletion, and descriptor mapping. MAVEN stands out for its ability to disentangle and interpret latent space variables, offering a unique generative capability within the autoencoder framework. We've also developed a methodology to quantify the level of disentanglement achieved, rooted in information theory principles. We show the utility of MAVEN by interpreting experimental XANES of palladium and palladium hydride nanoparticles. These are renowned for their lattice expansion, which MAVEN distinguishes from particle size effects via coordination number analysis. The comparison of trends from the MAVEN algorithm to those obtained from extended X-ray absorption fine structure (EXAFS) spectral analysis using Demeter software indicates MAVEN's potential for high-fidelity real-time analysis of local structures. Our discussions will explore the applications of this technique in bimetallic nanoparticles systems and assess its effectiveness on experimental XANES spectra. The promising results suggest that MAVEN could be a vital tool for real-time analysis of local structures, especially in conjunction with experimental spectroscopy of functional nanomaterials like catalysts, batteries, and fuel cells.

SESSION MT01.07: Machine Learning and Simulations VII

Learning Grain Boundary Thermodynamic Spectra in Polycrystals Christopher A. Schuh[1,2], Nutth Tuchinda[2], Thomas Matson[2] and Malik Wagih[2]; [1]Northwestern University, United States; [2]Massachusetts Institute of Technology, United States

The thermodynamics of alloy components determine material structures, properties and hence the processability and performance matrices of engineering alloys. Incorporating grain boundaries in thermodynamic models is not a simple task: grain boundary defects in polycrystals occupy a wide 5-dimensional configuration space, imposing a computational barrier in evaluating thermodynamic data across the chemical space. This complexity calls for a combination of recent advances in data science approaches and computational materials science. This talk will first discuss an isotherm approach in modeling equilibrium solute behavior at grain boundaries and show that relevant spectral thermodynamic quantities can be extracted from atomistic simulations. Then, data-science and machine-learning enabled accelerated models are presented to extend the work to many alloy systems. Finally, a full-spectral case study of a binary alloy system with the inclusion of rapid estimations of dilute segregation energies, solute-solute interactions at grain boundaries and excess vibrational entropy of segregation is presented. These accelerated models open opportunities to construct an embedded alloy grain boundary atlas, which ultimately can assist in alloy design.

9:00 AM *MT01.07.02
Artificial Neural Network Interatomic Potentials Developed for Grain-Boundary Modeling in Al_2O_3 Ceramics Katsuyuki Matsunaga[1,2], Tatsuya Yokoi[1] and Yu Ogura[1]; [1]Nagoya University, Japan; [2]Japan Fine Ceramics Center, Japan

Excellent structural and functional properties of ceramic materials often originate from their grain boundaries and interfaces. Therefore, it is essential to obtain in-depth understanding of electronic and atomic structures of the grain boundaries for materials design. However, crystal structures of ceramic components such as oxides are generally low symmetry and thus contain many atoms, so that a great number of atoms should be inevitably handled in the grain boundary modeling. This often makes it difficult to systematically treat the ceramic grain boundaries at the first-principles level. In the present study, artificial neural network interatomic potentials trained by first-principles data were developed for Al2O3, which is a representative ceramic oxide, and applied for their grain boundaries. Grain boundary structures thus obtained were compared with experimental STEM images to verify accuracy of the potentials. On the basis of the calculated grain boundary structures, first-principles calculations were again applied to investigate specific electronic structures of the grain boundary cores that are closely related to the grain boundary properties. Some other examples such as extension to multicomponent systems for the segregated grain boundaries will also be discussed.

9:30 AM MT01.07.03
On Neural Networks for Grain Boundary Dynamics Fadi Abdeljawad[1], Malek Alkayyali[2] and Milad Taghizadeh[1]; [1]Lehigh University, United States; [2]Clemson University, United States

Nearly all structural and functional materials are polycrystals; they are composed of differently oriented crystalline grains that are joined at grain boundaries (GBs). Such interfaces play a critical role in controlling many engineering and functional properties. Understanding GB physics is, therefore, a key aspect of materials discovery and design efforts. Owing to their local atomic environments, GBs provide preferential sites for alloying elements to occupy. Indeed, the direct manipulation of GB chemical states has been found to influence a host of materials properties and processes, such as cohesion and fracture resistance, transport, electrochemical response, electrical conductivity, and processability during advanced manufacturing techniques. Of particular interest is the impact of GB solute segregation on boundary dynamics, as it influences microstructure formation and evolution pathways during processing treatments or under operating environments. For example, GB segregation has been used to mitigate grain coarsening and thermally stabilize nanograined structures. While GB solute segregation has been the subject of active research, most existing studies focus on the thermodynamics of GB segregation and the kinetic role (i.e., dynamic solute drag) remains unexplored. GB solute drag results when segregated alloying elements exert a resistive force on migrating GBs hindering their motion. The challenge here is that solute drag depends on several properties, such as alloy thermodynamics (e.g., heat of mixing), and dynamic processes including solute diffusion and boundary migration; solute drag is a hypersurface. In this talk, we unravel GB dynamic solute drag through theoretical analysis, mesoscale modeling, and machine learning studies. We establish design maps relating drag effects to relevant bulk alloy and GB properties. We find that solute drag is dominant in immiscible alloys with far-from-dilute compositions in agreement with experimental observations of GB segregation in metallic alloys. Further, asymmetric GB segregation is found to greatly influence solute drag values. On the whole, our work provides future avenues to employ GB segregation engineering to control GB dynamical processes.

9:45 AM MT01.07.04
Learning Grain Boundary Segregation Vibrational Spectra from Ni-Based Polycrystals Nutth Tuchinda[1] and Christopher A. Schuh[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Northwestern University, United States

Polycrystalline systems consist of a broad range of planar defect configurations that cannot be represented by simplified boundary models such as small symmetric tilt boundaries. The multiple-site nature of grain boundaries calls for a spectral approach as opposed to a single-site McLean model. However, evaluating solute segregation thermodynamic quantities at every site in large polycrystals is an exhaustive process, especially for the segregation vibrational entropy. Here we show an attempt to integrate a data science approach with computational materials modeling for computational tractability. A modified local harmonic method is applied in combination with a statistical approach to quantify grain boundary segregation vibrational spectra of embedded dilute Ni-based binary alloy pairs. The database allows more rigorous predictions of grain boundary enrichment at a function of concentration, grain size and temperature which are critical for solute segregation-stabilized nanocrystalline alloys.

10:30 AM MT01.07.05
Stability and Equilibrium Structures of Unknown Ternary Metal Oxides explored by Machine-Learned Potentials Seungwoo Hwang[1], Jisu Jung[1], Changho Hong[1], Wonseok Jeong[1], Sungwoo Kang[1] and Seungwu Han[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute for Advanced Study, Korea (the Republic of)

Ternary metal oxides are extensively utilized across various applications and have been comprehensively cataloged in experimental materials databases. Nonetheless, there remains a substantial portion of unexplored combinations of cations with oxide forms in terms of their stability and structures. Discovering new ternary metal oxides solely through experiments is both time-consuming and resource-intensive. Alternatively, theoretical databases offer hypothetical structures based on known prototypes. However, it is possible to miss “hidden” ground state structures that are not represented by prototype structures. This challenge can be addressed through the application of crystal structure prediction (CSP), which employs heuristic methods, such as evolutionary algorithm, to identify the lowest-energy structure for a given composition without prior knowledge. Nevertheless, the effectiveness of this approach is limited due to its reliance on computationally expensive density functional theory (DFT) calculations and an exhaustive search of the structure space, which is often impractical for finding complex equilibrium phases of ternary metal oxides.
Recent years have seen a growing interest in machine-learned potentials (MLPs) an effective alternative to the DFT method. MLPs can rapidly compute energy and atomic forces, achieving results comparable to DFT. Based on the concept that MLPs trained with disordered phases have been successful as surrogate models for DFT in CSP [1], a systematic CSP program called SPINNER (Structure Prediction of Inorganic crystals using Neural Network potentials with Evolutionary and Random searches) was developed, harnessing MLPs within an evolutionary algorithm [2]. In benchmark tests using experimental structure data, SPINNER identified 80% of the structures of 60 different ternary compounds with diverse crystal symmetries and identified 10^2 to 10^3 times faster than DFT-based heuristic methods.
In this study, we extensively employ SPINNER to explore experimentally uncharted chemical spaces [3]. We investigate 181 ternary metal oxide systems, encompassing most cations except those with partially filled 3d or f shells, and search up to 60,000 crystal structures in representative compositions derived from common oxidation states and a machine-learned recommender system to determine the lowest energy crystal structure. Our exploration yields 45 systems containing stable ternary oxides that do not decompose into binary or elemental phases. Interestingly, many of these are noble metal-containing systems that have not yet been well studied and have equilibrium structures that do not belong to the known prototype structure. Comparisons with other theoretical databases highlight the strengths and limitations of informatics-based material searches and point to the synergistic effect between direct and data-mining searches. With a relatively modest computational resource requirement, we contend that heuristic-based structure searches, as demonstrated here, offer a promising approach for future materials discovery endeavors.

Neural Network of Defect Kinetics for Multi-Principal Element Alloys Penghui Cao; University of California, Irvine, United States

The emergent multi-principal element alloys (MPEAs), commonly known as high entropy alloys, provide a vast compositional space to search for radiation-resistant materials for advanced nuclear reactor applications. However, the vast composition space of MPEAs makes identifying the desired composition and defect mechanisms a complex task. This presentation will introduce a machine learning strategy, specifically neural networks, to overcome this challenge. The machine learning-driven models have proven effective and efficient in predicting defect migration energy barriers across the complete compositional spectrum of MPEAs. The successful implementation of neural network kinetics model holds significant promise for harnessing

defect kinetics in the huge compositional space. It could significantly accelerate the alloy selection process, paving the way for engineering new alloy compositions with enhanced radiation performance.

11:15 AM MT01.07.07
Machine Learning Derived Periodic Table for High Entropy Alloys Scott Broderick, Md T. Islam and Qinrui Liu; University at Buffalo, United States

This work explores new high entropy alloys (HEAs) which address the challenges in trade-offs between strength, ductility and various environmental effects. To address the limitations in traditional regression approaches which can generate large amounts of data rapidly but do not account for the complex interplay in correlating properties, we instead apply an unsupervised learning approach. By mapping the high dimensional nature of the systematics of elemental data embedded in the periodic table, the influence of specific combinations of elements on engineering properties of HEAs are captured. This approach is designed to capture the interplay between chemistry, microstructure and phase stability, which allows us to identify chemical design rules for improving mechanical properties with minimal trade-offs. This work uses a graph representation approach to capture the thermodynamic and structural complexity of high entropy alloys (HEAs). This approach has
been used for materials discovery based on first principles, but now we are using it to design engineering alloys. We identify the potential existence of new combinations of phases not previously identified by tracking the connections in the network, which are analogous to tie lines in a traditional phase diagram representation. In this way, mechanical properties are rationally designed through proposed chemical design rules across the entire HEA search space, resulting in a machine learning based representation of a periodic table based on HEA properties.

11:30 AM MT01.07.08
Electronic Moment Tensor Potentials (eMTP): Application to Refractories and Shape-Memory Alloys Prashanth Srinivasan[1], Yongliang Ou[1], David Demuriya[2], Alexander Shapeev[2] and Blazej Grabowski[1]; [1]University of Stuttgart, Germany; [2]Skolkovo Institute of Science and Technology, Russian Federation

We present the electronic moment tensor potentials (eMTPs), a class of machine-learning interatomic models and a generalization of the classical MTPs, reproducing both the electronic and vibrational degrees of freedom, up to the accuracy of *ab initio* calculations (Srinivasan et al., 2023). Following the original polynomial interpolation idea of the MTPs, the eMTPs are defined as polynomials of vibrational and electronic degrees of freedom, corrected to have a finite interatomic cutoff. Practically, an eMTP is constructed from the classical MTPs fitted to a training set, whose energies and forces are calculated with electronic temperatures corresponding to the Chebyshev nodes on a given temperature interval. The eMTP energy is hence a Chebyshev interpolation of the classical MTPs. With eMTPs, one can access the temperature-dependent electronic and vibrational free energies and the coupling between the two, separately.

The performance is demonstrated on two classes of systems: (1) refractory Nb and TaVCrW high-entropy alloy, and (2) equiatomic Nickel-Titanium (NiTi) shape-memory alloy (SMA). The refractories demonstrate a significant electronic, vibrational, and coupling contribution to the free energy, all of which get captured accurately by performing a thermodynamic integration (Jung et al., 2022) to the eMTPs. We are able to reach full density-functional theory accuracy in thermodynamic properties all the way to the melting point without any further *ab initio* calculations.

The NiTi SMA is considerably more challenging to model owing to several energetically competing phases (body-centered cubic B2, monoclinic B19', orthorhombic B19 and base-centered orthorhombic B33). We train an eMTP to obtain the thermodynamic phase stability including all relevant contributions. The experimentally observed low-temperature martensitic (B19') and high-temperature austenitic (B2) phases get entropically stabilized. Both the vibrational and electronic contributions also significantly affect the B2-B19' phase transformation, bringing the behavior much closer to experiments. The eMTP-thermodynamic integration approach enables us to analyze the accuracy of different exchange correlation functionals and *ab initio* parameters. Lastly, to investigate kinetic effects, we perform large-scale molecular dynamics simulations using the eMTP to model the stress-induced and temperature-induced phase transformation.

11:45 AM MT01.07.09
Machine Learning and Kinetic Monte Carlo Models of Transport in Concentrated Alloys Anjana Talapatra[1], Matthew Wilson[1], Ying Wai Li[1], Anup Pandey[1], Ghanshyam Pilania[1], Danny Perez[1], Soham Chattopadhyay[2], Dallas Trinkle[2] and Blas P. Uberuaga[1]; [1]Los Alamos National Laboratory, United States; [2]University of Illinois at Urbana-Champaign, United States

With the increasing interest in so-called high entropy, multi-principal component, or compositionally complex alloys, there is a greater need to understand how transport is affected by the complex chemistry of these materials. As compared to a simple elemental solid, in which every lattice site is identical and transport can be described by a handful of saddle points, these materials exhibit a very rugged potential energy surface in which every site has a unique chemical environment. This means that every site exhibits a different defect formation energy and corresponding migration barriers for motion to neighboring sites. As the number of elements in these systems increases, it becomes increasingly challenging, and soon impossible, to enumerate the energetics of every site in the system. Alternative approaches are necessary.

Machine learning has become a popular choice to describe the chemistry-dependent properties of defects in these alloys. By training on atomistic data, machine learning models can predict the energetics of defects in unseen environments and be subsequently used in kinetic Monte Carlo simulations of defect transport. However, for the transport simulations to be thermodynamically valid, the underlying machine learning model must obey detailed balance.

Here, we describe various ways that detailed balance can be enforced in a machine learning model of defect formation and migration energies. Specifically, we consider a brute force model, a "soft constraint" model in which penalty associated with detailed balance is added to the loss function, and two "hard constraint" models in which detailed balance is explicitly included in the architecture of the model. We find that these physically-constrained models exhibit superior performance in maintaining detailed balance. This is demonstrated by determining the error in the energy of the system as defects traverse closed loops. We conclude that detailed balance must be considered to obtain valid trajectories.

We then use the machine learning model to determine the kinetic properties of defects. Using a recently-developed approach in which the complex correlated+uncorrelated kinetic Monte Carlo problem is mapped rigorously onto an uncorrelated surrogate, we then use this to identify which atomic scale events are most critical in describing the trajectory of the defect. This provides a route to close the loop, so to speak: to build an autonomous workflow in which the events that the trajectory is most sensitive to are further refined to improve the description of the material. We demonstrate the elements of this workflow for a vacancy in the simple Cu-Ni alloy, highlighting how we can then quickly determine the diffusion tensor for defects in complex alloys when

given appropriate computational resources.

Finite-Element-Based Physics-Informed Convolutional Neural Networks Ryan B. Sills and Pranav Sunil; Rutgers University, United States

Physics informed neural networks have become very popular as a technique for solving physics-derived partial differential equations. However, many PINN techniques do not allow for variation in geometry and parameters after training. Relatedly, PINNs are usually constructed with fully-connected NNs, making them costly to train. In this talk, we present a PINN methodology which leverages the finite element method to enable variation in geometry and parameters within a convolutional NN architecture. The heart of the method is a new type of convolutional operation called stencil convolution which utilizes the finite element inverse isoparametric map. We demonstrate the method with applications to deformations of linear elastic solids.

Probing Defect-Controlled Small Scale Plasticity via Machine Learning Approach and Defect Dynamics Modeling Ill Ryu; The University of Texas at Dallas, United States

Mechanical behaviors of metals at small scale have attracted much attention due to their widespread applications in modern MEMS/NEMS devices due to their enhanced properties. To understand the underlying microscopic deformation mechanisms that control the mechanical properties of nanostructured metals, an insight into the intricate interaction of dislocations and grain boundaries is vital. Computational simulations of materials have advanced significantly in recent years, shifting from analyzing experimental observation to providing capability to predict mechanical behaviors for use in advanced material development. Machine learning has been a topic of great interest in recent years within the engineering community.
In this study, we employed a multiscale modeling approach to investigate defect interaction. For the prediction of dislocation interactions with grain boundaries, we will present an efficient physically informed machine learning framework that has potential to significantly improve predictive capability of computational modeling, which in turn would reduce the number of prototypical experimental validation. With the atomistically informed mesoscale defect dynamics model, we explore the effect of varying misorientation angle for pure twist and pure tilt grain boundaries on plastic deformation of nanostructures, which could provide a better understanding of dislocation driven plasticity for polycrystalline metals at small scale. For complex loading and environmental condition, the unified defect dynamics model which coupled dislocation dynamics (DD) and finite element model (FEM) has used, which could play an important role in obtaining a fundamental understanding of deformation mechanism at small scale. The developed multiscale framework will shed light on fundamental investigation of “defect-controlled” mechanical behaviors in metallic materials.
